Since the very early days of atomic force microscopy (AFM), voltage modulation (VM) of AFM has been used to try to quantify a host of electronic, electrochemical and electromechanical functionalities across nanometer length scales. The critical importance of such information has resulted in the development of a plethora of VM-AFM techniques for exploration of either long or short-range forces. Of relevance for ferroelectrics, piezoresponse force microscopy (PFM) imaging and spectroscopies have effectively opened the door to the exploration of nanoscale ferroelectric properties. The rise of PFM, however, can also be associated with the emerging trend of claims of ferroelectricity in materials which were subsequently thought to be not ferroelectric.[1] even unlikely materials such as soda-lime glass. Furthermore, quantification of piezoelectric properties with PFM is notoriously difficult, and is known to be influenced by parasitic effects including factors such as long range electrostatic forces, tip-sample contact stiffness variations, cantilever frequency dependent dynamics. In this talk, we will explore the parasitic effects during normal PFM operation, including some recent results that:

Demonstrate that some hysteretic interactions surprisingly originate from common long-range dynamics. This hysteresis seems to be linked to sample surface water, suggesting that ionic dynamics in the surface water layer must be accounted for in nanoscale electromechanical measurements.

Demonstrate experimental approaches for using interferometric AFM[2] for quantifying both the inverse piezo sensitivity, d33 and hysteresis loops.

Since surface water is ubiquitous in ambient conditions for even mildly hydrophilic surfaces, these observations may explain the plethora unexpected hysteretic behavior discussed above. Finally, another significant result of the interferometric approach is that it allows putting quantitative limits on the electromechanical sensitivity. For example, we have demonstrated that [end] --> for soda-lime glass mentioned above, much smaller than that implied by conventional VM-AFM measurements.

8:30 AM EP01.09.02 Spin Mixing and Loss of Spin During Tunneling in Ferromagnet/Ferroelectric Junctions—Is a Strong Ferroelectric Polarization Desirable? Ibrahim B. Misirlidou1,2, Canhan B. Sen1, Wael B. Aldulaimi1 and Omid B. Moradi1; 1Sabanci University Nanotechnology Application Center, Sabanci University, Istanbul, Turkey; 2Integrated Manufacturing Technologies Research and Application Center, Sabanci University, Istanbul, Turkey; "Faculty of Engineering and Natural Sciences, Sabanci University, Istanbul, Turkey.

Electric field control of magnetization allows further miniaturization of integrated circuits relying on functional layers for binary bit processing and data storage as it eliminates the need for bulky sophisticated systems to induce magnetic fields. Tailoring magnetoelectric coupling inherent to the bulk of multiferroic thin films and piezoelectric strain control of spin orientation in magnetic layers have been two approaches standing out. One other phenomena, namely spin-dependent screening has been studied especially from the perspective of spin selective tunnel junctions. In this work, we analyze the spin-dependent screening of ferroelectric polarization in a film interfacin and electrodes with a magnetic structure using the continuity equations in continuum media. The effect of ferroelectric polarization on the ferromagnetism of the electrodes near the interfaces are discussed in the light of our results. The competition between the electrostatic screening and the mean-field exchange between spins in the ferromagnetic (FM) electrodes gives rise to a reduction in the net magnetic moment near the interface extending to a distance comparable to the Thomas-Fermi screening length. This apparent loss of magnetic order at the interface is due to spin mixing that is held partly responsible for reduction in the tunnel magnetoresistance (TMR) effect. In fact, even in an ideal system with no other effects to cause spin flips, our results imply that interface states can lead to great losses in spin polarization during tunneling.
Correlation Between the Structural, Ferroelectric, Piezoelectric and Dielectric Properties of Lead-Free BCT-BZT Piezoelectrics

We report the structural, ferroelectric, piezoelectric and dielectric properties correlation in lead-free Ca(Ta,Ga)Si2O7 (1-x)BaTiO3 (x; x = 0.55, 0.45) piezoelectric ceramics. These piezoelectrics were synthesized by conventional solid state reaction method and further analyzed using different characterization techniques such as x-ray diffraction (XRD), Raman spectroscopy, scanning electron microscope (SEM), polarization-electric field (P-E) loop, strain-electric field (S-E), etc. XRD analysis along with the Rietveld refinement shows that the 55BCT8 and 45BCT8 piezoelectrics possess both the tetragonal (T: space group P4mm) and orthorhombic (O: space group Amn2) crystal structure which is further confirmed from Raman spectroscopy analysis. Also, the structural phase transitions with temperature were studied in details from the temperature dependent Raman spectroscopy analysis. The scanning electron micrographs shows dense microstructure for both the piezoelectrics with larger grain size 7-10 µm for 45BCT8. Also, the elemental mapping analysis indicates the microstructural distribution of the constituent elements. The presence of P-E and S-E hysteresis loop confirms the ferroelectric and piezoelectric nature of these piezoelectrics. Further, the polarization current density-electric field curves show the presence of two sharp peaks in opposite directions which suggests the two stable states with opposite polarity. The higher values for maximum polarization (Pm = 22.47 µC/cm²), remnant polarization (Pr = 11.61 µC/cm²), coercive electric field (Ec = 4.77 kV/cm) and % Strain (Sm = 0.21) were observed for 55BCT8 while higher values of piezoelectric coefficients (d33 ~ 220 pC/N and d31 ~ 295 pm/V) and electrostrictive coefficient (Q33 ~ 0.0509 m4/C2; higher than the conventional lead based piezoelectrics (0.026 m4/C2) i.e. PbMgNbO3-PbTiO3) were observed for 45BCT8. Temperature dependent dielectric measurements at different frequencies show the phase coexistence (T + O) near room temperature (consistent with XRD and Raman spectra analyses); exhibiting O to T phase transition at 285 K and 298 K for both the 55BCT8 and 45BCT8, respectively. Moreover, the Curie temperature (Tc) ~ 410 K observed to be same for both the studied piezoelectrics. The observed trends in the ferroelectric, piezoelectric and dielectric properties can be explained in detail on the basis of structural phase contribution (55BCT8: 28% T + 72% O & 45BCT8: 41% T + 59% O) as analyzed from Rietveld fitted XRD pattern and Raman spectrum of 55BCT8 and 45BCT8. The observed properties shows that the environment friendly lead-free piezoelectrics in the present work are suitable for ferroelectric memory device, piezoelectric sensor, capacitor, etc. applications and can replace the toxic lead based piezoelectric ceramics (e.g. PbZn0.5Ti0.5O3, PbMgNbO3-PbTiO3, etc).

Stability, Transport and Electromechanical Properties of Ca1-xTal-xGa,xSi2O7 Piezoelectric Crystals at Elevated Temperatures

Application of piezoelectric materials at elevated temperatures faces many restrictions including thermally induced changes of the dielectric, piezoelectric and electromechanical properties, increased loss with temperature, and chemical instability (decomposition, oxidation). In this respect, piezoelectric crystals of the langasite (LGS, LaGa3SiO10) family are recognized as excellent candidates for high temperature applications as their piezoelectric activity is present up to temperatures above 1300 °C. CTGS (Ca1-xTal-xGa,xSi2O7) is a relatively new crystal of the langasite family which has a fully ordered structure with lower conductivity and loss than LGS.

This work focuses on detailed and thorough investigations of CTGS temperature behavior. In particular, the full set of dielectric, piezoelectric, and elastic constants are determined in the temperature range from 4.2 K to 900 °C. Further, the electromechanical loss is determined as a function of temperature and described in the framework of a model that includes several physical mechanisms. Moreover, investigations of atomic transport mechanisms in CTGS are carried out at temperatures up to 1300 °C and correlated with electromechanical properties. Finally, the evaluation of CTGS long-term stability at high temperatures is performed by examination of its electric conductivity and resonant properties. CTGS crystals used in this study are grown by the Czochralski technique by IKZ (Berlin, Germany), Fomos-Materials (Moscow, Russia) and SICCAS (Shanghai, China). The material constants are determined using two independent methods, namely resonant and ultrasonic pulse-echo. Additionally, piezoelectric coefficients are derived using laser Doppler vibrometry. The investigations of electromechanical loss are performed by means of impedance spectroscopy and a tone-burst excitation technique. The sample preparation process, measuring techniques and crystals cuts and geometries used for the investigations are described in [1, 2].

The analysis of ion transport mechanisms is performed in the temperature range of 1000-1300 °C by application of stable tracer isotope 18O and subsequent secondary ion mass spectrometry and provides oxygen self-diffusion coefficients of CTGS. These coefficients are found to be at least 3 orders of magnitude lower than those of LGS, confirming better high-temperature stability of CTGS.

Long-term measurements of CTGS conductivity and resonance frequency are performed in air during one year of uninterrupted thermal treatment at 1000 °C. The resonance frequency is found to change by about 0.4% during 8000 hours of heat treatment.

Physical Nature of Negative Capacitance Emerged in Ferroelectric-Gate FETs

Recently, the power consumption of integrated circuits has increased because the scaling of the operating voltage is limited. To solve this issue, it is necessary to overcome the limit of subthreshold swing of 60 mV/decade at 300 K. Negative capacitance FET (NCFET), in which gate dielectric is replaced with a ferroelectric material, is attracting much attention because of the capability of overcoming the limitation by using the NC effect of ferroelectric. A number of papers have demonstrated sub-60 mV/decade switching in ferroelectric-gate FETs. However, the physical nature of emerging the NC have not been clarified. To investigate the physical nature, we simulated the time-developed electrical behaviors, such as the voltage across the ferroelectric gate (Vf), surface potential of semiconductor (φS) and electric displacement of ferroelectric layer (Df), for the applied voltage (Vgs) in metal-ferroelectric-semiconductor capacitor (MFS) by using Landau-Khalatnikov equation which includes the dynamics of ferroelectric polarization switching. In this simulation, the ferroelectric properties similar to ferroelectric HfO2 films were used, because the HfO2 film is expected to be the most suitable for the ferroelectric-gate insulator in the NCFETs due to its compatibility with the complementary metal-oxide-semiconductor (CMOS) process and scaling.
ability. As the results, when $V_d$ is swept from negative to positive, the entire $V_d$ and the depolarization voltage from a semiconductor (p-type) due to the remanent polarization are simultaneously applied to the ferroelectric layer before polarization switching. Whereas, after polarization switching, $V_d$ divides into the ferroelectric layer and surface potential of semiconductor because of the formation of depletion layer at the semiconductor surface. Therefore, $V_d$ decreases with increasing $D_0$ ($\partial D_0/\partial V_d$) indicating that NC emerges. For this reason, transient NC in MFS capacitor is realized under the effect of the depolarization field from semiconductor due to the remanent polarization before polarization switching and the non-linear response of a semiconductor and a ferroelectric materials against external electric field after polarization switching. The subthreshold slope of $I_d$-$V_d$ characteristic is below 10 mV/decade due to the effect of the transient NC. The simulations were also performed by using the ferroelectric properties with different remanent polarization (P=$10$, $15$, $20$ $\mu$C/cm$^2$). As the results, NC is recognized regardless of the remanent polarization, as far as the carrier modulation at the semiconductor surface against the potential change is much faster than the ferroelectric switching speed.5

9:30 AM EP01.09.06 Negative Piezoelectric Effect in the Organic Supramolecular Ferroelectric BTA Indre Urbanaviciute1, Xiao Meng1, Yingfen Wei2, Tim Cornelissen1, Rint Sijbesma2 and Martin Kemerink1; 1IFM, Linköping University, Linköping, Sweden; 2Faculty of Science and Engineering, University of Groningen, Groningen, Netherlands; 3Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, Netherlands.

Due to their softness and flexibility, organic ferroelectrics may become relevant for a wide variety of applications like conformal and/or flexible sensors and actuators for which inorganic ferroelectrics are unsuitable. Yet, with the notable exception of the ferroelectric copolymer P(VDF-TrFE), the piezoelectric properties of organic ferroelectrics are only sparsely known and far from completely understood. The vast majority of piezoelectric materials demonstrate a positive piezoelectric effect. Even though it has been recently discussed that the negative piezoelectric coefficient could be theoretically found in certain ferroelectrics, in practice PVDF and its copolymers have remained the only ferroelectric materials showing this anomalous effect of longitudinal contraction with increasing applied field.5

Here, we investigate the piezoelectric activity in an archetypical class of organic ferroelectrics – small-molecular liquid-crystalline BTA (benzene-1,3,5-tricarboxamide).6 Interestingly, both the large- and small-signal piezoelectric responses, measured interferometrically on BTA solution-processed thin-film capacitors, reveal a pronounced negative piezoelectric effect with $d_{33}$ reaching values as high as ~20 pm/V. The measured ‘inverted’ piezoelectric butterfly hysteresis loops are of close-to-ideal form with a well-expressed negative slope.

The dipolar disc-like BTA molecules self-assemble in columns that further pack tightly in a hexagonal lattice. In real device conditions this interruption is interrupted by zones with higher disorder. Therefore, the negative $d_{33}$ in such structure can be explained by the so-called dimensional effect, which considers the ferroelectric layer as a set of rigid dipoles that are distributed in an easily deformable matrix. The dimensional effect is also considered to underly the negative electrostrictive and piezoelectric coefficients in P(VDF-TrFE). We show that in BTA the magnitude of $d_{33}$ decreases with increasing disorder and remnant polarization. Comparison of the piezoelectric response under large- and small-signal conditions further reveals that irreversible extrinsic polarization switching processes dominates the large-signal strain.

Studies on the ferroelectric liquid-crystal BTA enrich our general understanding about the negative piezoelectric effect in soft ferroelectrics and reveal the application potential of the material for cost-efficient flexible piezoelectric devices.

10:15 AM *EP01.09.07 Strain and Size Effects on the Structure and Properties of Relaxor Ferroelectric Thin Films Jieun Kim1, Hiroaki Takenaka1, Yubo Qi2, Anoop R. Damodaran3, Abel Fernandez3, Ran Gao3, Shishir Pandya1, Margaret McCarver4, Andrew M. Rappe3 and Lane W. Martin1, 4; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Department of Chemistry, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Department of Physics, University of California, Berkeley, Berkeley, California, United States; 4Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 5Department of Physics, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

The large field-induced strains produced by single crystals of solid solutions between relaxors and ferroelectrics make them technologically important materials. Understanding and ultimately controlling these large effects requires intimate knowledge of how the local polar order and resulting small-sized domains separated by low-angle domain walls form and evolve under applied stimuli. Traditionally, the evolution of polar structures in relaxors with various thermodynamic forces including temperature, composition, electric field, and hydrostatic pressure has been studied in bulk single crystals. The instability under large, non-hydrostatic pressure (such as uni- or bi-axial strain) in bulk materials, however, has limited our understanding of how these polar entities evolve under driving forces that enhance long-range order. In addition, there is a lack of understanding of how relaxors behave in low dimensions (i.e., size effects). In this work, we use a combination of thin-film epaxy, X-ray diffuse scattering, dielectric and ferroelectric characterization, and molecular-dynamics simulations to investigate the evolution of and correlations between polar structures and properties in the prototypical relaxor ferroelectric 0.68$\beta$PbMg$\text{_{1/3}}$Nb$\text{_{2/3}}$O$\text{_{3}}$-0.32PbTiO$\text{_{3}}$. First, we investigated the effect of epitaxial strain to understand the relationship between structure and properties of relaxors under a driving force towards enhanced long-range order. Increasing the bi-axial, in-plane compressive strain (from -0.5 to -1.5%) drives an increase in the dielectric maximum temperature (from 150 to 210°C), intermediate temperature (from 230 to 320°C), and the Burns temperature (from 290 to 350°C). Diffuse-scattering experiments reveal marked strain-induced changes in the diffuse-scattering pattern, namely from a classical butterfly- to a disc-shaped pattern; which is attributed to polarization rotation and an increase of the correlation length of polar domains (from 8 to 25 nm). Molecular-dynamics simulations provide direct visualization of the domain structures and analysis of local dynamics reveals that such changes are due to the anomalous correlation behavior of unit cells with complex chemistries. Using the same thin-film platform, we further explored size effects in relaxor thin films. Here we demonstrate that reducing the size, contrary to popular belief, first enhances relaxor behavior until a threshold thickness below which the critical temperatures that characterize various relaxor phases (i.e., dynamic, static, and frozen) collapse together, indicating destabilization of the relaxor
state. Using temperature-dependent diffuse scattering and ferroelectric measurements, we demonstrate that the relaxor loses its defining characteristics below this threshold thickness. The mechanism for destabilization of realtor behavior below the critical thickness is discussed in terms of faster dynamics of polarization fluctuations in ultrathin relaxor films.

10:45 AM EP01.09.08 Surface Pyroelectricity in SrTiO3 Elena Meirzadeh1, Evgeniy Makagon1, Dennis V. Christensen2, David Ehre1, Meir Lahav1, Nini Pryds2 and Igor Lubomirsky3, 5; 1, 5Weizmann Inst of Science, Rehovot, Israel; 2Department of Energy Conversion and Storage, Technical University of Denmark, Roskilde, Denmark.

Single crystals of perovskite-structured SrTiO3 are used in a variety of applications ranging from catalysis to substrates for epitaxial thin film growth. Although SrTiO3 is paraelectric (space group Pm-3m), it is incipient ferroelectric. Surface structure of SrTiO3 changes under various conditions and has been thoroughly studied over the years both computationally and experimentally. It has been suggested that the crystal undergoes surface relaxation leading to the formation of a near-surface polar layer[1]. Improvements in current measurement equipment during the last decade have increased the sensitivity of pyroelectric measurement[2], allowing us to measure surface pyroelectricity from single crystals of SrTiO3. Our results provide a direct experimental proof for the presence of a near-surface polar layer in this material. We have found that annealing the crystals in the presence of TiO2 powder eliminates the surface pyroelectricity while chemical treatment with dilute nitric acid restores it.

One can expect that the existence of the surface pyroelectric layer might affect the structure and macroscopic properties of the functional materials for which SrTiO3 is used as a substrate.

11:00 AM EP01.09.09 Optimizing a Floating-Base Bipolar Heterojunction Phototransistor by Piezo-Phototronic Effect Fangpei Li, Zijian Pan, Wenbo Peng and Yongming He; Xian Jiaotong University, Xian, China.

Recently, extensive research works have demonstrated significant modulation on photoresponse performances by the piezo-phototronic effect in various optoelectronic devices. However, although piezo-charges of both positive and negative polarities always appear in pairs and in same amount simultaneously and equally, most research works till today only utilize piezo-charges of one polarity, either positive or negative, excluding the potential combined advantages of utilizing both positive and negative piezo-charges at the same time. In this work, a p-Si/n-ZnO/p-PEDOT:PSS bipolar heterojunction phototransistor is fabricated, and its strain-induced improvements in photoresponses are reported: the photoresponsivity is improved from 62.80 to 90.30 mA/W (with an improvement of almost 50%) and the specific detectivity is improved from 0.31×10⁹ to 0.42×10⁹ Jones (with an enhancement of about 35%). Experimental results also show interesting optimizing behaviors, of which the fundamental physics are thoroughly explained by carefully analyzing the strain-induced modulations in local energy band diagrams at p-Si/n-ZnO and n-ZnO/p-PEDOT:PSS interfaces, respectively. For the first time, the piezo-phototronic effect has been validated in a ZnO-based bipolar heterojunction phototransistor, where the device structure of two back-to-back p-n heterojunctions possesses great potential capability to achieve low noise, large photoresponsivity and high speed qualities. More importantly, by successfully utilizing both positive and negative piezoelectric charges in one device, this work advances the practical applications of the piezo-phototronic effect in tri-/multi-layer device structures where excellent performances can be expected.

11:15 AM EP01.09.10 Tunable Electroresistance and Electro-Optic Effects of Transparent Molecular Ferroelectrics Shengjiang Ren; University at Buffalo, The State University of New York, Buffalo, New York, United States.

Recent progress in molecular ferroelectrics (MOFEs) has been overshadowed by the lack of high-quality thin films for device integration. We report a water-based air-processable technique to prepare large-area MOFE thin films, controlled by supersaturation growth at the liquid-air interface under a temperature gradient and external water partial pressure. We used this technique to fabricate Im2ClO4 thin films and found a large, tunable room-temperature electroresistance: a 20-fold resistance variation upon polarization switching. The as-grown films are transparent and consist of a bamboo-like structure of (2,-1,0) and (1,0,-2) structural variants of $d_{33} = 38.8$ pm/V. Polarization switching results in a change of the refractive index, $n$, of single domains, $\Delta n/n = 0.3$. The remarkable combination of these characteristics renders MOFEs a prime candidate material for new nanoelectronic devices. The information that we present in this work will open a new area of MOFE thin-film technologies.

11:30 AM EP01.09.11 Blowing Polar Skyrmion Bubbles in Oxide Superlattices Zijian Hong1, 3 and Long-Qing Chen1; 1The Pennsylvania State University, State College, Pennsylvania, United States; 3Department of Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Particle-like topological structures such as skyrmions and vortices have garnered ever-increasing interests due to their rich physical insights and potential broad applications in spintronics. Here we discover the reversible switching between polar skyrmion bubbles and ordered vortex arrays in ferroelectric superlattices under an electric field, reminiscent of the Plateau-Raleigh instability in fluid mechanics. An electric field phase diagram is constructed, showing a wide stability window for the observed polar skyrmions. A ‘volcano’-like Pontryagin density distribution is formed, indicating the formation of a smooth circular skyrmion. The topological charge $Q$ at different applied field is calculated, verifying the field-driven topological transition between $Q=0$ and $Q=\pm 1$ states. This study is a demonstration for the computational design of field-induced topological phase transitions, giving promise for the design of next-generation nanoelectronic devices.

11:45 AM EP01.09.12 Inducing Magnetism in the Electron Gas at LaAlO3/GdTiO3/SrTiO3 Interfaces Nikita Lebedev1, 2; 1Kamerlingh Onnes Laboratory, Leiden University, Leiden, Netherlands; 2Physikalisches Institut (EP 3), Universität Würzburg, Würzburg, Germany; 3MESA+ Institute for Nanotechnology, University of Twente, Enschede, Netherlands; 4School of Engineering and Technology, BML Munjal University (Hero Group), Gurugram, India.

At the interface between band insulators LaAlO3 (LAO) and SrTiO3 (STO) a two-dimensional electron gas (2DEG) can be formed. There are also indications that the Ti3+ ion can give rise to (spurious) magnetism. However, fabricating a homogeneous spin-polarized electron gas is still a challenge.
One strategy is to bring rare earth ions close to the interface. After inserting a 2-unit-cell layer of the band insulator EuTiO$_3$ (ETO) an anomalous Hall effect (AHE) was reported [1], as a signature for magnetism. In our work we inserted 2 unit cells of the Mott insulator GdTiO$_3$ (GTO) between LAO and STO. Note that the Eu-ion in ETO is divalent (like Sr), while the Gd-ion in GTO is trivalent (like La). Samples were prepared by Pulsed Laser Deposition. The temperature dependence of the sheet resistance shows that a 2DEG has formed. Gating the system at low temperatures with a negative voltage leads to a metal-insulator transition, with a Kondo like resistance minimum. For positive voltages, the system becomes increasingly metallic and shows an AHE as well as hysteretic behavior of Hall coefficient. It appears that magnetism is induced, but only at finite gate voltages.

SESSION EP01.10: Non-Conventional Applications of Polar Materials
Session Chairs: Jennifer Andrew and Thomas Fix

Magnetoelectric Sensors—PicoTesla Magnetometers and Ultracompact Acoustically Actuated Antennas Nian Sun, Hwaider Lin and Neville Sun; ECE Department, Northeastern University, Boston, Massachusetts, United States.

Recent research have demonstrated strong magnetoelectric (ME) coupling realized through strain mediated interactions in layered magnetic and ferroelectric multiferroic heterostructures. Most ME effects have been demonstrated in a static or quasi-static process used in applications such as reconfigurable RF components and spintronics. However, utilizing the strong ME coupling effect dynamically at very high frequency (VHF) and ultra-high frequency (UHF) will allow for receiving and transmitting electromagnetic waves with devices on the micro-scale. Here we present the most recent progress on novel RF nanomechanical ME resonators with pico-Tesla sensitivity and a new antenna miniaturization mechanism to create acoustically actuated nanomechanical ME antennas. Modern compact antennas that rely on electromagnetic (EM) wave resonance typically have a size greater than λ/10, making it difficult to reach VHF and UHF. The large electromagnetic wavelength λE puts a constraint on miniaturizing antennas for wireless communication systems where ultra-compact antennas can help save space. This novel concept utilizes the acoustic wave resonance due to the ME affect instead of relying on the electromagnetic wave resonance to reduce the antenna size 1-2 orders of magnitude without any performance degradation.

2:00 PM *EP01.10.02
Functional Oxide Thin Films for Diverse Applications Wilfrid Prellier; CRISMAT Laboratory, Caen, France.

Transition metal oxides often having a perovskite structure form a wide and technologically important class of compounds. In these systems, ferroelectric, ferromagnetic, ferroelastic, or even orbital and charge orderings can develop and eventually coexist. These orderings can be tuned by external electric, magnetic, or stress field, and the cross-couplings between them enable important multifunctional properties, such as piezoelectricity, magneto-electricity, or magneto-elasticity. Here, I will illustrate the utilization of emerging materials prepared as thin films. By growing PrVO$_3$ thin films epitaxially on an SrTiO$_3$ substrate, I will show that the role of oxygen vacancies can be rationalized to introduce a chemical strain similar to the so-called mechanical strain (±2%), which in turns produce a nontrivial evolution of Neél temperature in a range of 30 K. The possible ferroelectricity will also been discussed.

Financial support from ANR, Labex, and Region Normandie (INCOX project) are acknowledged.

2:30 PM EP01.10.03
Structure-Function Relations in Mixed Phase BiFeO$_3$ via Phase Population Control—The Roles of Electric Field and Nanoscale Stress Aaron Nadeau$^{1, 2}$, David Edwards$^{3, 4}$, Sabine M. Neumayer$^{3, 5}$, Joseph Guy$^1$, Brian J. Rodriguez$^3$, Nazanin Bassiri-Gharb$^5$ and Amit Kumar$^1$; $^1$Queen's University Belfast, Belfast, United Kingdom; $^2$School of Chemistry, University of St Andrews, St Andrews, United Kingdom; $^3$School of Physics and Conway Institute, University College Dublin, Dublin, Ireland; $^4$Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; $^5$G.W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Mixed phase BiFeO$_3$ (BFO) films have recently attracted significant attention due to their advantageous functional properties which are often strongly related to the films’ microstructures. The crystallographically mixed phase microstructure is obtained through epitaxial growth on substrates with a large lattice mismatch with the BFO film. In such systems, monoclinic phases with alternating tetragonal- and rhombohedral-like structures (which we refer to as T- and R-phase for brevity) form spontaneously in order to accommodate the epitaxial strain. Despite the favourable properties of these films, significant challenges remain in understanding the precise nature of the interplay of structural transitions and ferroelectric switching and how this behaviour of phenomena influences the behaviour of mixed phase BFO.

Here we demonstrate deterministic nanoscale control of the R/T-phase population between ~100 % and ~30 % T-phase using electric field and nanoscale stress applied through an atomic force microscope (AFM) tip. To develop a truly holistic understanding of the phase population, we explore the effects of electric field and nanoscale stress on the electromechanical properties of the material using a variation of band excitation piezoresponse force microscopy. Simultaneously application of these external fields via the AFM tip results in enhancements in the electromechanical response which manifest in the form of peaks, or noses, in the piezoresponse loops at a single given polarity of applied electric field: when the AFM tip is biased positively relative to the bottom electrode, corresponding nominally to a downward polarisation. By collecting nanoscale electromechanical hysteresis loops and simultaneously monitoring the elastic behaviour during switching, we develop a comprehensive picture of the complex interplay of ferroelastic structural transitions and ferroelectric switching and its impact on the overall functional response. Such an understanding is a crucial step towards realising practical electronic devices, such as pressure sensors, incorporating this promising material.

3:15 PM EP01.10.04
High-Field Nonlinear Dielectric and Piezoelectric Properties of Fe$_3$O$_4$ Doped PMA$_x$PZN-PZT Ceramics Huaizhang Zhang, Jie Shen, Quan Wei, Kunkun Han, Jing Zhou and Wen Chen; State Key Laboratory of Advanced Technology for Materials Synthesis and Processing, School of Materials
High-power devices, such as ultrasonic motors, underwater acoustic transducers and piezoelectric transformers, require piezoelectric ceramics with low dielectric loss tan δ, high mechanical quality factor Qm (low mechanical loss), and simultaneously large piezoelectric constant d33 and electromechanical coupling factor k2. In our previous work, Fe3O4 doped Pb(Mn1/3Nb2/3)O3-Pb(Zn1/3Nb2/3)O3-Pb(Zr, Ti)O3 (PMnS-PZN-PZT) ceramics were found to possess a relatively high piezoelectric property and an extremely low dielectric loss [3], showing that the ceramics are promising for high-power applications. Nevertheless, the electric field-dependence of piezoelectric property and the origin of the low losses of Fe3O4 doped PMnS-PZN-PZT ceramics are still remained to be clarified.

In this study, electric field dependence of dielectric and piezoelectric properties in subswitching field range, and effect of temperature on high-field nonlinearity of dielectric property for Fe3O4 doped PMnS-PZN-PZT high-power piezoelectric ceramics are investigated. To characterize the domain wall motion, the electric field dependent dielectric and piezoelectric properties are discussed in terms of Rayleigh analysis [4-5]. Results show that with the increase of electric-field level, both the dielectric and piezoelectric properties deviate their low-field values and exhibit increase trends, due to the enhanced domain wall motion at high field. Rayleigh analysis reveals the contribution from lossless reversible domain wall motion to the high-field nonlinear dielectric and piezoelectric properties in Fe3O4 doped PMnS-PZN-PZT ceramics. This behavior is associated with the orderly distribution of defect pinning centers, and is thought to be responsible for the low losses of the ceramics. At elevated temperatures, the mobility of the oxygen vacancies increases, so that the distributions of the defect pinning centers are gradually randomized, which consequently lead to the enhancement of high-field nonlinearity.

Ferroelectric Materials—A New Antimicrobial Class
Sandeep K. Shukla, Rahul Vaish and Satvasheel Powar; Indian Institute of Technology Mandi, Mandi, India.

Bacterial contamination is one of the major concerns around the world especially in developing countries where safe drinking water and bacterial diseases are still a primary risk. Current antibacterial substances suffer from their own limitations such as sustainability, resistance and cost. Herein, we propose a novel method for bacterial disinfection using ferroelectric materials. Ferroelectric materials like Ba0.5Ca0.5Ti0.5Zr0.5O3 (BCTZO), BaTiO3 possess remnant polarization on the surface as a result of aligned dipoles, attained through electric field poling. The effect of poling on the photocatalytic performance of ferroelectric materials has been investigated. The improved photocatalytic performance of poled samples attributed to the charge separation capability of poled samples. The antibacterial property of ferroelectric materials found to be surface selective as the positive side of ferroelectric materials electrostatically attracts negatively charged bacterial cells. The effect of photocatalysis on bacterial degradation studied further under UV irradiation. The antibacterial performance of poled ferroelectric material was tremendously improved in combination with UV irradiation. The complete bacterial eradication attained in less than 60 min of exposure when tested in combination. DCFDA assay study confirmed that the reactive oxygen species produced during electrolysis of water is one of the crucial factors for this remarkable photo-driven antibacterial performance. Poled ferroelectric materials exhibited excellent photocatalytic property for resazurin ink (Rz) and bacterial degradation. Interestingly, a synergistic effect observed against Rz ink and bacteria employing Ferro-photocatalysis and piezocatalysis. With these promising results, we believe, Ferrocailalys will open new ways for disinfection of drinking water, food products, and environmental pollutants.

Polymer-Based Efficient and Robust Piezoelectric Energy Harvesters
Deepa Singh1,2, Aditya Choudhary1 and Ashish Garg1; 1Department of Materials Science and Engineering, Indian Institute of Technology Kharagpur, Kharagpur, India; 2Department of Physics and Astronomy, Western University, London, Ontario, Canada.

Ferroelectric materials are the most sought out electronic materials because of their multifunctional applications in energy harvesting, sensing, memory and biomedical applications. Organic devices based on ferroelectricity are a promising approach towards the development of a low cost, low temperature, solution processed technology. Here, we demonstrate flexible devices with MgO-Poly(vinylidenefluoride-trifluoroethylene)(P(VDF-TrFE)) nanocomposites. P(VDF-TrFE) is known for its high remnant polarization, low switching time and highly insulating properties. Incorporation of a small amount of MgO leads to improved dielectric, ferroelectric and piezoelectric performance without affecting its other electrical properties such as leakage current and breakdown strength: two long-lasting problems with nanocomposites. MgO, a hygroscopic material, is considered to have inherent –OH bonds at its surface. These –OH bonds form hydrogen bonds with PVDF-TrFE as estimated by FTIR measurements. This interaction further improves electric fatigue and leakage current by reducing the gauche defects such as chain folding and kinks. PVDF-TrFE polymer can sustain larger strains compared to conventional inorganic materials due to their flexibility. This makes them more appropriate for harvesting energy from mechanical fluctuations. Flexible nanocomposite devices exhibit 50% improvement in piezoelectric properties. The piezoelectric coefficient (d33) value of ~65 pm/V was obtained for 2wt % MgO(P(VDF-TrFE) nanocomposites in contrast to pure P(VDF-TrFE) devices with d33 value of about ~40 pm/V. In addition, output voltage response increases two times with MgO nanoparticles as compared to pure P(VDF-TrFE) based devices. Bending test confirmed that d33 values remain unaffected even after 10000 bending cycles. This corroborates the beneficial role of MgO in sensing and memory applications.

SYMPOSIUM EP02

Materials for Manipulating and Controlling Magnetic Skyrmions

Symposium Organizers
Skyrmion Dynamics—From Thermal Diffusion to Ultra-Fast Motion

Mathias Klaui
1, 2: 1Univ Mainz, Mainz, Germany; 2Materials Science in Mainz, Johannes Gutenberg University Mainz, Mainz, Germany.

The three key requirements for spintronics devices are: (i) stable spin structures for long term data retention; (ii) efficient spin manipulation for low power devices and (iii) ideally no susceptibility to stray fields as realized for antiferromagnets. We explore different materials classes to tackle these challenges and explore the science necessary for a disruptive new technology.

To obtain ultimate stability, topological spin structures that emerge due to the Dzyaloshinskii-Moriya interaction (DMI), such as chiral domain walls and skyrmions are used. These possess a high stability and are of key importance for magnetic memories and logic devices [1,2]. We have investigated in detail the dynamics of topological spin structures, such as chiral domain walls that we can move synchronously with field pulses [3]. We determine in tailored multilayers the DMI, which leads to perfectly chiral spin structures. For ultimately efficient spin manipulation, spin torques are maximized by using highly spin-polarized ferromagnetic materials [2] and using spin-orbit torques, we can efficiently manipulate magnetization [4-6].

We then combine materials with strong spin-orbit torques and strong DMI where novel topologically stabilized skyrmion spin structure emerge [5]. Using spin-orbit torques we demonstrate in optimized low pinning materials for the first time that we can move a train of skyrmions in a “racetrack”-type device reliably [5,6]. We find that skyrmions exhibit a skyrmion Hall effect leading to a component of the displacement perpendicular to the current flow [6]. We study the field - induced dynamics of skyrmions [7] and find that the trajectory of the skyrmion’s position is accurately described by our quasi particle equation of motion.

While thus highly reproducible driven skyrmion motion is possible, we have recently developed new ultra-low pinning multilayer stacks, which exhibit thermally activated dynamics of skyrmions [8]. Here the energy landscape is sufficiently flat so that we observe pure diffusive motion of skyrmion quasiparticles at room temperature [8]. Furthermore, in contrast to the analytical calculations, we find a strong temperature dependence of the diffusion and explain these observations based on thermally activated excitations. Finally we can employ skyrmion diffusion in a skyrmion reshuffler device enabling novel stochastic computing approaches [8].

Real-Space Observation of Topological Spin Textures and Their Dynamics in Thin Chiral-Lattice Magnets

Xiuzhen Yu; RIKEN CEMS, Saitama, Japan.

The real-space spin textures have recently attracted enormous attention owing to their topological nature and emergent electromagnetic properties [1]. Here, I will present real-space observations of nanometer-scale topological spin textures and their lattice forms, such as meron-antimeron square lattice (sq.-ML), hexagonal skyrmion lattice (hex-SkL) and their structural transition from the sq.-ML into hex-SkL with finely tuning the magnetic field which is applied normally to a thin chiral-lattice magnet, Co$_8$Zn$_9$Mn$_3$. The topological phase transition between a hex-SkL phase and non-topological spin textures, helical or conical structure, have been demonstrated by means of the in-situ Lorentz transformation electron microscopy observations with current excitation [2] or quenching the thermal equilibrium SkL in thin helimagnets [3]. In addition, the skyrmion dynamics, such as the Brownian motion of skyrmion in a chiral-lattice insulator, the collective transformation of sparsely-populated skyrmions to microcrystals of skyrmions, and the current-driven skyrmion motion will be shown.

These works were done in collaborations with Profs. Yoshinori Tokura, Naoto Nagaosa, Masashi Kawasaki, Taka-hisa Arima, Maximam Mostovoy, Yusuke Tokanaga, Fumitaka Kagawa and Masahiko Morishizuki and Drs. Tasjirou Taguchi, Wataru Koshibae, Shinichiro Seki, Naoya Kanazawa, Tomoyuki Yokouchi, Daiuke Morikawa, Masao Nakamura, Kiyou Shibata, and Yoshih Kaneko.

via a giant AHE for single crystals of Mn3Sn and Mn3Ge [7,8]. In general Mn-rich Heusler compounds with heavy transition metals such as Mn2RnSn can be designed with frustrated spins, large Berry curvature as a consequence of Weyl points close to the Fermi energy [6]: this has recently been proven to induce Weyl points in magnetic fields, which break time-reversal symmetry [3-5]. However, even antiferromagnetic Manganese-rich Heusler compounds applications that result from the large Berry phases that they exhibit: these lead to giant anomalous Hall effect (AHE), spin Hall effects (SHE) and tunable topological insulators, half metallic ferromagnets and non collinear topological spin structures [1]. The required band inversion has already been unambiguously identified by angle-resolved photoemission (ARPES) and transport [2]. Weyl and Dirac semimetals open up new research directions and applications that result from the large Berry phases that they exhibit: these lead to giant anomalous Hall effect (AHE), spin Hall effects (SHE) and topological spin structures. In the C1b Heusler compounds such as GPdB, the inclusion of rare earth atoms allows the use of magnetic exchange fields to induce Weyl points in magnetic fields, which break time-reversal symmetry [3-5]. However, even antiferromagnetic manganese-rich heusler compounds can be designed with frustrated spins, large Berry curvature as a consequence of Weyl points close to the Fermi energy [6]: this has recently been proven via a giant AHE for single crystals of Mn5Sn and Mn5Ge [7,8]. In general Mn-rich Heusler compounds with heavy transition metals such as Mn5RnSn show a large Dzyaloshinskii-Moriya interaction (DMI) and therefore non-collinear spin structures [9,10]. Skyrmions, topologically stable spin textures, are of great interest for new generations of spintronic devices. Depending on the crystal symmetries, two distinct types of swirling of the skyrmions, named Bloch and Neel types, have been observed experimentally. In a family of acentric tetragonal Heusler compounds with D4h crystal symmetry Skyrmions with a special type of spin-swirling, called antiskyrmions, can even be realized. The interplay between the anisotropic exchange and DMI modifies a helical magnetic phase that propagates in the tetragonal basal plane into antiskyrmions arranged on a hexagonal lattice. The flexibility of their manipulation in the present system is demonstrated by the achievement of antiskyrmions up to 400 K and their zero field metastable state at low temperatures [11]. The family of tetragonal Heusler materials including non-collinear spin structures and Skyrmions opens a new spintronics direction including the realization of skyrmionics.

4:00 PM EP02.02.02
Terbium, Europium and Thulium Iron Garnets as a Platform for Insulator Spintronics Ethan Rosenberg, Jackson A. Bauer, Lukas Beran, Can Onur Avci, Bingjian Song, Geoffrey Beach and Caroline A. Ross; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Rare earth (RE) garnets with formula RE Fe2-xGd2x/3O3 provide a rich class of ferrimagnetic insulators in which anisotropy, saturation magnetization and temperature compensation can be tuned by choice of rare earth, ratio of rare earth to iron, and oxygen off-stoichiometry. Here we describe the growth, magnetic and spintronic properties of epitaxial terbium iron garnet (TBIG) and europium iron garnet (EuIG) thin films with perpendicular magnetic anisotropy (PMA), in comparison to the better-studied thulium iron garnet (TmIG). Reciproc space mapping shows that all the films are lattice matched to gadolinium gallium garnet (GGG) or substituted GGG (SGGG) substrates without strain relaxation, even for films up to 56 nm thick. The PMA is governed by magnetoelastic anisotropy, and both EuIG and TbIG are under in-plane compression on GGG. EuIG exhibits PMA for both (111) and (100) GGG orientations whereas TbIG exhibits PMA for (111) but not (100) GGG, as expected from the sign of the magnetostriction coefficients. In contrast, TbIG on SGGG (111) is in tension and has an in-plane easy axis. Films grown at higher oxygen pressures have excess rare earth which is believed to replace Fe2+ on the octahedral sites, altering the sublattice magnetization. TbIG films have a compensation temperature of around 330K. The EuIG films have damping parameter of 0.025, whereas damping in TmIG is 0.016 and increases when a Pt overlayer is added. Polycrystalline EuIG was grown on a range of substrates and showed PMA when the thermal expansion mismatch led to in plane compression. Anomalous Hall effect (AHE) measurements of Pt/EuIG/GGG Hall cross show that the spin mixing conductance of Pt/EuIG is orientation-dependent, with values for (111) EuIG being an order of magnitude larger than those of (001) EuIG. AHE measurements of Pt/TbIG/GGG Hall crosses reveal a sign change in the AHE amplitude at the compensation point, analogous to all-metallic Pt/ferrimagnet systems, and indicating that the spin Hall magnetoresistance-induced AHE is dominated by the Fe sublattice rather than the net magnetization. Pt/TmIG/GGG showed a Dzyaloshinskii-Moriya interaction (DMI) field of ~50 Oe, sufficient to stabilize homochiral Neel-type domain walls in 5 nm thick TmIG. Moreover, magnetic imaging showed domain sizes of 10 – 20 nm. These results show that RE garnet/Pt heterostructures are excellent candidates for obtaining skyrmions and other chiral textures at room temperature.

4:15 PM EP02.02.03
Current-Driven Dynamics of Chiral Domain Walls in Thulium Iron Garnet/Platinum Bilayers Can Onur Avci, Ethan Rosenberg, Lucas M. Caresza, Lukas Beran, Felix Buettner, Caroline A. Ross and Geoffrey Beach; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Magnetic insulators (Mls), especially iron-based garnets, possess remarkable properties such as ultralow damping, long magnon decay lengths and high structural quality which can provide significant advantages for practical applications with respect to their metallic magnetic counterparts. Recently, robust perpendicular magnetic anisotropy is obtained in ferrimagnetic thin films of thulium, europium, and terbium iron garnet (TmIG, EuIG, and TbIG) grown on gadolinium gallium garnet (Gd3Ga5O12) substrates down to a thickness of 5.1 nm with saturation magnetization close to the bulk value [1,2]. By using the spin Hall effect in Pt we have demonstrated efficient spin current injection through the TmIG/Pt interface, which we quantified by the spin Hall magnetoresistance and harmonic Hall effect measurements [1-3]. This spin current is strong enough to realize deterministic spin-orbit torque-driven magnetization switching of TmIG (~10 nm)/Pt bilayer both with quasi-dc (5 ms) as well as pulsed currents down to 2 ns width [1,4]. The switching current density through Pt is found to be of the order of ~10^-7 A/cm~2 using dc (pulsed) current comparable to the reported values, e.g., for Pt/Co[5]. We then investigated the structure and current-driven dynamics of domain walls in TmIG/Pt bilayer. We found that, solely using electrical currents, domain walls can be efficiently.
moved indicating the presence of Neel-type domain wall texture in this system. Detailed analysis revealed that homochiral domain walls are stabilized by the Dzyaloshinskii-Moriya interaction occurring at the TmIG/Pt interface which produces an effective field of ~50 Oe. By using nanosecond-long pulses we determined the current-driven domain wall intrinsic velocities of the order of ~800 m/s per current densities as low as ~1.2x10^4 A/m^2, one of the highest reported in any ferromagnetic system thus far. In this presentation, along with the above findings, we will discuss the scanning transmission x-ray microscopy imaging of chiral textures in TmIG/Pt and the possibility of obtaining skyrmions in rare earth-based garnets at room temperature.

4:30 PM EP02.02.04 Rare Earth-Transition Metal Alloys as Promising Materials for Small Skyrmions and Ultrafast Chiral Spin Texture Dynamics Lucas M. Caretta¹, Maxwell Mann¹, Felix Buettner¹, Kohei Ueda¹, Bastian Pfau¹, Cristian Guenther¹, Piet Hessing², Alexandra Cherukova¹, Christoph Klose², M Schneider², D Engel², Colin Marcus², David Boni², Kai Bagchi³, Stefan Eisebitt² and Geoffrey Beach³; ¹Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; ²Max-Born Institute, Berlin, Germany; ³DISY, Hamburg, Germany.

Spintronics is a research field geared towards understanding and controlling spins on the nanoscale, enabling next-generation data storage and manipulation. Ultimately, the technological and scientific challenge is to create ultrasmall solid-state magnetic bits (<10 nm) and to control their motion efficiently with ultrahigh velocities (>1 km/s). Inspired by materials used for hard disk drives, research so far has focused on ferromagnetic materials. However, these materials show fundamental limits for speed and size making applications unlikely. Ferromagnetic materials have large stray fields, causing ferromagnetic spin textures to repel each other over long distances. Stray field interactions also lead to a preferred demagnetization of the material, i.e., skyrmions are large (>100 nm) if they are not assisted by external fields or strong pinning. In addition, the velocity of magnetic solitons is fundamentally limited by the precessional dynamics underlying any coherent spin texture displacements, ultimately making motion inefficient. For skyrmions, the velocity is also limited by stripe-out instabilities and by topological damping. In both cases, the observed skyrmion velocities in ferromagnetic materials have always been lower than ~100 m/s. Moreover, ferromagnetic materials suffer from a large skyrmion Hall angle and from topological damping. These fundamental limitations of ferromagnets call for new materials systems.

Here, we demonstrate that compensated rare earth - transition metal ferrimagnets (FiM) are not affected by these limits. FiM, comprised of two antiferromagnetically coupled sublattices, have two compensation temperatures: the magnetization compensation temperature TM, defined by Ms(TM)=0, and the angular momentum compensation temperature TA with vanishing spin density S(TA)=0. Near TA, the spins align with the magnetic field without any precession and a driving force immediately leads to acceleration in the direction of force. Near TM, stray fields become negligible and spin textures are stabilized by the competition of local exchange, anisotropy, and Dzyaloshinskii-Moriya interaction (DMI). Thus, zero field skyrmions with less than 10 nm in diameter can be realized at room temperature and interactions skyrmions is completely suppressed. In other words, very efficient dynamics are expected to occur near TA and very small spin textures can be realized at TA. Using these concepts in ferrimagnetic Pt/GdCo/Ta films, we realize a record-fast current-driven domain wall velocity of 1.3 km/s and record small room-temperature stable ~10 nm diameter skyrmions near TA and TM, respectively. Moreover, TA and TM are engineered to be near each other and near room temperature for both fast dynamics and small textures. Compensated FiM are a promising spintronics candidate, as a range of easily accessible knobs, such as interfaces, annealing, sample temperature, and composition can control their properties.

4:45 PM EP02.02.05 Electrical-Field-Control of Ferromagnetism and Magnetic Skyrmions in 2D CrI3 Monolayers Pinghu Mo¹, Mengchao Shi¹, Jiwu Lu¹ and Jie Liu¹; ¹College of Electrical and Information Engineering, Hunan University, Changsha, China; ²Department of Electrical Engineering, University of Washington, Seattle, Washington, United States.

We report our recent research findings about the electrical-field-controllability of ferromagnetism and magnetic Skyrmions in two-dimensional chromium tri-iodide monolayers [1][2]. By combining the fully first-principles non-collinear self-consistent field density functional theory (DFT) with relativistic spin-orbital coupling effects and the Monte Carlo calculations, we show that, an externally-applied out-of-plane electrical field can significantly alter the spin configuration of a free-standing two-dimensional chromium tri-iodide (CrI3) ferromagnetic monolayer.

The electrical-field-dependent Dzyaloshinskii-Moriya interaction, magnetocryalline anisotropy, and magnetic exchange effects are quantitatively analyzed. It is shown that, by taking advantage of the counterbalancing effects of anisotropic symmetric exchange energy and antisymmetric exchange energy, the intrinsic ferromagnetism can be manipulated by externally applied out-of-plane electric fields. It is revealed that the out-of-plane electrical field could induce topologically-protected Neel-type Skyrmion ground state due to the breaking of inversion symmetry. By taking advantage of the above-mentioned properties, it is shown that 4-level data can be stored in a single monolayer-based spintronic device, which is of practical interests to realize the next-generation energy-efficient quaternary logic devices and multilevel memory devices.

SESSION EP02.03: Nucleation and Stabilization of Magnetic Skyrmions Session Chairs: Karin Everschor-Sitte and Song Jin Thursday Morning, November 29, 2018 Hynes, Level 2, Room 204

8:00 AM *EP02.03.01 Electrical Writing, Processing and Deleting of Room-Temperature Ferrimagnetic Skyrmions Seonghoon Woo; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

In spintronics, magnetic skyrmions are one of the most promising candidate for the next-generation memory-type application due to their nanometer-size, topological stability and efficient current-driven motion. [1] Recent efforts have realized the room-temperature stabilization of magnetic skyrmions and their current pulse-induced dynamic behaviours on nanotracks in magnetic heterostructures. [2, 3] However, there still exist many practical limitations for

Reference:
the realization of fully functional skyrmionic devices. In this presentation, we show our recent experimental demonstrations of the electrical writing, processing and deleting of ferrimagnetic skyrmions observable static and dynamic soft X-ray microscopy.

We first demonstrate a new type of skyrmion, called ferrimagnetic skyrmion. Ferrromagnetic skyrmions show undesirable topological effect, the skyrmion Hall effect, which leads to their current-driven motion towards device edges, where skyrmions could easily be annihilated by topographic defects. In this work, we present the stabilization of antiferromagnetically exchange-coupled skyrmions – ferrimagnetic skyrmions - and their current-driven dynamics in GdFeCo films. We demonstrate that ferrimagnetic skyrmions can move at a velocity of ~50 m s⁻¹ with significantly reduced skyrmion Hall angle, ΔH_{Hall} < 20°, which highlights the possibility to build more reliable skyrmionic devices using ferrimagnetic materials. [4]

Using the same material, we then demonstrate the electrical writing and subsequent deleting of a single magnetic skyrmion at room temperature, which are essential prerequisites for device application but have remained elusive so far. We also present that the number of written and destroyed skyrmions can be controlled by modulating the strength of spin orbit torques. The stroboscopic pump-probe X-ray measurement serves as a key technique to reveal the deterministic and completely reproducible nature of the observation. Micromagnetic simulations reveal the microscopic origin behind the observed topological fluctuation with great qualitative and quantitative agreement. Our findings show that the deterministic field-free writing and deleting of magnetic skyrmions can be readily achieved using electrical methods, which leap over a crucial hurdle toward building a practical skyrmionic device. [5]

Isolated Magnetic Skyrmions—From a Fundamental Understanding to the Observation of Ultrasmall Skyrmions at Room Temperature Felix Büttner1, Ivan Lemesl1, Lucas M. Caretta1, Maxwell Mann1, Kohei Ueda1, Bastian Pfaü1, Christian Günther1, Pier Hessing2, Alexandra Churikova2, M Schneider2, D Engel2, Christopher Klose2, Kai Bagschik2, Stefan Eisебitz3 and Geoffrey Beach1; 1Massachusetts Institute of Technology, Cambridge, United Kingdom; 2Max Born Institut, Berlin, Germany; 3Technische Universität Berlin, Berlin, Germany; 4DESY, Hamburg, Germany.

Skyrmions are the smallest non-trivial entities in magnetism with great potential for data storage applications. They were recently observed at room temperature in magnetic multilayer systems [1-4], most of them in materials with sizable Dzyaloshinskii-Moriya interaction (DMI). Despite this experimental breakthrough, our understanding of skyrmions is still limited because existing theories cannot analytically predict how the skyrmion energy changes as a function of its size. In particular, for many decades, the 6-fold integral of the stray field energies was considered unsolvable and the contributions of DMI and stray fields to stabilizing skyrmions could not be distinguished.

This problem has now been solved. In this talk, I will present a unified theory that analytically approximates the energy, including stray fields, of isolated skyrmions of all sizes with 1% precision [5]. I will show that there are indeed two types of skyrmions, 'stray field skyrmions' and 'DMI skyrmions', but in contrast to common belief it is not the domain wall angle (Neel or Bloch type) that distinguishes these two types. Surprisingly, the type of skyrmion is also not a material property: DMI and stray field skyrmions can even co-exist in the same material at the same field. This form of bi-stability opens a whole new area of potential skyrmion applications.

There is a strong desire to make room-temperature skyrmions small and to move them fast. However, all room temperature skyrmions observed so far are stray field skyrmions, and I will show that this fundamentally limits their stable size to much larger than 10 nm at room temperature. By contrast, DMI skyrmions can be smaller than 10 nm even at room temperature and zero applied field. All presently available data indicates that such skyrmions cannot exist in ferrimagnetic materials. Instead, ferrimagnets and antiferromagnets are the most promising materials for finding room-temperature DMI skyrmions. This theoretical prediction is confirmed by our first observation of sub-15 nm skyrmions in a ferrimagnetic material with strong DMI, where we also confirm that these skyrmions remain stable and retain their size at zero applied field.

8:45 AM EP02.03.03
Stability and Manipulation of Magnetic Skyrmions Giovanni Finocchio; University of Messina, Messina, Italy.

Magnetic skyrmions are topological protected solitons with a chirality that can be stabilized by the Dzyaloshinskii-Moriya interaction (DMI). Understanding the physical properties of magnetic skyrmions is important for fundamental research with the aim to develop new spintronic device paradigms where both logic and memory can be integrated at the same level or for unconventional computing. We have recently studied different mechanism of stabilization of skyrmions in confined devices, one of them needs a large DMI to introduce in the energy landscape an energetic minimum associated with a metastable skyrmion state and one that gives a skyrmion state which size depends on a trade off among magnetostatic, exchange and DMI energies. In this invited talk, we will show a universal model based on the micromagnetic formalism combining a proper ansatz and scaling relationships and a specific Q-d phase space (quality factor Q vs. reduced DMI d) that can be used to study skyrmion stability as a function of magnetic field and temperature[1]. We consider ultrathin, circular ferromagnetic magnetic dots. These results show that magnetic skyrmions with a small radius—compared to the dot radius—are always metastable, while large radius skyrmions form a stable ground state. The change of energy profile determines the weak (strong) size dependence of the metastable (stable) skyrmion as a function of temperature and/or field. We also show as this fundamental results can be used for specific application in a racetrack memory device where the skyrmions in the track are metastable and therefore small—giving a high storage density while are detected under a magnetic tunnel junction having a polarized layer with a magnetization pointing along the out-of-plane direction which generates a dipolar field parallel to the skyrmion core magnetization [1]. This field can modify the stability properties of the skyrmion in the region below the contact, moving it through the Q-d phase space. By shifting the skyrmions across the line of stability, their radius will expand significantly making it much easier to detect from the tunnel magnetoresistance signal. After leaving the detection regions, the skyrmions will return to their small size in the metastable region.

Finally, I will discuss the SHE-driven dynamics of a skyrmion in presence of an anisotropy gradient showing a scenario where the skyrmion is accelerated[2].

Magnetic skyrmions are topologically stable spin textures exhibiting quasi-particle like behavior and consequently can be directed with low electric currents. The controlled manipulation of magnetic skyrmions at room temperature in thin films is envisioned to enable skyrmion-based low-power information technologies, and consequently has engaged the interest of the scientific community in recent years [1]. Using trilayered heterostructures we have demonstrated how diverging electric charge currents combined with the spin Hall effect in a heavy metal layer can be used to generate and manipulate magnetic Néel skyrmions in an adjacent ferromagnetic layer [2,3]. Under application of homogeneous currents, the motion of magnetic skyrmions is experimentally shown to exhibit transverse motion relative to the current direction, i.e., the skyrmion Hall effect [4]. This effect arises due to the non-trivial topological charge of the skyrmions and is the analogue of the ordinary Hall effect for electrical charges in the presence of a magnetic field. With increasing current density, the skyrmion Hall angle first increases monotonically, which can be linked to the influence of pinning by defects, and then saturates, indicating the flow regime for motion has been reached. From an applications perspective, minimizing the skyrmion size is equally important to controlling the creation and motion of skyrmions. To this end, we have investigated inversion asymmetric [Pt/FM/X]Nmultilayers, where FM is a ferro- or ferrimagnet and X a transition or rare earth metal, which allows for various competing interactions to be tuned. Using magneto-optic Kerr imaging and Lorentz transmission electron microscopy, we show how the skyrmion size varies depending on the choice of metal X, the trilayer repetition number N, and the magnetic field.

Work at Argonne was supported by the Department of Energy, Office of Science, Basic Energy Science, Materials Sciences and Engineering Division.

Skyrmions in UltraThin Films

Stephan von Malottki1, Pavel Bessarab2, Soumyajitoyi Haldar1, Anna Delin1-3 and Stefan Heinze1; 1Institute of Theoretical Physics and Astrophysics, University of Kiel, Kiel, Germany; 2Department of Applied Physics, School of Engineering Sciences, KTH Royal Institute of Technology, Kista, Sweden; 3Department of Physics and Astronomy, Materials Theory Division, Uppsala University, Uppsala, Sweden; 4School of Engineering and Natural Sciences, Science Institute, University of Iceland, Reykjavik, Iceland.

The thermal stability of magnetic skyrmions is a key issue for potential applications in spintronic devices. An Arrhenius law can be used to describe the skyrmion lifetime as a function of temperature, which requires knowledge of the energy barrier and the pre-exponential factor. While the energy barrier has already been addressed by several studies (e.g. [1]), the pre-exponential factor for the skyrmion collapse remains largely unexplored [2, 3]. Here, we obtain skyrmion lifetimes by calculating not only the energy barriers but also the pre-exponential factors for ultrathin films such as Pd/Fe bilayers on Ir(111) – a system which has been extensively studied from experiment [4]. We have developed an analytical topological soliton model containing expressions of the long range demagnetising and exchange curvature energies, two key ingredients to stabilize bubbles and skyrmions in ferromagnetic thin films. This allowed us to construct a skyrmion and bubbles phase diagram and explore quantitatively the possible transitions between them. The observed skyrmion-bubble transition present similarities with the liquid-gas transition, in particular a critical point is present above which the transformation between both spin textures becomes continuous. While distinct characteristics of skyrmions and bubbles remain, their common nature as topological solitons is emphasised.

Magnetic skyrmions in noncentrosymmetric chiral magnets form ordered lattices with a periodicity ranging from 3-100 nm. This lengthscale lends itself to soft x-ray scattering experiments owing to the large resonant scattering cross-section for 3d elements, the excellent reciprocal space resolution, as well as the tunable surface sensitivity. We will present an overview of the capabilities of resonant elastic x-ray scattering (REXS) for the study of magnetic skyrmions [1], highlighting the following effects:

1) Topology [2]: Using circularly polarized light, REXS is capable to accurately determine the topological winding number of a skyrmion. This topology determination principle is a general experimental strategy, applicable to a wide range of topologically ordered magnetic materials.

2) Microscopic skyrmion properties [3]: By exploiting the polarization dependence of REXS, the exact surface helicity angles of twisted skyrmions for both left- and right-handed chiral bulk Cu2OSeO3 was determined.

3) Full 3D spin structure of skyrmions [4]: Using polarization-dependent REXS we found a continuous transformation of the skyrmion tubes from pure Néel-twisting at the surface to pure Bloch-twisting in the bulk over a distance of several hundred nanometers.

4) Rotating lattices [5]: In a magnetic field gradient, skyrmions undergo rotation with well-defined dynamics. This provides an effective way of controlling skyrmions in racetrack memory schemes.

Stabilizing Spin Spirals and Isolated Skyrmions at Low Magnetic Field Exploiting Vanishing Magnetic Anisotropy Marie Hervé1, Bertrand Dupé2, Rafael Lopes3, Marie Böttcher1, Maximilianio Martino1, Timofey Balashov1, Lukas Gerhard4, Jairo Sinova5 and Wulf Wulfhekel4, 4Physikalisches Institut, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; 2Institut für Physik, Johannes Gutenberg Universität Mainz, Mainz, Germany; 3Serviço de Nanotecnologia Laboratório de Nanoscopia, Centro de Desenvolvimento da Tecnologia Nuclear, Belo Horizonte, Brazil; 5Institute of Nanotechnology, Karlsruhe Institute of Technology, Karlsruhe, Germany.

Skyrmions are topologically protected non-collinear magnetic structures. The non-collinear Dzyaloshinskii-Moriya interaction originating from spin-orbit coupling drives their formation. The Dzyaloshinskii-Moriya interaction is enhanced at surfaces and interfaces via the hybridization of the magnetic atoms with 5d elements. It competes with Heisenberg exchange and magnetic anisotropy favoring collinear states. Isolated skyrmions in ultra-thin films so far coupling drives their formation. The Dzyaloshinskii-Moriya interaction is enhanced at surfaces and interfaces via the hybridization of the magnetic atoms with 5d elements. It competes with Heisenberg exchange and magnetic anisotropy favoring collinear states.

Skyrmions Under the X-Rays

Christos Panagopoulos; Nanyang Technological University, Singapore, Singapore.

Multilayers of Fe/Fe(x)/Co(y)/Pt enable us tailor the magnetic interactions governing skyrmion (Sk) properties, thereby tuning their thermodynamic stability parameter by an order of magnitude. In particular, Sk’s exhibit a crossover between isolated (metastable) and disordered lattice configurations across samples, while their size and density can be tuned by factors of 2 and 10, respectively. To study magnetization dynamics, we determined the damping parameter characterizing the magnetization response, and identified a gyrotropic Sk excitation that persists over a wide range of temperatures and across varying sample compositions. To explore the interaction of skyrmions with electrical current we carried a detailed microscopic investigation, which allowed us identify magnetic structures forming via Sk-Sk interaction and their role in designing and interpreting electrical signatures in materials and devices hosting Sk’s.

Magnetic Imaging and Magnetotransport Measurements of Skyrmion Hosting Cubic B20 Fe1-xCoSi and Fe1-xCoGe Nanostructures Nitish Mathur1, Matthew J. Stolt1, Sebastien G. Schneider2, Kodai Nishiu3, Xiazhun Vu4, Bernd F. Rellingerhaus3, Yoshihori Tokura3 and Song Jin1; 1University of Wisconsin-Madison, Madison, Wisconsin, United States; 2IFW, Dresden, Germany; 3RIKEN Center for Emergent Matter Science (CEMS), Wako, Japan.

Magnetic skyrmions are topological spin textures that have shown promise due to their potential application in high density and energy efficient memory nanodevices. Stable skyrmion phase can exist in chiral helimagnets with the non-centrosymmetric cubic B20 crystal structure, such as Fe1-xCoSi and Fe1-xCoGe.
FeGe, that have antisymmetric spin exchange interaction known as the Dzyaloshinskii-Moriya interaction (DMI). Nanostructuring further enhances the stability regime of skyrmion phases in these materials to larger range of temperature and applied magnetic field. We have developed “bottom-up” chemical vapor deposition (CVD) synthetic techniques to synthesize single-crystal FeGe nanowires (NWs), and cobalt alloyed Fe1-xCoSi (x<0.5) NWs and Fe1-xCoGe (x<0.1) nanowires (NPLs). We have imaged the spin structures in these nanostructures with Lorentz transmission electron microscopy (LTEM) for Fe1-xCoSi NWs and more intensive TEM-based magnetic imaging technique known as off-axis electron holography (EH) for Fe1-xCoGe NPs. Further, the evolution of different spin structures under varying applied magnetic field below Tc could be electrically detected by the field-dependent magnetoresistance (MR) measurements which enable us to determine the critical fields for magnetic state transitions at different temperatures. For the Fe1-xCoGe NPLs, Hall measurements further revealed the topological Hall effect (THE) characteristics of skyrmion phases. The imaging and transport measurements were used in conjunction with one another to construct representative magnetic phase diagrams for the Fe1-xCoSi NWs and Fe1-xCoGe NPs respectively. These B20 materials can serve as nice model systems to study skyrmion physics and prototype devices by taking advantage of nanometer-sized magnetic skyrmion domains.

Emergent Transport Effect in Chiral Spin Textures Yuriy Mokrousov1, 2, Fabian Lux3, Jan-Philipp Hanke1, 2, Matthias Redies1, Patrick Buhl1, Frank Freimuth1 and Stefan Bluegel1;
1Forschungszentrum Juelich, Juelich, Germany; 2University of Mainz, Institute of Physics, Mainz, Germany.

In the field of skyrmionics the progress in creation and manipulation of skyrmions with various size and charge has been truly remarkable. From the side of theory, in the past years various novel chiral particles such as chiral bobbers or hopfions have been predicted to exist under certain conditions. On the other hand, for experimental discovery and integration of these particles into future generation of devices their realizable detection by means of magnetotransport is imperative. Currently, this presents a significant problem, since our understanding of the transport properties of chiral spin textures is at a very preliminary level. In my talk I will review the recent progress in our understanding of the Hall effects and orbital magnetism exhibited by chiral particles of various nature. In particular, by starting from the adiabatic viewpoint that has been very successful in predicting various physical properties of chiral magnets such as topological Hall and topological spin Hall effects, we will arrive at and unravel the emergence of chiral and topological orbital magnetism in one- and two-dimensional spin systems. We will demonstrate that the emergent orbital magnetism has remarkable properties such as topological quantization, and its dynamics in skyrmionic systems can be used not only to detect the formation of skyrmions with different charge, but also to distinguish various types of dynamical “breathing” modes of skyrmion dynamics. Moreover, we will show that while beyond the adiabatic viewpoint the orbital magnetism of spin textures goes hand in hand with emergent Hall transport properties, remarkably, engineering the details of spin-orbit interaction and electronic structure in interfacial chiral systems allows for tuning the orbital and transport characteristics over orders of magnitude. We trace back such sensitivity of the emergent transport properties to the unique interplay of real-space and reciprocal-space topologies, and demonstrate that the Hall and orbital magnetization measurements can be used to categorize and uncover various topologically distinct phases of complex chiral magnets. This work was supported by Deutsche Forschungsgemeinschaft (projects MO 1731/5-1 and MO 1731/7-1) as well as by the DARPA TEE program through grant MIPR# HR0011831554 from DOD.

Detection and Manipulation of Magnetic Skyrmions in Metal Silicide and Germanide Nanostructures Song Jin; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Skyrmions, novel topologically stable spin vortices, hold promise for next-generation magnetic storage due to their nanoscale domains to enable high information storage density and their low threshold for current-driven motion to enable ultralow energy consumption. One-dimensional (1D) nanowires are ideal hosts for skyrmions since they not only serve as a natural platform for magnetic racetrack memory devices but also can stabilize skyrmions. We have developed synthetic methods for nanowires (and nanoplates) of non-centrosymmetric cubic B20 monosilicides (MnSi, FeSi, CoSi) and monogermanides (FeGe) and their alloys (such as Fe1-xCoSi and Fe1-xCoGe), many of which display exotic helimagnetic and skyrmion magnetic phases with domain sizes from 10 to 230 nm. Collaborating with several groups, we have used Lorentz TEM, off-axis electron holography (EH), magnetotransport measurements, and dynamic magnetic cantilever measurements to confirm that magnetic skyrmion phases are stable over a larger magnetic field-temperature range in these nanostructures compared to bulk crystals and thin films. Magnetoresistance (MR) measurements revealed the critical magnetic fields for the transitions between different magnetic spin structures at different temperatures. Topological Hall effect (THE) measurements of MnSi nanowires and Fe1-xCoGe (x<0.1) nanowires further confirmed the extended skyrmion stability. Particularly, FeGe nanowires and Fe1-xCoGe (x<0.1) nanowires can host skyrmions with stability up to about 280 K. We have further demonstrated the current-driven motion of skyrmions in this extended skyrmion phase region in MnSi nanowires. These results open up the exploration of nanowires as an attractive platform for investigating skyrmion physics in 1D systems and exploiting skyrmions in magnetic storage concepts.

3:45 PM *EP02.04.05
Various Topological Spin Textures and Emergent Phenomena in B20-Type Chiral Magnets Naoya Kanazawa; Department of Applied Physics, University of Tokyo, Tokyo, Japan.

Topological properties of skyrmions, such as topological Hall effect and current-driven skyrmion motion, stimulate researches on design of new topological spin textures in pursuit of further functionalities. Examples of those spin textures include biskyrmions, Néel-type skyrmions, and chiral soliton lattice. One guiding principle for creating such winding spin textures is utilizing antisymmetric spin exchange interaction, namely Dzyaloshinskii-Moriya (DM) interaction, allowed in crystals without local/global space inversion symmetry. We have realized various topological magnetic structures in a prototypical skyrmionic material, so-called B20-type compounds, by changing DM interaction, magnetic anisotropy and electronic structure, which are controlled by element substitution and device manufacturing. In this talk, we would like to show our recent results on formations of topological magnetic structures and consequent emergent phenomena in bulk and films of B20-type compounds [1-3].

Effect measurements [3], iii) the... thimel (RT) in magnetic multilayers through engineering of interfacial DMI [1].

In this presentation, I will present experimental imaging at RT on small skyrmions (30-80 nm) in several types of multilayers associating magnetic layers of Co and nonmagnetic layers of heavy metals (Pt, Ir, Ru etc…). First, the talk will be devoted to illustrate the wealth of skyrmions and describe some of our key recent results. We will discuss: i) the creation of skyrmions by current pulses and its mechanism (spin transfer torque vs thermal effects) [2], ii) the detection of skyrmions (one by one) by Anomalous Hall Effect measurements [3], iii) the current-induced motion of skyrmions, the influence of defects on velocity and Skyrmion Hall Angle [2]. Then, we will present some experimental results together with modelling on shaping skyrmions in 3D [4] by a control of the relative values of DMI and dipole interactions for a given number of layers experimentally revealed by x-ray magnetic scattering (XRMS) [5] and its impact on spin torque induced dynamics. These advances made in technologically relevant materials opens the way for the development of several concepts of skyrmion based devices going from race-track memory type to MRAM, from still highly silicon-compatible memories, such as multi-level MRAM or skyrmion racetrack memories to disruptive “beyond CMOS” technologies such as neuro-inspired architectures.

Magnetic quasi-particles such as skyrmions are of importance for novel magnetic information storage designs. In ultrathin multilayer systems skyrmions are stabilised by the interfacial Dzyaloshinskii-Moriya interaction which is present at interfaces between ferromagnets and heavy metals [3]. The room temperature stability of skyrmions in these multilayers is a desirable property for technological applications (2-5). Active focal areas are electrical skyrmion detection and manipulation. In the experiment outlined here we stabilized skyrmions in a 2 μm wire of [Pt/CoB/Ir]. Short current pulses (10 ns) were used to move the skyrmions through the wire while a static out of plane magnetic field was applied. Scanning transmission microscopy images were taken after each current pulse. The velocity and Skyrmion Hall angle was evaluated and a field dependence on the Skyrmion Hall angle was observed.

This work was funded by Horizon 2020 MagicSky and has received funding from the EU H2020 research and innovation programme under grant agreement N 654360 having benefitted from the access provided by the Paul Scherrer Institut in Villigen within the framework of the NFFA Europe Transnational Access Activity.

9:45 AM *EP02.05.03*

**Skyrmions with Antiferromagnets** Oleg Tretiakov; Tohoku Univ, Sendai, Japan.

Skyrmions are topologically protected spin textures, which can be used in spintronic devices for information storage and processing. Ferromagnetic skyrmions attracted a lot of attention because they are small in size, better than domain walls at avoiding pinning sites, and can be moved very fast by electric current in ferromagnet/heavy-metal bilayers due to novel spin-orbit torques.

Meanwhile, the ferromagnetic skyrmions also have certain disadvantages to employ them in spintronic devices, such as the presence of stray fields and transverse to current dynamics. To avoid these unwanted effects, we propose a novel topological object: the antiferromagnetic skyrmion. This topological texture has no stray fields and its dynamics are faster compared to its ferromagnetic analogue. More importantly, I will show that due to unusual topology it experiences no skyrmion Hall effect, and thus is a better candidate for spintronic applications. Then I will discuss the lifetimes of both antiferromagnetic and ferromagnetic skyrmions at finite temperatures.

Lastly, I will talk about antiskyrmions -- unusual anisotropic topological objects, which were recently observed in systems with anisotropic Dzyaloshinskii-Moriya interaction. I will make predictions for the antiskyrmion existence and properties in antiferromagnets.

10:15 AM *EP02.05.04*

**Skyrmion Dynamics, Nucleation and Stability in Ultrathin Metallic Heterostructures** Geoffrey Beach; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Magnetic skyrmions [1,2] are particle-like chiral spin textures that are topologically protected from being continuously ‘unwound’. Their topological nature gives rise to rich behaviors including ordered lattice formation, emergent electrodynamics and robust current-driven displacement by spin-orbit torque. This talk focuses on skyrmions in ultrathin ferromagnetic transition metal multilayers in which interfaces with heavy metals generate a strong Dzyaloshinskii-Moriya interaction (DMI) [3]. Inversion-asymmetric multilayer stacks such as [Pt/CoFeB/MgO]N have been shown to host room-temperature-stable skyrmions and skyrmion lattices, with sizes <50nm and current-driven velocities in excess of 100 m/s [4]. Here, we describe their current-driven creation and dynamics probed with x-ray microscopy, and their stability and materials-based design through an accurate fully-analytical model. Using time-resolved imaging, we demonstrate that in low-pinning CoFeB-based structures, current-induced shifting is repeatable over billions of cycles, and we reveal an analogue to the conventional Hall effect, in which the skyrmion trajectory depends on its topological charge much as a particle in a magnetic field is deflected due to its electric charge [5]. We then demonstrate deterministic current-induced skyrmion writing at sub-nanosecond timescales through the combined action of DMI and spin-orbit torque [6], and show that thermal excitation can drive morphological phase transitions between chiral phases in a controlled way [7]. Finally, we present an analytical framework [8] for computing the energy and structure of any skyrmion in any material, and apply the resulting design principles to experimentally realize room-temperature stable skyrmions with sizes approaching 10nm [9].

10:45 AM EP02.05.05

**Controlling the Dynamical Properties of Single Skyrmions in Magnetic Multilayers by Spin-Orbit Torques** Jan-Philipp Hanke1,2, Frank Freimuth2, Bertrand Dupé3, Stefan Bluegel4 and Yuriy Mozgousov2,4; *1 Institute of Physics, Johannes Gutenberg University Mainz, Mainz, Germany; 2Peter Grünberg Institut and Institute for Advanced Simulation, Forschungszentrum Jülich, Jülich, Germany.

Originating from the interplay of spin-orbit coupling and broken spatial inversion symmetry, the antisymmetric exchange interaction, also known as Dzyaloshinskii-Moriya interaction (DMI), attracts ever-growing attention as it mediates the formation of fascinating chiral spin textures that are perceived to be of great technological relevance, e.g., for future memory devices. Recently, the interfacial DMI was shown to be tunable in magnetic heterostructures of Co sandwiched between different heavy transition metals such as Pt and Ir, heralding bright prospects for the observation of small magnetic skyrmions at room temperature [1,2]. In this context, the phenomenon of current-induced spin-orbit torques (SOTs) can be envisaged to provide a particularly efficient means for controlling and manipulating the dynamical properties of such chiral nano-scale objects. Remarkably, electrically driven switching of the
magnetization due to SOTs in inversion-asymmetric crystals has been demonstrated in single ferromagnetic layers [3] and even in antiferromagnets [4].

Here, we apply a recently developed advanced Wannier interpolation for the Berry phase expressions of DMI and SOTs [5,6] to correlate the microscopic origin of these phenomena with the ab-initio electronic structure of the considered magnetic trilayers Ir(8 nm)/Co/Pt and Au(1 nm)/Co/Pt. Strikingly, we find that the DMI changes sign if we tune the chemical composition ratio in these heterostructures, which promotes the corresponding systems as promising candidates for detailed experimental studies of the antisymmetric exchange interaction. While the DMI is nearly isotropic with respect to the orientation of the ferromagnetic Co moments, the current-induced antidamping torques in clean Ir/Co/Pt reveal a particularly pronounced dependence on the magnetization direction according to our density functional theory calculations. Finally, we elucidate how the obtained anisotropy of fieldlike and antidamping SOTs imprints on the general control and manipulation of the dynamical properties of chiral nano-scale spin textures in Co-based trilayers, including in particular magnetic skyrmions and anti-skyrmions. Our ab-initio results pave the way towards a universal design principle for the skyrmion motion in magnetic multilayers.

11:00 AM *EP02.05.06 Micromagnetic Simulations of Skyrmion Dynamics at Nonzero Temperature Jonathan Leliaert, DyNaMat Group, Ghent University, Gent, Belgium.

The dynamics of magnetic skyrmions at nonzero temperatures is governed by the complex interplay between driving forces, thermal fluctuations and material disorder. This interplay leads to rich behavior, e.g. creep, which needs to be fully understood before skyrmions can be reliably used in technological applications like the racetrack memory[1]. Because skyrmions do not always behave as rigid objects, micromagnetic simulations are indispensable to bridge theoretical models and experimental results. To this end, we developed an algorithm offering a twentyfold speedup without a loss of accuracy to perform simulations at nonzero temperatures [2], thus mitigating the problem that large numerical studies were practically infeasible due to the extremely small time steps required. First, a validation of this methodology is shown against theoretical results for skyrmion diffusion [3]. Next, we present a large scale study of the impact of temperature and disorder on the skyrmion motion and compare the results against experimental data of the velocity and skyrmion Hall angle as function of the driving force[4]. [1] A. Fert, et. al, Nat. Nanotech. 8, 152156 (2015) [2] J.Leliaert, et al., AIP Adv. 7, 125010 (2017) [3] J. Millat, et al., Phys. Rev. B 97, 214426 (2018) [4] K. Litzius, et al., (under review)

11:30 AM *EP02.05.07 Skyrmion Clustering, Creep and Depinning Charles Reichhardt: Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

We examine skyrmion depinning and sliding dynamics in systems with random and periodic pinning arrays. For finite temperature, we find a skyrmion creep regime where the motion is dominated by thermal jumps or avalanches. In this regime the average skyrmion velocity is finite but the skyrmion Hall angle is zero. At higher drives the skyrmion motion becomes continuous and the skyrmion Hall angle increases from zero to its intrinsic value. In general we find that the skyrmion Hall angle increases with increasing temperature at a fixed drive. We also find that for strong pinning, the moving phases are unstable against the formation of a clustered or segregated state where skyrmions attract one another due to the Magnus force. These results are in agreement with recent continuum based simulations which also show clustering of moving skyrmions when the quenched disorder is strong.

SESSION EP02.06: Emerging Topics in Magnetic Skyrmions
Session Chairs: Shinichiro Seki and Oleg Tretiakov
Friday Afternoon, November 30, 2018
Hynes, Level 2, Room 204

1:30 PM *EP02.06.01 Electric Excitation of Topological Defects in Mott Insulators Maxim Mostovoy: Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands.

Topological nature of magnetic skyrmions recently observed in chiral magnets is a source of rich and interesting physics. Effective electromagnetic fields acting on electrons and magnons propagating through non-coplanar spin configurations result in unconventional spin, charge and heat transport. Skyrmion dynamics in magnetic conductors under applied electric currents can be used in new magnetic memory and data processing devices.

Mott insulators with competing Heisenberg exchange interactions form a new class of materials where topological magnetic defects, such as skyrmions, can exist in absence of inversion symmetry breaking [1-4]. Skyrmions in centrosymmetric materials have more degrees of freedom and show more complex dynamics than skyrmions in chiral magnets. In addition, the electric polarization induced by non-collinear spin textures couples topological magnetic defects to an applied electric field [5]. The magneto-electric coupling allows for an electric control of skyrmions in Mott insulators accompanied by low energy losses. In my talk I will discuss stability, dynamics and ferroelectric properties of skyrmions and merons in frustrated magnets. I will also discuss materials that can host these topological defects.

Twisted Domain Walls in Perpendicularly Magnetized Multilayers

Ivan Lemesh and Geoffrey Beach; Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Multilayer films with perpendicular magnetic anisotropy (PMA) are highly active media in modern magnetic technologies and research. Domain walls in such materials are usually treated either in 2D, similarly to homogeneous magnetic layers (via the so-called effective medium model, in which all the magnetic constants are effectively scaled), or as in multilayers, but with a trivial assumption of a fixed domain wall width Δ and angle ψ across the layers. However, recently it has been argued that the actual equilibrium configuration of the domain walls in multilayers is rather different. Both Δ and ψ, as revealed from the explicit multilayer simulations in these studies, vary from layer-to-layer, with the Néel-like caps of opposite chirality developing at the bottom and the top layers.

In this work, we rigorously prove that such a twist is indeed a ground state in PMA multilayers and find that it persists even for films with high Dzyaloshinsky-Moriya Interaction (DMI). The key aspect of our work is that it — for the first time — provides an accurate and complete calculation of the magnetostatic energy in multilayers, including the contributions that were inherently ignored in the well-known effective medium model.

By solving the exact magnetostatic integrals, we evaluate the total micromagnetic energy density of the domain walls in multilayers analytically and derive the equilibrium Δ and ψ in every magnetic layer. We find that the value DMI at which all the layers become Néel (threshold DMI) is underestimated by the earlier 2D model and provide the exact numerical relations for the new 3D model that contains the wall twist. We analyze the exact influence of this twist on the size of the domains and skyrmions and detect notable differences from the expressions provided by the 2D model. We also find that the extraction of DMI from the domain width measurements is highly inaccurate in the region of small and intermediate values of DMI, where the wall twist usually persists.

Finally, we identify the impact of the domain wall twist on the dynamics of skyrmions in multilayers under the influence of injected currents carrying the spin-orbit torque. We show that the skyrmion velocity and skyrmion hall angle derived from the exact multilayer theory can vary significantly compared with the predictions of the 2D model. We provide the numerical multilayer relations that are valid at low and intermediate values of current density (j). We also explore the high-j regime with the help of multilayer micromagnetic simulations and reveal new physical phenomena, such as the domain wall precession that result in the impeded skyrmion motion.

Our findings are confirmed with explicit multilayer micromagnetic simulations. The corresponding paper is under the preparation to be submitted to Physical Review Letters journal.

X-Ray Spectroscopy of Non-Trivial Spin Textures and Their Ultrafast Dynamics

Peter Fischer1, 2; 1Lawrence Berkeley National Lab, Berkeley, California, United States; 2Physics Department, University of California, Santa Cruz, Santa Cruz, California, United States.

Spin textures and their dynamics hold the key to understand and control the properties, behavior and functionalities of novel magnetic materials, which can impact the speed, size and energy efficiency of spin driven technologies. Advanced characterization tools that provide magnetic sensitivity to spin textures at high spatial resolution, ultimately at buried interfaces and in all three dimensions, and at high temporal resolution to capture the spin dynamics across scales, are therefore of large scientific interest.

Magnetic soft X-ray spectro-microscopies [1] provide unique characterization opportunities to study the statics and dynamics of spin textures [2,3] in magnetic materials combining X-ray magnetic circular dichroism (XMCD) as element specific, quantifiable magnetic contrast mechanism with spatial and temporal resolutions down to fundamental magnetic length and time scales.

Current developments of x-ray sources aim to increase dramatically the coherence of x-rays opening the path to new techniques, such as ptychography [4] or x-ray interferometry that will allow unprecedented studies of nanoscale heterogeneity, complexity, and fluctuations.

We will report a recent study of topological spin textures [5] that were imprinted from the vortex state in a 30nm thin permalloy (Py) nanodisk with diameters from 250-1000nm into a multilayer Ir/Co/Pt film with strong DMI. Using element-specific magnetic soft x-ray microscopy we were able to image the magnetic structure of the Py nanomagnets and the spin texture in the DMI film independently. We found a significant increase of the imprinted domain period (240nm) in the DMI film compared to the free film (80nm). Depending on the size of the nanodisks, we observed a change of the skyrmion diameter, and we found evidence for target Neel skyrmions due to an asymmetric expansion of the domain walls as a function of applied magnetic fields. Further, we will show results from a study at LCLS using x-ray photo correlation spectroscopy (XPCS) with a novel 2-pulse scheme that allowed us to discover an unexpected and drastic change of the correlation times in nanoscale spin fluctuations near phase boundaries, i.e., in the skyrmion phase, and near the boundary with the stripe phase of a multilayered Gd/Fe system [6].

References:
Its basic functioning does not require any knowledge of the reservoir topology or node weights for training purposes and can therefore utilize naturally existing networks formed by a wide variety of physical processes.

In this talk we will discuss how a random skyrmion “fabric” composed of skyrmion clusters embedded in a magnetic substrate can be effectively employed to implement a functional reservoir. This is achieved by leveraging the nonlinear resistive response of the individual skyrmions arising from their current dependent anisotropic magneto-resistance effect (AMR). Complex time-varying current signals injected via contacts into the magnetic substrate are shown to be modulated nonlinearly by the fabric’s AMR due to the current distribution following paths of least resistance as it traverses the geometry. By tracking resistances across multiple input and output contacts, we show how the instantaneous current distribution effectively carries temporally correlated information about the injected signal. This in turn allows us to numerically demonstrate simple pattern recognition. We argue that the fundamental ingredients for such a device to work are threefold: i) Concurrent probing of the magnetic state; ii) stable ground state when forcings are removed; iii) nonlinear response to input forcing. Whereas we demonstrate this by employing skyrmion fabrics, the basic ingredients should be general enough to spur the interest of the greater magnetism and magnetic materials community to explore novel reservoir computing systems.

3:45 PM DISCUSSION TIME

Non von Neumann Computing with Skyrmion Diode and Skyrmion Transistor
Linjie Liu, Weijin Chen, Ye Ji and Yue Zheng; State Key Laboratory of Optoelectronic Materials and Technologies, Sun Yat-Sen University, Guangzhou, China.

Magnetic skyrmions are a class of topological defects with non-coplanar swirling spin structure. Recently, they attracted intensive attention for their non-trivial physical properties and potentials in high-density memory and new type spintronic devices. Importantly, latest studies indicate that devices based on skyrmions are particular suitable for so-called Non von Neumann devices, which combine the processing and memory units and avoid large communication cost between them. However, there are few concepts about new types of skyrmion devices until now. This work demonstrates new types of skyrmion devices, which are termed as skyrmion diode and skyrmion transistor. These devices are based on the interaction between terrace-like structures and skyrmions. Micromagnetic simulation indicates that terrace-like structures can effectively modulate the velocity of skyrmions (in both the directions and the speed), due to the potential energy changes of skyrmions. Further investigation shows that output characteristics of skyrmion diodes are tunable by changing the geometry. Moreover, as a type of basic devices, skyrmion diodes can be coupled with each other to form a new devices with more complex functions. Based on these ideas, we design a skyrmion transistor by coupling two skyrmion diodes. In the transistor, transport characteristics of skyrmions can be controlled by other skyrmions on the gate line. Our study for the first time proposes the concept about skyrmion diodes and their important implication on the design of complex skyrmion devices.

4:15 PM EP02.06.07
Controlling the Configuration of Magnetic Skyrmions Visualized by Full-Field Soft X-Ray Microscopy
Mi-Young Im1, Soong-Geun Je1, Jung-Il Hong1 and Anjan Soumyanarayanan3; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2DGIST, Daegu, Korea (the Republic of); 3Data Storage Institute, Singapore, Singapore.

Magnetic skyrmion is a spin structure stabilized by Dzyaloshinskii–Moriya interactions and/or dipolar interactions. Magnetic skyrmions have attracted enormous interests not only because of their fascinating topological character but also due to their potentials in a wealth of technological applications such as high efficient storage and computational devices. In the past couple of years, generating skyrmions at room temperature and realizing their movements have been main research directions and soft X-ray microscopy has been a vital role in such researches [1,2]. Another critical issue in the study of skyrmions has been to tune the topological properties of skyrmions and skyrmion configurations. In our works, we experimentally addressed the issue by direct observation of skyrmions and skyrmion configurations in Pt/Co/Fe/Ir and Pt/Co/Pt multilayered heterostructures utilizing a soft X-ray transmission microscope at Advanced Light Source (XM-1, BL6.1.2), enabling the direct observation of in-plane and out-of-plane magnetic components with a high spatial resolution down to 25 nm. We demonstrated that the properties of skyrmions such as size and density of skyrmions could be controlled by varying Co and Fe thicknesses in Pt/Co/Fe/Ir [3]. Through the work, a platform for investigating functional room temperature skyrmions for the development of skyrmion-based memory devices was established. In Pt/Co/Pt systems, the controllability of skyrmion configurations was investigated. We observed that skyrmion configuration significantly changes by injecting current pulses. Skyrmions could be either created or annihilated by the injected current pulse depending on the strength of applied magnetic field [4]. Our results suggest that the Joule heating plays a critical role in the formation and/or elimination of the bubbles and skyrmions. In the work, the schematic phase diagram for the creation and annihilation of bubbles is presented, suggesting an optimized scheme with the combination of magnetic field and electric current necessary to utilize skyrmions in the practical devices.

Chiral Domain Walls and Skyrmions in Co/Pd Exchange Coupled Multilayers—Statics and Dynamics
Shawn D. Polland1, Joseph Garlow2, Marco Beleggia3, Kaining Cai1, Yiming Zhu1,4, and Hyunsoo Yang1; 1Department of Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore; 2Materials Science and Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; 3Center for Electron Nanoscopy, Technical University of Denmark, Kgs Lyngby, Denmark; 4Condensed Matter Physics and Materials Science, Brookhaven National Laboratory, Upton, New York, United States.

Magnetic skyrmions in multilayer geometries have gained significant attention in recent years, as they provide the opportunity to simultaneously tune demagnetization, anisotropy, exchange, and interfacial Dzyaloshinskii-Moriya interaction (DMI) energies by varying layer thicknesses and compositions. We demonstrate the presence of zero field, room temperature Néel skyrmions in Co/Pd multilayers using Lorentz transmission electron microscopy (L-TEM), investigate their nucleation and annihilation processes [1]. We show this to be a consequence of the strong DMI associated with the Co/Pd multilayer geometry, confirmed with MOKE microscopy imaging of asymmetric bubble expansion. This structure differs from conventional multilayer geometries as, traditionally, a multilayer stack is composed of three different materials, HM1/FM/HM2, where HM1 and HM2 are heavy metals with...
varying signs of DMI, to prevent cancelation from top and bottom interfaces. Further, due to orbital hybridization of Pd with Co, the entire layer is exchange coupled. Using micromagnetic simulations, we show that this has important consequences in the domain wall structure and can play a role in the dynamics of magnetic skyrmions in magnetic multilayers.

We further extend previous studies using L-TEM to quantify the thickness-averaged domain wall deviation from pure Bloch or Néel states, which originates from the completion between demagnetization and DMI energies. This technique complements measurements such as X-ray resonant magnetic scattering [2] by providing nanoscale maps of the local domain structure. Further, it is sensitive to the magnetization of the entire multilayer stack, allowing for full determination of the averaged structure, unlike various surface sensitive techniques (i.e. photoemission electron microscopy or SEMPA) [3,4]. Using L-TEM, we determine the nature of the domain wall as a function of Co thickness and repetition number. This technique is extendable to other multilayer systems and could allow for the determination of a full magnetic phase diagram of systems with strong interfacial DMI.

Excitation-Induced Transition to Indirect Band Gaps in Monolayer TMDCs

Daniel Erben, Alexander Steinhoff, Gunnar Schönhoff, Tim O. Wehling, Christopher Gries and Frank Jahnke; Institute for Theoretical Physics, University of Bremen, Bremen, Germany; Bremen Center for Computational Materials Science, Bremen, Germany; MAPEX Center for Materials and Processes, Bremen, Germany.

Monolayers of transition metal dichalcogenides (TMDCs) exhibit an exceptionally strong Coulomb interaction between charge carriers due to their two-dimensional nature and weak dielectrical screening. Modifying the interaction via changing the dielectric environment or exciting charge carriers offers a possibility to control the interactions and as a consequence also the macroscopic optical properties. More generally, due to their many-body interactions, excited charge carriers directly influence the electronic and optical properties of monolayer TMDCs. This includes scenarios of electrical and optical excitation as well as charge carrier doping. In this talk the strong many-particle renormalizations caused by the Coulomb interaction of the excited carriers will be investigated for MX$_2$ with M = (Mo, W) and X = (S, Se).

To study the properties of these four TMDCs we solve the semiconductor Bloch equations on the full Brillouin zone using ab initio methods. To this end we construct the respective Hamiltonians for all the considered materials. To account for the electronic and optical properties of these materials, we perform computations over the full Brillouin zone, taking explicitly into account the many-body effects. In addition, we study the influence of an external electric field and the modification of the dielectric environment.

The central finding of our investigation is a relative shift between the K- and the neighboring Σ-valley in the conduction band induced by the many-body effects. All four TMDCs show a tendency to become more indirect as the Σ-valley shifts to energetically lower values than K. While monolayer TMDCs are usually celebrated for offering direct band gaps, we predict a transition from a direct to an indirect band gap for MoS$_2$ and WS$_2$. This transition is tunable up to 90 meV by varying the trion-phonon coupling as a function of temperature, electric field and substrate orientation. Our work provides a platform to realize unprecedented selective tunability of the quasiparticles in 2D semiconductors, driven by many body effects.

In this work, we present characterization of MoS$_2$-WS$_2$ lateral heterostructures based on morphology, electrical properties, photovoltaic properties, and nanoscale optical microscopy. These characterizations were performed using a variety of techniques. In particular, we used atomic force microscopy (AFM) for imaging, Scanning Kelvin Imaging for mapping the surface potential, Raman microscopy to map the optical properties, and tip-enhanced Raman and PL microscopy to map the surface potential with high spatial resolution.

A unique collection of characterization techniques were used to map the surface potential and capacitance change dramatically in a reversible manner when the heterostructures are illuminated by a laser, highlighting their photovoltaic properties. Raman and photoluminescence (PL) maps were recorded with 532 nm excitation, which enabled collection of Raman and PL bands from both materials simultaneously with reasonable separation. In addition, the tip-enhanced Raman and PL maps were collected across the interface, with sub-diffraction limited spatial resolution. In summary, a unique collection of characterization techniques were used based on AFM-Raman instrumentation to study morphological, electrical, photovoltaic properties, and chemical composition of MoS$_2$-WS$_2$ lateral heterostructures.
There is an ever-increasing need for portable and wearable electronics, because of the societal demand for active, efficient, and integrated devices. With the emerging Internet of Things, these devices require wireless communication devices that are lightweight and portable. Therefore, new fabrication techniques are needed to develop these unobtrusive wireless communication devices. Antennas for these novel devices are required to be conformal and compact, but retain good radio-frequency conductivity which is an essential property of antenna materials. Recently, nanomaterials such as graphene, carbon nanotubes, carbon onions and conductive polymers have come into play, but low conductivity is a limitation for their use. However, discovered in 2011, 2D titanium carbide MXene eliminates the problem of conductivity due to its metallic behavior. The conductivity of MXene Ti3C2 film reaches 10000 S/cm which makes it a promising candidate for portable wireless communication devices. Here we show a class of radio-frequency devices for wireless communication based on two-dimensional titanium carbide MXene prepared by a single step spray coating. We fabricated a transparent MXene antenna with less than 100 nm thickness with less than -10 dB reflection coefficient at a resonant frequency of 2.4 GHz. By increasing the antenna thickness to 8 μm, we achieved -70 dB of reflection coefficient. Additionally, we fabricated a 1-μm-thick MXene RFID tag in the 875 MHz band reaching a read range of 8 meters. Our findings show that two-dimensional MXenes operate below the skin depth of copper or other metals as well as give an opportunity to produce transparent antennas. Being the most conductive among the solution processed two-dimensional materials, as well as water dispersible, MXenes open new avenues for manufacturing various classes of radio-frequency devices. Using MXene as a conductor will thus be essential for the development of novel portable, flexible, and wearable electronic devices.

propylene carbonate upon sonication, producing thin flakes observable by transmission electron microscopy. The flakes with lateral sizes of 0.5-3 µm showed clear electron diffraction patterns which matched structurally to [Sr2N]+•e−, confirmed also by X-ray diffraction. From these results, we can conclude that the structure of [Sr2N]+•e− is retained after exfoliation.

In addition to comparing structural characteristics, it is also important to observe changes in the electronic properties. UV-Vis-NIR spectroscopy was performed on the exfoliated [Sr2N]+•e− sample to visualize band transitions occurring within the material. A Drude-Lorentz response typical of metals was observed with two peaks at 375 nm and 625 nm and a linear tail in the infrared region, which was attributed to reflection by the electron gas. The band structure confirms the metallicity of [Sr2N]+•e− since the electron gas band crosses the Fermi level, and the two peaks observed in the spectrum correlate to peaks in the joint density of states, which is an integration of the band transitions near the Fermi level. From these results, we can conclude that the electronic properties of [Sr2N]+•e− are also retained in the electrene form. Given the low workfunction for bulk [Sr2N]+•e−, the 2D form of this layered electride could act as a strong electron donor to other two-dimensional materials, defining a new kind of heterostructure not demonstrated previously.

Future work for electrene [Sr2N]+•e− will involve further quantifying the electron donation ability of this new 2D material.

Locally Controlled Cu-Ion Transport in Layered CuInP2S6
Sabine M. Neumayer1, Nina Balke1, John Brehm2, Michael A. Susner1, Brian J. Rodriguez3, Stephen Jesse1, Sergey V. Kalinin1, Sokrates Pantelides4, Michael McGuire1 and Petro Makysmovych1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Vanderbilt University, Nashville, Tennessee, United States; 3University College Dublin, Dublin, Ireland.

Van-der-Waals crystals of metal thiophosphates can be seen as derivatives of transition metal dichalcogenides where 1/3 of metal atoms is replaced with diphosphorous, thereby stabilizing the remaining 2/3 of metal ions in low oxidation states. As a result, thiophosphates develop a panoply of desired properties, such as magnetic, dipolar and correlated electron orderings, all of which are rare or non-existent in the dichalcogenide family. Thiophosphates therefore enable ultrathin magnetic, ferroelectric and Mott insulating materials, while also presenting new opportunities for multifunctional interfaces with electronic 2d materials. We recently established giant out-of-plane piezoelectric coefficients, ferroelectric switching, and dielectric tunability in copper indium thiophosphate (CuInP2S6) [1]. Here, we reveal that CIPS additionally exhibits ionic conductivity that enables localized extraction of Cu ions from the lattice above the Curie temperature upon application of electric fields via a conductive scanning-probe-microscopy tip. Surprisingly, the extraction is fully reversible, dependent on the polarity of the applied electric field. Cu crystalites of up to 90 nm in height can be formed and erased on the surface utilizing ion transport in a process that can be precisely controlled by the amplitude of the applied voltage, frequency, temperature, and position of the tip. The underlying resilience of CIPS to large-scale ionic displacements and Cu vacancies is further corroborated by density-functional-theory calculations. At room temperature, newly created vacancy-rich areas exhibit even higher electromechanical response than pristine CIPS areas, making it possible to tailor piezoelectric properties through ion transport. The tunable surface deformation provides interesting opportunities for applications as sensors and actuators, and control of van-der-Waals heterostructures.

Dipolar Disorder of a van-der-Waals Surface Revealed by Direct Atomic Imaging
Michael A. Susner1, Michael McGuire1 and Petro Makysmovych1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Air Force Research Laboratory, Dayton, Ohio, United States.

Recently, the family of van-der-Waals layered transition metal thiophosphates – exhibiting ferroelectric, antiferromagnetic and correlated electron ground states – have gained attention as possible control dielectrics for the rapidly growing family of 2D and quasi-2D electronic materials [1]. Being van-der-Waals crystals, the surfaces of these materials can be created without dangling bonds, unlike those of complex oxides. Yet, because of robust insulating properties, the structure of their surfaces, the role of disorder, the structure of the topological defects in the order parameter and many other properties directly relevant to their prospective interfaces is almost entirely unknown. Here we present the first atomically resolved imaging of CuInP2S6 – carried out using cryogenic non-contact atomic force microscopy. The surface exhibits good crystalline ordering at the atomic scale, revealing contrast on sub-unit cell level. The most remarkable property is long-range commensurate modulation of the surface morphology, with a topographic amplitude of only 2-3 pm. Combined with XRD analysis of the bulk and Monte-Carlo simulation of the Ising model on triangular lattice, we propose that the modulation arises from antiferroelectric polarization domains, albeit with frustrated long-range order. The key structural ingredient for this state is centrosymmetric position of Se2− within the layer, which forces the surrounding displacing Cu+ ions to adopt a frustrated antiferroelectric state - in direct analogy frustrated magnetic systems. We will further discuss the peculiarities of electronic imaging of this materials from the statistical analysis of the variation of images between scan, as well as the force-distance curve arrays. The possibility to directly visualize polar order opens broad opportunities to understand the atomistic aspect of ferroelectric, glassy and incommensurate phases in this material class, beginning with CuInP2S6 – which exhibits Curie temperature ~315K and giant negative electrostriction [2]. More generally, non contact atomic force microscopy promises to resolve structural and defect properties of 2D materials particularly those with large band-gaps or isolated from electrical contacts. Research was sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U. S. Department of Energy. Microscopy experiments were conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

Electric Field Effects on Few-Layer WS2/S6O: Investigated by Scanning Nonlinear Dielectric Microscopy
Kohei Yamase, Toshiaki Kato, Toshihiro Kaneko and Yasuo Choy; Tohoku University, Sendai, Japan.

Ultrathin transition metal dichalcogenides (TMDs) have recently been under intense research towards their electronic device applications. Some of TMDs such as MoS2 and WSe2 have band-gaps and retain semiconductor properties even if they are atomically thin. The application of TMDs to field-effect transistors (FETs) needs understanding how carrier type and carrier concentration are controlled with electric field effects in a nanoscale. Therefore, a tool for the nano-scale investigation of the electric field effects is important for boosting the studies in this field. Scanning nonlinear dielectric microscopy (SNDM) [1] is a scanning probe microscopy method, which can determine dominant carrier types and give information on carrier concentration...
out-of-plane polarizability of excitons and trions in monolayer WSe₂

Excitons in monolayer semiconductors such as MoS₂ are strongly confined in the plane layer with minimal freedom to orient themselves in the out-of-plane direction. Recent gated spectroscopy measurements have suggested that this may not be the case. However, there is a large discrepancy in the experimental and theoretical polarizability values. Here we investigate the out-of-plane polarizability of excitons in monolayer WSe₂ up to large electric fields of ~1.5 V/μm using double-gate photoluminescence spectroscopy and electroabsorption spectroscopy. The double gate configuration allows us to independently control the doping level and the vertical electric field while avoiding unintentional laser-induced photo-doping effects. We find that the photo-doping density increases linearly with vertical electric fields due to interfacial charge traps even when the sample is encapsulated in hexagonal boron nitride (hBN) crystals. We show that neutral excitons exhibit negligible Stark shift contrary to the earlier experimental observations. On the other hand, charged exciton energy was found to exhibit small but linear Stark shift suggesting the presence of permanent dipole moment.

Dynamics and Spin-Valley Locking Effects in Monolayer Transition Metal Dichalcogenides

Monolayer transition metal dichalcogenides have been the primary materials of interest in the field of valleytronics for their potential in information storage, yet the limiting factor has been achieving long valley coherence times. We explore the dynamics of four monolayer TMDCs (MoS₂, MoSe₂, WS₂, WSe₂) by describing electron-electron and electron-phonon interactions from first principles. We isolate the crucial impact of spin-orbit coupling on the valence band edge by over an order of magnitude, with a corresponding rise in hole mobility. This drastic change is attributed to spin-valley coupling. At temperatures of 50 K, we find valley coherence times on the order of 100 ps, with a maximum value of ~140 ps in WSe₂. Our results capture the entangled relationship between spin and valley degrees of freedom, which is critical for valleytronic applications. Further, our work points towards interesting quantum properties on-demand in transition metal dichalcogenides that could be leveraged via driving spin, valley and phonon degrees of freedom.

Layer Resolved Splitting for Atomic Precision-Control of 2D Materials
Sanghoon Bae1, Jaewoo Shim1, Wei Kong1, Kuan Qiao1, Doyoon Lee1, Ruike Zhao1, Suresh Sundaram2, Xin Li3, Jagadeesh S. Moodera1, Xuanhe Zhao1, Chris Hinkle3, Abdallah Ougazzaden2 and Jeewhan Kim1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Georgia Institute of Technology, Metz, France; 3The University of Texas at Dallas, Dallas, Texas, United States.

Heterostructures formed by weak van der Waals interactions between 2D materials have revealed novel physics and device functionalities. However, it is challenging to precisely control the number of layers at wafer scale. The tape mechanical exfoliation method has been used as main method to obtain few monolayer 2D flakes from various bulk crystals, which allows stacking of multiple 2D materials. The method relies on trial-and-error based operation, which lead substantial time-consuming. In addition, the typical size of stacked heterostructures is only limited to hundreds of microns. An effort to avoid these issues focuses on direct growth of 2D materials on wafers. However, it has been noted that controlling nucleation of 2D layers via growth is even more challenging because of easy-additional nuclei formation on top of the initial nuclei. Accordingly, it has been required to develop alternative way. Here we report a layer-resolved splitting (LRS) for 2D materials that permits precise control of the number of layer of 2D materials. It produces multiple monolayers of wafer-scale 2D materials from one multilayer 2D material growth. We grow thick 2D materials, such as WS₂, hBN, WSe₂, and MoSe₂, and precisely split them into multiple monolayers. We study the underlying mechanics of LRS for the 2D material multilayers into many individual monolayers. The wafer-scale monolayer of transition metal dichalcogenides after LRS exhibits substantial photoluminescence enhancement uniformly across a 2-inch wafer which relates to indirect-to-direct band gap transition. Through this LRS approach, we successfully demonstrate van der
Waals heterostructures with single-atom resolution. We strongly believe LRS will open up new venue for 2D material research community.

1:45 PM EP03.02.02
Near-Field Coupled Two-Dimensional InSe Photodetector on Optical Fiber Zehua Jin, Fan Ye, Xiang Zhang, Shuai Jia, Liangliang Dong, Sidong Lei, Robert Vajtai, Jacob T. Robinson, Jun Lou and P. M. Ajayan; Rice University, Houston, Texas, United States.

Two-dimensional (2D) van der Waals layered materials possess unique advantages as integrable sensors, due to their thinness, flexibility and sensitivity. They can be seamlessly integrated onto surfaces with different geometries where detection of near-field signal is desired. In this study, we develop a device transfer technique to integrate 2D devices onto an arbitrary smooth surface. Such technique utilizes a sacrificial polymer under layer and achieves clean and non-destructive full device transfer. For demonstration, we transferred a complete 2D multilayer InSe photodetector onto a stripped optical fiber. Due to the extreme vicinity of the 2D photodetector with the fiber core, the device can efficiently couple with the evanescent-field and accurately detect information transmitted inside the optical fiber. In addition, these super thin flexible devices can be integrated onto the fibers themselves to non-invasively monitor the optical fiber performance. The demonstration of optically coupled, conformal 2D devices on substrates of different form factors can enable a variety of near-field optical and sensor applications.

Electrical and Magnetic Doping of Transition Metal Diselenides Layers Grown by van der Waals Epitaxy Matthieu Jamet, Céline Vergnaud, Minh-Tuan Dau, Alain Marty, Cyrille Beigne, Carlos J. Álvarez, Hanako Okuno, Maxime Gay, Olivier Renault, Gilles Renaud and Jean-François Jacquot; CEA Grenoble, Grenoble, France.

Top-down exfoliation from bulk transition metal dichalcogenides like MoS₂ usually leads to micron-sized flakes. We have recently developed an alternative growth method of two-dimensional transition metal diselenides (TMDs) from multilayers down to a single layer based on the Van der Waals (VdW) epitaxy. In the VdW epitaxy, the TMD is grown either on a passivated surface with a very low density of dangling bonds (it is then called quasi-VdW epitaxy) or on a layered VdW substrate. The basic concept of this growth method relies on the very weak interaction between the epilayer and the substrate in order to largely release the constraint of lattice matching. Therefore it leads to the formation of fully relaxed TMDs layers. Moreover, this technique allows for the growth of uniform layers over centimeter scale surfaces making it compatible with the development of a large scale 2D electronics substrate in order to largely release the constraint of lattice matching. Therefore it leads to the formation of fully relaxed TMDs layers. Moreover, this technique allows for the growth of uniform layers over centimeter scale surfaces making it compatible with the development of a large scale 2D electronics.

1:45 PM EP03.02.04
Alloying of Monolayer Transition-Metal Dichalcogenides—Role of Native Defects Hossein Taghinejad1, Ali A. Eftekhar1, P. M. Ajayan2, Evan J. Reed3 and Ali Adibi1; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Stanford, Palo Alto, California, United States; 3Rice University, Houston, Texas, United States.

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) are currently under widespread scrutiny for a diverse set of optoelectronic applications. At the monolayer limit, TMD crystals offer a direct optical bandgap, enabling the light emission within a large spectral range covering a large portion of the visible spectrum and the near infra-red regime. In this line, the synthesis of ternary alloys has served as a powerful technique for changing the optical/electrical bandgap of monolayer TMD crystals beyond what a binary compound (i.e., MX₂; M: transition metal and X: chalcogen) may offer. We have previously shown that “ternary” alloys can be produced via doping a “binary” MX₂ crystal by an isoelectronic element (e.g., X') to yield MoS₂X₂Sx₁. The approach has shown a great promise in the formation of ternary heterostructures with arbitrary shapes and dimensions [1, 2]. In this approach, the quality of the as-synthesized alloys depends on the fine details of the starting binary MX₂ crystal.

Here, we study the influence of native defects in starting MX₂ monolayers on the obtained properties of the MX₂X₃₋ₓSₓ alloys. For the demonstration purpose, we use monolayer MoSe₂ films as starting crystals in which replacing Se atoms by S atoms yields MoS₂SₓSe₂₋ₓ ternary compounds. Our results show that native point defects (primarily chalcogen vacancies) in the starting MoSe₂ lattice serve as atomic sites from which S atoms incorporate into the lattice of MoSe₂ and form the MoS₂Se2₋ₓ alloy. Thus, the abundance of the chalcogen vacancies in the starting MoSe₂ films promotes the alloying process and reduces the required temperature needed for this process. We believe that our findings shed light on the fundamental details of the alloying mechanism in 2D TMD crystals as well as opening a new avenue for synthesis of complex alloys via defect engineering.

2:15 PM EP03.02.05
Size-Dependent Properties of Solution Processed 2D Transition Metal Carbides (MXenes) Kathleen A. Malecký1, Chang Evelyn Ren1, Mengjiang Zhao1,2, Babak Anasori2 and Yury Gogotsi1; 1Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Physics and Astronomy, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Two-dimensional (2D) transition metal carbides and/or carbonitrides (MXenes) have been developed as promising materials for a wide variety of applications due to their advantageous mechanical, electrochemical, electrical, and optical properties. MXenes exhibit a general formula of Mₓ₋ₓTx₀₋ₓ, where M represents a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen, and Tₓ represents surface terminations. Along with the high electronic conductivities (8,000-10,000 S/cm), the materials are hydrophilic and can be synthesized in large quantities (~100 g per batch) and high concentrations (>50 mg/mL), making them fundamentally feasible for solution processing. However, the as-produced colloidal solutions contain flakes with widespread lateral sizes (ranging from 0.1 to ~5 µm), presenting a challenge for maintaining precise control over properties and performance.

Here, we will discuss recent progress on developing size selection methods to control and sort 2D MXene flake sizes after synthesis based on sonication and density gradient centrifugation, respectively. Furthermore, characterization of size-dependent properties will be discussed, including tuning the
conductivity of free-standing films, changes in optical absorption, and differences in electrochemical behaviors. This size selection methodology allows for control of a diverse family of materials, optimizing the performance in applications for MXenes beyond energy storage, including but not limited to, gas sensors, conductive inks, coatings, fibers, and electronic, optic and biomedical devices.

EP03.02.07
Making the Colloidal 2D PbS Brighter

Liangfeng Sun1, Antara Antu2, Zhoufeng Jiang1, Shashini M. Premathilaka1, Yiteng Tang1, Jianjun Hu2 and Ajit Roy1; 1Bowling Green State University, Bowling Green, Ohio, United States; 2Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States.

Colloidal quasi-two-dimensional ( quasi-2D) nanoplatelets and nanosheets have attracted a broad interest due to the novel properties resulted from their anisotropic nanostructures. As an infrared material, quasi-2D PbS has its own unique properties due to its small energy gap, large exciton Bohr radius, and strong spin-orbit coupling. Since a larger nanosheet has more surface states, the photoluminescence quantum efficiency of nanosheets is low. To improve their optical properties, reducing the diameter of the nanosheets is one of the solutions since the number of surface trap states per sheet can be significantly reduced.

In our experiments, colloidal lead sulfide (PbS) nanoribbons are synthesized using organometallic precursors with chloroalkane co-solvents. The few-atom-thick nanoribbons have a typical width 20 nm and a length of more than 50 nm. In contrast to nanosheets, the nanoribbons are much brighter. At room temperatures, well-passivated nanoribbons have achieved a typical 30% photoluminescence quantum yield in the infrared spectrum. While the best one has reached 60% photoluminescence quantum yield, exceeding the well-developed colloidal lead chalcogenide quantum dots of the similar energy gap.

The highly bright nanoribbons are advantageous to explore the intrinsic novel properties of the PbS caused by the anisotropic confinement in the quasi-2D nanostructure including enhanced optical radiative recombination and slow Auger recombination as well as to find the applications in infrared photonic and optoelectronic devices.

EP03.02.09
Low-Temperature Synthesis of Crystallized Molybdenum Disulfide Using Atomic Layer Deposition

Wonsik Ahn1, Taejin Park1,2, Hyangsook Lee1, Hoi Jo Kim1, Mirim Leem1 and Hyungsung Kim1; 1School of Advanced Materials Science and Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of); 2Department of Semiconductor and Display Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of); 3Semiconductor R&D Center, Samsung Electronics, Hwasong, Korea (the Republic of); 4Samsung Advanced Institute of Technology, Suwon, Korea (the Republic of).

To accelerate the commercialization of various innovative electronic and optical devices using molybdenum disulfide (MoS2), it is required to develop a large-scale deposition method of MoS2 with a high film quality and a low thermal budget. Among many deposition techniques, atomic layer deposition (ALD) is the most ideal approach due to its atomic-scale thickness controllability. Recently, several researchers have demonstrated initial feasibilities for the ALD of MoS2 using several Mo precursors, such as Mo(CO)6, Mo(NMe2)4, Mo(thd)3 and MoCl5 [1-6]. However, there are still many problems to be solved, such the requirement of high deposition temperature or high-temperature post-deposition annealing to improve film crystallinity. In addition, more in-depth understanding of the effects of various process parameters on the film growth and quality is required.

In this presentation, a few-layered MoS2 films were synthesized via ALD using MoCl5 and H2S precursors at temperatures less than 450 °C. Particularly, the effects of various process parameters, such as a substrate temperature, a MoCl5 canister temperature, and H2S flow rate on the MoS2 film characteristics were investigated. The nucleation density and final surface coverage of the MoS2 films were examined using scanning electron microscopy, transmission electron microscopy, and atomic force microscopy. Raman and photoluminescence characteristics were also studied, and the electrical properties were evaluated by fabricating transistor devices.

4:00 PM EP03.02.10
Photo-Mediated Defect Passivation of MoS2 by Adsorption of Ambient Gas Molecules

Monolayers of transition metal dichalcogenides (TMD) are promising components for flexible optoelectronic devices due to their direct band gap and atomically thin nature. The photoluminescence (PL) from these materials is strongly dependent on mid-gap defects which serve as non-radiative recombination sites for excitons. Improving the PL is a key step towards realizing high efficiency optoelectronics such as solar cells and light emitting diodes. Here, we demonstrate up to a 200x increase in PL intensity by exposing MoS2 synthesized by chemical vapor deposition (CVD) to laser light in ambient. This spatially resolved passivation treatment is air and vacuum stable, which indicates strong bonding of moieties from ambient. Regions unexposed to laser light remain dark in fluorescence despite continuous impingement of ambient gas molecules. This suggests a large barrier towards adsorption and subsequent PL brightening. A wavelength dependent study confirms that the PL brightening is concomitant with excitation generation in the MoS2; laser light below the optical band gap of MoS2 fails to brighten the TMD. In contrast to previous laser modification studies that use mW's of laser
power, we highlight the photo-sensitive nature of the process by successfully brightening with a broadband white light source (< 10 mW). Cryogenic studies show that the treatment results in an increase of both the bound and neutral exciton intensities. Additionally, we measure higher absorption from the laser brightened MoS2 regions. We decouple changes in absorption from defect passivation by examining the degree of circularly polarized PL. This measurement, which is independent of excitation generation, confirms that the laser brightening reduces non-radiative recombination sites in the MoS2. We propose that isovalent O2 passivates sulfur vacancies in the CVD-grown MoS2 but requires photo-generated excitons to overcome the large adsorption barrier. This work represents an important step in understanding the passivation of CVD synthesized TMDs.

This research was performed while S.V.S and M.R.R held a National Research Council fellowship and H.-J.C. held an American Society for Engineering Education fellowship at NRL.

Ionic Solutions of Two-Dimensional Materials and Their Use as Reducing Agents Patrick L. Cullen; Department of Chemical Engineering, University College London, London, United Kingdom.

Exfoliating layered materials within liquids to create dispersions of nanosheets allows for a scalable method to both isolate and manipulate 2-dimensional materials. However, most methods for this so-called “liquid phase exfoliation” rely on aggressive chemical or physical processes to separate the layers, followed by ultracentrifugation to remove large aggregates, making the processes difficult to scale-up. Moreover, such routes typically result in metastable suspensions of fragmented, physically damaged, or chemically modified nanosheets. I will discuss recent work on the true, spontaneous dissolution of 2-dimensional materials from layered materials [1,2]. For the naturally uncharged layered materials, true dissolution into polar aprotic solvents is achieved by introducing charges onto the layers via intercalation of ions. This gentle process maintains the morphology of the starting material, is stable against reaggregation and can achieve solutions containing exclusively individualized, crystalline monolayers. The charge on the anionic nanosheets solutes is reversible, enables targeted deposition over large areas via electroplating and can initiate novel self-assembly upon drying. I will go on to present more recent work which takes advantage of the charge on the nanosheets for further processing. Specifically, a distribution of metal nanoparticles of optimal size and high uniformity has been achieved on 2-dimensional materials for the oxygen reduction reaction (ORR), resulting in a catalyst with remarkable stability.

4:30 PM EP03.02.12

Band Edge Tuning for Selective CO2 Reduction in MoS2-xSex Films Yi-Rung Liu1, 2, Wen-Hui Cheng1, Matthias H. Richter1, Joseph S. DuChene1, Cora Went1, Zakaria Al Balushi1, Deep M. Jarwala1, Li-Chyong Chen2 and Harry A. Atwater1; 1California Institute of Technology, Pasadena, California, United States; 2Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan; 3Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Molybdenum disulfide (MoS2) and its related layered transition-metal dichalcogenides (TMDs) have attracted much attention as potential electrocatalysts for converting carbon dioxide to fuels due to their lower price compared with precious metals and their prominent catalytic features. MoS2 and MoSe2 have recently been shown to perform as excellent electrocatalysts in ionic-liquid-based systems for the CO2 reduction reaction (CO2RR)1,2. However, achieving selectivity in the CO2RR is challenging due to the numerous possible chemical reaction pathways and their very similar reduction potentials, often leading to a multitude of CO2RR products. Theoretical calculations3 indicate that the conduction band (CB) edge position of TMD materials can be tuned by adjusting the layer thickness (i.e. monolayer vs. bilayer), as well as by chemical alloying (e.g. MoSSe). The TMDs therefore offer a suitable material system for adjusting the CB edge of the catalyst relative to a given reduction potential for CO2RR. Herein, we report the thickness-controllable, large-area (~1 cm²) synthesis of MoS2-xSex thin-films for the CO2RR via metal–organic chemical vapor deposition (MOCVD) followed by a post-selenization process. The post-treatment enables the Se incorporation into the MoS2 films as well as tunability of the S/Se ratio in MoS2-xSex alloys. As a first step, we evaluated bulk crystals of MoS2, MoSSe, and MoSe2 for electrochemical CO2RR in aqueous K2CO3 solution (pH = 6.8) at -0.4 V vs. RHE. The results showed that both MoSSe and MoSe2 produce 4 times more CO and CH4 than MoS2. To further explore the effect of the CB edge position relative to the CO2RR, we examined the performance of thickness-controlled, MoS2-xSex electrodes incorporated on glassy carbon substrates for electrocatalysis. We found that the MoS2-xSex, (x=0.46) films own the highest faradaic efficiencies about 16.6%, which is much higher than MoS2 film. The CO2RR product analysis as a function of film composition will be discussed and compared to the relevant CO2RR reduction potentials.

SESSION EP03.03: Scalable Synthesis and Large Area Growth of 2D Materials II

Session Chairs: Feng Miao and Qing Hua Wang

8:00 AM EP03.03.01

Synthesis of Titanium Di- and Tri- Sulfides by Atomic Layer Deposition Saravanan Balai Basuvilangal, Marcel Verheijen, Wilhelmus (Erwin) Kessels and Aageh A. Bol; Eindhoven University of Technology, Eindhoven, Netherlands.

Recently, two-dimensional transition metal chalcogenides (TMC) such as MX2 and MX3 (M= Mo, W, Nb, Ti; X= S, Se, Te) have gained considerable attention due to their unique physical and chemical properties. Among these TMCs, titanium trisulfide (TiS3) has a unique semiconducting behaviour independent of its thickness with a direct band gap of ~1eV which could be ideal for future (opto) electronics applications4. On the other hand, titanium disulfide (TiS2) is a highly conductive semimetal which is suitable for energy storage5, photovoltaics6, and catalysis7 applications. Synthesising both TiS2 and TiS3 at low temperature in a controlled manner over a large area would be beneficial for the aforementioned applications. Atomic layer deposition (ALD) provides advantages such as precise thickness control, low temperature processing environment, uniformity over large area, and conformality over a 3D substrate. Therefore, ALD could be a valuable method to grow layered titanium sulfides for a wide range of applications compared to other deposition techniques.

In this work, TiS2 and TiS3 thin films were deposited by ALD using a metalorganic precursor and H2S at temperatures between 50 and 250°C. TiS2 growth was achieved by both thermal and plasma-enhanced atomic layer deposition (PE-ALD) processes, whereas TiS3 growth was only attained by PE-ALD
process where H2S plasma was used as the co-reactant. To the best of our knowledge, this is the first work to report on synthesising TiS2 by ALD. *In situ* spectroscopy ellipsometry was used to confirm the self-limiting ALD behaviour and also to measure the growth per cycle (GPC). For both TiS2 and TiS3 films, GPC between ~1.6 and 2.5 Å was achieved with both ALD processes in the studied temperature range. In case of PE-ALD process, TiS2 was only grown at lower temperature, whereas at higher temperature pyrolysis leads to formation of TiS3. The synthesis of both TiS2 and TiS3 was elucidated by Raman spectroscopy studies where vibrational modes identical to two-dimensional TiS2 and TiS3 structure were observed. X-ray photoelectron spectroscopy and Rutherford back scattering measurements indicated sulphur deficient TiS2 films, while for TiS3 excess sulphur content was detected. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) revealed control over film morphology was achieved by varying the processing conditions. Four point probe measurements yielded low resistivity for TiS2 films in the order of $1 \times 10^{-4}$Ω-cm. To summarise, we show a novel low temperature process to synthesis both di- and tri- sulfides with precise thickness control over a large area.

8:15 AM EP03.03.02

Single-Step, Direct Silicon-Substrate Growth of Black Phosphorus with *In Situ* Sn Passivation

Nezhueyotl Izquierdo, Stephen Campbell and Sushil Kumar Pandey; University of Minnesota, Minneapolis, Minnesota, United States.

Over the past decade, the class of 2D materials has been mined for substances with unique properties to serve as the foundation for a potential post-silicon or silicon-plus era. The effects of scaling which demands a miniaturization of the device size in all three dimensions, has led research into single or few-layer thick materials. Black phosphorus (BP) is highly attractive since it contains a direct band gap ranging from 0.3 (bulk) to 1.7-2.0 eV (monolayer) allowing for the electrical properties of the material to be tailored to specific devices, such as optoelectronics and transistors, while retaining a high carrier mobility. Mono and few-layer films of BP are called phosphorene.

A synthesis method to grow large area phosphorene films under easily obtained conditions is required in order for commercialization. A reasonable first step would be the growth of black phosphorus thin films directly onto substrates. Here we present a single-step growth of black phosphorus thin film crystals directly on silicon using a self-contained short-way transport technique under relatively low-pressure conditions (<1.5 MPa). The synthesis proceeds with SnI4, Sn, and red phosphorus as the starting materials. The region of precursor concentrations and growth conditions required for thin film crystals are found to be substantially different from bulk crystal growth. Violet phosphorus has been suggested to be an important intermediate in the bulk growth process. We find that it is the preferred phosphorus phase at low SnI4 concentrations, while black phosphorus is the preferred phase at higher SnI4 concentrations. The effect of the starting molar ratio has been mapped to optimize direct growth of BP on silicon wafers. However, the successful direct growth of BP has also been achieved on silicon dioxide, silicon nitride, and sapphire wafers. The same phase forms on each substrate, however, silicon is found to produce slightly larger crystals. This may be due to the fact that the optimization was done on Si and suggests that substrate epitaxy is not a critical factor in growing BP thin films.

Raman spectroscopy of many of the BP deposits show no sign of degradation for A1g, B2g, and A2g phonon modes found at 360.5, 436.5, and 464 cm$^{-1}$, respectively. This is true up to several months of exposure to ambient conditions. Auger electron spectroscopy reveals an ultra-thin (~3 atoms) layer of Sn only grown at lower temperature, whereas at higher temperature pyrolysis leads to formation of TiS2. The synthesis of both TiS2 and TiS3 was elucidated by X-ray photoelectron spectroscopy and Rutherford back scattering measurements indicated sulphur deficient TiS2 films, while for TiS3 excess sulphur content was detected. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) revealed control over film morphology was achieved by varying the processing conditions. Four point probe measurements yielded low resistivity for TiS2 films in the order of $1 \times 10^{-4}$Ω-cm. To summarise, we show a novel low temperature process to synthesis both di- and tri- sulfides with precise thickness control over a large area.

Chemically and Atomically Ordered states in 2D Crystal Alloys

Nasim Alem; Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States.

Alloying and doping are considered versatile strategies for tuning charge and heat transport in nanostructures. Whether the resulting alloy structure is random or ordered can have a profound impact on the macroscale electronic, optoelectronic, vibrational, and transport properties of the material. In this talk, we present structural and chemical ordering as a mechanism to design anisotropy in the family of 2D transition metal dichalcogenides (TMDs) alloys. Leveraging recent advancements in atomic resolution scanning/transmission electron microscopy imaging and spectroscopy, we show the formation of chemically ordered states and vacancy/dopant coupling that leads to unusual relaxation effects around dopant-vacancy complexes leading to local strain and symmetry breaking around individual dopant sites. In addition, we will further uncover the defect structure, i.e. grain boundaries and anti-phase boundaries, and their stability and dynamics in monolayer TMD crystals and their alloys. This understanding can have a strong impact on the synthesis and functionality of novel nanostructure alloys and provides the key to properly design devices for heat dissipation applications, energy storage, electronics, optoelectronics, and thermoelectrics.

9:00 AM EP03.03.04

Building Atomically Thin Integrated Circuits

Jiwoong Park; University of Chicago, Chicago, Illinois, United States.

Manufacturing of paper, which started two thousand years ago, simplified all aspects of information technology: generation, processing, communication, delivery and storage. Similarly powerful changes have been seen in the past century through the development of integrated circuits based on silicon. In this talk, I will discuss how we can realize these integrated circuits thin and free-standing, just like paper, using two-dimensional materials and how they can impact the modern information technology.

In order to build these atomically thin circuits, we developed a series of chemistry-based approaches that are scalable and precise. They include wafer-scale synthesis of three atom thick semiconductors and heterojunctions (*Nature*, 2015; *Science* 2018), a wafer-scale patterning method for one-atom-thick lateral heterojunctions (*Nature*, 2012), and recently, atomically thin films and devices that are vertically stacked to form more complicated circuitry (*Nature*, 2017). Once realized, these atomically thin circuits will be foldable and actutable, which will further increase the device density and functionality. The fact that these circuits could be realized and function without any substrate will allow them to be used tether-free (or wirelessly) in environments not previously accessible to conventional circuits, such as water, air or in space.

9:30 AM BREAK

10:00 AM EP03.03.05
Epitaxial Growth and Properties of Transition Metal Dichalcogenide Monolayers, Alloys and Heterostructures by Gas Source CVD Joan M. Redwing, Xiaotian Zhang, Tanushree H. Choudhury and Mikhail Chubarov; The Pennsylvania State University, University Park, Pennsylvania, United States.

Monolayer transition metal dichalcogenides (TMDs, MoS2, WSe2, etc.) possess a range of intriguing optical and electronic properties including direct bandgap, large exciton binding energies, valley polarization, etc. Current research is typically carried out using flakes exfoliated from bulk crystals or monolayer domains grown by powder source chemical vapor deposition (CVD) which are challenging to scale to large area. Our research is aimed at the development of an epitaxial growth technology for layered dichalcogenides, similar to that which exists for III-V and other compound semiconductors, based on gas source CVD. This approach provides a high overpressure of chalcogen species needed to maintain stable growth at elevated temperature and excellent control of the precursor partial pressures to achieve monolayer growth over large area wafers.

Our initial studies focused on the epitaxial growth of binary TMD monolayers (MoS2, WS2, WSe2 and MoSe2) using metal hexacarbonyl and hydride chalcogen precursors on 2° sapphire substrates in a cold-wall CVD reactor. A multi-step precursor modulation growth method was developed to independently control nucleation density and the lateral growth rate of monolayer domains on the substrate. This approach also enables measurement of metal-species surface diffusivity and lateral growth rate as a function of growth conditions providing insight into the fundamental mechanisms of monolayer growth. Using this approach, uniform, coalesced monolayer and few-layer TMD films were obtained on 2° sapphire substrates at growth rates on the order of ~1 monolayer/hour. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to the sapphire with narrow X-ray full-width-at-half-maximum indicating minimal rotational misorientation of domains within the basal plane. Post-growth transmission electron microscopy carried out on monolayers transferred from the sapphire demonstrates that the films consist of large single crystal regions with anti-phase grain boundaries that result from a merging of 0° and 180° oriented domains that form on sapphire. Growth of (Mo,W)S2 alloy mono- and few layers was also achieved over the entire composition range by controlling the inlet gas phase ratio of Mo and W hexacarbonyl precursors. Applications and challenges of this technique for the growth of vertical 2D heterostructures will also be discussed.

10:30 AM *EP03.03.06
Scalable Synthesis and Electrocatalytic Activities of 2D Sulfides and Tellurides Judy Cha1, 2, Yale Univ, New Haven, Connecticut, United States; 2Canadian Institute for Advanced Research, Toronto, Ontario, Canada.

The layer-dependent material properties and emergent electronic properties of van der Waals heterostructures make 2D materials attractive for a wide range of electronic and energy applications. However, the biggest hurdle for realizing these applications lies in the lack of scalable synthesis of 2D materials with precision control over crystallinity, doping, and other parameters that greatly influence their electrical properties. In this talk, I will discuss our efforts in scalable synthesis of sulfides, tellurides, and their heterostructures and the effects of strain on the crystalline quality and morphology of the synthesized thin films [1-4]. Based on these results, an alternative synthetic route is being explored for large-area synthesis. I will also discuss the electrocatalytic activities of MoS2 and WTe2 for hydrogen evolution reaction, paying particular attention to how electron injection and transport within the catalyst can be a rate limiting step [5], irrespective of thermodynamic energy considerations of hydrogen adsorption on the catalytic site. By performing the electrochemical hydrogen evolution reaction on nanodevices of isolated flakes and heterostructures, we showed that the presence of a Schottky barrier between a catalyst and an electrode can significantly inhibit the catalytic reactions. The nanodevice approach based on a single-crystalline flake enables us to measure interfacial effects accurately, which is challenging in complex nanostructured catalysts. Our finding is broadly applicable to other semiconducting catalysts or catalysts with low electrical conductivity.

11:00 AM *EP03.03.07
Liquid Exfoliation and Defect Engineering of Inorganic 2D Materials Claudia Backes; Applied Physical Chemistry, Heidelberg University, Heidelberg, Germany.

Liquid exfoliation has become an important production technique to give access to large quantities of two-dimensional nanosheets in colloidal dispersion.[1] Importantly, this is a highly versatile technique that can be applied to numerous layered materials beyond graphene such as transition metal dichalcogenides, III-VI semiconductors, black phosphorus, layered oxides to name just a few. These can be cast into films and composites and have proven useful in a number of application areas. Recent progress in size selection has enabled the production of high quality nanosheet dispersions with controlled thickness and lateral size.[2] This was made possible by spectroscopic size and thickness metrics that allow us to extract nanosheet lateral size, thickness and monolayer content from simple measurements such as extinction spectroscopy.[2,3,4] We now use this basic understanding to systematically compare a range of 2D materials with respect to exfoliation, size selection and size-dependent properties to identify unifying principles. In all cases, we investigate chemical degradation/oxidation via the characteristic optical fingerprints. In addition, we explore different ways for further functionalisation of TMD nanosheets by various methods. This includes noncovalent approaches, where we can track the functionalization in optical spectra due to the dielectric screening of the excitonic transitions. We also elaborated ways to chemically modify the basal plane [5,6] or edge sites [7] of TMDs. For example, we demonstrate that chemical functionalisation of vacancy defect sites can be used to protect otherwise instable materials from degradation while edge defects such as thiols can be converted to disulfides in redox reactions. These findings present an important step towards defect engineering in 2D materials.

11:30 AM EP03.03.08
Controllable Wafer-Scale Doping of Monolayer Semiconducting Transition Metal Dichalcogenides Hui Gao1, 2, Joonki Suh2, Michael Cao1, Kan-
Doping plays a crucial role for tuning the functionalities of semiconductors. The ability to control the charge carrier density and polarity as well as their optical properties is the fundamental to our current optoelectronic technology. Atomically thin transition metal dichalcogenides (TMDs) have been the material of focus in recent years due to their exceptional physical properties and great potential as the platform for next generation optoelectronic devices. 

Here we present an air stable and scalable doping method based on metal-organic chemical vapor deposition (MOCVD) where the charge carrier polarity (electrons or holes) and carrier densities can be precisely controlled. Using gas phase precursors, we achieved 2 cm by 2 cm scale (limited by the size of the furnace) growth of Nb-doped and Re-doped MoS$_2$ which are p-type and n-type semiconductors respectively, that is homogeneous over the entire substrate. The amounts of dopants of each polarity can be precisely tuned from sub 1% to 25%. The resulting film is stable in ambient up to months evident by the intact conductivity of the as fabricated FETs. Furthermore, the resulting p-type and n-type films can be further detached from the substrate and stacked together generating more functional devices in large scale.

**Single Atomic Vacancy Catalysis**

**Jieun Yang**, Viacheslav Manichev, Maureen Lagos, Yan Wang, Raymond Fullon, Leonard C. Feldman and Manish Chhowalla; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Single atom catalysts provide exceptional activity and turnover frequencies. However, single atom catalytic activity is often measured by dispersing atoms and nanoparticles on catalyst support. This makes it difficult to study the fundamental activity from a single atom in real electrochemical environments.

Here, we report catalytic activity from precise number of sulfur vacancies on two dimensional molybdenum disulfide grown by chemical vapor deposition. The vacancies were introduced by precisely varying the dose of helium ions in a helium ion microscope (HIM). We then counted the number of vacancies per cm$^2$ using high resolution scanning transmission electron microscope (STEM). The catalytic activity was measured using micro-electrochemical cells previously developed in our group [1]. The devices allow precise control of the area over which the catalytic properties are measured to ensure that activity is only coming from the sulfur vacancies. Our results show that the catalytic properties of the MoS$_2$ improves with the number of vacancies. More importantly, we demonstrate that it is possible to extract the activity from a single sulfur vacancy. We have found that at a vacancy concentration of 5.4 x 10$^{14}$cm$^{-2}$, the intrinsic turn over frequency (TOF) and Tafel slope of a single atomic vacancy is ~ 6 s$^{-1}$ and 38 mV/dec, respectively. The TOF is amongst highest reported and the Tafel slope approached that of platinum.

**SESSION EP03.04: Photonic Properties and Optoelectronic Devices I**

**Layered Material Heterostructures for Photovoltaics and Photocatalysis**

**Harry A. Atwater**, California Institute of Technology, Pasadena, California, United States.

The strong absorption and visible spectrum energy bandgaps for the transition metal dichalcogenides (TMDs) of molybdenum and tungsten render them as attractive candidates for photovoltaics (PV) and optoelectronics. Further, the atomically thin nature is favorable for efficient separation and collection of photo-excited charge carriers. Thus if the three major optoelectronic criteria, i.e., i) sunlight absorption, ii carrier collection and iii) operating voltage can be addressed for TMD materials, they may be candidates for high efficiency photovoltaics and photocatalysis. We recently demonstrated near-unity broad-band absorption of above band-gap photons for <15 nm TMD layers, and have also achieved high external quantum efficiency in <10 nm thick active layer photovoltaic devices in a pn junction of WSe$_2$/MoS$_2$ with graphene contacts. To date, achievement of high open-circuit voltage (Voc) has remained an outstanding challenge for achieving high photovoltaic efficiency. We report here high open circuit voltages (Voc) in TMD absorbers based photovoltaic devices, achieved by tailoring the conduction and valence band-alignments between a single TMD absorber layer and carrier-selective contact layers for electron collection (titanium oxide) and hole collection (nicket oxide), respectively. The band alignments measured using X-ray photoelectron spectroscopy indicate the asymmetric and selective nature of the metal oxide carrier-selective contacts, and we observe open circuit voltages indicate the asymmetric and selective nature of the metal oxide carrier-selective contacts, and we observe open circuit voltages.
Exciton Manipulation for Valley/Spin Devices with 2D TMDCs

A. K. Geim, K. S. Novoselov

Exciton manipulation for valley/spin devices with 2D TMDCs.

**2:15 PM**

**EP03.04.03**

Exciton Manipulation for Valley/Spin Devices with 2D TMDCs Andras Kis; Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

The band structure of transition metal dichalcogenides (TMDCs) with valence band edges at different locations in the momentum space could be harnessed to build devices with operation relying on the valley degree of freedom. To realize such valleytronic devices, it is necessary to control and manipulate the charge density in these valleys. In addition, the long lifetime of interlayer excitons in TMDC heterostructures and the associated long diffusion length offer new opportunities. In my talk, I will present our recent efforts in this direction. In the first part, I will present our direct measurements of the conduction band splitting in MoS2 quantum point contacts. In the second, I will present our recent results on the electrical manipulation of interlayer excitons in TMDC heterostructures.

Band-Bending Junctions—A New Concept for Carrier Transport in 2D Materials Joeson Wong1, Artur Duvoym1, Deep M. Jariwala1–2, Bolin Liao1–4, Eli Rotenberg1, Chris Jozwiak1, Aaron Bostwick1, Ahmed Zewail1 and Harry A. Atwater2, 1California Institute of Technology, Pasadena, California, United States; 2Electrical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Mechanical Engineering, University of California, Santa Barbara, Santa Barbara, California, United States.

Metal-semiconductor contacts are one of the most ubiquitous and fundamental types of junctions in all optoelectronic devices, usually associated with the formation of a Schottky barrier and a depletion region. In the limit that the metal-induced depletion region is larger than the thickness of the semiconductor, an effective doping of the semiconductor is obtained. Two-dimensional junctions such as MoS2 present an attractive platform to examine this proximity effect because of their naturally passivated surfaces and interlayer van der Waals interactions, allowing them to be placed on arbitrary substrates. We explore this substrate interaction through angle resolved photoemission spectroscopy measurements of few-nmn thick MoS2 on As, showing evidence for Fermi level shifts that are dependent on the thickness of MoS2. This effect suggests the possibility of creating novel homojunction devices through thickness variation, even in the absence of bandstructure renormalization. Here, for the first time to the best of our knowledge, we measure the spatiotemporal dynamics of such junctions with ultrafast scanning electron microscopy. We observe ultrafast anisotropic carrier transport in space and time. We further investigate the carrier dynamics in such a complex junction with laser-induced photocurrent mapping, which suggests counter-intuitive carrier dynamics. We conclude by analyzing and describing the time and length scales that are relevant for these junctions, which have far-reaching consequences for applications in atomically-thin semiconductor devices.

**EP03.04.05**

Excitonic Electro-Optical Phenomena in van der Waals Heterostructures Goki Eda; National Univ of Singapope, Singapore, Singapore, Singapore.

Excitons in two-dimensional (2D) semiconductors possess giant oscillator strength and play a fundamental role in mediating the strong light-matter interaction. Among others, monolayer transition metal dichalcogenides exhibit strong excitonic absorption due to band nesting [1] and allow exploration of hybrid quasi-particle states such as plexcitons [2] through strong dipole-dipole coupling [3]. The first part of this talk will focus on our approaches to realizing electrical generation, manipulation, and detection of excitons and their complexes based on various van der Waal heterostructures. Specifically, I will discuss how MIS-type heterostructures allow electrically tunable excitonic electroluminescence and electro-optic upconversion in linear optics regime. We demonstrate that hexagonal boron nitride can serve as a unipolar tunnel barrier that allows hot carrier injection and energy harvesting [4]. The second part will discuss our recent discovery of a novel monolayer MoS2 growth mechanism based on vapor-liquid-solid conversion [5]. We show that alkali metal plays a key role in reducing the melting point of the precursors and triggering the vapor-liquid-solid mode, yielding epitaxial growth of monolayer nanoribbons.

Layered hexagonal boron nitride (hBN) is a wide band gap semiconductor (> 6 eV), which attracts a growing interest for its strong UV photoluminescence properties [1]. The optical properties of bulk hBN as well as BN layers are governed by strong excitonic effects. They have been studied recently, but experiments are difficult because of the necessity to work in the far UV range [2].

In this contribution, we present a detailed theoretical study of the first excitonic levels, and characterize their energies and shape by combining ab initio calculations (GW plus Bethe-Salpeter equation) and a simple tight-binding model (as put forward by Wannier long time ago) [3].

In case of the monolayer, we analyse the first five excitons of single layer hBN, corresponding to the first three bright peaks and two dark states. Strong deviations from the usual hydrogenic model are evidenced due to both lattice effects and the 2D nature of the screening which can be approximated by a potential of the Keldysh type. Moreover, the analysis of the excitonic dispersion at finite $q$ is also discussed. Then the effects of the number of layers on quasiparticle energies, absorption spectra and excitonic states is presented, placing particular focus on the Davydov splitting of the lowest bound excitons. We show that for $N > 2$ (N being the number of layers), one can distinguish between surface excitons mostly localized on the outer layers, and inner excitons, which leads to an asymmetry in the energy separation between split excitonic states. In particular, the bound surface excitons lie lower in energy than their inner counterparts. Additionally, this enables us to show how the layer thickness affects the shape of the absorption spectrum [4].

As hosts for tightly-bound electron-hole pairs carrying quantized angular momentum, atomically-thin direct-gap semiconductors of transition metal dichalcogenides provide an appealing platform for studying exciton physics and for optically addressing the valley degree of freedom. In ultra-high quality WSe$_2$ monolayers, the photoluminescence (PL) emission peaks are sharp and can arise from excited exciton states at high energies and multi-particle bound states at low energies. We observe PL of the 1s, 2s, 3s and 4s Rydberg series [1]. Interestingly the 2s exciton exhibits much better valley polarization and coherence than the 1s exciton [2]. We also observe PL emission from correlated quantum states involving three, four and five particles [3]. Through a set of control experiments including charge doping, thermal activation, and magnetic-field tuning, we determine that the biexciton consists of a bright exciton and a dark exciton, while the exciton-trion is composed of a bright trion and a dark exciton, and that both of them are intervalley entities. Such unique spin-valley configuration gives rise to emissions with large, negative valley polarizations in contrast to that of the well-known two-particle excitons. We also observe PL emission from correlated quantum states involving three, four and five particles [3]. The energy splitting of the biexciton and exciton-trion complexes is larger than that of the 2s exciton [2].

**References**

Strong Coulomb interactions in single-layer transition metal dichalcogenides (TMDs) result in the emergence of strongly bound excitons, trions and biexcitons. These excitonic complexes possess the valley degree of freedom, which can be exploited for quantum optoelectronics. However, in contrast to the good understanding of the exciton and trion properties, the binding energy of the biexciton remains elusive, with theoretical calculations and experimental studies reporting discrepant results. In this work, we resolve the conflict by employing low-temperature photoluminescence spectroscopy to identify the biexciton state in BN encapsulated single-layer WSe$_2$. The biexciton state only exists in charge neutral WSe$_2$, which is realized through the control of efficient electrostatic gating. In the lightly electron-doped WSe$_2$, one free electron binds to a biexciton and forms the trion-exciton complex. Improved understanding of the biexciton and trion-exciton complexes paves the way for exploiting the many-body physics in TMDs for novel optoelectronics applications.
SiO$_2$ Substrates  Omke Wi and Young Jae Song; Sungkyunkwan University, Suwon, Korea (the Republic of).

The environmental stability of the large-sized and single-crystalline antimony flakes was systematically investigated with temperature and time dependence at the fixed humidity. The antimony flakes used in this work were grown by chemical vapor deposition (CVD) directly on SiO$_2$ substrates, where antimonene layers are stacked up to 100 nm thick with typical area of ~100 mm$^2$. As antimony oxide (Sb$_2$O$_3$) has clear fingerprint prints of Ramon peaks, comparing with those in antimonene, spatial and spectral variations in Raman measurements had been traced for the samples stored in ambient conditions even up to 3 months to confirm the environmental stability of the single-crystalline antimony flakes without severe oxidation, where no significant shift nor oxidation signature in Raman bands could be observed. Further investigations for the oxidation condition of antimony, therefore, has been performed with different heating temperatures at the fixed ambient humidity of ~42%, where spatial distributions, spectral signatures and stoichiometric information of the oxidized antimony flakes were quantitatively measured and analyzed by optical microscopy (OM), Raman spectroscopy, scanning electron microscopy (SEM) with energy-dispersive X-ray spectroscopy. The single-crystalline antimony flakes are still chemically robust without any oxidation below 250 °C, while the $A_h$ peak of antimony oxide in Raman spectroscopy comes out above the temperature. And at 350 °C, the surface of the antimony flake will be almost fully oxidized within 10 minutes. Therefore, the successful CVD growth of large-sized and single-crystalline antimony flakes and the characteristics of their environmental stability in this work might motivate further studies on the electrical and chemical properties of antimonene as another alternatives for future applications.

EP03.05.02  Effect of Doping on Few Layer Pristine Black Phosphorus  Seunghun Han$^2$, Ho Won Jang$^2$ and Chul-Ho Lee$^1$; $^1$KU-KIST Graduate School of Converging Science and Technology, Korea University, Seongbuk-gu, Korea; $^2$Department of Materials Science and Engineering, Research Institute of Advanced Materials, Seoul National University, Seoul, Korea (the Republic of).

The elemental two dimensional material, Black phosphorus (BP), exhibits layer-dependent tunable optical and electronic characteristics. [1] BP is known for its widely tunable and thickness dependent band gap which makes it a choice of material for various applications. [2] Each application demands an operational band gap and a material with a wide band gap range will suit the purpose. [3] There are no simple and reliable technique to control the thickness of BP without introducing defects or in-gap states. This study demonstrates two ways of doping BP to tune the band gap by defect doping and by chemical doping. [4-6] Doping, a non destructive method, was used to efficiently modulate the carrier concentration by extracting or injecting carriers into few layer pristine BP enabling a convenient pathway to control its optical and electronic properties. Here, we study the effects of the doping by engineering the defects and tuning the in-gap states introduced during the process. This opens up opportunities to expand the potential applications of few layer pristine BP. Effect of doping on few layer pristine Black phosphorus.

EP03.05.03 Superior Visible Light Photocatalytic and Gas Sensing Performance of Metallic Ag and MoS$_2$ Loaded Graphitic Carbon Nitride Vijay Kumar$^1$, Ritu Malik$^2$ and S.P. Nehra$^3$; $^1$University of California, Berkeley, Berkeley, California, United States; $^2$Technical Faculty, Institute of Material Science, University of Kiel, Kiel, Germany; $^3$University of California, Santa Barbara, Santa Barbara, California, United States.

Two-dimensional (2-D) materials are emerging as new class of multifunctional materials with an extensive range of promising attributes for futuristic energy and environmental applications. In this work, we report the synthesis of ordered mesoporous Ag-MoS$_2$/g-CN nanohybrid by using a facile nanocasting method using cubic mesoporous silica (KIT-6) as hard template. With its 3D mesoporous architecture, the Ag-MoS$_2$/g-CN nanohybrid revealed outstanding visible-light photocatalytic performance, high stability and reusability towards Rhodamine B (RHB) dye which could be due to the improved charge separation properties of photo-induced e-•h$^+$ pairs. The remarkably high degradation efficiency (~98.9%) results from the combined effect generated from the catalytically active Ag and MoS$_2$ nanoparticles loaded in cubic mesoporous g-CN and intrinsic 3D ordered mesoporous morphology of the nanohybrid. In addition to the degradation performance, the Ag-MoS$_2$/g-CN nanohybrid also possesses an excellent volatile organic compounds (VOCs) sensing performance with significantly higher sensitivity, selectivity and short response/ recovery towards n-butanol at lower working temperatures. This study demonstrates a simple and scalable approach to design and develop next generation of 3D layered ordered mesoporous materials for multifunctional applications.

EP03.05.04 Anomalous Pressure Characters of Defects in Hexagonal Boron Nitride Flakes  Baoquan Sun; Institute of Semiconductors, Chinese Academy of Sciences, Beijng, China.

The research on hexagonal boron nitride (hBN) has been intensified recently due to its application as a promising system of single photon emitters. As yet its single photon origin remains under debate even though a lot of experiments and theoretical calculations have been done. We have measured the pressure-dependent photoluminescence (PL) spectra of hBN flakes at low temperature by using diamond anvil cell (DAC) device. It is found that the absolute values of pressure coefficients of discrete PL emission lines are all below 15 meV/GPa which is much lower than 36 meV/GPa, the pressure-dependent photoluminescence (PL) spectra of hBN flakes at low temperature by using diamond anvil cell (DAC) device. It is found that the absolute values of pressure coefficients of discrete PL emission lines are all below 15 meV/GPa which is much lower than 36 meV/GPa, the pressure-dependent red-shift rate of hBN bandgap. These PL emission lines are originated from the atom-like localized defect levels confined within the band gap of hBN flakes. Interestingly, the experimental results of pressure-dependent PL emission lines present three different types of pressure response, corresponding to red-shift (negative pressure coefficient) and blue-shift (positive pressure coefficient), or even a sign change from negative to positive. Density functional theory calculations indicate that there is a competitive relation between the intralayer and interlayer interaction contributions, which leads to the different pressure-dependent behaviors of the PL-peak shift.

EP03.05.05 Atomically Thin Heterojunction Catalysts for Efficient Photoelectrochemical Hydrogen Production  Jae Yoon Lee$^1$, Sungwoo Kang$^2$, Donghun Lee$^1$, Seokhoon Choi$^1$, Sooho Choi$^1$, Soo Min Kim$^1$, Seung Hoon Yang$^1$, Yoon Seok Kim$^1$, Ki Chang Kwon$^2$, Haeli Park$^1$, Woong Huh$^1$, Hee Seong Kang$^1$, Insoo Kim$^1$, Jin Young Cho$^1$, Young Ho Song$^1$, Jong Seob Kim$^1$, Youngil Yoo$^1$, Sang Hyun Kang$^1$, Qinke Wu and Young Jae Song; Sungkyunkwan University, Suwon, Korea (the Republic of).

Anomalous pressure characters of defects in hexagonal boron nitride flakes  Baoquan Sun; Institute of Semiconductors, Chinese Academy of Sciences, Beijng, China.

The research on hexagonal boron nitride (hBN) has been intensified recently due to its application as a promising system of single photon emitters. As yet its single photon origin remains under debate even though a lot of experiments and theoretical calculations have been done. We have measured the pressure-dependent photoluminescence (PL) spectra of hBN flakes at low temperature by using diamond anvil cell (DAC) device. It is found that the absolute values of pressure coefficients of discrete PL emission lines are all below 15 meV/GPa which is much lower than 36 meV/GPa, the pressure-induced red-shift rate of hBN bandgap. These PL emission lines are originated from the atom-like localized defect levels confined within the band gap of hBN flakes. Interestingly, the experimental results of pressure-dependent PL emission lines present three different types of pressure response, corresponding to red-shift (negative pressure coefficient) and blue-shift (positive pressure coefficient), or even a sign change from negative to positive. Density functional theory calculations indicate that there is a competitive relation between the intralayer and interlayer interaction contributions, which leads to the different pressure-dependent behaviors of the PL-peak shift.
Catalysts that can reduce a kinetic overpotential, a potential barrier for charge transfer from a solid-state electrode to a liquid-phase electrolyte, are necessary for the realization of efficient photoelectrochemical (PEC) hydrogen generation. Recently, atomic layered transition metal dichalcogenides (TMDCs) such as MoS2 have emerged as a promising candidate for non-precious and earth-abundant catalysts. Considerable research efforts have been devoted to identifying the active sites such as atomic edges and vacancies in those layered materials and activating (or maximizing) such catalytic sites for efficient hydrogen evolution reaction (HER). In addition to the optimization of catalytic active sites, the photo-excited charges must be efficiently separated and transported from the photocathode to the electrolyte for further enhancement on the PEC performances. To achieve such a goal, many previous studies have attempted to utilize the heterojunctions that form the cascade alignment between the band edge of a semiconductor and the hydrogen reduction potential. In this respect, the capability to build atomically thin heterojunctions with the designed energy alignment using various TMDCs with different band edges and work functions offers unexplored opportunities in optimizing the interfacial kinetics of photoelectrolysis. Nevertheless, it is difficult to exactly correlate PEC performance with the specific properties of the heterostructures and to study the corresponding HER mechanism due to ensemble averaging effects of various active sites. Here, we propose a novel strategy to reduce an overpotential by employing the atomically thin TMDC heterojunction as a HER catalyst. To prove our hypothesis, we newly develop the spatially-resolved PEC characterization platform using scanning photocurrent microscopy combined with a standard electrochemical measurement, allowing not only to visualize the enhanced PEC activity of the heterojunction catalyst but also to solely reveal their effects on HER without ensemble averaging effects of other extrinsic factors. Through the spatially-defined characterization under global illumination, we further confirm that the overpotential and charge transfer resistance at the interface can be significantly reduced by the atomically thin heterojunction catalyst. Our demonstration offers unprecedented opportunities not only to investigate the fundamental HER mechanism correlating with the tailored properties of a catalyst, but also to design highly efficient PEC cells.

EP03.05.06
Fast, Self-Driven, Air-Stable and Broadband Photodetector Based on Vertically Aligned PtSe2/GaAs Heterojunction Zeng Longhui; The Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Two-dimensional (2D) layered transition metal dichalcogenides (TMDS) are favorable for use in electronic and optoelectronic device application due to their excellent electrical and optical properties. Platinum diselenide (PtSe2), is exciting and interesting a Group-10 transition metal dichalcogenide (TMD), which has unique electronic properties such as high carrier mobility, tunable bandgap, stability, and flexibility. Particularly, PtSe2 exhibits widely tunable bandgaps transition from monolayer (1.2 eV) to semimetal at bulk with zero bandgap. In this work, we demonstrate high-performance photodetector based on vertically aligned PtSe2-GaAs heterojunction, which exhibits a broadband sensitivity from deep ultraviolet to near-infrared light, with peak sensitivity from 650 to 810 nm, is reported. The response speed of t½/t∞ is in the range of μs, which represents the best result achieved for Group-10 TMDs based optoelectronic device thus far. According to first-principle density functional theory, the broad photosensitivity ranging from visible to near-infrared region is associated with the semiconducting characteristics of PtSe2 which has interstitial Se atoms within the PtSe2 layers. It is also revealed that our heterojunction photodetector does not exhibit performance degradation after six weeks in air.

EP03.05.07
Nitrogen-Doped Graphene Electrode for Lowering Contact Resistance of MoS2: Dong-jae Seo1, Yong Duck Kim2, Jaejun Lee1, Dukwan Na3, Jaeheun Yoo1, Takashi Taniguchi2, James Hone3, Keunsoo Kim1 and Heonjun Choi1; 1Department of Materials Science and Engineering, Yonsei University, Seoul, Korea (the Republic of); 2Department of Physics, Kyung Hee University, Seoul, Korea (the Republic of); 3National Institute for Materials Science (NIMS), Sengen, Japan; 4Department of Mechanical Engineering, Columbia University, New York, United States; 5Department of Physics, Sejong University, Seoul, Korea (the Republic of).

Semiconducting two-dimensional transition metal dichalcogenide(TMDC) with wide visible range bandgaps of about 1-2 eV has been extensively studied for potential applications in electronics, optoelectronics, a memory device, and sensor. Furthermore, the combination of spin valley and valley degrees of freedom in semiconductor TMDC creates the possibility of manipulating them for future applications in spintronics and valleytronics devices. However, there are still challenges such as air stable and thermally stable Ohmic contacts with an order of magnitude lower contact resistance. To date, large gate doping is required for graphene contact and 1T-phase of TMDC is considered to be unstable in phase at cryogenic temperature. Here, we demonstrate low resistance Ohmic contact to single layer molybdenum disulfide (MoS2) using highly n-type graphene, nitrogen-doped graphene, which has a work function similar to the electron affinity of single-layer MoS2. FETs fabricated on hexagonal boron nitride (hBN) encapsulated MoS2 has n-type behavior with an on/off ratio of about ~10⁶ and a field-effect mobility of 65 cm²/Vs at room temperature. The Vth of the transistors fabricated on pristine MoS2 flakes falls in the negative regime (~7 to 5 V) with an average on/off current ratio of ~10⁻⁶. Transfer characteristics (IDS versus VGS) for different source-drain voltages VSD (10-50 mV) recorded in 2-point configuration shows pronounced increase of IDS at positive VGS due to the formation of an n-type channel. By decreasing the temperature of MoS2 transistor can be left-shifted from the more n-type behavior of nitrogen-doped graphene to enhancement mode with the dominance of the pyridinic-N configuration in N-doped graphene. This work demonstrates the Vth tuning of the MoS2 transistor and the newly developed contact engineering approach is applicable to a wide range of TMDC, compatible with conventional semiconductor processes. Also, this is expected to be a good electrode material for observing the band split in the conduction band of MoS2 for future application in spintronics and valleytronics.

EP03.05.08
Controllable Water Vapor Assisted Chemical Vapor Transport Synthesis of WS2-MoS2 Heterostructures Yuzhou Zhao and Song Jin; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Two-dimensional transition metal dichalcogenides (MX2) have attracted considerable research interests in their electro-optical properties and potential application of high-performance and flexible electronic-photonic devices. Although 2D MX2 can be directly grown on various substrates by vapor deposition synthesis, such synthesis can often be unreliable and recently people realize water vapor or uncontrolled environmental humidity can play important roles in the growth of MX2, regardless if metal chlorides, metal oxides, or MX2 bulk powder precursors are used. It was found that water vapor can work as a transport agent that react with bulk transition-metal dichalcogenide at high temperature and form volatile metal oxyhydroxide species (MO2(OH)x) and hydrogen chalcogenides (HxM) that dramatically increase the effective vapor pressure. Here we report the controllable synthesis of WS2, MoS2 and their heterostructures using water-assisted chemical vapor transport (CVT). The amount of water vapor can be tunably controlled by utilizing the thermal decomposition of calcium sulfate dihydrate (CaSO4·2H2O), which as a solid state source of water vapor not only provides much lower vapor pressure baseline than liquid water, thus guarantees a wider tunable range, but can also be easily integrate into a chemical vapor deposition system without changing the setup. This allows precisely control of the nucleation and growth on the substrate, leading to the lateral epitaxial growth on the edge of transition-metal dichalcogenide and more reproducible growth of large area heterostructures. Raman spectral mappings confirm the heterostructure and electrical transport measurements revealed the p-type transport behavior for WS2 and the n-type transport behavior for MoS2. Our research provides chemical insight into the growth mechanism of transition-metal dichalcogenide and it can potentially be a general approach to controllable grow other metal chalcogenides.

EP03.05.09
Large-Area CVD Growth of Uniform Multilayer h-BN as an Excellent Template for 2D Materials Yuki Uchida1, Sho Nakandakari1, Kenji

Two-dimensional (2D) layered transition metal dichalcogenides (MX2) have attracted considerable research interests in their electro-optical properties and potential application of high-performance and flexible electronic-photonic devices. Although 2D MX2 can be directly grown on various substrates by vapor deposition synthesis, such synthesis can often be unreliable and recently people realize water vapor or uncontrolled environmental humidity can play important roles in the growth of MX2, regardless if metal chlorides, metal oxides, or MX2 bulk powder precursors are used. It was found that water vapor can work as a transport agent that react with bulk transition-metal dichalcogenide at high temperature and form volatile metal oxyhydroxide species (MO2(OH)x) and hydrogen chalcogenides (HxM) that dramatically increase the effective vapor pressure. Here we report the controllable synthesis of WS2, MoS2 and their heterostructures using water-assisted chemical vapor transport (CVT). The amount of water vapor can be tunably controlled by utilizing the thermal decomposition of calcium sulfate dihydrate (CaSO4·2H2O), which as a solid state source of water vapor not only provides much lower vapor pressure baseline than liquid water, thus guarantees a wider tunable range, but can also be easily integrate into a chemical vapor deposition system without changing the setup. This allows precisely control of the nucleation and growth on the substrate, leading to the lateral epitaxial growth on the edge of transition-metal dichalcogenide and more reproducible growth of large area heterostructures. Raman spectral mappings confirm the heterostructure and electrical transport measurements revealed the p-type transport behavior for WS2 and the n-type transport behavior for MoS2. Our research provides chemical insight into the growth mechanism of transition-metal dichalcogenide and it can potentially be a general approach to controllable grow other metal chalcogenides.
Multilayer hexagonal boron nitride (h-BN) has been widely recognized as an ideal insulator to bring out the intrinsic properties of 2D materials [1,2]. Catalytic chemical vapor deposition (CVD) method is capable to produce large-area h-BN films suitable for practical applications [3-5]. However, Cu foils/films mainly give monolayer h-BN, which is not thick enough to screen out influences from substrate surface [3,4]. Recently, CVD growth of multilayer h-BN film was reported by using Fe foil, in which dissolution and segregation processes occur during the CVD due to relatively high B and N solubilities in Fe, but the multilayer h-BN film lacks uniformity [5].

Here, we demonstrate the successful synthesis of large-area, uniform multilayer h-BN on Ni-Fe alloy by suppressing the grain boundaries and tuning the solubilities of B and N [6]. To compare the crystallinity of Fe and Ni-Fe alloy catalysts, we measured their electron back-scatter diffraction (EBSD) after h-BN growth. Although Fe has polycrystalline structure with different crystal planes, Ni-Fe alloy is highly crystallized with a low density of grain boundaries. Moreover, the multilayer h-BN film transferred from Ni-Fe alloy to SiO$_2$/Si substrate shows a uniform optical contrast, while the one transferred from Fe indicates a large variation of thickness. Raman $E_{2g}$ intensity collected from the h-BN film produced on Ni-Fe alloy is highly uniform, supporting the high uniformity of the h-BN thickness. To demonstrate the performance of our multilayer h-BN as a substrate for 2D materials, we have investigated the optical properties of WS$_2$ grown on the multilayer h-BN [6]. Intriguingly, we observed an intense and narrow PL peak from the WS$_2$ grown on h-BN as compared with that on SiO$_2$/Si. The minimum PL line width of WS$_2$/h-BN (24 meV) is much narrower than that observed on SiO$_2$ substrate (67 meV) and is almost comparable to that of WS$_2$ on mechanically exfoliated h-BN (26 meV) [2]. This result demonstrates that our h-BN is effective as a substrate for 2D materials. Therefore, our CVD-grown multilayer h-BN is expected to offer an ideal platform for 2D materials, greatly contributing to their practical applications.

EP03.05.10
Hydride-Free Metal-Organic Vapour Phase Epitaxy of Coalesced 2D WS$_2$ Layers on Sapphire

Annika Grundmann1, Michael Heuken2, 1, Holger Kalisch3 and Andrei Vescan1; 1Compound Semiconductor Technology, RWTH Aachen University, Aachen, Germany; 2AIXTRON SE, Herzogenrath, Germany.

The 2D transition metal dichalcogenide (TMDC) WS$_2$ has attracted great interest due to its unique properties and prospects for future electronics. However, compared to MoS$_2$, the development of a reproducible and scalable deposition process for 2D WS$_2$ has not advanced very far yet. Here, we report on the systematic investigation of 2D WS$_2$ growth on sapphire (0001) substrates using a hydride-free metalorganic vapour phase epitaxy (MOVPE) process in a commercial AIXTRON planetary hot-wall reactor in 10 × 2" configuration. Tungsten hexacarbonyl (WCO, 99.9%) and di-tert-butyl sulfide (DTBS, 99.9999%) are used as MO sources. MO precursors allow a high-purity material synthesis as well as fine-tuning the H$_2$ partial pressure which is crucial for controlling nucleation, lateral growth and unwanted C deposition. Sapphire substrates enable a 3-on-2 superstructure of WS$_2$ and hence a clearly defined crystal alignment and orientation. All samples are characterized using Raman spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM), and optical in-situ and ex-situ reflectometry.

MOVPE processes are started with a substrate prebake step at 1050 °C for 15 min in H$_2$. Our previous work on 2D MoS$_2$ has shown that such a step prior to growth can reduce the nucleation density and strongly inhibit the formation of a parasitic carbonaceous film directly on the sapphire surface. On the prebaked substrate, WS$_2$ is deposited at 30 hPa total pressure in N$_2$ atmosphere. Comparably to MoS$_2$, the suitable growth temperatures for WS$_2$ lie between 750 °C and 845 ºC (845 ºC chosen as optimum here). However, temperatures lead to an increasing parasitic C deposition, while lower temperatures result in a rapid decrease of the WS$_2$ domain size. Because nucleation and growth of TMDC are mainly controlled by the metal species, the influence of the WCO flow on lateral growth was investigated. Increasing the WCO flow during the stacking of layers.

EP03.05.11
Microscopic Description of Localized Quantum-Dot-Like States in Molybdenum Disulfide Nanostructures

Michael Lorke, Christian Carmesin, Matthias Florian, Daniel Erben, Tim O. Wehling and Frank Jahne; University of Bremen, Bremen, Germany.

Atomically thin two-dimensional semiconductors have emerged as an interesting class of material systems, both for applications and fundamental studies. For opto-electronic applications like displays, light sources, and photovoltaics, transition-metal-dichalcogenides (TMDS) are an appealing system, as they combine great mechanical strength with high carrier mobility and an direct optical band gap. In this rapidly developing field, attention has recently shifted towards the realization of nanostructures.

The generation of localized state, either induced via defects or via systematic confinement engineering, opens the possibility to deterministically generate single-photons or, more generally, provide sources of quantum light. For this purpose, flakes of TMDS have been placed on nanowires, over gold edges and over etched holes to form single-photons emitters. We focus on a different platform, which consists of TMDS nano-bubbles that develop if air is enclosed during the stacking of layers.

The physics governing all of these examples has predominantly been discussed in terms of strain engineering. Due to the high bending rigidity, strain induces large variation of the band gap that can lead to a transition from a direct to an indirect band gap. Another, much less discussed, mechanism is the change of the dielectric environment which also induces strong bandgap variations.

We report on results of atomistic tight-binding calculations of different sizes and height-to-diameter ratios of these nanostructures and demonstrate that the
formation of confined quantum-dot-like single-particle states is caused by an interplay of strain and dielectric screening. We show that the strain pockets are caused by a crumpling of the material due to its high bending rigidity and discuss the implications of the underlying physics to other TMD-based nanostructures.

EP03.05.12
**Nonequilibrium Doping, Conversion and Formation of Lateral Heterostructures**

Masoud Mahjouri-Samani¹, Andrew Lupini², Alexander Puretzky³ and David B. Geohegan³; ¹Auburn University, Auburn, Alabama, United States; ²Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Controlled doping and formation of heterostructures in bulk semiconductors have been the key processes in controlling the transport characteristics of electronic devices. Developing similar processes are essential in order to unleash the full potential of the emerging atomically-thin two-dimensional (2D) semiconductors.

In this work, we demonstrate a nonequilibrium process that allows controlled doping of 2D materials from few atoms to the full conversion state. In contrast to the near-equilibrium growth processes, CVD, where the control of flux, activation energy, diffusion, and reaction time are challenging, the digital delivery and tunable kinetic energy of atoms in the laser ablation process can be a powerful tool to overcome these barriers. Formation and digital delivery of atoms in the pulsed laser ablation allows us to precisely tune the doping concentration while the kinetic energy helps us to overcome the potential barriers. We show that by coupling this nonequilibrium technique with conventional lithography and patterning processes, selective conversion and formation of patterned arrays of lateral heterojunctions between monolayer 2D semiconductors, e.g., MoSe₂/MoS₂, can be obtained. For example, the e-beam lithography and deposition processes are used to mask monolayer MoSe₂ crystals with desired patterns where the exposed regions are selectively converted to MoS₂ by pulsed laser generated sulfur atoms. This approach provides a unique capability for controllable and selective doping and conversion of crystals in predefined locations. The doping concentration and heterojunctions are studied by Raman and photoluminescence spectroscopy, atomic-resolution scanning transmission electron microscopy (STEM). This nonequilibrium process appears to be a powerful technique that could be extended to form other metallic, insulating, and semiconducting regions within 2D materials required for ultrathin electronics.

Biography
Dr. Mahjouri-Samani is Assistant Professor of Electrical & Computer Engineering at Auburn University (AU). His research interest is focused on developing laser-based approaches for synthesis, processing, and in-situ/real-time characterization of emerging low-dimensional materials and devices.

EP03.05.13
**Molecular Mechanics of MoS₂ Monolayer with Point Defect and Grain Boundary**

GangSeob Jung and Markus Buehler; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Molybdenum disulfide (MoS₂) monolayer is a two-dimensional (2D) material, which is expected to provide the next generation of electronic devices together with graphene and other 2D materials. Due to its significance for future electronics applications, gaining a deep insight of the fundamental mechanisms upon MoS₂ failure is crucial to prevent mechanical failure towards reliable applications. Here, we report atomic simulations to investigate how the mechanical properties are affected by various point defects and grain boundary. The mechanical properties (elasticity and strengths) of three different point vacancies (S₁, S₂, Mo) and three different point substitutions (MoS, MoS₂, Mo₂S₂) are systematically investigated from the defect ratios 0 to 30%. Also, the bi-crystals with different tilt angles (0–60°) are generated from our newly developed algorithm, where the defect shapes show good agreement with those from the previous experiments. The strengths of the bi-crystals reveal novel mechanistic insight into MoS₂ with various defects and grain boundary.

EP03.05.14
**Metallic Atomic-Glue for Clean Interface in van der Waals Heterostructures**

Doyoon Lee, Sanghoon Bae and Jeehwan Kim; Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

2D material-based heterostructures have been intensively studied because of their unique device functionalities and novel physics. However, it is extremely challenging to have clean interface in the large area 2D heterostructures because a transfer method always accompanies residue issue on top of the 2D materials, which degrades the performance of the 2D heterostructures. For example, the most common approach for transfer of the 2D material at large scale is based on a polymer supporting layer such as poly(methyl methacrylate). It always remains the polymer residue on the 2D materials and wet-processing during the transfer is unavoidable, which can have extra molecular contamination involved at interface of 2D heterostructures during stacking. Accordingly, it has been required to develop an alternative way to produce extremely clean interface in 2D heterostructures

Here, we report that atomically smooth metal glue for 2D heterostructures. We studied the underlying mechanisms to find a suitable material for 2D materials transfer. It was important to investigate and simulate the interfacial toughness at each interface and the internal stress in the material to induce driving force for exfoliation and transfer. Based on our experience, nickel is the best material which satisfies the crucial criteria for atomically smooth glue for 2D material stacking. Removing metal has been extensively studied and we could find the best way to get rid of the nickel glue from the 2D materials. In addition, this approach does not accompany wet-process during transfer and stacking, which preserves the cleanliness at interface uniformly across wafer.

We also confirmed that this discovery substantially improved uniformity in terms of electrical and optical properties of a wafer-scale heterostructure compared to one of 2D heterostructures made by wet-process. We believe this finding will lead a new opportunity for 2D material research since it can preserve ultra clean interface at 2D heterostructures at wafer-scale.

EP03.05.15
**Intrinsic Mobilities of Charge Carriers in Two-Dimensional Metal Dichalcogenides**

Yuanvye Liu and Long Cheng; The University of Texas at Austin, Austin, Texas, United States.

Although two-dimensional metal dichalcogenides (MX₂) have showed great potential for electronics and optoelectronics, they are limited by a low carrier mobility, which has been recognized as one of the major challenges impeding their further developments, and urges efforts to understand the mobility-limiting factors as well as discovery of higher-mobility alternatives.

Here using the density functional perturbation theory, Wannier interpolation of the electron-phonon matrix, as well as analytical derivations, we reveal the underlying physical factors that govern the electron and hole mobility in MX₂. Moreover, we derive a simple descriptor that can be used for rapidly screening the 2D MX₂ database for high-mobility semiconductor candidates. [1]

EP03.05.16
**Superhydrophobic 2D MoS₂-Based Multifunctional Sponge for Spontaneous Detection and Absorption of Spilled Oil**

Tae-Jun Ko, Jae-Hoon Hwang,
Oil spill pollution in marine environment is a major threat to the ecosystem, thus invokes immediate yet viable solutions. Amongst various technologies developed for oil-water separation, directly applying sorbent materials of high porosity to spilled oil presents advantages of low cost and operational simplicity. Efficient sorbent materials should combine high hydrophobicity and high porosity for simultaneous water repulsion and oil absorption, which has generally been achieved by their complicated surface modification. In this study, we report two-dimensional (2D) molybdenum disulfide (MoS2) coated polydimethylsiloxane (PDMS) sponge and demonstrate their high proficiency in rapid and spontaneous oil-water separation and spilled oil detection. This novel sorbent material realized by the simple template-assisted fabrication of sponges and the dip-coating of 2D MoS2 layers benefits from followings; 1) hydrophobic and semiconducting 2D MoS2 layers for water repulsion and oil detection, respectively, and 2) intrinsic porosity in the sponge for oil absorption. The MoS2-PDMS sponge presents the water contact angle of > 152° demonstrating excellent superhydrophobicity as well as achieving high oil absorption (> 100 wt%) for various tested oils including vegetable oil and fuel waste such as standard bilge mix (SBM). Also, the material can be recycled for > 10 times upon repetitive absorption/squeezing maintaining the excellent oil absorption capacity, enabled by its intrinsically excellent elasticity. The versatility of this sorbent material has been further extended for the spontaneous detection and identification of oils containing electrically conducting components, e.g., crude oil and SBM.

Rhological Characteristics of 2D Titanium Carbide (MXene) Dispersions—A Guide for Processing MXenes
Akuzum Bilgen1, 2, Kathleen A. Malecki1, Babak Anasori1, Pavel Lelyukh1, Nicolas Alvarez1, Emin C. Kumbur2 and Yury Gogotsi1; 1Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 2Mechanical Engineering and Mechanics, Drexel University, Philadelphia, Pennsylvania, United States; 3Chemical and Biological Engineering, Drexel University, Philadelphia, Pennsylvania, United States.

In recent years, 2D transition metal carbides, also known as MXenes, have attracted much attention and found applications in many different areas due to their unique physical structure and properties [1]. High electronic conductivity, good chemical and structural stability, and high surface area of MXenes allowed them to find applications ranging from energy storage to medicine to optoelectronics [1-2]. However, in spite of a clay-like behavior, not much is known about the rheological response of MXenes in solution. Understanding the rheological properties of two-dimensional (2D) materials such as MXenes in suspension is critical in the development of solution processing and manufacturing techniques. In this study [3], some of our most recent work on investigating the rheological response of single- and multi-layer TiC2 MXenes in aqueous environments will be presented. Viscosity and viscoelastic properties of these solutions at various loadings will be combined with “processability charts” to understand the suitability of different MXene morphologies for various fabrication techniques.

Optical Behavior of Bioinspired Encapsulated Black Phosphorous
Stephen F. Bartolucci and Joshua A. Maurer; U.S. Army ARDEC, Watervliet, New York, United States.

Phosphorene is a promising semiconducting nanomaterial for electronic and optoelectronic applications. It exhibits tunable photoluminescence in the infrared, based on the number of phosphorene layers. However, phosphorene rapidly degrades in the presence of water and oxygen, which significantly limits its viability for real-world applications. In this work, we have developed a biomimetic strategy for encapsulation of phosphorene for degradation stabilization. To control oxygen diffusion, which results in degradation, phosphorene has been encapsulated in self-assembled natural and synthetic lipid bilayers. The kinetics of degradation have been examined by measuring changes in lipid bilayer vesicle size using dynamic light scattering, fluorescence, coupled quartz crystal microbalance analysis, and scanning probe microscopy. Additionally, the tunability of this biomimetic protective layer has been examined using vesicles composed of different lipid compositions and photo-crosslinkable lipids.

EP03.05.19
Mechanisms of Nitridation of MXene Carbides
Patrick Urbanowski1; 1Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Chemical and Biomolecular Engineering, School of Engineering and Applied Sciences, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

MXenes are a growing family of 2D transition metal carbides and nitrides, including 2D Ti2C, Ti3C2, Mo2TiC2 and W1.33C. In recent years, since the discovery of Ti3N4, this family grew to include nitrides. 2D transition metal nitrides have attracted attention due to their potential applications in plasmonics and energy storage, due to their higher values of electrical conductivity. Although most MXene carbides are synthesized by the selective etching of bulk MAX phase precursors, new routes have been investigated for the synthesis of MXene nitrides. Recently reported 2D Mo3N and V3N/VN can be synthesized using one of several new routes, nitridation. With this technique, MXene carbides are used as precursors that are transformed into 2D metal nitrides via treatment under ammonia at elevated temperatures. While this procedure yields materials with higher electrical conductivities than their precursors with new potential applications, the mechanism of this transformation and the products that are formed are not well understood. In this study, we present the nitridation of MXene carbides using a multiphase fluid flow exfoliation method for producing 2D h-BN nano sheets using a multiphase flow of 2D layered materials suspended in a high pressure gas undergoing expansion. The expanded gas-solid mixture is sprayed in a suitable
solvent, where a significant portion (up to 10%) of the initial hexagonal boron nitride (h-BN) material is found to be exfoliated with a mean thickness of 4.2 nm. Moreover, 33% of the exfoliated h-BN were found to be 10 layers or less thick, while retaining a flake length of 276 nm and a concentration of 0.22 mg/mL in Isopropyl Alcohol (IPA) after mild centrifugation. Shear-induced exfoliation occurs due to the high velocities that expanding and accelerating gases can achieve in small orifices coupled with viscous friction effects resulting in a high shear rate ($\gamma > 10^5$ s$^{-1}$) experienced by the bulk h-BN particles. Decoupling of exfoliation step from liquid suspension step leads to a very stable suspension of h-BN nano sheets in IPA for a long time (6 months). The CFE method has significant advantages over current 2D material exfoliation methods, such as chemical intercalation and exfoliation, as well as liquid phase shear exfoliation, with the most obvious benefit being the fast, continuous nature of the process. Other advantages include environmentally friendly processing, reduced occurrence of defects and versatility to be applied to any 2D layered material using gaseous medium. Scaling this process to industrial production has a strong possibility of reducing the cost of creating 2D nanomaterials.

To demonstrate the utility of our ultrafast CFE method, we considered improving the barrier property of polyethylene terephthalate (PET) by reinforcing it with exfoliated h-BN nano sheets. PET is commonly used for food and beverage packaging where the simultaneous requirements of high optical transparency and limiting oxygen transport have proven to be a technical challenge. The PET films remained transparent (>90%) when 0.017 and 0.15 vol% of CFE-BN were added. Addition of 0.15 vol% CFE-BN resulted in an improvement of the modulus of PET by 21%. Also this resulted in the dropping of oxygen permeation rate (OPR) of the PET film by 26%.

EP03.05.21
Electrochemical Exfoliation of Black Phosphorus
Alexandra Burger, Gonzalo Abellán, Frank Hauke and Andreas Hirsch; Universität Erlangen-Nürnberg, Erlangen, Germany.

Black phosphorus (BP) has recently attracted great attention due to its tunable, layer-dependent bandgap, high carrier mobility, good current on/off ratio, as well as unique in-plane anisotropy, which renders the material attractive for nanoelectronic, thermoelectric and photonic devices.[1,2] This major challenge for a successful application lies in the fabrication of few- or single layer nanosheets of BP. Several methods have been developed, while chemical and liquid exfoliation of the bulk crystals figure amongst the most prominent ones.[3,4] However, large-scale exfoliation leading to uniform and stable dispersions in high yield remains a challenge.

Herein, we present the electrochemical exfoliation of BP, which has already been successfully employed for graphene and other 2D materials, yielding nanosheets in good quality and high yield. Importantly, this technique is not limited to aqueous systems[5] but has also been reported for various organic solvents and ionic liquids, which have an outstanding protective effect on BP.[6] We present a screening of different electrolytes and anodic/cathodic conditions for the exfoliation process. Finally, Raman spectroscopy, atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS) have been applied to characterize the material, confirming the formation of BP nanosheets of good quality and in high yields.

EP03.05.23
CVD Growth and Characterization of Two-Dimensional MoO2 Nanoplatelets
Natalia Vorobeva1, Alexey Lipatov1, Dmitry Muratov1, 2 and Alexander Sintskii2, 3; 1University of Lincoln-Nebraska, Lincoln, Nebraska, United States; 2National University of Science and Technology “MISIS”, Moscow, Russian Federation; 3University Center for Materials and Nanoscience, Lincoln, Nebraska, United States.

Ultrathin and two-dimensional materials have an enormous potential for device applications because they offer very diverse electronic properties and are generally compatible with planar fabrication technologies. We report on the chemical vapor deposition synthesis of MoO2 nanoplatelets by sublimation of MoO3 and its reduction in a hydrogen atmosphere at 750 °C. When grown on Si/SiO2 substrates, the platelets primarily assume a rhomboidal shape and have thicknesses ranging from several to tens of nm. The morphology of MoO2 crystals was found to depend on the chemical nature of substrates. MoO2 platelets on Si/SiO2 were characterized by a number of microscopic and spectroscopic techniques, and the electrical measurements revealed the metallic nature of their conductivity averaging at about 2300 S/cm. Raman spectroscopy of MoO2 platelets on graphene indicates their strong hole injection property. Small thickness, planar morphology, high chemical stability and metallic conductivity of ultrathin MoO2 platelets make them potentially interesting for integration with other two-dimensional materials in a variety of electronic structures and devices.

Zero-Valent Cu and Sn Intercalation into GeS Nanoribbons—Tailoring Ultrafast Photocative Response
Guanjiang Li1, Mengjing Wang2, Katerina Kushnir3, Kristie Koski3 and Lyubov V. Titova1; 1Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2Chemistry, Brown University, Providence, Rhode Island, United States; 3Chemistry, University of California Davis, Davis, California, United States.

GeS belongs to a class of 2D group-IV monochalcogenides with a layered structure similar to that of black phosphorus. It has been theoretically predicted to combine robust room temperature ferroelectricity, high carrier mobility, and large excitonic effects [1-5]. We have recently demonstrated that photoexcitation of GeS nanoribbons results in an ultrafast shift current, suggesting possible applications in solar energy conversion devices based on the bulk photovoltaic effect [6]. Theory also predicts that extraordinary anisotropie electronic and optical properties of GeS can be engineered by strain and accelerating gases can achieve in small orifices coupled with viscous friction effects resulting in a high shear rate ($\gamma > 10^5$ s$^{-1}$) experienced by the bulk h-BN particles. Decoupling of exfoliation step from liquid suspension step leads to a very stable suspension of h-BN nano sheets in IPA for a long time (6 months). The CFE method has significant advantages over current 2D material exfoliation methods, such as chemical intercalation and exfoliation, as well as liquid phase shear exfoliation, with the most obvious benefit being the fast, continuous nature of the process. Other advantages include environmentally friendly processing, reduced occurrence of defects and versatility to be applied to any 2D layered material using gaseous medium. Scaling this process to industrial production has a strong possibility of reducing the cost of creating 2D nanomaterials.

To demonstrate the utility of our ultrafast CFE method, we considered improving the barrier property of polyethylene terephthalate (PET) by reinforcing it with exfoliated h-BN nano sheets. PET is commonly used for food and beverage packaging where the simultaneous requirements of high optical transparency and limiting oxygen transport have proven to be a technical challenge. The PET films remained transparent (>90%) when 0.017 and 0.15 vol% of CFE-BN were added. Addition of 0.15 vol% CFE-BN resulted in an improvement of the modulus of PET by 21%. Also this resulted in the dropping of oxygen permeation rate (OPR) of the PET film by 26%.

Extensive reports have shown band-gap tuning in transition metal dichalcogenides (TMDs), from indirect band gap in the bulk material to a direct gap in single layer due to the absence of interlayer coupling. This unique property stems from the modified electronic states. The phonic properties are extremely critical in optimizing and understanding such electronic and optoelectronic behaviors. Several physical phenomena such as layered effect, quantum confinement effect, inhomogeneous heating effect, doping effect and disorder induce effect have strong influence on the phonon lineshape of TMDs. Using WS$_2$ as a prototype, we employ analytical studies to elucidate on how each of these process affect the phonon modes and provide a systematic route on how to clearly delineate these effects in the phonon lineshapes of TMDs.

EP03.05.25

Enhanced junction reliability and long-term stability with TMDs-based FET are attracting attention in two-dimensional (2D) nano-scale electronic devices. We investigate heterostructures of compositionally and electronically different 2D atomic layers of TMDs to improve contact properties of 2D metal-semiconductor heterojunction. Through interfacial doping with niobium atoms, we engineered composition of transition region between semiconducting WS$_2$ atomic layer channels and metallic NbSe$_2$ contact layers. This van der Waals junction with W$_x$Nb$_{1-x}$Se$_2$ mixed transition regions considerably lower the potential barrier of the heterojunction and enhancing the performance of the corresponding 2D TMDs-based FET devices. Also, it has atomically sharp semiconductor heterojunction.

Two-Dimensional Atomic-Layered FET Utilizing Metallic-Semiconducting TMDs Heterostructure Deok Min Seo, Yoon Jun Kim and Myoung Gwan Hahn; Materials Science and Engineering, Inha University, Incheon, Korea (the Republic of).

Two-Dimensional Atomic-Layered FET Utilizing Metallic-Semiconducting TMDs Heterostructure Deok Min Seo, Yoon Jun Kim and Myoung Gwan Hahn; Materials Science and Engineering, Inha University, Incheon, Korea (the Republic of).

AA′-Stacked Trilayer Hexagonal Boron Nitride for Proton Exchange Membrane Fuel Cells Seong In Youn$^1$, Dong-Jun Seo$^2$, Kwangwoo Kim$^3$, Tae-Young Kim$^4$ and Hyeon Suk Shin$^5$; 1Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 2Buam Fuel Cell Center, Buam, Korea (the Republic of).

Hexagonal boron nitride (h-BN) and graphene have emerged as promising materials for proton exchange membranes because of their high proton conductivity and chemical stability. However, the defects and grain boundaries generated during the growth and transfer of two-dimensional materials limit their practical applicability. Here, we report the fabrication of membrane electrode assemblies using large-area single-oriented AA′-stacked trilayer h-BN (3L-BN), which exhibits very few defects during the growth and transfer, as a proton exchange membrane for use in fuel cell systems. The fuel cell based on AA′-stacked 3L-BN showed a H$_2$ permeation current density as low as 2.69 mA cm$^{-2}$ and an open circuit voltage (OCV) as high as 0.958 V; this performance is much superior to those for cells based on Nafion (3.7 mA cm$^{-2}$ and 0.942 V, respectively) and single-layer h-BN (10.08 mA cm$^{-2}$ and 0.894 V, respectively). Furthermore, the fuel cell with the AA′-stacked 3L-BN membrane almost maintained its original performance (OCV, maximum power density, and H$_2$ permeation current density) even after 100 h of an accelerated stress test at 30% RH and 90 °C, while the fuel cells with the Nafion and single-layer h-BN membranes exhibited severely deteriorated performances. The stability of the cell based on the AA′-stacked 3L-BN membrane was better because the membrane prevented gas crossover and suppressed the generation of reactive radicals during cell operation.

EP03.05.27

Controlled and Tunable Light Emission of Heat Treated Black Phosphorus—Towards Optoelectronic Devices Sarah A. Alodan$^1$, Justin M. Gorham$^1$, Frank DeRic$^2$ and Mohammed Amer$^1$; 1King Abdulaziz City for Science and Technology, Riyadh, Saudi Arabia; 2Material Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Layered black phosphorus (BP) has shown exceptional optical properties due to its layer-dependent band gap, which ranges from 0.3 to 1.7 eV for bulk to monolayer, respectively. However, instability of black phosphorus nanosheets can be a major hurdle in controlling this light emission and requires various passivation methods. Moreover, the tunability of the emitted light can only be controlled by changing the nanosheet thickness, which in turns changes the band gap energy. Here, we show for the first time a well-controlled tunable light emission from heat treated black phosphorous nanosheets. We show tunable wideband photoluminescence (PL) between 590nm to 720nm, with a tunability resolution of 5nm. This tunable PL is found to be anisotropic and can last for at least 10 days when nanosheets are properly stored. The origin of this light emission is found to be the formation of stable suboxides on the surface of black phosphorus, as confirmed with i-XPS measurements. Our findings unlock doors for optoelectronic applications of layered black phosphorus nanosheets.

EP03.05.28

Spectral Light Absorption and Plasmon Resonance in Monolayer MoS$_2$ with Vertically Standing Nanoflakes Bok Ki Min$^1$, Van-Tam Nguyen$^{1,2}$, Seong Jun Kim$^3$, Youn Sik Yi$^4$ and Choon-Gi Choi$^{1,2}$; 1Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); 2University of Science and Technology, Daejeon, Korea (the Republic of).

Molybdenum disulfides (MoS$_2$), is composed of one layer of Mo atom covalently bonded with two S atoms on either side, has attracted much interest for the optoelectronic applications due to its significantly high photon absorption and electron-hole pair creation at even room temperature resulting from the strong interaction with the incident light. However, the absolute light absorption and the spectral selectivity of a monolayer MoS$_2$ are limited by its atomically thin layers and the electronic band gap, respectively. Recently, several methods, including the plasmonic surface and 3D nanostructure with the high surface area, have been developed with the aim to increase the light-matter interaction for light absorption enhancement and broad detection ranges.
Especially, the desirable dispersion relation of a monolayer MoS₂ allows readily controlling their plasmon resonance wavelength ranges than metals. According to the Drude model, a plasmon resonance within selective wavelength ranges can be observed by controlling the doping concentration in the semiconductors. Generally, the doping concentration should be larger than $10^{17} \text{cm}^{-3}$ for observing the plasmonic peaks in the NIR and visible regions. Thus, developing the 3D plasmonic surface of a monolayer MoS₂ can be one of the crucial methods to effectively promote the detection ability of photodetectors by amplifying photoelectric gain and extending the detection range.

In this study, the spectral light absorption and plasmon resonance induced by the charged exciton (named as trion) in a monolayer MoS₂ with highly doped vertical nanoflakes are explored. First, we successfully synthesize the monolayer MoS₂ with vertically standing nanoflakes using one-step chemical vapor deposition (CVD) process. The size and density of the nanoflakes can be controlled by the CVD condition such as the Mo source/target substrate distance and the growth time. From the photoluminescence (PL) analysis, a higher contribution of the charged exciton in the nanoflake regions than the lateral MoS₂ layer is observed, which evidence that the structural defects from the edges of nanoflakes induce the excess charge carriers. Furthermore, the electron concentration of the nanoflakes can be tuned from $10^{19}$ to $10^{21} \text{cm}^{-3}$ by the oxygen chemical bonding. The absorption peak in the range of 800-1000 nm is observed that is evidence of the presence of the plasmon resonance in a monolayer MoS₂ with highly doped vertical nanoflakes. This result is consistent with the theoretical estimates of plasmonic peaks as a function of doping concentration. Finally, we demonstrate the enhancement of photodetection ability regarding broadening detection ranges toward NIR as well as the visible regions in a monolayer MoS₂ with vertical nanoflakes compared with a monolayer MoS₂.

**Cellulose Acetate-Assisted Clean Transfer of Transition Metal Dichalcogenides Grown by Chemical Vapor Deposition**

Tianyi Zhang¹, Kazunori Fujisawa², Tomotakah Granzier-Nakajima³, Fu Zhang¹, Zhong Lin², Nestor Perea-Lopez², Ana Laura Elias³, Yin-Ting Yeh² and Mauricio Terrones¹,²,³; ¹Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; ²Department of Physics and Center for 2-Dimensional and Layered Materials, The Pennsylvania State University, University Park, Pennsylvania, United States; ³Department of Chemistry, The Pennsylvania State University, University Park, Pennsylvania, United States.

The implementation of chemical vapor deposition (CVD)-grown two-dimensional (2D) transition metal dichalcogenides (TMDs) into practical applications largely relies on a robust and efficient transfer of TMDs onto target substrates. However, conventional transfer approaches such as the poly(methyl methacrylate) (PMMA)-based wet-transfer technique, suffer from surface contamination from polymer residues and structural damages induced by high-temperature etching process. In this work, using cellulose acetate (CA) as an alternative protection layer, we developed a facile CA-transfer technique for CVD-grown TMDs which can address the issues above. The structural and optical properties of the transferred TMD materials are well-preserved in the CA-transferred samples. Atomic force microscopy (AFM) in combination with scanning transmission electron microscopy (STEM) characterizations reveal largely improved micro- and nano-scale cleanliness and no observable wrinkles and/or cracks in TMDs transferred with CA-assisted method. The surface cleanliness and morphology improvement can be attributed to the low adhesion energy between CA and TMDs, as well as the usage of room-temperature etching process. Furthermore, we also demonstrated the capability of CA-transfer to be integrated with a deterministic transfer system for transferring flakes to selected locations on the substrate despite the substrate fragility. The CA-transfer technique developed in this work can be used as a clean and low-cost alternative to the PMMA-transfer method, thus paving the way to the high-resolution nanometer-scale characterizations and the implementations of novel applications of CVD-grown TMDs.

**Investigation on Growth Mechanism of Multilayer Hexagonal Boron Nitride on Ni(111)**

Kyung Yeol Ma and Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Hexagonal boron nitride (h-BN) have received considerable attention as promising materials for two-dimensional dielectric material, along with graphene and other such materials. Recently, large-area, high-quality h-BN films have been fabricated by chemical vapor deposition (CVD) method. Especially, to control the number of layer, significant progress in understanding of the underlying growth mechanism of graphene has been achieved by many researchers. However, the growth control of h-BN is currently limited owing to the lack of understanding the growth mechanism. Herein, we present growth of multilayer h-BN by high-temperature and low-pressure CVD on the single crystal Ni(111) with an ammonia borane as a precursor. We found that an ammonia borane decomposes into B and N atoms and the only B atoms react with the Ni(111) to form a nickel boride structure on the Ni surface prior to growth of h-BN. Microscopic characterizations reveal that the nickel boride is epitaxially formed on surface of Ni(111) and subsequently, multilayer h-BN with AA’ stacking order was grown on the nickel boride surface. This work will provide to expansion of controlled growth of h-BN.

**Simulating Raman Spectra of Sputtering Deposited Polycrystalline MoS₂ Films by Phonon Confinement Model**

Seiya Ishihara¹,², Yusuke Hibino¹,², Yuya Oyanagi¹, Naomi Sawamoto¹, Takumi Ohashi³, Kentarou Matsuura³, Hitoshi Wakabayashi³ and Atsushi Ogura¹; ¹Meiji University, Kawasaki-shi, Japan; ²Research Fellow of the Japan Society for the Promotion of Science, Chiyoda-ku, Japan; ³Tokyo Institute of Technology, Yokohama-shi, Japan.

Molybdenum disulfide (MoS₂) has remarkable properties and is expected to be promising for next generation device applications. Fabrication of MoS₂ films with RF magnetron sputtering has various advantages, such as large area uniformity and reduction of carrier concentration. However, morphological properties of sputtered polycrystalline MoS₂ films are quite different from the single-crystal MoS₂ fabricated with mechanical exfoliation and chemical vapor deposition. For example, its grain size is greatly reduced due to fundamental problems of deposition environment, such as sulfur-deficient ambient originated from using Mo:S=1:2 target and high deposition rate. Moreover, such growth conditions produce vertically oriented MoS₂ grains in a thick region. Due to the morphological properties, Raman spectra of the sputtered MoS₂ films show unique behavior. In the case of single-crystal MoS₂, it is well known that frequency difference between $E_{2g}$ and $A_{1g}$ Raman modes (Doo) decreases with decreasing layer number. However, sputtered MoS₂ show a reverse trend. In addition, $E_{2g}$ and $A_{1g}$ Raman modes show shifting towards lower wavenumber in a thick region ($> 20$ nm). In order to reveal the origin of the unique phenomena and investigate the film characteristics, such as grain size, residual stress, and crystal orientation, we utilized thermal and strain influence introduced phonon confinement model (PCM) and simulated Raman spectra of horizontally and vertically oriented polycrystalline sputtered MoS₂ films. From the results of PCM simulation, the grain size of sputtered MoS₂ film deposited at 250°C was estimated to be 10 nm. The residual stress value increase with increasing film thickness, which was caused by crystal orientation transition and the difference of the linear expansion coefficient between a- and c-axis.

This work was partly supported by JSPS KAKENHI Grant Number 16H11377 and JST CREST JPUMCR16F4.

**Wettability of MoS₂ Thin Films Supported on Transparent Quartz Substrates**

Buddhi Singh¹, Subhasis Ghosh¹ and D. Kabiraj²; ¹Jawaharlal Nehru University, New Delhi, India; ²Inter-University Accelerator Centre, New Delhi, India.

We fabricated MoS₂ thin films on transparent quartz substrates by chemical vapor deposition method. The quality of MoS₂ thin films has been characterized by x-ray photoelectron spectroscopy, Raman spectroscopy, and transmission electron microscopy. The water contact angle ($θ_w$) measurement
sh ed a light on the MoS₂-water interaction which will be crucial for the development of future MoS₂-based applications. The θ₀w increased with increasing number of MoS₂ layers. The θ₀w of the bare quartz substrate is ~57.3° and coating of MoS₂ layers results θ₀w as 85.9° ± 0.3°, 88.2° ± 0.3°, 90° ± 0.3°, and 95° ± 0.3° for 3 nm, 5 nm, 9 nm, and 16 nm, respectively. An increase in θ₀ of MoS₂ by almost 50 % from the bare quartz substrate indicates that MoS₂ can efficiently screen the van der Waals (vdW) interaction of the underlying substrate with water. The observed advancing and receding θ₀w are 95.8° and 39.40°, respectively indicates a significant contact angle hysteresis of 42°. This represents an adhesion between water and MoS₂ layer. The kinetics of wetting and spreading of a water molecule on bulk MoS₂ has been discussed via a single exponential behavior i.e. \cosθ₀(τ) = \cosθ₀(0) + \beta(1 - \exp(-τ/τ₀))

by considering intrinsic defects as a surfactant. Here, β is a dimensionless parameter depends on the initial and final θ₀, and τ is the time scale of water molecule transfer from the drop to the solid-liquid interface. We obtain c=0.88, which is little smaller than the single exponential case (c=1) indicates a slower approach to final θ₀. Neuman’s equation of state theory is used to determine the surface free energy of MoS₂ layer and is estimated to be about 39 mJ/m².

EP03.05.34
Raman Scattering Modulated by Excitonic Effects in Monolayer MoS₂
Yuanxi Wang1, Bruno R. Carvalho2 and Vincent Crespi1; 1The Pennsylvania State University, State College, Pennsylvania, United States; 2Universidade Federal do Rio Grande do Norte, Natal, Brazil.

The resonance Raman spectra of monolayer MoS₂ contains a rich variety of frequency-dependent features. Strong excitonic effects present in this 2D semiconductor call for further scrutiny on its Raman intensities. We present a first-principles computational framework to calculate resonance Raman intensities (beyond the Placzek approximation) based on perturbation theory, where the Bethe-Salpeter equation (BSE) is only solved once statically, offering a clear advantage compared with finite differences methods where the BSE is solved twice for each Raman mode. Comparisons with experimental Raman spectra for monolayer MoS₂ using more than 50 laser excitation lines are discussed.

EP03.05.35
Roll-to-Roll Production of Layer-Controlled Molybdenum Disulfide—A Platform for 2D Semiconductor-Based Industrial Applications Yi Rang Lim1, 2, Wooseok Song1, Sung Myung1, Ki-Seok An1, Sun Sook Lee2 and Jongsun Lim1; 1Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Yonsei University, Seoul, Korea (the Republic of).

Molybdenum disulfide (MoS₂) opens up new possibilities for 2D electronic devices in terms of applications for low standby and low operating power electronics coupled with further miniaturization beyond Moore’s Law. Unfortunately, previous synthetic approaches appear to be technically hampered for practical applications due to their inability to obtain large-area and continuous MoS₂ layers. Here, a facile methodology for the large-scale production of layer-controlled MoS₂ layers on an inexpensive substrate involving a simple coating of single source precursor with subsequent roll-to-roll-based thermal decomposition was developed. The resulting 50 cm-long MoS₂ layers synthesized on Ni foils possessed excellent long-range uniformity and optimum stoichiometry. Moreover, this methodology was promising because it enables simple control of the number of MoS₂ layers by simply adjusting the concentration of (NH₄)₂MoS₂. For actual industrial applications, not only a method for large-scale production but also an efficient transfer method following the synthesis to locate the sample onto diverse substrates is a prerequisite. We thus transferred layer-controlled MoS₂ onto PET films using our custom-made roll-to-roll transfer machine. Based on these results, it is envisaged that the cost-effective methodology will trigger actual industrial applications, as well as novel research related to 2D semiconductor-based multifaceted applications.

EP03.05.36
Plasma-Assisted Fabrication and Gate-Tunable Transport Properties of ‘In-Depth’ Doped MoS₂ Vertical Homoostructure Xiao-Mei Zhang; Department of Mechanical Engineering, Tokyo Institute of Technology, Tokyo, Japan.

Two-dimensional (2D) atomic layered crystals are believed to be the most promising candidates for optoelectronic applications, due to their unique properties such as their optimum thickness scalability, superior intrinsic strain limit and near ideal transparency. Large-bandgap transition metal dichalcogenides (TMDs) (for example, MoS₂ and WSe₂) offer experimental mobility approaching single-crystal silicon thin-film transistors (TFTs), with two orders of magnitude thinner profile and high scalability (up to 20-30%L). More importantly, the broad spectrum which MoS₂ can absorb light from near-infrared spectral region (350-950 nm) is higher than GaAs and SiL. Although the layered transition metal dichalcogenides (LTMDs) exhibit very strong light-matter interactions and very high light absorption coefficients, atomically thin p-n junctions from van der waals-bonded TMDs layers with superior photovoltaic (PV) performance have not been demonstrated. The junctions exhibit both rectifying electrical characteristics and PV response, but the maximum achievable photovoltage is limited by the smallest band offsets for electrons and for holes. For example, in the case of MoS₂/WSe₂, the band offset for electrons is approximately 0.7 eV.[1]

In this work, I present the characterization of a MoS₂ vertical homoostructure in the intermediate thickness regime (~15nm) between the monolayer and the bulk. The MoS₂ vertical homoostructure is fabricated via an ‘In-Depth’ doping process by plasma surface treatment. To generate a p-n homojunction in multilayer (ML)-MoS₂, an effective doping depth control is a challenging due to their atomistically thin dimensions. Compared to surface functionalization and substitutional CVD doping, plasma treatment emerges as the most effective doping technique for layered MoS₂ due to a wide range of doping that can be achieved with good control and selectivity. Fluorine (F)- and oxygen (O) atoms are the critical dopants responsible for the p-doping in MoS₂ due to their inability to obtain large-area and continuous MoS₂ layers. Here, β is a dimensionless parameter depends on the initial and final θ₀ and τ is the time scale of water molecule transfer from the drop to the solid-liquid interface. We obtain c=0.88, which is little smaller than the single exponential case (c=1) indicates a slower approach to final θ₀. Neuman’s equation of state theory is used to determine the surface free energy of MoS₂ layer and is estimated to be about 39 mJ/m².

Fabrication of WS₂ Film by DC Bias Applied High-Temperature Sputtering Yuuya Oyanagi1, Seiya Ishihara1, 2, Yusuke Hibino1, 2, Naomi Sawamoto1, Takumi Ohashi1, Kentarou Matsuura1, Hitoshi Wakabayashi1 and Atsushi Ogura1; 1Meiji University, Kawasaki, Japan; 2Research Fellow of the Japan Society for the Promotion of Science, Chiyoda, Japan; 3Tokyo Institute of Technology, Yokohama, Japan.

Tungsten disulfide (WS₂), a two-dimensional layered material, has attracted attention due to its unique properties such as the band structure change from an indirect transition type of 1.35 eV in bulk to a direct transition type of 1.79 eV in a single layer, and no dangling bond on the surface. Because of these...
favorable physical, chemical, and optical properties, researchers have been developing channel materials and various sensors. We have been fabricating WS$_2$ and other TMD thin films with sputtering deposition. In order to fabricate film with high quality, the substrate is heated to a high temperature. However, S atoms tend to desorb from the film at high substrate temperature. In this research, positive DC bias was applied for the purpose of suppressing desorption of S atoms in the sputtering process even with high substrate temperature. WS$_2$ thin films were prepared by RF magnetron sputtering. The deposition was carried out on SiO$_2$ substrate using WS$_2$ target. As sputtering conditions, the sputtering time was 46.7 s, the RF power was 100 W, the substrate temperature was 250 °C, and the Ar flow rate was 7.6 sccm. The bias voltage was varied from 0 to +60 V. The prepared samples were evaluated for chemical bonding state by X-ray photoelectron spectroscopy. The formation of the bond between W and S was confirmed from the peak positions of W 4f and S 2p spectra. The composition ratio of W and S was calculated using the peak area ratio. As a result, the W/S ratio increased as the bias voltage increased positively, and the desired value of 2.0 was achieved with a bias voltage of +40 V. From this result it is suggested that the positive bias voltage effectively attracts S$^2$-.

Growth of NbS$_2$/NbSe$_2$ Monolayer Superconductor Heterostructures and Alloys

Kwang Hyun Park$^1$, Hyo Jung Kim$^2$, Sun-gyu Park$^1$, Gaetanee Jin$^{1,3}$, Jun Sung Kim$^{1,3}$, Tae-Hwan Kim$^2$ and Moon-Ho Jo$^{1,3}$, 1Center for Artificial Low Dimensional Electronic Systems, Institute for Basic Science (IBS), Pohang, Korea (the Republic of); 2Department of Physics, Pohang University of Science and Technology, Pohang, Korea (the Republic of); 3Department of Materials Science and Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Atomic monolayer (ML) NbS$_2$ and NbSe$_2$ crystals provide interesting platforms to explore electronic phase transitions at the atomic thickness limit. Here, we report controlled growth of ML heterostructures, composed of NbS$_2$ and NbSe$_2$, via sequential chemical vapor deposition. We have achieved two kinds of heterostructures, such as lateral epitaxial NbS$_2$/NbSe$_2$MLs and ML alloys, with growth kinetics controls. Initial observations of superconducting transitions at the ML interfaces, probed by scanning tunneling microscopy, are discussed around the critical roles of point and extended defects on coupled transitions.

EP03.05.39
Selective Deposition of van der Waals Semiconductor Monolayers in Wafer-Scales

Gangtae Jin$^{1,3}$, Chang-Soo Lee$^{1,3}$, Juho Kim$^{1,3}$ and Moon-Ho Jo$^{1,3}$, 1Department of Materials Science and Engineering, Pohang University of Science and Technology (POSTECH), Pohang, Korea (the Republic of); 2Center for Artificial Low Dimensional Electronic Systems, Institute for Basic Science (IBS), Pohang, Korea (the Republic of).

Spontaneously area-selective deposition of van der Waals (vdW) semiconductor monolayers in large scales, i.e., transition-metal dichalcogenides (TMDCs) in wafer-scales, can provide a new 2D device platforms without conventional lithography for various applications. In fact, such self-assembled 2D structures may establish “clean” atomically thin crystals, free of defects and impurities from lithography and lift-off fabrication processes. In this work, we utilize a cost-effective spin-on polymer mask, which can be easily patternable and removable in large scales, as an inhibitor layer during crystallization of various TMDC monolayers. Thereby selective deposition of MoS$_2$ monolayers in wafer-scales is achieved by metal-organic chemical vapor deposition. We discuss the critical roles of such inhibitor layers within the framework of nucleation kinetics in vdW epitaxy.

EP03.05.40
High Performance Indium Selenide Field-Effect Transistor with Tunneling Barrier Enabled by Atomic-Scale Surface Oxidation

Yi-Hsun Chen$^1$, Han-Ting Liao$^2$, Shih-Wei Huang$^1$, Chih-Yi Cheng$^1$, Wei-Liang Bai$^2$, Raman Sanka$^2$, Fang-Cheng Chou$^2$, Kenji Watanabe$^2$, Takashi Taniguchi$^3$, Chun-Wei Chen$^2$ and Wei-Hua Wang$^1$, 1Academia Sinica, Taipei, Taiwan; 2National Taiwan University, Taipei, Taiwan; 3National Institute for Materials Science, Tsukuba, Japan.

Two-dimensional (2D) semiconductors have emerged as a promising channel material for next-generation electronics due to the ultrathin channel and the lack of short channel effect [1,2]. 2D-semiconductor-based field-effect transistors (FETs) incorporated with layered insulators for enabling low contact resistance has been reported [3]. However, a feasible method to grow large-area, high-quality tunneling barrier has not been realized. We demonstrate highly controlled surface oxidation in layered indium selenide (InSe) FETs to achieve enhanced transport properties. By utilizing the inherent layered structure of 2D materials, the surface oxidation can be controlled with atomic-scale precision as indicated by transmission electron microscopy. The characteristics of the oxide layer is further examined by a combination of Raman spectroscopy, X-ray photoelectron spectroscopy, and atomic force microscopy. The InSe FETs with oxide tunneling barrier exhibit distinct transport properties, including a field-effect mobility of 1240 cm$^2$/Vs, ohmic contact at low temperature, low trap state density, and a contact barrier of 13 meV. With the ultrathin oxide barrier, we successfully achieve the suppression of the Fermi-level pinning effect, which severely limits the tunability of the electrical transport properties. Consequently, the contact barrier of the InSe FETs can be effectively modified by using contact metals with different work functions. The realization of high-performance InSe FETs with low contact barrier via oxide tunneling barrier shows promising results in utilizing 2D semiconductor materials for practical applications.

Hybrid Black Phosphorus/Zero-Dimensional Quantum Dot Phototransistors—Tunable Photodoping and Enhanced Photoresponsivity

A-Young Lee, Hyun-So Ra, Min-Hye Jeong and Jong-Soo Lee; DGIST, Daegu, Korea (the Republic of).

Recently, black phosphorus (BP) with direct band gap exhibited excellent potential for optoelectronic applications because of its high charge carrier mobility and low dark current as well as the variable band gap of 0.3–1.5 eV depending on the number of layers. However, few-layer BP-based phototransistors (photo-FETs) have been limited in sensitivity and wavelength selectivity. To overcome the drawback of these photo-FETs, we studied hybrid photo-FETs combined with the novel properties of the two materials between the channel and sensitizer layers. By combining a strong absorbance of a quantum dot (QD) layer and a two-dimensional layer material with high carrier mobility, the hybrid photo-FETs are expected to produce high-performance photodetectors that can effectively control the responsivity, detectivity, and response time. In this study, we demonstrate that the photogenerated carriers formed from QD sensitizer layers migrate to the BP transport layer with high charge mobility and not only improve the photodetector performance but also enhance the photodoping effect of the BP transport layer with an ambipolar characteristic by electrons transferred from n-type CdSe QDs or holes injected from p-type PbS QDs. The responsivity and detectivity of hybrid BP/0D photo-FETs exhibit $1.16 \times 10^4$ AW$^{-1}$ and $7.53 \times 10^3$ Jones for the BP/CdSe QD photo-FET and $5.36 \times 10^4$ AW$^{-1}$ and $1.89 \times 10^3$ Jones for the BP/PbS QD photo-FET, respectively. The photocurrent rise
Methods for synthesizing nanosheet materials are divided into two types, the top-down method and the bottom-up method. In the top-down method, the ultrasonic exfoliation method is known as a common process which is simple and highly productive process, but it is hard to synthesize few-layered solid solutions such as Mo(S,Se)₂; because a bulk solid-solution is required as a starting material. On the other hand, as a representative of the bottom-up method, the chemical vapor deposition method is widely known for the synthesis of nanosheets with high quality and large area, but its drawbacks include low yield, poor productivity, and a vacuum process entailing high process costs. Thus, each recent technology entails trade-offs between quality, productivity and cost. Therefore, this study proposes a synthesis method of metal chalcogenide solid solutions with high productivity under supercritical reductive conditions. Moreover, this process realizes synthesizing Mo(S,Se)₂ and (Mo,W)S₂ nanosheets from MoO₃, WO₃, pure sulfur, selenium and non-toxic solvents at 400°C for a shorter time than 60 min. XRD patterns and Raman spectrum for Mo(S,Se)₂ and (Mo,W)S₂ were consistent with previous reports. The peak shift was observed by Se or W being incorporated in MoS₂. TEM images revealed that Mo(S,Se)₂ and (Mo,W)S₂ have edge-rich structures composed of nanosheets for both samples. The formation of this nanosheet structure should be caused by high affinity between supercritical fluid and the surface of TMDs nanosheets. The XPS analyses showed the almost stoichiometric composition (Metals : Chalcogens ≈ 1 : 2) among the both samples. The hexavalent Mo and W derived from MoO₃ and WO₃ were not detected, whereas only tetravalent Mo and W were detected; thus, we concluded that the reduction process had completely progressed. Furthermore, STEM images at an atomic level showed that elements were solid-dissolved without segregation.

We achieved the synthesis of Mo(S,Se)₂ and (Mo,W)S₂ using less-toxic starting materials for a short time. This synthesis process combining environmental adaptability and easiness can be also be applied for synthesis of various other kinds of two-dimensional metal chalcogenides.

**Synthesis of Mo(S,Se)₂ and (Mo,W)S₂ Nanosheets from Metal-Oxide and Pure-Chalcogen Precursors In Supercritical Fluids**

Yuta Nakayasu, Hiroki Kobayashi and Ibaru Honma; Tohoku University, Sendai, Japan.

Few layer black phosphorus (BP) has attracted tremendous interest in optoelectronic applications due to their optical and excellent semiconducting properties. It has a thickness-dependent bandgap of 0.3 eV for bulk to ~2 eV for single layer, high hole mobility of ~1000 cm²V⁻¹s⁻¹ and high on-off ratio up to 10⁵. Under air ambient condition, the surface of black phosphorus is rapidly degraded by forming phosphorus oxide. In our study, we demonstrate that 1, 2-ethanediethiol (EDT) treatment effectively reduces oxygen atoms weakly adsorbed on the BP surface. The oxygen reduction mechanism on the degraded BP by EDT treatment is analyzed by utilizing density functional theory (DFT) calculations, transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). Also, the reduction of surface oxides by EDT treatment results in the recovery of the electrical properties. Furthermore, we show that BP field-effect transistors (FET) are preserved against humidity in air for more than one week using hexagonal boron nitride as a passivation layer. The results suggest that the EDT treatment to degraded BP FET presents a potential for practical semiconductor device applications, such as logic gates, photodiodes, and solar cells.

**Recovering Effect on Oxygen-Degraded Black Phosphorus by 1,2-ethanediethiol Surface Treatment**

Dohyun Kwak, Hyun-Soo Ra, Min-Hye Jeong, A-Young Lee and Jong-Soo Lee; DGIST, Daegu, Korea (the Republic of).

Two-dimensional layered black phosphorus has shown great potential for next-generation electronics with tunable band gap and high carrier mobility. For the electronic applications, the thickness modulation of a BP flake is an essential due to its thickness-dependent electronic properties. However, controlling the precise thickness of few-layer BP is a challenge for the high-performance device applications. In this study, we demonstrate that thermal treatment under ambient condition precisely controls the thickness of BP flake. The thermal etching method utilizes the chemical reactivity of BP surface with oxygen and water molecules by the repeating formation and evaporation of phosphoric acid during thermal annealing. The thermally etched BP FETs show a high hole mobility of ~576 cm²V⁻¹s⁻¹ and a high on-off ratio of ~10⁵. In spite of the thermal treatment under air ambient condition, the BP FETs showed long-term stability without significant degradation for one month resulting from the conservation of phosphorus layered structure under phosphorus oxide layers.

**Thickness-Controlled Black Phosphorus with Enhanced FET Stability Under Ambient Condition**

Min-Hye Jeong, Dohyun Kwak, Hyun-Soo Ra, A-Young Lee and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology, Daegu, Korea (the Republic of).

The interfaces between magnetic nanoparticles(NPs) and atomic layer material(ALM) are receiving attention in developing high-density magnetic memory devices because of the finding of the ALM-induced perpendicular magnetic anisotropy [1, 2] and the template effect of ALM nanomesh(NM), which is a kind of moiré structures, for the ordered growth of metal nanoparticles [3]. In this study, we report a successful growth of monodisperse FePt NPs on hexagonal boron nitride(h-BN) NM. The h-BN NM was grown on a Ru(0001) thin film on sapphire c-plane by means of chemical vapor deposition. FePt was deposited on the surface of h-BN NM by means of RF magnetron sputtering at room temperature. Through the scanning tunneling microscopy measurements, we found that FePt deposited on h-BN NM/Ru(0001) forms monodisperse disk-like NPs with a diameter of 3 nm which corresponds to the periodicity of h-BN NM. In contrast to Fe which has been reported to aggregate into large NPs on AL NM [3], this study demonstrated that small monodisperse FePt NPs can be grown by utilizing h-BN NM as a template. In the conference, we are going to discuss the magnetic properties of the FePt NPs and the effect of thermal annealing.

Fully-printable devices have attracted much interest in the field of large-scale printable electronics. Apart from high-performance inks for conductive patterns, a dielectric component is also very important in electronics, for example, in capacitors and electroluminescent devices. The current printable dielectric inks most commonly utilise barium titanate (BaTiO3) as the main filler material, having the drawbacks of high cost, thick printed layer and demanding curing process. Here, we employed solution processed hexagonal boron nitride (h-BN), as a filler material incorporated into a commonly used polymer binder matrix, with enhanced dielectric properties, enabling a cost effective, single-pass printable, pin-hole free dielectric ink.

We exfoliate the h-BN directly into the solvent and polymer binder matrix by ultrasonication for 12 hours followed by centrifuge. This 'one-pot' process introduces exfoliated h-BN flakes directly into the ink system and does not require any additional chemical surfactant or post processing. A stable h-BN ink system is formulated by an optimised proportion of the h-BN filler material, polyurethane (PU) polymer binder and butyl cellosolve (BC) solvent. The ink shows excellent printability on polymer substrates (e.g. PET) with 15mPa.s viscosity at 10 s⁻¹ shear rate under 25°C, and is suitable for coating and printing. The deposited film has a high transparency with ~ 85% transmittance. Measurement on printed parallel-plate capacitor arrays with our inks containing 0.6wt% h-BN show a two-fold increase in relative permittivity (εr) over pristine PU. An average areal capacitance 336pF/cm² is achieved by averaging an array of capacitor samples with an electrode-overlap area of 20-50mm². We then incorporate our printed capacitors to construct a simple 4-bit dynamic random-access memory (DRAM), demonstrating the viability of our ink for printable electronics.

MoS2 FETs with Doped HfO2 Ferroelectric/Dielectric Gate Stack

Atomristors—2D Non-Volatile Memory and Switches

We have observed non-volatile resistance switching (NVRS) memory effect in semiconducting or insulating atomic sheets in a standard vertical device configuration. In this work, we demonstrate NC-MoS2 FETs by incorporating a ferroelectric doped HfO2 (Al:HfO2 or Si: HfO2 ) in the FET gate stack. Standard HfO2 has monoclinic crystal structure which can be transformed into orthorhombic phase by temperature, pressure, or doping. The electrical properties of the doped HfO2 thin-films can be tuned from dielectric to ferroelectric and even antiferroelectric by changing dopant type (Zr, Al, Si, Gd, Y, etc.), dopant fraction and/or capping layer. The ferroelectric nature of typical doped HfO2 thin film can be confirmed by the polarization measurement. Here, Si:Hf composition is kept fixed by controlling the 3DMAS/TEMAH pulses during the ALD. We observe steep SS in FETs when used these FE in the gate stack with carefully matched FE/DE bilayer. The NC-MoS2 FET built on a typical FE/DE bilayer showed a significant enhancement of the SS to 57 mV/dec at room temperature, compared with SSS = 67 mV/dec for the MoS2 FET with only HfO2 as a gate dielectric.

Neuristors from Solution-Processed 2D Materials

Non-linear dynamical systems such as neuristors embody essential complexity in spike-timing behavior for hardware implementation of neuromorphic computing architectures. In order to experimentally realize a neuristor, the constituent materials need to possess attributes that enable concurrent functionality as a distributed energy source, an energy storage element, and an active channel. Towards this end, two-dimensional (2D) materials such as MoS2, show promise for neuristors since they have demonstrated bipolar resistive switching at low fields, gate-tunable learning response, heterosynaptic plasticity in memtransistors, and multi-bit memory. Furthermore, solution-processed 2D material thin films possess versatile chemical tailoring, compositional tunability, and compatibility with flexible substrates for large-area printed electronics. In this talk, solution-processed thin-film MoS2 memristors are shown to possess all-or-nothing spiking behavior in a geometry that is amenable to in situ optical, Raman, and photoluminescence microscopy. Furthermore, in situ thermal imaging reveals three kinds of switching behaviors (i.e., soft switching with negative differential negative resistance, hard switching with thermal runaway, and irreversible switching) that are correlated with distinct features of filaments and dendrites. This resistive switching is found to be a generalized phenomenon across a wide range of 2D materials such as MoS2, WS2, ReS2, and InSe films since the morphology of composite thin-films with large curvature flakes plays a dominant role in field-emission transport between neighboring flakes. The net result is that curvature-induced large local fields achieve resistive switching at low electric fields (~4 kV cm⁻¹) due to electrical discharge. Overall, this work utilizes temperature as a new state-variable, which can be exploited for a range of applications including higher-order memristors, neuristors, random number generators, and chaotic circuits. In particular, the circuit modeling neuristors based on solution-processed MoS2 thin-films are used to realize Pearson-Anson oscillators with qualitative features similar to the Hodgkin-Huxley axon model.

Atomristors—2D Non-Volatile Memory and Switches

We have observed non-volatile resistance switching (NVRS) memory effect in semiconducting or insulating atomic sheets in a standard vertical device configuration. Results suggest a rich multi-physics effect persistent in both poly- and single-crystalline monolayer and few-layer sheets. NVRS is observed in several TMDs including MoS2, MoSe2, WSe2, and WS2 and also in h-BN. This alludes to a universal memory effect in non-metallic 2D materials. Our findings overturn the contemporary thinking that non-volatile memory is not scalable below a few nanometers. Emerging concepts in non-volatile flexible memory fabrics, zero static power radio-frequency switches, and brain-inspired (neuromorphic) computing could benefit substantially from the pervasive NVRS effect in atomic sheets. Experimentally results for FE switching have been achieved at operating frequencies beyond 50GHz with the potential for
Fundamental Properties and Device Prospectives of Emerging Two-Dimensional Materials

Han Wang; Department of Electrical Engineering, University of Southern California, Los Angeles, California, United States.

In this talk, I will discuss our recent work in studying the electronic, optical and ferromagnetic properties of emerging two-dimensional materials, and in developing them for novel electronic and photonic device applications. The first part of the talk will focus on discussing the basic properties of emerging 2D materials such as black phosphorus and its applications in mid-infrared optoelectronics. Our recent research on the phonon-spin and phonon-electron coupling in ferromagnetic monolayer materials will also be presented. In the second part of the talk, I will discuss our work on the origami and kirigami of 2D materials and the development of substrate-free foldable and adaptive membrane electronics based on these materials. A unique method for the deterministic folding of 2D materials and their heterostructures will be discussed. Reconfigurable electronic devices and circuits realized through the patterned folding of 2D material heterostructures will be reported. I will conclude with remarks on promising future research directions of two-dimensional electronic and photonic devices, and how the newly developed 2D material origami and kirigami techniques may enable adaptive reconfigurable electronics and advanced sensor technologies.

Synaptic Barristor Based on Phase-Engineered Two-Dimensional Heterostructures

Woong Huh1, Seonghoon Jang1, Jae Yoon Lee1, Donghun Lee1, Jung Min Lee2, Hong-Gyu Park2, Jong Chan Kim1, Hu Young Jeong4, Gunuk Wang1 and Chul-Ho Lee2; 1KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea (the Republic of); 2Department of Physics, Korea University, Seoul, Korea (the Republic of); 3School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 4UNIST Central Research Facilities, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Heterostructures built from various two-dimensional (2D) layered materials, including semimetallic graphene, semiconducting transition metal dichalcogenides, and insulating hexagonal boron nitride, are emerging material platforms for low-power and high-performance electronic devices because of their high-quality heterointerfaces with atomic precision as well as the exceptional properties from their atomically thin constituent materials. In addition, the competitive ability to electrostatically control the energy barrier (or band alignment) at the van der Waals (vdW) interfaces allows us to rationally design 2D functional heterostructures by band-structure engineering for a variety of gate-tunable electronic devices. Particularly, a vertical triode with a gate-controlled Schottky barrier, so-called the ‘barristor’, has been proposed as a new switching device with potential advantages in scaling and integrating highly-networked device functionality. Such unique capabilities of 2D heterostructured devices can also offer unexplored opportunities for realizing an energy-efficient artificial synapse with high controllability. Nevertheless, the artificial synapse based on 2D heterostructures has rarely been realized elsewhere, but only bulk form of the diode was developed at that time. [Yan, R. et al., Nano Lett. 2015, 15 (9), 5791] The point is that gate-tunable p-n heterojunction and band-to-band tunneling are the key to operate as TFET.

Here, we demonstrated black phosphorus–tin diselenide (BP-SnSe2) heterostructure tunneling field-effect transistors operating as both Esaki diode mode with negative differential resistance (NDR) region and backer diode mode at negative and positive gate bias, respectively. By introducing relatively high carrier concentration even in few-layer form of SnSe2 sheets, only BP channel was able to be modulated by global electrostatic gating, making the device fabrication and operation much simpler. Gate-tunable 2 staggered band alignment at the heterojunction was demonstrated by scanning photocurrent microscopy (SPCM). Temperature-dependent NDR behavior was unlikely with a conventional tunneling diode, but it was successfully explained by series resistance and thermal assisted tunneling mechanism. Also, the backward rectification behavior followed the thermionic emission theory, which confirmed that the another potential barrier had been created at the heterojunction due to the negative bias electrostatic gating. Besides, we pointed out that deposition conditions of the Al2O3 passivation on the device were important to observe these effects.
Two-dimensional (2D) layered materials have been actively explored for electronic device applications because of their ability to form van der Waals heterostructures with unique electronic properties. Vertical integration of atomically thin 2D materials can enable the design of three-dimensional (3D) circuit which is a promising pathway to continuously increase device density. In this study, we vertically stack 2D materials, such as graphene, MoS2 and black phosphorus (BP) to build transistors, heterostructure p-n diodes and 3D logic circuits. The vertical transistors built from MoS2 or BP semiconductor exhibit a good on-off ratio of up to 105 and high current density of ~200 A cm−2 at a very small VOCs of 50 mV. The graphene/BP/MoS2 vertical heterostructure p-n diodes show a high gate-tunable rectification ratio of 106. Finally, we have demonstrated a 3D CMOS inverter by vertical integration of graphene, BP (p-channel), graphene, MoS2 (n-channel) and a 50-nm-thick gold film in sequence. The ability to vertically stack 2D layered materials by van der Waals interactions offers an alternative way to design future 3D integrated circuits.

Vertically Stacked van der Waals Heterostructures of 2D Layered Materials for Electronic Devices and 3D Logic Circuits

Jinshui Miao1, Zhihao Xu1, Haschuan Wai1 and Chuan Wang1; 1Electrical and Systems Engineering, Washington University in St. Louis, St. Louis, Missouri, United States; 2Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 3Michigan State University, East Lansing, Michigan, United States.

As the dimensions of semiconducting channels in field effect transistors (FETs) decrease, the contact resistance of metal-semiconductor interface at the source and drain electrodes dominates the performance. Two dimensional (2D) transitional metal dichalcogenides (TMD) such as molybdenum disulphide (MoS2) have been demonstrated to be excellent semi-conductors for ultra-thin FETs. However, unusually high contact resistance has been observed across the metal-2D TMD interface. Recent studies have shown that van der Waals (vdW) contacts formed by graphene on 2D TMDs provide lowest contact resistance. However, vDW contacts between evaporated three-dimensional metal and 2D TMDs have yet to be demonstrated. Here, we report the realization of ultra-clean vDW contacts between indium metal electrodes and thin MoS2. Using scanning transmission electron microscopy (STEM) imaging, we show that the indium-MoS2 interface is atomically sharp with no detectable chemical interaction between the metal and 2D TMD, suggesting van-der-Waals-type bonding between the metal and MoS2. We show that the contact resistance of indium electrodes is ~ 800 Ω-μm – amongst the lowest observed for metal electrodes on MoS2 and is translated into high performance FETs with mobility in excess of 100 cm2-V-s−1. We also demonstrate low contact resistance of 220 Ω-μm on NbS2 and near ideal band offsets, indicative of defect free interfaces, in WS2 and WSe2 contacted with indium.

Rewritable Floating Gates in Two-Dimensional Electronics by Tunnelling Triboelectrification

Tae Yun Kim1, Seongsu Kim2, Christian Falconi1 and Sang-Woo Kim1; 1 Electronic Engineering, University of Tor Vergata, Rome, Italy; 2 Advanced Material Science & Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

Gates can electrostatically control charges inside two-dimensional materials. However, integrating independent gates typically requires depositing and patterning suitable insulators and conductors. Moreover, after manufacturing, gates are unchangeable. Here we introduce tunnelling triboelectrification for localizing electric charges in very close proximity of two-dimensional materials. As representative materials, we use chemical vapour deposition graphene deposited on a SiO2/Si substrate. The triboelectric charges, generated by friction with a Pt-coated atomic force microscope tip and injected through defects, are trapped at the air-SiO2 interface underneath graphene and act as ghost floating gates. Tunnelling triboelectrification uniquely permits to create, modify and destroy p and n regions at will with the spatial resolution of atomic force microscopes. As a proof of concept, we draw rewritable p/n- and p/p+ junctions with resolutions as small as 200 nm. Our results open the way to time-variant two-dimensional electronics where conductors, p and n regions can be defined on demand.
IAEs in 2D interlayer. Here, we report a new type of 2D electrode with van der Waals layered structure with 2D electron gas at intralayer space. The experimental and theoretical investigation on the electrical and ferromagnetic properties of 2D van der Waals [YCl]2+2e- and [LaCl]2+2e- electrides will be discussed. Our findings provide an important insight into the design strategy of new 2D electrides with magnetism based on the IAEs.

Strain-Induced Villari and Nagaoka-Honda Effects in a Two-Dimensional Ferromagnetic Chromium Tri-Iodide Monolayer

Mengchao Shi1, Pinghui Mo2, Jiuw Lu1 and Jie Lii3; 1College of Electrical and Information Engineering, Hunan University, Changsha, China; 2Department of Electrical Engineering, University of Washington, Seattle, Washington, United States.

We report our recent research findings on the impacts of strain on the emerging two-dimensional ferromagnetic chromium tri-iodide monolayer [1]. By combining first-principles density functional theory and Metropolis Monte Carlo methods, the strain-dependent magnetocrystalline anisotropy energy, Heisenberg isotropic symmetric exchange effects, anisotropic symmetric exchange effects, magnetic moment, and Curie temperature are quantitatively analyzed.

The Villari effect, i.e. the inverse magnetostriective effect, and the Nagaoka-Honda effect, i.e. the inverse Barret effect are unresponsive. It is shown that, though a small strain exhibits small impacts on the Curie temperature, it can noticeably influence the hysteresis curve shape and significantly alter the coercive magnetic field. This offers one of the possible explanations of the large variation of coercive magnetic field measured on the strain-proxexfoliated CrI3 monolayers [2]. This also indicates the importance to push strain to reduce device-to-device variation of magnetic properties in the monolayer-based spintronics memory and logic devices. It is revealed that strain can induce changes on a series of key magnetic properties (e.g., the strain-induced magnetization direction flip, the strain-induced ferromagnetic/antiferro- magnetic transition, the strain-induced change of magnetic coercivity, etc.). The strain-induced properties unreported here are of practical interests to implement next-generation monolayer-based devices and sensors.

In Situ Substitutional Doping of Monolayer MoS2—The Significance of Substrates

Kehao Zhang1, Brian Bersch1, Nicholas Borys2, Ke Xu3, Simin Feng4, Jaydeep D. Joshi5, Rafik Addou6, Chexi Zhang7, Ke Wang8, Robert Wallace9, Kyeongjae Cho5, Patrick Vora10, Mauricio Terrones1, Susan Fullerton-Shew1, Feliciano Schuck2, and Joshua Robison1; 1The University of Pennsylvania State University, University Park, Pennsylvania, United States; 2Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 4George Mason University, Fairfax, Virginia, United States; 5The University of Texas at Dallas, Richardson, Texas, United States.

Doping, as a fundamental technique to functionalize conventional semiconductors, holds unique promise to tune the properties of 2D materials. However, due to the ultra-low thickness and simple structure of 2D materials, the chemical environment (i.e. substrates) may drastically modify the properties of synthetic 2D materials, leading disagreements between the experiments and simulations. Indeed, realizing the in-situ substitutional doping of monolayer MoS2, by chemical vapor deposition necessitates the in-depth understanding of the substrates’ properties. Here, we present successful in-situ doping studies achieved by fine-tuning the substrate properties. First, the substrate surface ineffectiveness directly impacts on the doping efficacy of manganese (Mn). Substitutional Mn doping of monolayer MoS2 can only be achieved on 2D substrates such as graphene due to the presence of polarized dangling bonds on the surface. On 3D substrates such as graphene and SiO2, Mn is adsorbed by the surface dangling bond instead of being bonded in the MoS2 lattice (Nano Lett., 2015, 15 (10) 6586-6591). Second, the substrate surface termination guides the film/substrate charge transfer and limits carrier density tunability by foreign dopants. Aluminum terminated sapphire (c-sapphire) surface exhibits strong electron doping to the synthetic MoS2 monolayers, leading the 100X higher electron concentration in MoS2 than its counterpart grown on oxygen terminated sapphire (r-sapphire) surface, evident by field effect transistor characterization. Meanwhile, the reduced electron doping and the interaction between Mn and surface oxygen on r-sapphire results in 100X enhancement of photoluminescence (PL) intensity and carrier lifetime (~ 1 ns) (Sci. Rep., 7 (1), 16938). Utilizing r-sapphire, nearly degenerately n-doped MoS2 is realized by 1 at% Re substitutional doping, evident by various electronic measurements including conductive atomic force microscopy, scanning tunneling microscopy and FETs, agreeing well with density function theory (DFT) calculations. In contrast, 1 at% Re doping is unable to effectively tune the electron doping from the strong electron doping from Al terminated substrate. Surprisingly, X-ray photoelectron spectroscopy (XPS) and low temperature PL indicates that Re doping is also able to reduce the density of sulfur vacancies by 25% (Adv. Funct. Mater., 2018, 28, 1706950), demonstrating the possibility of multifunctional doping of 2D materials.

Rational Design of 2D Magnetic Materials

Nathan Frey, Hemant Kumar, Liang Dong and Vivek Shenoy; Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Recent experimental success in the realization of twodimensional magnetism has invigorated the search for low-dimensional material systems with tunable magnetic anisotropy that exhibit intrinsic long-range ferromagnetic order. Using a crystal field theory model and first-principles simulations, we demonstrate intrinsic ferromagnetism, high magnetic moments, high Curie temperatures, and intrinsic semiconducting and half-metallic transport behavior in nitride and ordered double-transition-metal MXenes. We report that modifying the surface termination and transition metal in monolayer Mn3N2, nitride MXenes gives rise to a rich diversity of noncollinear spin structures and finely tunable magnetocrystalline anisotropy. We predict that manipulating the strength of the spin-orbit interaction and electron localization via the chemical degrees of freedom can induce sufficient anisotropy to counteract thermal fluctuations that suppress long-range magnetic order. Ti3N2 and Mn3N2 MXenes have continuous O(3) and O(2) spin symmetries, respectively, that may be broken by an applied field, while Cr2N2O and Mn2N2O are intrinsic Ising ferromagnets with out-of-plane easy axes and magnetic anisotropy energies up to 63*105 eV/atom. These systems also exhibit both gapped and gapless Dirac points near the Fermi level. Our work suggests that nitride MXenes offer a promising avenue for achieving both practical spintronic devices and investigating fundamental spin processes in two-dimensional materials.

With the discovery of graphene, there is a renewed interest in two-dimensional (2D) nanostructures due to their unique physical and chemical properties, as well as their potential applications in different fields ranging from electronics to biomedical ones. Many inorganic (IGAs) structures similar to graphene have been synthesized and are being exploited for novel applications. Many of these structures are van der Waals 2D solids, and it is possible that these solids are not stable after 200 ps (picoseconds) and [001] oriented plane is the most stable one [1].

3:00 PM BREAK

3:30 PM EP03.07.06
Ferromagnetic Quasi-Atomic Electrons in Two-Dimensional Interlayer Space of Digadolinium Carbide Electride Seungyong Lee1, Jae-Yeol Hwang1, Jongho Park1, Chandani N. Nandadasa2, Seong-Gon Kim2 and Sung Wng Kim1; 1Department of Energy Science, Sungkyunkwan University, Suwon, Korea (the Republic of k); 2Department of Physics & Astronomy and Center for Computational Sciences, Mississippi State University, Mississippi, United States.

Electride is a generalized form of interstitial anionic electrons (IAEs) confined in the positively charged cavities as found in many compounds and elements. Depending on the size and geometry of cavities, IAEs show different degrees of localization, exhibiting various exotic properties. The most strongly localized IAEs are theoretically conceptualized as quasi-atoms in elemental electrides under high pressure. However, there is an experimental evidence for quasi-atomic IAEs has yet been discovered in practical electrides. Furthermore, as the pressurized potassium can be stabilized by ferromagnetic ordering, a quasi-atomic IAE, which is the simplest magnetic system with a distinct magnetic moment, can behave as a ferromagnetic atom, but no ferromagnetic electride originating from quasi-atomic IAEs has been realized. In this talk, present the IAEs in layered [Gd2C]2+:2e− as atoms of ferromagnetic elements in two-dimensional interlayer space. We verified that the inherent quasi-atomic IAEs have their own magnetic moments of ~0.5 Bohr magneton per one IAE, which are critical for the ferromagnetism in [Gd2C]2+:2e−. It was found that the ferromagnetic IAEs facilitate the exchange interactions between not only intralayer gadolinium atoms but also interlayer gadolinium atoms across IAEs, forming ferromagnetic Gd-IDAE-Gd layer separated by non-magnetic carbon atomic layer, which exhibits a characteristic anisotropy in magnetoresistance analogous to those of typical ferromagnetic/non-magnetic layered systems. The substitution of paramagnetic chlorine atoms for IAEs proves the existence of ferromagnetic quasi-atomic IAEs from a clear transition to non-electride antiferromagnetic Gd3C3I caused by attenuating all interatomic exchange interactions of IAEs with gadoliniums, which are consistent with theoretical calculations. These results confirm that strongly localized quasi-atomic IAE at two-dimensional interlayer space acts itself as a single ferromagnetic element and triggers a spin alignment in antiferromagnetic [Gd2C]2− lattice framework. These results present a broad opportunity to tailor intriguing ferromagnetism originated from quasi-atomic interstitial electrons in low-dimensional materials.

Strong Phonon-Spin and Phonon-Electron Coupling in Monolayer Ferromagnetic CrBr3 Jiangbin Wu1, Miaolong Lin2, Amber McCreary3, Zhonghao Du1, Angela Hight Walker1, PingHeng Tan2 and Han Wang1; 1University of Southern California, Los Angeles, California, United States; 2Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China; 3National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The bulk chromic halides (CrCl3, CrBr3, and CrI3) have long been known as ferromagnetic materials with layered van der Waals structure. Recently, the monolayer CrI3 has been isolated and confirmed to be two-dimensional (2D) ferromagnet. Those 2D magnets offer an exciting platform for studying the interplay between the light and magnetic ordering. Here, we present the Raman spectroscopy study of monolayer CrBr3 from the chromic halides family, which also possesses ferromagnetic properties in its monolayer form. The phonon modes are identified by combining the polarized Raman spectroscopy and density functional perturbation theory (DFPT). The Raman frequencies show an abnormal redshift below the Curie temperature (CT) due to strong spin-phonon interaction. The CT of monolayer CrBr3 is measured to be at 20 K, which is about 15 K lower than that in its bulk form. Moreover, the resonance Raman spectroscopy measurement is used to reveal the mechanism of vibronic (phonon-electron) coupling in the monolayer CrBr3. The E2g mode at 150 cm−1 plays a key role in the Jahn–Teller distortion with the parity-forbidden d-d transition (4T2), which is confirmed by DFPT calculations. This study paves the way to understand the magneto-optical interaction in the 2D transition metal halides.

Electric Field Dependence of Dzyaloshinskii-Moriya Interaction in Two-Dimensional Ferromagnets Takashi Koretsune; Tohoku University, Sendai, Japan.

Recent experimental observations of ferromagnetism in two-dimensional van der Waals crystals open new possibilities in the applications of atomic layer materials. One characteristic feature in atomic layer films is the controllability of the electronic structures through the gate voltage or the electric field. In this study, we discuss the electric field dependence of the electronic structure in a two-dimensional ferromagnet, Cr3Ge2Te6, from first-principles calculations. Using the spin-current method[1], we evaluate the Dzyaloshinskii-Moriya interaction induced by the electric field. The results indicate the possibility of controlling the magnetic behavior by the electric field.

Fe₃GeTe₂ is one of the most promising candidates for two-dimensional (2D) ferromagnetic material based spin devices due to its high Curie temperature \( T_c = 220 \text{ K at bulk state} \). Long-range ferromagnetism in mechanically exfoliated Fe₃GeTe₂ flakes, which has a van der Waals layered structure, were investigated with varying thickness from bulk to a few layers. The Fe₃GeTe₂ crystal was synthesized with Fe deficiencies \( (x \approx 0.3) \) which yield significant variations in magnetic properties. The thickness dependence of the Curie temperature and magnetic coercivity were studied by observing the thickness dependent magnetic hysteresis loops using magneto optical Kerr effect (MOKE) and anomalous Hall effect measurements. Compared to Fe₃GeTe₂ with no Fe deficiencies, the Fe deficient Fe₃-xGeTe₂ shows much smaller coercivity, i.e. it is a magnetically softer material, at all thicknesses. Since soft ferromagnetism is advantageous for certain spin device applications such as current induced magnetic switching, Fe₃-xGeTe₂ is a 2D ferromagnetic material with high potential for spintronic applications.

Since the exfoliation of graphene, the magnetic orderings in two-dimensional (2D) materials have been intensively searched for the great potentials in nanostructured spintronics or valleytronics applications. However, the magnetism in 2D materials is once considered prohibited by Mermin-Wagner restriction and therefore the introduction of 2D magnetism may require external modulations, such as external electric field, defects, adatoms, and carrier doping. By density functional theory based first-principles calculations, we have predicted that substitutional doping of Co atoms at the edge of the most stable configuration of zigzag WSe₂ nanoribbons can induce long-range ferromagnetic ordering and robust half-metallicity that enables spin-selected doping. By density functional theory based first-principles calculations, we have predicted that substitutional doping of Co atoms at the edge of the most stable configuration of zigzag WSe₂ nanoribbons can induce long-range ferromagnetic ordering and robust half-metallicity that enables spin-selected transport along the nanoribbon edges. The half-metallicity was also found quite robust against large size, low doing density, and large tensile strain. The 2D extended materials with intrinsic magnetic ordering is more advantageous for practical spintronics or valleytronics applications due to their facile fabrication and good controllability. Recently in experiments, various 2D ferromagnets, such as CrI₃, have been synthesized, breaking the Mermin-Wagner restriction by realizing strong magnetocrystalline anisotropy in 2D structures. These results have attracted considerable attention in searching more ideal ferromagnetic 2D materials with high stability, robust long-range ordering, high Curie temperature \( T_c \), and possible tuning of magnetism. Through first-principles investigation, we have investigated a series of transition metal thiophosphate TMPS₄ monolayers and predicted their stable long-range ferromagnetic orderings with room-temperature \( T_c \). Integrated with 2D transition metal dichalcogenides (TMDCs) as heterostructures, they allow spin-valley coupled carrier injection from TMPS₄ into TMDCs.

Ferromagnetism Created from 2D Heterostructures Cheng Gong1, Peiyao Zhang2, Tenzin Norden2, Zhen Guo1, Apoorva Chaturvedi2, Yuan Wang1, Hao Zeng1, Hua Zhang2, Athos Petrou2 and Xiang Zhang1; 1University of California, Berkeley, Berkeley, California, United States; 2University at Buffalo, The State University of New York, Buffalo, New York, United States; 4Nanyang Technological University, Singapore, Singapore.

Intrinsic long-range ferromagnetic order has recently been discovered in two-dimensional (2D) atomic crystals. However, the prospect of 2D magnets remains largely hindered by the scarcity of 2D ferromagnets with limited diversity in magnetic attributes. In this context, creative ways to bring forth ferromagnetism from non-magnetic 2D materials are attractive and profitable for both fundamental physics and device applications. In this talk, I will show you the possibility of such creation based on our magneto-optical study of 2D heterostructures and discuss the underlying material physics. Our work paves the new path to harvest 2D ferromagnetism.

Surface Acoustic Wave Enhanced Photodetection of the Black Phosphorus-MoS₂ p-n Diode Enxiu Wu, Yuan Xie, Jing Liu and Daihua Zhang; Tianjin University, Tianjin, China.

We developed a new way to enhance the photoresponsivity of a van der Waals heterojunction p-n diode using surface acoustic waves (SAWs). The diode was constructed on top of a piezoelectric LiNbO₃ substrate and composed of p-type black phosphorus (BP) and n-type molybdenum disulfide (MoS₂) flakes that partly overlapped with each other. This layout facilitated the applied SAWs to rapidly drive carriers out of the depletion region. In this structural design, SAWs promoted the separation of photogenerated carriers, and thus greatly increased the photocurrent. The measured photocurrent for the device with SAWs was about 10³ times higher than that of the device without SAWs. The device using SAWs showed a photoresponsivity as high as 2.17 A/W at the wavelength of 532 nm.

This excellent performance was attributed to the SAWs suppressing electron–hole recombination in the device under light illumination. When light is incident on the surface of the material, the SAW piezoelectric field confines the photogenerated electrons and holes within the maxima and minima of the potentials in the conduction and valence bands, respectively. The potential along the confinement direction \( z \)-direction enables electrons and holes to rapidly shift their mean position and separates them spatially, which increasing carrier lifetime and lowering their recombination rate. Moreover, the BP and MoS₂ flakes form a V-shaped configuration that provides two misaligned paths that aid electrons and holes to rapidly drift into neutral regions. Our device exhibits promise as a high-performance photodetector and reveals new possibilities for acoustic devices in optoelectronics.
We investigate and compare changes in the optical response of 2H-MoTe2 and 2H-Mo1-xWxTe2 alloys as they undergo phase transition between semiconductor-to-semimetal phases in an all vdW device structure using an hBN gate dielectric and graphene contacts. Transition metal dichalcogenides (TMDs), such as Mo1-xWxTe2, exhibit a wide range of electronic properties (semiconducting, semimetal and metallic phases) with unique polymorphs that depend on atomic stacking and coordination. Phase modulation in TMDs is of interest for applications in electronics and optoelectronics. However, reversible tunability between such phases is challenging. This is largely due to a combination of significant differences in the free energy between TMD polymorphs and phase transition kinetic barriers. Phase modulation in MoTe2 has, however, gained recent interest due to the low barrier for transition (~40 meV) between its semiconducting and semimetal phases when compared to other TMDs. Evidently, dynamic control between the thermodynamically favorable semiconducting 2H phase and the metastable semimetal 1T' phase in MoTe2 is achieved with a variety of external stimuli, including strain, temperature and electrostatic doping. In the latter case, theory predicts that this phase transition occurs when the charge density exceeds ~10^{14} cm^{-2}, which has been experimentally verified in monolayer MoTe2 using ionic gating. However, reversible switching between these phases with a solid-state electrolyte gate still remains elusive. To circumvent the charge density requirements, theory predicts that the barrier for phase transition can be reduced in MoTe2 when alloyed with tungsten. Evidence of this was demonstrated by Zhang et al. (arXiv:1709.03835), where an all solid-state resistive random-access memory device fabricated with Mo1-xWxTe2 showed reversible switching between high and low resistance states. In addition to changes in conductivity, another feature of the phase transition in MoTe2 includes in-plane structural changes that should give rise to district optical anisotropic responses in monolayers. However, changes in the optical response in MoTe2 and Mo1-xWxTe2 alloys as they undergo phase transition remains highly unexplored.

In this study, both exfoliated and grown 2H-Mo1-xWxTe2 monolayers with x=0 and x=0.09 are explored. The optical response of the vdW stack are investigated using angle- and polarization-dependent reflection measurements as a function of gate voltage. Initial results showed changes in optical response of the vdW stack between (1.1–1.4) μm with applied gate voltage in alloys with x=0.09. Furthermore, polarization- and temperature-dependent Raman measurements are also performed to map out structural changes in Mo1-xWxTe2 as a function of applied gate voltage. These results will provide new insight into the optical response of these materials to enable new avenues for application in low-voltage and ultrafast modulators and other nanophotonic devices.
Laminar MoS₂ membranes are one of the two-dimensional (2D) materials showing outstanding practical applications in energy conversion/storage, as sensors, and as nanofluidic devices. Especially in water purification technologies, MoS₂ membranes forming abundant nanocapillaries from layered stacks of MoS₂ nanosheets demonstrate excellent ionic rejection with high water permeation rates, as well as long-term stability with no significant swelling when exposed to aqueous/organic solvents. Here, we demonstrate the dye functionalised MoS₂ laminar membrane (MoS₂/SY), under the influence of an applied electric potential, performed the ion transport through membrane as ionic sieving and size effect, which was found to decrease by about a factor of 5 in cations mobility at 3 μm thick compared to pristine exfoliated MoS₂ membrane as well as providing high stability in a range of pH conditions. Hydrated and non-hydrated cations were also performed with MoS₂/SY membranes, demonstrating that higher electric charge density affect predominantly toward inorganic cations of the comparable organic cation radii. We expect dye functionalized laminar MoS₂ membrane as performed ionic sieving with charge selectivity using chemically modified nanocapillary channels will be further utilized as electro-dialysis for water filtration technologies.

Exfoliation of Centimeter-Sized MoS₂ on Gold Substrate Facilitated by Strong Physisorption
Matěj Velecký1-3, Gavin E. Donnelly2, Héctor D. Abravanel and Fumin Huang1; 1Chemistry and Chemical Biology, Cornell University, Ithaca, New York, United States; 2School of Mathematics and Physics, Queen's University Belfast, Belfast, United Kingdom.

The conflict between the material quality and production scalability is one of the major challenges for future applications of two-dimensional (2D) materials. The typical size of monolayer transition metal dichalcogenides (TMDCs), such as MoS₂, achieved by mechanical exfoliation (which yields the highest quality materials) is currently limited to ca. 100 μm on insulating substrates. Recently, direct exfoliation or synthesis of TMDCs on metallic substrates of much larger dimensions has increasingly gained attention with a focus on potential applications in optoelectronics and catalysis. Herein, we report mechanical exfoliation of centimeter-sized monolayer MoS₂ on gold substrates, facilitated by strong physisorption between the two materials. The surface contamination and roughness of the Au substrates were found to be the key parameters for successful high-yield exfoliation. Microscopic and spectroscopic characterization of the MoS₂/Au heterostructures confirmed the existence of a strong van der Waals interaction (physisorption) between the two materials, resulting in a significant charge transfer without compromising the structural integrity of the monolayer MoS₂. Furthermore, electrochemical characterization revealed an efficient modulation of the monolayer MoS₂ density of electronic states by the underlying Au. This simple and reproducible exfoliation technique is a useful practical guide for the production of TMDCs, enabling studies of fundamental phenomena at the atomically-flat semiconductor-metal interface. It is likely that these findings will be applied in research areas such as electrode modification, photo voltaics, and photocatalysis.

Van der Waals Epitaxial Growth of 2D Metallic Vanadium Diselenide Single Crystals and Its Heterostructures
Zhepeng Zhang; Peking University, Beijing, China.

Two-dimensional (2D) metallic transition metal dichalcogenides (MTMDs) have recently emerged as a new class of materials for the engineering of novel electronic phases, 2D superconductors, magnets, as well as novel electronic applications. However, the mechanical exfoliation route is predominantly used to obtain such metallic 2D flakes, the batch production remains challenging. Herein, we report the van der Waals epitaxial growth of monocrystalline, 1T-phase, few-layer metallic VSe₂ nanosheets on an atomically flat mica substrate via a “one-step” chemical vapor deposition (CVD) method. The thickness of the VSe₂ nanosheets is precisely tuned from several nanometers to several tens nanometers. More significantly, the 2D VSe₂ single crystals are found to present excellent metallic feature, as evidenced by an extra-high electrical conductivity of up to 10⁶ S m⁻¹, 1-4 orders of magnitude higher than that of various conductive 2D materials. The thickness-dependent CDW phase transitions are also examined through low-temperature transport measurements, which reveal that the synthesized 2D metallic 1T-VSe₂ nanosheets should serve as good research platforms for the detecting novel many-body states. The heterostructures of VSe₂ and semiconducting TMDs also demonstrated in this work. The present results open a new path for the synthesis and property investigations of nanoscale-thickness 2D MTMDs crystals and their heterostructures.

Defects-Engineered WS₅ Exploration by KPFM—A Direct Insight into Band Structure
Xinyuan Wang; National University of Singapore, Singapore, Singapore.

Defects involved in the two-dimensional (2D) materials such as monolayer WS₂ during the chemical vapor deposition (CVD) process is always an inevitable and critical problem. Here, we report a simple and straightforward approach using Kelvin probe force microscopy (KPFM) to reveal the intrinsic structural defects distribution in monolayer WS₂. By combining the KPFM surface potential, conductivity, Raman and PL mapping, we found a vigorous correlation among them, which are consistent with our DFT estimation and STEM results. This KPFM potential image contains rich information of material band structure, which brings us a new perspective to explore material physical properties and may stand as a new reference of the band structure change in near future research.

EP03.08.09
Extrinsic P-Type Doping of Few Layered WS₂ Films with Niobium by Pulsed Laser Deposition
Urmilaben P. Rathod, Justin Egede, Andrey Voeyodin and Nigel Shepherd; Materials Science and Engineering, University of North Texas, Denton, Texas, United States.

The ability to control dopant profiles in the WS₂ and other transition metal dichalcogenide films is essential for creating p-n junctions, and applications in a wide range of electronic and optical devices including but not limited to transistors, photodiodes, and light emitting diodes. We report successful Nb doping of few layered 2H WS₂ films grown by pulsed laser deposition, by controlling the Nb content of the ablation targets. The undoped controls were n-type, exhibited a Hall mobility of 0.4 cm²/V.s, and characterized by a Fermi level at 1.41 eV from the valence band edge. The latter was determined using ultraviolet photoelectron spectroscopy. Films doped at 0.5 and 1.1 atomic percentages niobium were p-type, and characterized by Fermi levels at 0.31 eV and 0.18 eV from the valence band edge. With increased Nb doping, the hole concentrations increased from 2.7x10¹⁰ to 8.6x10¹⁵ cm⁻³, while the mobility decreased from 7.2 to 2.6 cm²/V.s, presumably due to increased ionized impurity scattering. X-ray photoelectron spectroscopy indicates that Nb substitutes on W lattice sites. The approach demonstrates the potential of PLD for targeted doping of transition metal dichalcogenides.

Towards Large-Scale, Low-Temperature van der Waals Epitaxy of 2D Materials Using Atomic Layer Deposition
Miika Mattinen, Georgi Popov, Juni Hämäläinen, Peter King, Mikko Ritiala and Markku Leskelä; Department of Chemistry, University of Helsinki, Helsinki, Finland.
Van der Waals (vdW) epitaxy is a special case of epitaxy, which may occur when a film/substrate interface consists of inert surfaces without dangling bonds – as is the case with 2D materials. In contrast to conventional epitaxy, an indispensable tool for high-quality film growth, in vdW epitaxy the absence of covalent bonding between the film and the substrate allows for epitaxial growth even in case of large lattice mismatch or different crystal structure.[1,2] Thus, vdW epitaxy offers unprecedented possibilities to grow high-quality 2D materials as well as 2D/2D and 2D/3D heterostructures.

Atomic layer deposition (ALD) is a gas-phase thin film deposition technique based on sequential surface-reactions of alternately pulsed precursors. ALD enables facile and accurate control and uniformity of film thickness on wafer scale and complex 3D structures. Nevertheless, ALD also has certain challenges in the deposition of 2D materials stemming from the typically low reactivity of precursors on 2D surfaces: the growth rates may be low, films may become rough, and the grain size may be small due to large nucleation density and low deposition temperatures. These challenges, perhaps excluding the growth rate, may be overcome using suitable vdW epitaxy substrates.

We present results on ALD of various 2D materials, including semiconductors SnS2,[3] ReS2,[4] and PbI2[5] on commonly used vdW epitaxy substrates, sapphire and muscovite mica. In contrast to most previous reports on vdW epitaxy based on CVD or MBE, the depositions are performed both at relatively low temperatures from 75 to 400 °C and in modest, mbar-level vacuum conditions. The epitaxial relations are studied by out-of-plane and in-plane X-ray diffraction. Different tested materials and substrates show varying degrees of registration to the substrate as well as different numbers of domains. In some cases, epitaxy is enabled or improved by mild post-deposition annealing. In general, we find muscovite mica more effective than sapphire in enabling low-temperature vdW epitaxy of large-scale 2D films by ALD with possible applications in (opto)electronics, photovoltaics, and catalysis, for example.

**Human-Eye-Inspired Soft OptoElectronic Device Using MoS2-Graphene Curved Image Sensor Array**

Changsoo Choi1, 2, Minsung Kim1, 2 and Dae-Hyeong Kim1, 2; 1School of Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of); 2Center for Nanoparticle Research, Institute for Basic Science (IBS), Seoul, Korea (the Republic of).

Soft bioelectronic devices provide new opportunities for next-generation implantable devices due to their large to minimal immune responses and tissue damage. However, a soft form of the optoelectronic device for optical sensing and retinal stimulation has not been developed yet mainly because of the rigidity and bulkiness of conventional imaging modules. In this study, we describe a human-eye-inspired soft opto-electronic device using a high-density curved image sensor (CurvIS) array that leverages the atomically thin MoS2-graphene heterostructure and strain-releasing device designs. Unique advantages of the soft omnidirectional CurvIS array include the high-density array design, small optical aberration, and simplified optical. High photosensitivity and infrared blindness are important benefits of the MoS2-graphene-based ultrathin imager, and the CurvIS array successfully acquires pixilated optical signals. It is the first attempt to achieve high-quality imaging using the ultrathin MoS2-based opto-electronic device in a hemispherically curved format with the single-lens optics. We corroborate the validity of the proposed soft materials and device designs through theoretical analysis based on mechanics and optics. The ultrathin CurvIS array is applied to the human-eye-inspired soft implantable optoelectronic device that can detect optical signals and apply programmed electrical stimulation to optic nerves with minimum mechanical side effects. The proposed human-eye-inspired soft optoelectronic device is a step forward to the next-generation soft bioelectronics and the soft imaging elements of the retinal prosthesis.

**ARPES Study of MoS2 Monolayer on Graphite—Electronic Band Structure and Charge Dynamics of a Model 2D Van der Waals Heterostructure Interface**

Fabio Bussolotti1, Hidroyo Kawai2 and Kuan Eng Johon Goh1, 2; 1Institute of Material Research and Engineering, Singapore, Singapore; 2National University of Singapore, Singapore, Singapore.

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) layers are currently being investigated intensely in anticipation that they may play a major role in future optoelectronic technology, their importance being mainly motivated by the wide range of band gap tunability, formation of strongly bounded excitons, and spin-valley coupling phenomena in the monolayer (ML) form [1]. Combining TMDC MLs with other 2D layers to form van der Waals heterostructures represents a promising strategy to further extend the span of control of the electronic and optical properties of TMDC layers [2] as charge redistribution and structural changes can generally occur within the neighboring layers, depending on their relative orientation and separation [3]. Understanding the impact of interlayer interactions and structural defects on the electronic properties in TMDC-based van der Waals heterostructures is therefore a critical first step towards asserting their advantage for optoelectronic devices. Here we report the electronic band dispersion of MoS2 single crystal ML on highly ordered pyrolytic graphite substrate (HOPG) [4], a model system for the study of 2D Van der Waals heterostructure interface, as investigated by angular resolved photoemission spectroscopy (ARPES). The role of the MoS2-substrate interaction in determining the valence band dispersion of the MoS2 layer has been investigated with the support of dedicated band structure calculations. The complex interplay of wave function spatial extension, substrate-layer interaction and interfacial defects in determining the quasiparticle dynamics in the MoS2 layer will be discussed and clarified via detailed ARPES lineshape analysis. We discuss the relevance of our results for charge-transport in single layer devices as well as for the control of valley polarization in TMDC-based van der Waals heterostructures.

**Reduction of Fermi Level Pinning at Cu-BP Interface by Passivating Atoms on the Surface of Cu(111)**

Pengfei Ou and Jun Song; Department of Mining and Materials Engineering, McGill University, Montreal, Quebec, Canada.

Black phosphorus (BP) is a semiconducting material with a direct bandgap of ~2.0 eV in its monolayer and has attention in the application of field effect transistors (FETs). It is known that BP has an n-type contact with Cu which is a high work function metal, representing the strong Fermi level pinning (FLP) at Cu-BP interface. However, such FLP may hinder the achievement of high performance of field effect devices. In this regard, it is crucial to understand the FLP which occurs at metal-semiconductor interface. So, the possibility to reduce the FLP at Cu-BP interface by passivating the Cu(111) surface was examined using first-principles calculations in this study. The passivation by chlorine, sulfur, fluorine, nitrogen, and hydrogen atoms has been
Silicene, a two-dimensional (2D) silicon nanosheet, has gained immense interest due to potential applications, better compatibility, and expected integration with current silicon (Si) technology. Inspired by graphene, researchers have proposed that a 2D layered silicon nanosheet, Silicene, with a honeycomb lattice and van der Waals (vdW) interlayer interactions will be a perfect alternative to silicon as an anode material. This work explores the effects of silicene sheet size on its optoelectronic properties using time-dependent density functional theory (TDDFT). Four structures of hydrogen-terminated Silicene (Si13H22, Si19H30, Si54H74, and Si104H134) are considered with 13, 19, 54 and 104 Si atoms, respectively. Calculations were carried with hybrid density functional B3LYP functional and 6-31G basis set in Gaussian 16 package. The size of the sheet plays a significant role in changing its optoelectronic properties. It is observed that the structures have size tunable spectral response in the IV spectrum. The sheets showed a relatively smaller physical deformation compared to equivalent sized 2D Germanium sheets, noticeable on the largest structure considered in this work. As the number of atoms increases, from Si13H22 to Si104H134, the excitation energy decreases substantially by 29%. The absorption spectrum from the TDDFT calculations shows that the optical absorption moves towards the visible range of light, with increase in size. It is observed that the absorption is higher in the large structures. IR spectra calculations of various bond vibration show a good match with reported experimental results.

**TDDFT Studies on Sheet Size-Dependency of Optoelectronic Properties of 2D Silicon Mo Rajvan Alam1, Ganesh Subramanian Alwarappan1, Aashka Bhandari1, Walid M. Hassan2, Mohamed F. Shibli3, Sunil Patel2, Reza Nekovei1 and Amrit Vernal1; 1Texas A&M University Kingsville, Kingsville, Texas, United States; 2Physical Chemistry, Qatar University, Doha, Qatar; 3Qatar University, Doha, Qatar; 4Indian Institute of Science Education and Research Mohali, Mohali, India, United States.**

Considered. The calculated results illustrate that the passivated atoms can prevent the direct contact between BP and Cu(111), thus reducing FLP at Cu-BP interface. In particular, significant reduction in FLP can be achieved by chlorine- and sulfur-passivation. Furthermore, chlorine- and sulfur-passivated Cu(111) can form ohmic contact with BP, indicating almost zero Schottky barrier height (SBH). Our results suggest an effective surface passivation route towards the control of SBH for the BP-Cu system.

**2D Materials as Active Tunable Elements for Flat Optics Ozgur Burak Aslan1, Yifei Yu2, Linyou Cao3, 4 and Mark L. Brongersma1; 1Materials Science and Engineering, Stanford University, Stanford, California, United States; 2Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; 3Physics, North Carolina State University, Raleigh, North Carolina, United States.**

The ability to tune the optical spectra of atomically thin (2D) semiconducting transition metal dichalcogenides (TMDCs) is valuable for optoelectronic applications [1]. Strain tuning has been repeatedly employed to engineer the excitonic emission and absorption of monolayer (1L) TMDCs [2-10]. Various ways of applying strain have been demonstrated and strain engineering has been established as an external control of 2D materials. Even though strain can significantly alter the optical properties, the strain-dependent dielectric functions of 1Ls, the relevant property for an optical element, has not yet been reported. Moreover, repeatability of strain over many cycles is needed for active optical elements [5,8]. In this study, we investigate the strain-dependent optical properties of suspended monolayers. We exert air pressure on the 1Ls and achieve large tensile strain [2]. This way, as the TMDCs are impermeable to air [11], we realize reversible tuning of the optical spectra and thus the dielectric functions of 2D materials. We demonstrate redshifts of 100s of meV in the excitonic features which dominate the optical spectra of 1Ls. Due to the spectrally narrow excitonic features, we observe that the reflection spectra of the 1Ls are strongly dependent on strain and the wavelength of interest. In this manner, we pave the way to the use of 2D materials as active tunable elements for flat optics.

**Large-Area Deposition of High Quality MoS2 Films for the Applications of High Mobility Field Effect Transistors Kwang Hoon Jung1, 2, Sun Jin Yun1, 2, Yongsek Choi1, Jung Ho Cho1, Jung Wook Lim1, 2, Hyun-Jun Chai1, 2, Dae-Hyoug Cho1, Yong-Duck Chung1 and Gayoung Kim1, 2; 1Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); 2Korea University of Science and Technology, Daejeon, Korea (the Republic of); 3SKKU Advanced Institute of Nanotechnology (SAINT), Sungkyunkwan University, Suwon, Korea (the Republic of).**

Recently, due to their remarkable electronic and optical properties, two dimensional (2D) transition metal dichalcogenides (TMDCs) have received much attention. Among 2D-TMDCs, molybdenum disulfide (MoS2) has been the most widely investigated. The monolayer MoS2 has a direct bandgap (1.8 eV) while the bulk MoS2 has an indirect bandgap energy of 1.2 eV. Monolayer MoS2 flakes had been first obtained by a mechanical exfoliation method. Although this exfoliation method has the potential to obtain high quality single crystalline MoS2 flakes, it is very unsuitable for large scale production and large area applications. On the other hand, large area methods of growing 2D-TMDCs thin films such as chemical vapor deposition (CVD) techniques require a high temperature and produce randomly distributed MoS2 islands on the substrate. Therefore, a new fabrication method to provide a high quality and wafer-scale uniformity is required for high quality and other 2D-semiconductors.

In typical CVD methods, S-vapor evaporated in the form of large S-molecules participates in the deposition of sulfides, and a high substrate temperature is required to obtain the high film quality. Contrarily, in the present work, we demonstrated a new method to obtain high quality MoS2 films on large wafer-scale substrates at a relatively low substrate temperature. We could produce small S-molecules by thermally cracking the evaporated large S-molecules. The S-molecules cracked in the high temperature cracking zone actively react with Mo precursor film to form MoS2 on the substrate. Very thin Mo precursor films were deposited on SiO2/Si substrates using an e-beam evaporator at room temperature. In the sulfuration chamber equipped with the S-cracker, the Mo films reacted with small S-molecules and formed high quality MoS2 films on wafer-scale large substrates which temperature was maintained at 570 °C or lower. The surface morphology and roughness of Mo and MoS2 films were characterized by atomic force microscopy and Raman spectroscopy was also carried out to determine the crystalline quality and uniformity of MoS2 films. The high resolution TEM images showed that the MoS2 film was successfully formed on SiO2 and the 6 nm-thick film was composed of well aligned 8-10 layers of MoS2. We also fabricated a field effect transistor with the MoS2 channel layer formed at 570 °C by the process proposed in this work. The MoS2 FETs using 6.1...
Selective Growth of Ultrathin HfS2 Layers on Hexagonal Boron Nitride for Highly Sensitive Photodetectors Dengeui Wang1,2, Xing Wang Zhang1,2, Junhua Meng1,2, Zhigang Yin1,2 and Jingbi You1,2; 1Key Lab of Semiconductor Materials Science, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China; 2College of Materials Science and Opto-electronic Technology, University of Chinese Academy of Sciences, Beijing, China.

Hafnium disulfide (HfS2) has attracted significant interest because of the predicted excellent electronic properties superior to group VIB transition metal dichalcogenides. For instance, the room-temperature acoustic-photon-limited mobility of HfS2 was calculated to be above 1800 cm2V-1s-1, which is much higher than that of widely studied MoS2 (340 cm2V-1s-1). These extraordinary properties make HfS2 attractive for applications in logic and optoelectronic devices. On the other hand, hexagonal boron nitride (h-BN) has a wide band gap, making it an ideal dielectric substrate for optoelectronic applications of other 2D materials. Recent reports reveal that heterostructures vertically aligned by two 2D materials exhibit novel properties, offering a promising approach to design and fabricate novel electronic devices. Thus, searching for a suitable 2D material as substrate to achieve high-quality 2D HfS2 is highly desirable.

Herein, for the first time we report the synthesis of high-quality HfS2 on h-BN transferred on SiO2/Si by chemical vapor deposition. It is found that the HfS2 layers are selectively grown on h-BN rather than on SiO2/Si. Density functional theory calculations are performed to help understand the mechanism of selective growth of HfS2. Furthermore, the photodetectors based on the HfS2/h-BN heterostructures exhibit excellent visible-light sensing performance, such as a high on/off ratio of more than 106, an ultrafast response rate of about 200 μs, a high responsivity of 26.5 mA W-1 and a competitive detectiveivity exceeding 3×1011 Jones, superior to the vast majority of the reported 2D materials based photodetectors. These results indicate that HfS2/h-BN heterostructures, as well as the selective direct growth of HfS2, are very promising for future applications in high performance nano-optoelectronics.

Stabilizing Phosphorene via Hexagonal Boron Nitride Passivation Natechanok Yutthasaksunthorn, Sanjay Behura and Vikas Berry; University of Illinois, Chicago, Chicago, Illinois, United States.

Layered crystals have revolutionized the field of nanoelectronics and optoelectronics due to their potential to be exfoliated (mechanically or chemically) into atomically-thin two-dimensional (2D) sheets (for example, graphene from graphite). Several 2D crystals and their complex van der Waals heterostructures are recently realized via micromechanical cleavage (peeling) technique. Phosphorene, a two-atom thick 2D material has found significant attention because of its unique physical properties including: sizable band gap (0.3-1.2 eV), in-plane anisotropy, and high charge carrier mobility. Further, the 2D phosphorene layers can be easily exfoliated from the bulk 3D black phosphorous crystals and can also be transferred onto any arbitrary substrates. However, the wide applications of photo-induced doping in nanomaterials are severely constrained by the low doping concentration and poor stability that can be reached. Here, we propose a novel photo-induced doping mechanism based on external photoelectric effect of metal coating on TMDs to significantly enhance the achievable doping concentration and stability. We demonstrate this photo-induced doping effect on Au coated MoS2 field effect transistors (FETs) annealed in the gas mixture of argon (Ar) and oxygen (O2) (V:V = 98:2). Under ultra-violet (UV) light illumination, the modified MoS2 achieves degenerated n-type doping density of 1014 cm-2 rapidly according to the experimentally observed >104 times incensement in the channel mobility. The doping level persists after the removal of UV illumination with non-obervable decrease over 1 day in vacuum (less than 23% over 7 days under ambient environment). In addition, we have applied the same approach to another two TMDs: ReS2 and MoSe2, both exhibit similar photo-induced doping effects. The achieved stable and high concentration doping on the annealed Au/MoS2 (M is Mo or Re, and X is S or Se) FETs by convenient UV treatment enables various photoelectronic applications such as photo-switch, photo-memory and photonic neuromorphic devices.
such as MoS₂, or MoSe₂ are n-type, while few materials, such as phosphorene, which suffers from rapid oxidation, are p-type. We tested the synthesized material. This is critical to fabricate devices such as p-n junctions and heterojunctions, since most of the recently discovered and studied layered materials overpotential to reach -10 mA/cm² is reduced by 210 mV, and the Tafel slope is reduced from 122 to 49 mV per decade (mV/dec) compared to undoped WS₂ nanotubes.

EP03.08.21
Rapid Flame Doping of Co to WS₂ for Efficient Hydrogen Evolution Xiniang Shi, Jens K Norskov and Xiaolin Zheng; Stanford University, Stanford, California, United States.

Transition metal sulfides have been widely studied as electrocatalysts for the hydrogen evolution reaction (HER). Though elemental dopant is an effective way to enhance sulfide activity for HER, most studies have only focused on the effect of doping sulfide edge sites. Few studies have investigated the effect of doping the basal plane or the effect of doping concentration on basal plane activity. Probing the dopant concentration dependence of HER activity is challenging due to experimental difficulties in controlling dopant incorporation. Here, we overcome this challenge by first synthesizing doped transition metal oxides and then sulfurizing the oxides to sulfides, yielding core/shell Co-doped WS₂/W₁₈O₄₉ nanotubes with a tunable amount of Co. Our combined density functional theory (DFT) calculations and experiments demonstrate that the HER activity of basal plane WS₂ changes non-monotonically with the concentration of Co due to local changes in the binding energy of H and formation energy of S-vacancies. At an optimal Co doping concentration, the overpotential to reach ~10 mA/cm² is reduced by 210 mV, and the Tafel slope is reduced from 122 to 49 mV per decade (mV/dec) compared to undoped WS₂ nanotubes.

EP03.08.22
High Yield Bottom-Up Synthesis of Layered Metal Sulfides and Phosphides Using Chemical Vapor Deposition and Top-Down Exfoliation of Monolayers Gilbert D. Nessing, Eti Teblum, Anat Itzhak, Yulia Kostikov and Tarik Aziz; Bar Ilan University, Ramat Gan, Israel.

Since the excitement about graphene winning the 2010 Nobel Prize, there has been extensive research in the synthesis of other non-carbon few/monolayers exhibiting a variety of bandgaps and semiconducting properties (e.g., n or p type). The main approaches to deposit few/monolayers on a substrate are: (a) bottom-up synthesis from precursors using chemical vapor deposition (CVD) or (b) top-down exfoliation (liquid or mechanical) of bulk layered material. Here we show a combined bottom-up and top-down approach where (a) we synthesize in one step high yields of bulk layered materials by annealing a metal in the presence of a gas precursor (sulfur or phosphorous) and (b) we exfoliate and dropcast few/monolayers on a substrate from a sonicated mixture of our material in a chosen solvent. It is important to note that, besides the structure being 2D layered, the properties of the nanomaterials synthesized slightly differ from the materials with the same stoichiometry synthesized using conventional chemical methods. We synthesized CuS₂ and characterized it using multiple spectroscopy, X-ray, techniques, and electrical AFM. We found that is a highly doped, p-type material. This is critical to fabricate devices such as p-n junctions and heterojunctions, since most of the recently discovered and studied layered materials such as MoS₂, or MoSe₂ are n-type, while few materials, such as phosphorene, which suffers from rapid oxidation, are p-type. We tested the synthesized CuS₂ as an electrode for Li-ion battery. These results were recently published in Chemistry of Materials (Vol. 30, 2379–2388, 2018).

Using the same approach, we synthesized high yields of bulk layered silver sulfide (Ag₂S), which exhibits very high performance for hydrogen evolution reaction (HER) and copper phosphide (Cu₃P), which shows a promising application in supercapacitors. We will also discuss progress in the synthesis of other metal sulfides and phosphides and enhancements of this process using custom-made mini-reactors. In this talk, we will discuss the synthesis, the extensive characterizations, the applications tested, and the promise of this technique for the fabrication of bulk materials for energy application and of p-n heterojunctions based on monolayers for future electronic devices.

EP03.08.23
Real-Time Observation of MoS₂ Crystal Growth in the Presence of Other Metals Neha P. Kondekar, Matthew G. Boebinger and Matthew McDowell; School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

MoS₂ is a layered transition metal dichalcogenide (TMDC) with crystallographic anisotropy featuring chemically active edge sites and relatively inert basal sites. Few-layered MoS₂ materials have chemical and electronic properties that can be tuned based on crystallographic orientation, making it attractive for (electro)catalytic applications for the hydrogen evolution reaction (HER) and for hydrodesulfurization (HDS). Doping MoS₂ crystals with transition metals has been shown to improve the HER and HDS activity due to the decoration of Mo edge sites with metals atoms. While the effect of additions of metal atoms to the MoS₂ lattice on physicochemical properties has been investigated, there is a lack of understanding of how the addition of other transition metals influences the synthesis and fabrication process of MoS₂ from the precursor stage. For the development of more efficient catalyst materials, improved knowledge of catalyst synthesis is essential to enable engineering of structure and properties. In this study, we use in situ transmission electron microscopy (TEM) to investigate the growth of MoS₂ crystals with and without the addition of a Ni metal film. Thermolysis of ammonium thiomolybdate is used to grow crystalline MoS₂ within the TEM. The pure MoS₂ precursor forms a polycrystalline film with predominantly small, vertically-oriented grains of MoS₂ at 400°C, with the grains growing until 700°C and transitioning to (100) or horizontal grains above 800°C. Using a similar thermolysis process in the presence of Ni, a polycrystalline film with a mixture of horizontal and vertical MoS₂ grains already form by 400°C and further heating causes the growth of large-area and horizontal single crystals with an average grain size of ~70 nm. Thermogravimetric experiments also suggest differences in the crystalization kinetics of MoS₂ upon addition of Ni. Finally, x-ray photoelectron spectroscopy (XPS) experiments are used as a complementary technique to probe the chemical interaction of metal films with edge sites and basal planes after synthesis. These findings have important implications for the synthesis of MoS₂-based catalysts, which is necessary for engineering catalytic materials with improved activity.

EP03.08.24
Synthesis of Large-Size Single-Crystal Hexagonal Boron Nitride Domains with Controlled Orientation on Epitaxial Nickel Thin Film Junhua Meng¹,², Ye Wang¹,², Menglei Gao³, Likan Cheng² and Xing Wang Zhang¹,²; ¹Key Lab of Semiconductor Materials Science, Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China; ²College of Materials Science and Opto-electronic Technology, University of Chinese Academy of Sciences, Beijing, China.

Atomically thin materials have attracted significant attention in recent years because of their unique structures and properties. Among the family of two-dimensional (2D) materials, hexagonal boron nitride (h-BN), an isomorph of graphene, has been intensively investigated as dielectric or substrate layers for other 2D materials due to its outstanding properties such as ultra-smooth surface, low density of dangling bonds/trapped charges, wide band gap, high thermal conductivity, and low dielectric constant. For electronic applications, high quality and large-area h-BN layers with few defects is strongly desirable. Thus far, many efforts have been devoted to synthesize large-size h-BN domains by optimizing the growth parameters or pretreating the substrate surface. However, the lateral size of single-crystal h-BN domains is still rather small, and further enlarging the domain size remains a challenge. In this work, we demonstrated the growth of millimeter-size single-crystal h-BN domains on the epitaxial Ni (111) substrate by ion beam sputtering deposition. Under the optimized growth conditions, the single-crystal h-BN domains up to 0.6 mm in edge length were obtained, the largest reported to date. The formation of large-size h-BN domains is mainly due to the reduced grain boundaries and the improved crystallinity of underlying Ni.
films. The conductive atomic force microscopy indicates that the merged h-BN layer exhibits quite uniform and excellent dielectric behavior. Furthermore, it was found that the in-plane orientation of the Ni thin film play an important role in the oriented configuration of the h-BN domains. Due to the stitching of the Ni(111) film deposited on the six-fold symmetrical sapphire substrate, the h-BN domains on Ni/sapphire show two antiparallel orientations. By using the three-fold symmetrical MgO(111) substrate, a perfect epitaxial Ni(111) film with only one in-plane orientation were demonstrated, and thus the h-BN domains with unique orientation were also successfully synthesized. This work provides an effective approach for synthesizing large-scale high-quality h-BN layers for electronic applications.

**Fully Printed Flexible and Transparent MoS2 Phototransistors with Organic Electrodes and Dielectric**

Seojun Chung1, 2, Jawook Ha1, Tae-Young Kim1, Hoichang Yang1, Yongtaek Hong2 and Takhee Lee1; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Electrical and computer engineering, Seoul National University, Seoul, Korea (the Republic of); 3Physics and astronomy, Seoul National University, Seoul, Korea (the Republic of); 4Chemical engineering, Inha University, Incheon, Korea (the Republic of).

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) have gained considerable attention as an emerging semiconductor due to their promising atomically thin film characteristics with good field-effect mobility and tunable band gap energy. However, their electronic applications have been generally realized with conventional inorganic electrodes and dielectrics implemented using conventional photolithography or transferring processes that are not compatible with large-area and flexible device applications. [1] Specifically, unnecessary procedures, such as a photoresist deposition or ultraviolet exposure, can degrade the electrical characteristics of TMDs channel layers. Recently, the use of graphene electrodes or hexagonal boron nitride dielectric layers to introduce dangling bond free interfaces on TMDs has been suggested. [2] However, these layers require complicated and time-consuming etching and transferring processes with additional supporting layers. To facilitate the advantages of 2D TMDs in practical applications, strategies for realizing flexible and transparent 2D electronics using low-temperature, large-area, and low-cost processes should be developed. Motivated by this challenge, we report fully printed transparent chemical vapor deposition (CVD)-synthesized monolayer molybdenum disulfide (MoS2) phototransistor arrays on flexible polymer substrates. [3] All the electronic components, including dielectric and electrodes, were directly deposited with mechanically tolerant organic materials by inkjet-printing onto transferred monolayer MoS2, and their annealing temperature of <180 °C allows the direct fabrication on commercial flexible substrates without additional assisted-structures. By integrating the soft organic components with ultrathin MoS2, the fully printed MoS2 phototransistors exhibit excellent transparency and mechanically stable operation under tensile stress. Furthermore, by conducting the carefully optimized printing processes, the fabricated fully printed phototransistors exhibited comparable photocharacteristics, including photoresponsivity and external quantum efficiency (EQE), to those of previously reported phototransistors with inorganic components fabricated by conventional photolithographic processes on rigid SiO2/Si substrates.

**Centimeter-Scale Periodically Corrugated Few Layer MoS2 with Tensile Stretch-Driven Tunable Multifunctionalities**

Emmanuel F. Okogbue1, 2, Jung Han Kim3, Jung-Tae Kim4, Hee-Suk Chung3, Adithi Krishnaprasad5, Jean Calderon Flores4, 6, Shradhha Nebate4, Md Golam Kaum4, Jong Bae Park2, Sei-Jin Lee7, Kalpathy Sundaram3, Lei Zhai4, 5, Tania Roy1, 2, 5 and Yeonwoong Jung1, 2, 5; 1Electrical and Computer Engineering, University of Central Florida, Orlando, Florida, United States; 2Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States; 3Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4NanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 5Analytical Research Division, Korea Basic Science Institute, Jeonju, Korea (the Republic of); 6Chemistry, University of Central Florida, Orlando, Florida, United States; 7Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States.

Two-dimensional (2D) transition metal dichalcogenide (TMD) layers exhibit superior optical, electrical, and structural properties unattainable in any traditional materials. Many of these properties are known to be controllable via external mechanical inputs, benefitting from their extremely small thickness coupled with large in-plane strain limits. However, the realization of such mechanically-driven tunability often demands highly complicated engineering of 2D TMD layer structures, which is difficult to achieve on a large wafer-scale in a controlled manner. In this work, we report chemically grown centimeter-scale corrugated 2D molybdenum disulfide (MoS2) layers with tailored dimensions and study their strain-tunable multi-functionalities. For the purpose of structural engineering of 2D MoS2 layers, we developed a water-assisted method to transfer them from the growth substrates onto the large area (~2cm2) pre-strained three-dimensionally patterned elastomeric substrate. The transferred and integrated 2D layers maintain precisely defined and corrugated structures preserving their intrinsic material characteristics while exhibiting the excellent controllability of in-plane strain. We identified the well-retained electrical conductivity of these large-area corrugated 2D MoS2 layers even upon significant (> 30 %) tensile stretch. In addition, these corrugated MoS2 layers present periodically tunable photoresponsivity, optical absorbance and surface wettability which are concurrently actualized upon mechanical stretching. These novel three-dimensionally structured 2D materials are believed to offer exciting opportunities for large-scale, mechanically deformable devices of various form factors.

**Thermal Edge Reconstruction and Size Control of Nanopores in Transition Metal Dichalcogenides**

Kevin Bogart1, 2, Tao Liu2, Massimo Spina2, Chris Boothroyd1, Martial Duchamp1, Silvia Gradecak1 and Slaven Garaj1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2National University of Singapore, Singapore, Singapore; 3Nanyang Technological University, Singapore, Singapore; 4Nanyang Technological University, Singapore, Singapore.

Atomically thin nanoporous membranes are versatile structures with applications in energy, sensing, and filtration platforms including reverse electrodialysis, DNA sequencing, and reverse osmosis. The functionality of these devices is derived from the chemistry and geometry of the nanopore edge. Current methods for nanopore formation and processing include electron beam drilling, electrochemical reaction, and oxidative annealing. Since one of these methods offers a set of trade-offs, no universal method exists to precisely control both pore nucleation (e.g. number and location) as well as functionality (e.g. size, shape, and edge chemistry). Here we report vacuum annealing as a route toward reproducible engineering nanopore edge in two-dimensional (2D) transition metal dichalcogenides (TMDs) with tunable pore sizes, shapes, and edge chemistries.

In order to study nanopore growth kinetics and edge reconstruction in 2D TMDs, nanopores were introduced and annealed in situ in an aberration-corrected scanning transmission electron microscope. We find that nanopore edges become more ordered at higher annealing temperatures, favoring metal-terminated edges along the zigzag orientation. Further, we observe that nanopore area increases quadratically with time with an Arrhenius temperature-dependent rate corresponding to an activation energy of approximately 0.6 eV for pore growth in a MoS2 model system. Our findings are guided and corroborated by Monte Carlo simulations comparing the relative effects of time, temperature, and pore size on growth rate. The implementation of these findings in the fabrication of nanopore devices will aid in the rational design of targeted geometries and chemistries of nanopore edges to optimize device performance.

From 3D Ferrocrystals to 2D Layers—Layered Structures from Modulated Elemental Precursors
Fabian Göhler1, Erik Hadland2, Danielle Hamann2, Niels Rösch1, Constance Schmidt1, Dietrich R. Zahn1, Florian Speck1, David C. Johnson2 and Thomas Seyller1; 1Institut für Physik, Technische Universität Chemnitz, Chemnitz, Germany; 2Department of Chemistry, University of Oregon, Eugene, Oregon, United States.

A lot of recent research efforts have been devoted to the creation of stacks of single sheets of 2D materials, due to their enticing possibilities in designing new materials. However, large scale production of such structures still poses a significant experimental challenge. The Modulated Elemental Reactants (MER) technique is a promising candidate for the synthesis of a variety of new heterostructures, as it allows independent control of constituents and layering sequence. MER uses a two-step process, where first an amorphous precursor mimicking the appearance of the target material is deposited on a substrate, which then self-assembles upon annealing at relatively low temperatures. Three-dimensional [MX1+δ]m[TX2]n layered structures grown with MER are generally referred to as ferrocrystals. They consist of nanocrystalline layers that show rotational disorder along the crystal's c-axis. Their unique structure leads to emerging properties which make them interesting for fundamental materials science research as well as potential applications.

This contribution will give an overview over recent results obtained from surface science techniques on various ferrocrystalline compounds. For example, X-ray photoelectron spectroscopy (XPS) is a powerful tool to investigate electronic interactions as well as structural modulations within and between the single layers, such as interlayer charge transfer in [SnSe1+δ]m[TiSe2]2, polytypism of MoSe2 layers, and antiphase boundary formation in rocksalt-like BiSe.

Furthermore, we will present the synthesis and characterization of new van-der-Waals heterostructures consisting of monolayer MoSe2 grown by MER on epitaxial graphene on SiC(0001), thus pushing the MER synthesis towards the 2D limit. Similar to 3D ferrocrystals, these two-dimensional structures show nanocrystalline domains and rotational disorder. This fundamental study may provide the base of expanding this concept to create more sophisticated heterostructures and devices by combining large-area epitaxial graphene grown on SiC(0001) with products of the MER synthesis.

Compression Induced Modification of Boron Nitride Layers—A Conductive Two-Dimensional BN Compound
Ana Paula M. Barboza1, Matheus Matos1, Helio Chacham1, Ronaldo Batista1, Alan Oliveira1, Mario Mazzoni2 and Bernardo Neves1; 1Universidade Federal de Ouro Preto, Ouro Preto, Brazil; 2Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

The ability of creating new materials with improved properties upon transformation processes applied to conventional materials is the keystone of materials science. Here, hexagonal boron nitride (h-BN), a large bandgap insulator, is transformed into a conductive two-dimensional (2D) material – bontril – that is stable at ambient conditions [1]. We report on the compression-induced modification of few-layered h-BN into such a conductive boron nitride 2D material via scanning probe microscopy (SPM) experiments. The full phenomenology of bontril's electronic properties is consistent with a proposed ab initio model of a hydroxylated, two-dimensional sp2-bonded BN material. In our calculations, pressure-induced sp2-sp3-ve-hybridization between the two uppermost BN layers in the presence of hydroxyl chemical groups lead to formation of this new material. Both experiments and theory indicate that bontril is a conductive magnetic material with a large work function. Finally, the present work may also mark the consolidation of a new strategy in the discovery of exclusively man-made materials via SPM nanomanipulation, resulting in the rise of unprecedented novel 2D materials with yet undescribed properties.

Synthesis of Tunable 2D TMDs and Their Applications in Opto-Electronics and Rechargeable Batteries
Wonbong Choi; University of North Texas, Denton, Texas, United States.
Recent advances in atomically thin two-dimensional transition metal dichalcogenides (2D TMDs) have led to a variety of promising technologies for nanoelectronics, photonics, sensing, energy storage, and opto-electronics, to name a few. The TMDs are finding niche applications for next-generation electronics and optoelectronics devices relying on ultrathin atomics in thicknesses [1]. Albeit several challenges in developing scalable and defect-free TMDs on desired substrates, new growth techniques compatible with traditional and unconventional substrates have been developed to meet the ever-increasing demand of high quality and controllability for practical applications. This talk will present two important subjects; (1) Synthesis of large scale 2D TMDs and their bandgap engineering for opto-electronics applications - especially our recent development of uniform and scalable single-layer TMDs by CVD method followed by a laser thinning process. Excitons’ behavior based on composition and layer dependent photoluminescence analysis will be highlighted [2-4]. (2) 2D MoS2 protective layer for Li-metal anodes in Li-S batteries - we observe stable Li electrodeposition and the suppression of dendrite nucleation sites from the 2D MoS2 coated Li-metal. The deposition and dissolution process of a symmetric MoS2 coated Li-metal cell operates at a current density of 10 mA cm\(^{-2}\) with low voltage hysteresis, and a three-fold improvement in cycle-life than using bare Li-metal. In a Li-S full cell configuration, we obtain a specific energy density of \(\sim 600\) Wh kg\(^{-1}\) and a Coulombic efficiency of \(\sim 98\%\) for over 1200 cycles at 0.5 C. Our approach can lead to the realization of high energy density and safe Li-metal based batteries [5]. The large-scale synthesis of 2D TMDs and their tunable optical properties and atomic layer passivation of 2D MoS2 on Li-metal could empower a great deal of flexibility in designing atomically thin optoelectronic devices and Li-metal batteries.

Novel Air-Stable Ultrahigh-Mobility Semiconducting 2D BOX Hailin Peng; Peking University, Beijing, China.

Identifying new 2D materials with both high carrier mobility and large electronic bandgap is a pivotal goal of fundamental research since the ultrathin limit cannot be reached for traditional semiconductors such as Si and GaAs. However, to date, air-stable ultrathin semiconducting materials with superior performances remain elusive. Here our recent studies on the controlled synthesis of high-mobility semiconducting 2D crystals such as layered bismuth oxchalcogenides (BOX, Bi\(_2\)O\(_x\)X; X = S, Se, Te), as well as their electronic and optoelectronic properties will be discussed. We report on chemical vapor deposition (CVD) growth of large-area layered Bi\(_2\)O\(_2\)Se single crystals with the thickness down to monolayer, exhibiting excellent air-stability, low electron effective mass of \(\sim 0.14\) m\(_e\), and tunable bandgap values of \(\sim 0.8\) eV. 2D BOX crystals can be fabricated into high-performance field-effect transistors and NIR photodetectors, in which pronounced quantum oscillations were also observed.

9:15 AM *EP03.09.05
Point Defects in Transition Metal Dichalcogenides Abhay N. Pasupathy; Columbia University, Ithaca, New York, United States.

Two dimensional (2D) transition-metal dichalcogenide (TMD) based semiconductors have generated intense recent interest due to their novel optical and electronic properties, and potential for applications. In this work, we characterize the atomic and electronic nature of intrinsic point defects found in single crystals of these materials synthesized by two different methods - chemical vapor transport and self-flux growth. Using a combination of scanning tunneling microscopy (STM) and scanning transmission electron microscopy (STEM), we show that the two major intrinsic defects in these materials are metal vacancies and chalcogen antisites. We show that by control of the synthetic conditions, we can reduce the defect concentration from above 10\(^{13}\)cm\(^{-2}\) to below 10\(^{11}\)cm\(^{-2}\). Because these point defects act as centers for non-radiative recombination of excitons, this improvement in material quality leads to a hundred-fold increase in the radiative recombination efficiency.

10:15 AM *EP03.09.06
Controlling and Tailoring the Electronic Properties of Chemically Reactive 2D Materials Mark C. Hersam; Northwestern University, Evanston, Illinois, United States.

Following the success of ambient-stable two-dimensional (2D) materials such as graphene and hexagonal boron nitride (hBN), new classes of chemically reactive layered solids are being explored since their unique electronic and optical properties hold significant promise for improved device performance [1]. For example, chemically reactive 2D semiconductors such as phosphorus (BP) and indium selenide (InSe) have shown significantly enhanced field-effect mobilities under controlled conditions that minimize ambient degradation [2]. In addition, 2D boron (i.e., borophene) is an anisotropic metal with a diverse range of theoretically predicted phenomena including confined plasmons, charge density waves, and superconductivity [3], although its high chemical reactivity has limited experimental studies to inert ultrahigh vacuum conditions [4,5]. Even the nominally ambient-stable transition metal dichalcogenides (e.g., MoS\(_2\)) are susceptible to chemically driven phase transformations under relatively benign conditions [6]. Therefore, to fully study and exploit the vast majority of 2D materials, methods for mitigating or exploiting their relatively high chemical reactivity are required. This talk will thus explore recent efforts to control and tailor the electronic properties of chemically reactive 2D materials. In particular, covalent organic functionalization of black phosphorus minimizes ambient degradation, provides charge transfer doping, and enhances field-effect transistor mobility and on/off ratio [7]. In contrast, noncovalent organic functionalization of borophene leads to the spontaneous formation of electronically abrupt lateral organic-borophene heterostructures [8]. Even in the absence of chemical reactants, field-driven bond breaking in polycrystalline MoS\(_2\) enables reconfiguration of doping profiles and novel device functionality such as hybrid memristor and transistor responses [9], which can be exploited in neuromorphic memtransistors [10]. Emerging efforts with additional chemically reactive 2D materials (e.g., InSe) will also be discussed.

References
resulted in p-type, while TeCl₄-assisted growth led to n-type behavior, as determined from the FET transport measurement on thick (over ≈ 50 nm) in 2H phase. For the semiconducting 2H phase, a choice of particular CVT transport agent dictated its intrinsic conductivity: iodine-assisted growth stabilize 2H phase or semimetallic 1T’ phase. A particular crystal structure was controlled by the growth temperature as well as by the post-growth. exfoliated layers were evaluated by TEM, SEM/EDS/EBSD, XRD, XPS, SIMS and Raman measurements. The CVT growth conditions were optimized to Ar ions is performed to induce S removal. X-ray Photoemission Spectroscopy measurements and Rutherford Backscattering Spectrometry showed that S and useful methods to adapt the MoS₂ properties for future applications.

MoTe₂ exists in two thermodynamically stable crystal forms: semiconducting 2H phase at ambient conditions, and semimetallic 1T’ phase at elevated temperatures. Reversibility of the 2H↔1T’ phase transition can be controlled by temperature or, as theoretically predicted, by other external stimuli [1], which makes this material attractive for advanced 2D electronics.

For this work, we have grown MoTe₂ single crystals by chemical vapor transport (CVT). Structural properties and composition of bulk MoTe₂ crystals and exfoliated layers were evaluated by TEM, SEM/EDS/EBSD, XRD, XPS, SIMS and Raman measurements. The CVT growth conditions were optimized to stabilize 2H phase or semimetallic 1T’ phase. A particular crystal structure was controlled by the growth temperature as well as by the post-growth annealing: 1T’ phase was stabilized by quenching at ≈ 900 °C processing temperature, while the growth/annealing temperature below ≈ 800 °C resulted in 2H phase. For the semiconducting 2H phase, a choice of particular CVT transport agent dictated its intrinsic conductivity: iodine-assisted growth resulted in p-type, while TeCl₄-assisted growth led to n-type behavior, as determined from the FET transport measurement on thick (over ≈ 50 nm) MoTe₂ layers. A conductivity type was additionally tuned by scaling down the FET channel thickness: for TeCl₄-assisted growth, the polarity was switching sign from n-type for thick to p-type for thin (below ≈15 nm) layers, with an ambipolar behavior for the intermediate, 15 nm to 50 nm, thickness range. On the contrary, for the iodine-assisted CVT growth, p-type polarity remained unaffected by reducing the MoTe₂ layer thickness in the ≈ 50 nm to ≈ 5 nm range.

The talk will conclude by comparing 2H↔1T’ phase transition in bulk MoTe₂ induced by the growth/annealing temperature, with the electric-field-induced reversible phase change during formation of conducting filaments in 2H-MoTe₂ memristive devices [2].

Biexciton Engineering in MoSe$_2$

Yuerui Lu; Research School of Engineering, College of Engineering and Computer Science, Australian National University, Canberra, Australian Capital Territory, Australia.

Biexcitons have been of keen interest for both fundamental studies of the remarkable many-body interactions and investigations of novel device applications, such as quantum logic gates, biexciton lasing devices, entangled photon sources, etc. [1] Recently, tightly bound biexcitons have been observed in monolayer TMDs, such as WSe$_2$, MoSe$_2$ and W$_5$. These biexcitons in monolayer TMDs show an ultra-large binding energy in the range of 50−70 meV, which is more than 1 order of magnitude higher than the values found in III−V quasi-2D quantum wells [2]. This strong binding necessitates the complete understanding of the structures of these biexcitons and their dynamics in 2D materials as well as characterization of their properties and full investigation of their potential functionalities. Hence, it is necessary to demonstrate a system that exhibits these biexcitons with high binding energy to make their study possible. Here we have successfully used PL spectroscopy to study biexcitons in free standing monolayer MoSe$_2$. We observed tightly bound biexcitons with a binding energy of ∼60 meV in atomically thin MoSe$_2$ [3]. The measured binding energy matches well with the theoretically predicted value of the excited state biexcitons in MoSe$_2$. We further probed the formation dynamics of these biexcitons and found that the density of biexcitons increases with increasing density of negative trions and decreases with increasing density of excitons. This finding suggests that the biexcitons observed here are excited state biexcitons instead of ground state biexcitons. More importantly, we successfully triggered the emission of excited state biexcitons at room temperature in a freestanding bilayer MoSe$_2$ by modulating three independent parameters: (1) dielectric screening, (2) density of trions, and (3) excitation power. The implications of the tightly bound biexcitons at room temperature in 2D materials are far reaching. It provides a room-temperature 2D platform to explore fundamental many-body interactions, which provides a route for quantum logical devices and entangled photon sources operating at room temperature.

Mechanical Properties of 2D Hybrid Organic-Inorganic Perovskites
Qing Tu1, 2, Ioannis Spanopoulos1, Poya Yasaei1, Shaqiang Hao1, Costas Stoumpos3, Christopher Wolverton1, Mercouri G. Kanatzidis1, Gajendra Shekhawat1 and Vinayak P. Dravid1; 1Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 2NUANCE Center, Northwestern University, Evanston, Illinois, United States; 3Northwestern University, Evanston, Illinois, United States.

Two-dimensional (2D) hybrid organic-inorganic perovskites (HOIPs) are new members of the 2D materials family with wide tunability, highly dynamic structural features and excellent physical properties. The mechanical properties of such functional materials are both fundamentally and practically important to achieve both high performance and mechanically stable (flexible) devices. Here we report for the first time both the in-plane and out-of-plane mechanical properties of 2D lead iodide perovskites. We measured the out-of-plane mechanical properties of a series of 2D layered lead iodide HOIPs as a function of structural sub-units (e.g., variation of the length of the organic spacer molecules -R and the number of inorganic layer -n) by nanoindentation. We found 2D HOIPs have much lower elastic moduli and hardness than 3D HOIPs, and larger n number and shorter R result in stiffer material. Furthermore, by AFM-based nanoindentation of suspended 2D HOIP membranes, we measured the in-plane Young’s modulus and breaking strength of ultrathin 2D HOIP membranes and their dependence on the membrane thickness. The in-plane Young’s modulus of 2D HOIPs are smaller than that of conventional covalently bonded 2D materials. Both the Young’s modulus and breaking strength first decrease and then plateau as the thickness increases from monolayer to 4 layers due to interlayer slippage during deformation. Our results show that ultrathin 2D HOIPs exhibit outstanding breaking strength/Young’s Modulus ratio compared to many other widely used engineering materials and polymeric flexible substrates, which renders them suitable for application into flexible electronic devices. We compared our findings with other 2D materials and shed light on routes to further tune the mechanical properties of 2D layered HOIPs.

Exciton Transport in Strained Monolayer WSe2
Darwin F. Cordovilla Leon1, Zidong Li2 and Parag Deotare2, 1; 1Applied Physics Program, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Electrical Engineering and Computer Science, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

A number of devices exploiting the remarkable optoelectronic properties of monolayer Transition Metal Di-chalcogenides (TMDs) have been demonstrated in recent years [1–3]. Most of these devices rely exclusively on the transport of unbound electrons or holes. However, purely excitonic devices leverage the high tunability of TMDs’ band structure and their large binding energies [4] to control the motion of excitons in room-temperature applications. Here, we experimentally demonstrate a visualization of exciton transport in a non-uniformly strained WSe2 monolayer. The strain modulates the monolayer’s direct band gap giving rise to a built-in excitonic potential that results in the funneling of excitons in the direction of the strain gradient.

Our device consists of 400nm diameter, 300nm tall SiO2 pillars on a Si substrate. The WSe2 monolayer is deposited onto one of the pillars using a dry transfer technique [5]. We performed the optical characterization of the strain field by measuring the photoluminescence (PL) emission of the monolayer across the strained region and tracking the shift in the spectra with respect to an unstrained point. In addition, by scanning an avalanche photodiode detector across the PL beam we obtained a map of the time-dependent exciton density as a function of position [6]. This technique reveals essential excitonic transport parameters such as diffusivity and mobility. Our measurements indicate two regimes of diffusive transport [7]: a short, super-diffusive regime characterized by a time-varying diffusivity ranging between 1.6–1.9cm2/s, and a sub-diffusive regime with a time-varying diffusivity ranging between 0.5–1.5cm2/s. Similarly, our measurements indicate that the excitons drift in the direction of the strain gradient in two steps: a fast drift with an approximate strain mobility of 11.4cm2/s, and a slow drift with a strain mobility of 5.3cm2/s. These results will prove to be vital in the design of next-generation excitonic devices.

4:30 PM EP03.10.07
Application of MXenes in Single-Molecule Biophysics
Mehran Mafiabavi1, Armin VahidMohammadi1, Majid Beidaghi2 and Meni Wanunu2; 1Department of Bioengineering, Northeastern University, Boston, Massachusetts, United States; 2Department of Physics, Northeastern University, Boston, Massachusetts, United States; 3Auburn University, Auburn, Alabama, United States.

Since the emergence of nanoprobes as promising biosensors for single-molecule detection, two classes of them have been developed: solid-state and biological (mostly protein-based). Solid-state nanoprobes have drawn attention during the past few years since they provide a more physically robust framework for hosting a nanopore, and further allow experiments under experimental conditions in which lipid membranes or protein channels may not be chemically compatible with. The quest to find an atomically thin membrane that can provide superior spatial resolution along with high mechanical...
stability has introduced two-dimensional (2D) materials such as Graphene, MoS₂, WS₂, and BN as second generation solid-state nanopores.

MXenes are an emerging family of 2D transition metal carbides and nitrides with a general formula of Mn+1XnTx (i.e. Ti₃C₂Tx), where M is a transition metal, X represents carbon or nitrogen (n=1, 2, and 3), and T indicates different functional groups (O, OH, F) present on surface of MXenes. MXenes are produced by selective removal of A layer atoms from a group of layered ternary carbides and nitrides called MAX phases. Since their discovery in 2011, MXenes have been vastly studied for a variety of applications including energy storage and sensors, however, their applications in single molecule sensing and biophysics has remained unexplored. Herein, we investigate the application of a freestanding thin membrane of MXenes, in biomolecules detection and characterization. After fabrication of sub -10 nm diameter pore on the ultrathin MXene membranes, and immersion of the membrane in two buffer baths such that the pore is a sole liquid junction between the two chambers, application of a small voltage across the membrane results in an electric field that threads polymers such as DNA through the nanopore. This results in a transient drop in the ion current, which is used to probe electrically and/or optically structural features in the polymer.

Our preliminary data shows that MXenes provide high mechanical robustness, long-time stability, and low-noise ionic currents through the pore for single molecule detection. With more than 20 different MXenes synthesized, each having different properties, and their facile tunability, this study provides the basis knowledge for application of MXenes as potential materials for second-generation solid-state nanopores.

4:45 PM EP03.10.08 Direct Observation of Atomic Healing in Two-Dimensional Semiconductors Shrawan Roy¹, Wooseon Choi¹, Sera Jeon², Do-Hwan Kim², Hyun Kim³, Seokjoon Yun¹, Yongjun Lee¹, Jaeckwang Lee², Young-Min Kim¹,² and Jeongyong Kim³;¹ Sungkyunkwan University, Suwon, Korea (the Republic of);² Department of Physics, Pusan National University, Busan, Korea (the Republic of);³ CINAP, Institute for Basic Science, Suwon, Korea (the Republic of).

Monolayer transition metal dichalcogenides (1L-TMDs) are promising two-dimensional semiconductors with direct bandgap that ranges the energy of visible and infrared light, suitable for atomically thin nanophotonic device applications. However the very low quantum yields of intrinsic 1L-TMDs is a major drawback for practical use. There have been extensive studies that were able to induce significant increase of light emission of 1L-TMDs, among which chemical treatment using bis(trifluoromethane) sulfonimide TFSI have been shown to be surprisingly effective giving rise to a few order of magnitude increase of photoluminescence. While the healing of sulfur vacancies of 1L-MoS₂ were pointed out as the origin of increased quantum yield, the mechanism of healing the defects is in veil, and hindering practical use of this technique. Here we provide direct observation of atomic healing of 1L-TMDs caused by TFSI treatment. We performed the optical characterization and STEM imaging on the same samples of CVD-grown 1L-MoS₂ and 1L-WS₂ before and after TFSI treatment and found that most (~90%) of sulfur vacancies observed in pristine 1L-MoS₂ were fully repaired with TFSI treatment. Such greatly reduced density of sulfur vacancies were not observed when other chemical treatment that caused moderate increase of PL was used, which indicates that sulfur atoms dissociated from TFSI molecules have filled in vacancies of pristine 1L-MoS₂. The direct filling of sulfur atoms was found to be energetically stable by density functional theory calculation. Our observation unveils the intriguing healing process of lattice defects of 1L-TMDs and suggests that 1L-TMDs can be made completely defect-free, widening and prompting the practical uses of 1L-TMDs in nanophotonic applications. This work was in part supported by the National Research Foundation of Korea (NRF) grants funded by the Korean government (NRF-2018R1D1A1B07042917).

EP03.11.01 Supramolecular Approach to 2D Heterostructures and to the Non-Covalent Functionalization of 2D Materials Manjodh Kaur¹, Navin K. Singh², Aritra Sarkar², Subi J. George³ and Chintamani Nagesa R. Rao³;¹ Sheikh Saqr Laboratory (SSL), International Centre for Materials Science (ICMS), Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India;² New Chemistry Unit, Jawaharlal Nehru Centre for Advanced Scientific Research (JNCASR), Bangalore, India;³ New Chemistry Unit and International Centre for Materials Science, Jawaharlal Nehru Centre for Advanced Scientific Research, Bangalore, India.

Synthesis of 2D heterostructures by van der Waals vertical stacking to modulate their properties has gained interest over the past few years. van der Waals stabilization is an efficient synthetic strategy to obtain 2D heterostructures, although precise sequence and composition of the components still remains a challenge. A new synthetic strategy of covalent cross linking of different 2D materials has been extensively explored by Rao et al.[1]. This novel class of covalently cross-linked 2D materials are different from van der Waals heterostructures and show exciting properties. Although, cross-linked heterostructures show superior properties, further advancement to obtain the heterostructures of higher complexity with multiple components and precise sequences is appealing to explore novel applications. Therefore, for the first time successfully, supramolecular non-covalent synthetic strategy has been utilised to obtain reversible non-covalent heterostructure assemblies with self-organising components.[ii] Wherein, Kumar et al reported the novel, stable and reversible multi-component heterostructures of graphene : BN and MoS₂ : graphene. The 2D-materials have been covalently functionalized by organic coupling reactions between surface functional groups and organic molecules. Thereafter, the covalently functionalized 2D sheets have been noncovalently attached in the presence of cucurbit[8]uril to obtain supramolecular heterostructures. The work has been extended to synthesise supramolecular heterostructures of MoS₂ : g-C₃N₄ and MoS₂ : BC-N. The supramolecular heterostructures have been investigated for their potential application in visible-light assisted photo and electrochemical H₂ evolution studies. These results for H₂ evolution were found to be in good agreement with current literature reports and these results will be presented.[iii] In order to tailor the electronic properties of 2D materials like MoS₂, which unlike graphene cannot be functionalized by π-π stacking or CT interactions, new strategy for non-covalent functionalization of MoS₂ with organic chromophores based on host-guest ternary complexation has been achieved.[iv] This strategy can be utilised to tune the electronic properties of other 2D materials.

Two-dimensional (2D) semiconductors are finding a renewed interest in recent years, due to their combination of physical properties, e.g., mobility, fluorescence and spin selectivity, with a potential implementation in new and emerging opto-electronic and spin-electronic devices. The current work discusses structural properties and various magneto-optical phenomena, found in three different 2D systems: The transition metal phosphorous trichalcogenides, indium sulfide and magnetically doped colloidal nanoplatelets. The magneto-optical properties are investigated by following optical polarization in the presence of an external magnetic field, as various temperatures, as well as implementing the use of optically detected magnetic resonance spectroscopy.

The transition metal phosphorous trichalcogenides resemble the most common layered dichalcogenides, but one-third of the metals are replaced with a P-P pair; hence, the chemical formula is written as M$_2$(P-P)$_3$X$_2$ or M$_3$P$_3$X$_6$. The dilution of metal site by non-magnetic atoms, endows a column like arrangement of the remaining metals, leading to a special magnetic properties, from a full antiferromagnetic Neel, through antiferromagnetic zigzag to ferromagnetic character. The various arrangements can be tuned by variation of the metal cations (among the first row of transitions metal atoms). The work focuses on the influence of the created magnetism on the magneto-optical properties of the M$_3$P$_3$X$_6$ semiconductors. The indium sulfide (In$_2$S$_3$) nanoplatelets crystallize in a few different morphological shapes, hexagon, dodecagon and truncated triangular structures, and are associated either with different crystallographic phases.

Transition metal dopant embedded in colloidal semiconductor nanoplatelets (NPLs) exhibit special magnetic properties, resemble the bulk diluted magnetic semiconductors. However, the NPLs confined thickness induces an extremely intense spin-exchange interaction between the resident photo-excited carriers and the guest magnetic spins. Such an interaction leads to a giant magnetization and g-factor, and consequently endows the materials with special magneto-optical properties. The work emphasizes the investigation of the spin-exchange interaction while varying the magnetic dopants, by following variation in the magneto-optical properties, when detecting either an ensemble of NPLs or a focus on a single platelet.**

** Magnetically doped NPLs project was carried out in collaboration with Prof. Volkan Hilmi Demir and his groups from Nanyang Technological University – NTU Singapore 639798, Singapore and from Bilkent University, Ankara 06800, Turkey.

**Magneto-Transport Properties of the MoTe$_2$ Layers Grown by Molecular Beam Epitaxy**

Marta Gryglas-Borysiewicz, Zuzanna W. Ogorzalek, Adam Kwiatkowski, Janusz Sadowski, Krzysztof Kormor, Magdalena Grzeszczyk, Dariusz Wasik, Rafal Bozek, Johannes Binder, Rafal Mirek and Wojciech Pacuski; Faculty of Physics, University of Warsaw, Warsaw, Poland; MAX-IV Laboratory, Lund University, Lund, Sweden; Institute of Physics, Polish Academy of Sciences, Warsaw, Poland.

The transition metal dichalcogenides are promising materials due to their unusual magnetic, optical and electrical properties. As it has been recently shown, Weyl semimetal including MoTe$_2$ can exhibit carrier mobility of 4000 cm$^2$/Vs and giant magneto-resistance (MR) of 16 000% in a magnetic field of 14 T at 1.8 K [1]. Most of the transport results of the MoTe$_2$, a relatively unexplored transitional metal dichalcogenide, are obtained on mechanically exfoliated samples and concern only most of temperature dependence of resistance [2–3]. Nowadays, there is a substantial progress in obtaining MoTe$_2$ by thin-film epitaxy or deposition [4–8]. In this paper, we present the studies of the MoTe$_2$ layers grown by molecular beam epitaxy (MBE). As it is well known the substrate is of critical importance for the electronic properties of the thin 2D layer. We have studied the role of the substrate using many different substrates: Al$_2$O$_3$, GaAs [100], silicon and GaAs [111B] with and without ZnTe buffer. An appropriate choice of growth temperature allows us to switch between 2H and 1T’ polytypes. It also influences the sample morphology, changing it from regular plane to nanodendrites. Magneto-transport properties of the layers will be presented and the impact of substrate will be discussed.

**Synthesis and Processing of PbI$_2$ 2D Crystals for Applications in Opto-Electronics**

Anna Sinhu and Jamie Warner; University of Oxford, Oxford, United Kingdom.

Two-dimensional materials have attracted tremendous interest amongst the scientific community. Their ultrathin dimension makes them a desirable candidate for applications in electronics as well as their ability to form van der Waals heterostructures with other 2D materials opens the possibility to engineer novel properties and devices. Developments in this area of research requires study of broad range of 2D materials, including but not limited to graphene and transition metal dichalcogenides (TMDs). In this talk, I will present recent studies on the lesser studied material lead iodide (PbI$_2$).

PbI$_2$ is a luminescent, layered and 2.4eV direct band gap material and one of the very important materials for fabricating highly efficient solar cells. In this talk, I will present our recent results on mechanical exfoliation and chemical exfoliation of PbI$_2$ crystals in various solvents with studies on structure and layers using different microscopy techniques and device measurements. Comparisons will be made to monolayer graphene and other well known TMD materials. These results help shed light on how PbI$_2$ can be integrated with other molecular monolayers for expanding the application in opto-electronics.

## EP03.11.05

**Mechanical and Electrical Properties of Ti$_3$C$_2$Tx MXene**

Alexey Lipatov, Mohamed Alhabeb, Haidong Lu, Maria Lukatskaya, Alexei Gruverman, Yury Gogotsi and Alexander Sinitskii; University of Nebraska–Lincoln, Lincoln, Nebraska, United States; Drexel University, Philadelphia, Pennsylvania, United States.

Two-dimensional (2D) transition metal carbides and nitrides, known as MXenes, are a large class of materials that are finding numerous applications ranging from energy storage and electromagnetic interference shielding to water purification and antibacterial coatings. Yet, despite more than 20 different MXenes that have been synthesized, the mechanical properties of a MXene monolayer have not been experimentally studied. Here, we measured the elastic properties of monolayers and bilayers of the most important MXene material to date, Ti$_3$C$_2$Tx (T stands for surface termination). We developed a method for preparing well-strained membranes of Ti$_3$C$_2$Tx monolayers and bilayers, and performed their nanoindentation with the tip of an atomic force microscope to record the force-displacement curves. The effective Young’s modulus of a single layer of Ti$_3$C$_2$Tx was found to be 0.33 ± 0.03 TPa, which is the highest among the reported values for any solution-processed 2D material, including graphene oxide. This work opens the pathway to study the
mechanical properties of monolayers of other MXenes and extends the already broad range of MXenes’ applications to structural composites, protective coatings, nanoelectronics, and membranes that require materials with exceptional mechanical properties. Electronic properties of individual MXene flakes, which are important for understanding the potential of these materials, also remain largely unexplored. We report a modified synthetic method for producing high-quality Ti3C2Tx flakes. We fabricated field-effect transistors (FETs) based on monolayer Ti3C2Tx flakes and measured their electronic properties. Individual Ti3C2Tx flakes exhibit a high conductivity of 46000 ± 100 S/cm and field-effect electron mobility of 2.6 ± 0.7 cm²/Vs. We found that the resistivity of individual flakes is only one order of magnitude higher than the resistivity of multilayer Ti3C2Tx films, which indicates a surprisingly good electron transport through the surface terminations of different flakes, unlike in many other 2D materials. Finally, we used the fabricated FETs to investigate the environmental stability and kinetics of oxidation of Ti3C2Tx flakes in humid air. The high-quality Ti3C2Tx flakes are reasonably stable and remain highly conductive even after their exposure to air for more than 24 h. We demonstrate that after the initial exponential decay the conductivity of Ti3C2Tx flakes linearly decreases with time, which is consistent with their edge oxidation.

Transition Metal Chalcogenides as Active Phase-Change Materials for Infrared Photonics

Yifei Li1, Akshay Singh1, Ichiro Takeuchi2, Ju Li3 and Rafael Jaramillo1; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2University of Maryland, College Park, Maryland, United States.

Transition metal di-chalcogenides (TMDs) form in 2H (trigonal prismatic) and 1T' (distorted octahedral) polymorphs. For transition metals from the VIB and IBV columns, the 2H phase is semiconducting and the 1T' phase is a narrow-gap semiconductor or semi-metal. Switching between the 2H and 1T' phases could be the basis for useful phase-change technology, and the structural distortion between the phases – a martensitic translation of a single plane of chalcogen atoms in a van der Waals material – suggest that phase-change behavior could be relatively immune to fatigue. We will present our work towards designing phase-change TMDs for application to infrared photonics. Our density functional theory (DFT) calculations predict that the refractive index contrast between the 2H and 1T' phases is large and useful in the near-infrared (NIR) wavelength range 1 – 1.5 mm that is relevant to telecommunications. We study the (Mo,Co,Mo)(S,Se)2 valley system to optimize the energy and accelerate the kinetics of switching. Our DFT calculations predict that the 2H – 1T' transition occurs near 50 at. % Cr or Ti. To experimentally access this range of materials we use combinatorial metal sputtering, followed by sulfurization/selenization using H2S and H2Se gas, to make composition-graded TMD films across 2” wafers. We use Raman and X-ray diffraction mapping to distinguish the phase transition boundary and confirm our DFT calculations, and we use ellipsometry to measure the complex refractive index in the NIR. Our work helps build the foundation for rational design of thin film TMD phase-change materials that can be switched optically, electrically, and mechanically.

**EP03.11.07**

Solution-Processable 1T' WSe2 Nanosheets for Electrocatalytic Hydrogen Reduction

Maria S. Sokolikova, Peter C. Sherrell, Pawel Palczynski and Cecilia Mattevi; Imperial College London, London, United Kingdom.

Transition metal dichalcogenide (TMD) monolayers are three-atom thick and can exist in many different polymorphs where metal atom coordination changes from trigonal prismatic (1H phase) to octahedral and distorted octahedral (1T and 1T' phases). These crystal types demonstrate distinct electronic properties varying in a wide range from semiconducting to metallic to topological insulators. WSe2 monolayers synthesised via physical deposition techniques or wet chemical approaches acquire the thermodynamically favourable semiconducting 1H phase that can be then converted into the 1T (1T') as a result of either an electron transfer or applied mechanical strain. However, small energy difference between 1H and 1T' phase suggests that the metastable 1T' phase can be directly obtained under certain reaction conditions. Up until now the 1T' WSe2 has nearly not been synthesized and it has been predicted to be a quantum spin Hall insulator in monolayer limit. We report on direct solution phase synthesis of the 1T' WSe2 nanosheets from tungsten carbonyl precursor in a coordinating solvent. WSe2 forms well-defined flower-like nanostructures with atomically thin petals reaching 50 nm in lateral size. The 1T' phase can be converted into the semiconducting 1H phase upon thermal annealing at 400 °C preserving the starting flower-like morphology. The phase conversion was confirmed by high-resolution X-ray diffraction mapping to distinguish the phase transition boundary and confirm our DFT calculations, and we use ellipsometry to measure the complex refractive index in the NIR. Our work helps build the foundation for rational design of thin film TMD phase-change materials that can be switched optically, electrically, and mechanically.

Multidirection Piezoelectricity in Mono- and Multilayered Hexagonal α-In2Se3

Fei Xue1,2, Junwei Zhang3, Weijin Hu4, Wei-Ting Hsu5, Ali Han6, Sui-Fung Leung7, Jing-Kai Huang8, Yi Wan9, Shuhai Liu10, Junli Zhang11, J-Hau He12, Wen-Hao Chang13, Zhong Lin Wang14, Xixiang Zhang15 and Lain-Jong Li16; Physical Sciences and Engineering Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 1Beijing Institute of Nanoenergy and Nanosystems, Chinese Academy of Sciences, Beijing, China; 2Shenyang National Laboratory for Materials Science, Institute of Metal Research (IMR), Chinese Academy of Sciences (CAS), Shenyang, China; 3Department of Electrophysics, National Chiao Tung University, Hsinchu, Taiwan; 4Computer, Electrical, and Mathematical Sciences and Engineering Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 5School of Advanced Materials and Nanotechnology, Xidian University, Xi’an, China.

Piezoelectric materials have been widely used for sensors, actuators, and electronics, and energy conversion. Two-dimensional (2D) ultrathin semiconductors, such as monolayer h-BN and MoS2 with their atom-level geometry, are currently emerging as new and attractive members of the piezoelectric family. However, their piezoelectric polarization is commonly limited to the in-plane direction of odd-number ultrathin layers, largely restricting their application in integrated nanoelectromechanical systems. Recently, theoretical calculations have predicted the existence of out-of-plane and in-plane piezoelectricity in monolayer α-In2Se3. Here, we experimentally report the existence of out-of-plane and in-plane piezoelectricity in monolayer to bulk α-In2Se3, attributed to their noncentrosymmetry originating from the hexagonal stacking. Specifically, the corresponding d33 piezoelectric coefficient of α-In2Se3 increases from 0.34 pm/V (monolayer) to 5.6 pm/V (bulk) without any odd-even effect. In addition, we also demonstrate a type of α-In2Se3-based flexible piezoelectric nanogenerator as an energy-harvesting cell and electronic skin. The out-of-plane and in-plane piezoelectricity in α-In2Se3 flakes offers an opportunity to enable both directional and nondirectional piezoelectric devices to be applicable for self-powered systems and adaptive and strain tunable electronics/optoelectronics.
Rapid, Light-Induced Degradation of Molybdenum Disulfide in Water 
Lu Zhi, Adam Tetreault and Michael A. Pope; University of Waterloo, Waterloo, Ontario, Canada.

Single or few-layer molybdenum disulfide (MoS2) has demonstrated significant promise in a wide variety of applications including solar cells, transistors, supercapacitors, batteries and as photo/electrocatalysts. Chemical exfoliation of MoS2 by the traditional n-butyllithium route remains one of most common and efficient exfoliation methods which provides relatively high yields of single layers. However, it also results in the partial conversion of the MoS2 from the initially semiconducting 2H polymorph to the 1T polymorph which is a metastable metallic phase. Due to its metallic properties, 1T-MoS2 is the preferred polymorph when used, for example, as an electrocatalyst for the hydrogen evolution reaction (HER), in photoelectrochemical (PEC) water splitting and as electrodes for batteries and supercapacitors. Due to its technological promise, the air and water stability of 1T- and 2H-MoS2 single layers have drawn considerable attention. Herein, we report the discovery of a photo-induced degradation mechanism that can cause the rapid oxidation of MoS2 in water. Ambient light and pH are found to play a significant role in rate of oxidation of a 1T polymorph-dominated aqueous dispersion. Under certain conditions, only one week is necessary to cause the near complete conversion of the MoS2 into oxidation products and one month to convert an initially dark dispersion to transparent. The time evolution of the chemical and structural changes within the material and dispersion are monitored by a variety of advanced techniques such as Raman spectroscopy, Fourier transform infrared spectroscopy, UV/vis spectroscopy, atomic force microscopy and zeta-potential analysis. From these results, we discuss the nature of the decomposition product and the mechanism of the light-induced degradation. We probe conditions under which degradation is slow enough that the material remains stable and discuss the most suitable analytical techniques for detecting decomposition. We believe that the findings from this study will be of great value to those using MoS2 monolayers in various applications, where the stability of the active material is of paramount importance.

Large Area Growth of 2D- MoTe2 Niraj Bhatteri1,2, Rajendra P. Dula1, Andrew Forbes1,2, Ian L. Pegg1,2 and John Philip1,2; 1Department of Physics, The Catholic University of America, Washington, District of Columbia, United States; 2Vitreous State Laboratory, Washington, District of Columbia, United States.

Epitaxial single crystal thin films are very interesting which has drawn great scientific attention in recent time. Such thin films lack grain boundaries because of which they exhibit unique electric and transport properties leading a broad way for large scale applications in nanoelectronics, optoelectronics. Thin films over very large areas can be grown with controlled thicknesses, which paves the door for fabricating large-scale novel devices using MoTe2. We have grown 2D-MoTe2 thin film on Si/SiO2 substrate by chemical vapor deposition. We will present the growth, structural and transport studies of these films. These films exhibit semimetallic behavior and has unsaturated quadratic magnetoresistance. Hall resistivity measurements confirm the majority charge carriers are holes and using single band model, the concentration of holes is 6×1021 cm⁻³ at 10 K and increases with the increase in temperature.

Influence of Local Spatial Parameters of Transition Metal Dichalcogenides on Cellular Adhesion
Anthony Palumbo, Robert Chang and Eui-Hyeok Yang; Stevens Institute of Technology, Hoboken, New Jersey, United States.

Transition metal dichalcogenides (TMDs) are two-dimensional semiconductor analogues to graphene that have been widely explored for biomedical applications. However, cell-substrate interactions of TMDs are not well reported in literature, and TMD-incorporated cell culture platforms require further study to illuminate the influence of TMDs on the adhesive interactions of biological cells and the subsequent integration of these nanomaterials for potential biological applications involving biotic/abiotic interfaces.

We have explored cell-substrate interactions in which the influence of TMD geometric features on the resulting cellular morphology and proliferation is characterized quantitatively, offering insight into manipulating the adhesion of cells on TMD surfaces. We utilized WS2 and MoS2 on cytotoxic and cytocompatible substrates as cell culture platforms, and probed cell-substrate interactions via metrology and analysis of cellular morphometric features (i.e., cell area and eccentricity). Further, we performed analyses relating the influence of local TMD spatial parameters to the resulting cellular morphology, which provides a greater understanding on the causal relationship between TMD surfaces and cell attachment.

Our results show that TMD surfaces in arbitrary order can be used to enhance cell adhesion on substrates that are inerly undesirable to cell attachment, rendering otherwise cytotoxic substrates that are useful as 2D cell culture platforms. We also plotted and determined the significant correlation between TMD geometric variables and the resulting morphometric features of adherent cells, demonstrating that increased TMD island count and size parameters correlated to significantly larger and more elongated cells. These results indicate that by tailoring the geometric parameters of TMDs to a size scale comparable to the adhered cells, one can further guide the desirable adhesion of cells on diverse substrates (even those inherently adverse or cytotoxic to cells), which ultimately influences cellular survival, proliferation, differentiation and migration; coupled with TMD’s unique electronic and chemical properties, these findings can be further explored and applied in fields that utilize biotic/abiotic interfaces including biosensing, pharmacological testing, and organ printing.

Basal Plane Functionalization of Group VI Layered Transition Metal Dichalcogenides
Ali Jawaid and Richard Vaia; Air Force Research Laboratory, Wright, Ohio, United States.

Integration of Group VI 2H-MX2 Transition Metal Dichalcogenides (M = Mo, W; X = S, Se Te) into technologies ranging from chemical sensors to thermal-optical coatings and structural nanocomposites require direct chemical modification of the chalcogenide basal surface. Defect termination with elemental chalcogenide or organic ligands with terminal chalcogenides are routine, however the electronic structure of Group VI Transition Metal Dichalcogenides (TMDs) leads to an inert basal surface. Hybridization strategies therefore rely on extreme reduction processes to drive a transformation from the inert 2H to the reactive 1T phase. However, conversion back to the 2H phase is incomplete, resulting in heterogeneous materials. Here in, we demonstrate an alternative method for direct hybridization of Group VI 2H-MX2 TMDs via alkyl organometallic chemistry. Using the recently development redox exfoliation method, single to few layer TMDs are stabilized in a range of polar organic solvents that are compatible with organometallic chemistries. X-ray Absorption spectroscopy demonstrate strong chalcogen-ligand interaction while X-ray diffraction resolve an expanded interlayer gallery consistent with short-chain organics. The functionalized Group VI 2H-MX2 can be transferred to polar solvents (THF, CH3Cl, C2H5Cl), and show enhanced stability from oxidation and degradation. Finally, the organometallic chemistry is tolerant to –ene and –yne, facilitating post-functionalization modification via click chemistry, such as thiol-ene and thiol-yne conjugation. Tuning the optical, electrical and mechanical properties of MoX2 and NbX2 through integration into composites via surface functionalization is demonstrated.
Synergy of Redox Exfoliation and Mechanical Forces for Large Scale Exfoliation of Layered Transition Metal Dichalcogenides (Group IV – VII) by Ali Jawad, Allyson Ritter and Richard Vajta; Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States.

Transition Metal Dichalcogenides (TMDs) have attracted considerable attention due to their extensive property suite, which compliments many other low dimensional nanomaterials (e.g. graphene, BN, aluminosilicates, phosphenes, etc.). However, energy intensive sonication, aggressive chemistries, and a small choice of stabilizing solvents limit scalable exfoliation strategies, and thus access to large quantities of well-defined layers. Mechanically, exfoliation of low-dimensional nanoparticles from a large crystalline particle has two crucial steps: favorable modification of the nanoparticle surface, and subsequent nanoparticle separation to expose new surfaces. Therefore, the rate and efficiency of exfoliation is optimal for a combination of mechanical forces and surface chemistry; that is either alone is insufficient. Here in, we demonstrate that high-speed shear mixing rather than aggressive sonication balances the rate of chemical processes with nanoparticle separation for TMD exfoliation by the redox method. Chemically, this strategy generates in-situ polyoxometalates, which stabilize single-to-few layer Group IV – VII TMD sheets via coloumbic repulsion. Introduction of shear mixing during the formation of the polyoxometalates, rather than during the initial oxidation step or after the termination of chemical processing, significantly increases single layer exfoliation yields (> 10%) while drastically reducing reaction times (~ 24 hrs). Stable dispersions of Group IV – VII TMD TMDs in polar organic solvents (acetone, acetone, alcohols) at high concentration (10% w/w) are demonstrated for use in numerous bulk technologies, such as thermal/optical coatings, structural nanocomposites, and inks for flexible electronics.

EP03.11.14
CVD Growth of Monolayer MoS2 on Sapphire Substrates by Using MoO3 Thin Films as a Precursor for Co-Evaporation Sajeevi S. Withanage and Saiful Khondaker; University of Central Florida, Orlando, Florida, United States.

Molybdenum disulfide (MoS2) is an atomically thin semiconductor with direct bandgap in single layer (SL) which shows a great potential to wide range of applications in modern 2D electronics and optoelectronics. CVD based co-evaporation of molybdenum (Mo) and sulfur (S) precursors is becoming prevalent for the synthesis of SL MoS2; since conventional exfoliation methods cannot produce large scale samples for scalable device fabrication. For certain optoelectronic applications, choice of transparent growth substrate is critical as it can avoid transfer methods that involve chemicals which can degrade optical and electrical quality of grown SL crystals. Sapphire being an excellent candidate to serve this purpose has the additional benefit of good control over the crystal orientation of MoS2; hence the successful growth of large area MoS2 films on sapphire substrates is critical for scalable device fabrication. Here, we demonstrated that thin film based technique also produce MoS2 crystals with high reproducibility on sapphire without any special substrate treatments and we also studied the effects of parameters such as MoO3 film thickness and S concentration on the crystal growth. These crystals are as large as 25µm confirmed to be in the high quality SL MoS2 by atomic force microscopy measured thickness of 0.65 nm, 18.5 cm-1 gap between A1g and E2g peaks of the Raman single spectrum and very high photoluminescence (PL) response at 1.95eV. High optical quality of these crystals attests to their applications in next generation optoelectronic devices.

EP03.11.15
Elucidation of the Growth Mechanism of MoS2 During the CVD Process Sajeevi S. Withanage, Mike Lopez, Wasee Sameen, Vanessa Charles and Saiful Khondaker; University of Central Florida, Orlando, Florida, United States.

Chemical vapor deposition (CVD) based co-evaporation is a well-established method for the single crystal growth of transition metal dichalcogenides (TMDs) including molybdenum disulfide (MoS2) with excellent electrical and optical properties, still reproducibility of the results has been a challenge since the growth is very sensitive to small perturbations of the growth conditions. Poor understanding in the growth mechanism of this single crystal growth makes it even harder to control growth parameters for reproducible growth. Atomic scale control of the precursors in the vapor phase is the key for such growth. We found this is very hard to achieve with the solid precursors and other limited resources such as lacking independent temperature control of precursors, changes and turbulence of the flow due to internal and external conditions, etc. We evidenced that majority of the growth results in intermediate sub-oxidized MoSx (Sx/sub-2) crystals rather than single crystal MoS2 on the substrate due to these less optimized conditions, especially excess molybdenum environment. Characterization of these microcrystals by Raman spectroscopy showed that they are a combination of MoO3 and MoS2. We were able to successfully sulfurize and recrystallize them into MoS2 single crystals which are confirmed by Raman spectroscopy, photoluminescence spectroscopy and atomic force microscopy. We present systematic experimental results for MoSx formation and resulfurization process elucidating the growth mechanism of this CVD process. This study shows that MoSx formed at the intermediate state can be useful toward reproducible growth of MoS2.

EP03.11.16
CVD Growth of Monolayer MoS2 by Using MoO3 Thin Films as a Precursor for Co-Evaporation Sajeevi S. Withanage1, Mike Lopez1, Hirokjyoti Kalita1, Hee-Suk Chung1, Tania Roy1, Yeonwoong Jung1 and Saiful Khondaker1; 1University of Central Florida, Orlando, Florida, United States; 2Korea Basic Science Institute, Jeonju, Korea (the Republic of).

Transition metal dichalcogenides (TMDs) including molybdenum disulfide (MoS2) is a new class of 2D materials which has a wide range of applications due to their unique optical and electronic properties. Weak inter-layer Van der Waal bonding, direct band gap in single layer, photo conductivity, high sensitivity and high mobility of these materials has promising applications in next generation electronics and optoelectronics. Significant amount of research has been done over the years to synthesize high quality large area monolayers of MoS2; a solid method for large area single crystal growth with good reproducibility is yet to be achieved. We report novel method for chemical vapor deposition (CVD) based growth of monolayer MoS2; by using thermally evaporated thin films of molybdenum trioxide (MoO3) as the molybdenum (Mo) source for co-evaporation. Compared to the commonly used MoO3 powder, thin films give much precise control over the amount of MoO3 and uniform evaporation rate of these films creates a stable vapor pressure at the growth phase hence facilitate much uniform, clean single crystal growth reproducibly. These high quality monolayer crystals are as large as 95µm and were characterized by Raman spectroscopy, photoluminescence spectroscopy, atomic force microscopy and transmission electron microscopy. The bottom gated field effect transistors (FETs) fabricated on as grown single crystals shows a type transistor behavior with a good on/off ratio of 104 and mobilities up to 4.5 cm2/Vs under ambient conditions approving the ability of these materials in future semiconductor electronics.

EP03.11.17
Low Temperature Photodetector Based on GQDs/MoS2 with Laser Tunable Responsivity Minook Min1, Gustavo A. Saenz1 and Anupama Kaul1, 2, 3; 1Department of Materials Science and Engineering, University of North Texas, Denton, Texas, United States; 2Electrical Engineering, University of North Texas, Denton, Texas, United States; 3PACCAR Technology Institute, University of North Texas, Denton, Texas, United States.
Transition metal dichalcogenides (TMDs), which are semiconductors of the type MX2, where M is a transition metal atom such as Mo or W and X is a chalcogen atom such as S or Se are available as building blocks for novel optoelectronic and photonic devices. Among the various TMDs materials, Molybdenum disulfide (MoS2) a representative n-type semiconductor, possesses a band gap ranging from an indirect bandgap (1.2 eV) in bulk form to a direct bandgap (1.8 eV) in the monolayer which enables its applications in photo-electronics such as photocatalyst and phototransistors devices. Monolayer MoS2 demonstrated mobility of ~0.1-10 cm2V-1s-1 and on/off ratios of 106 at room temperature. The reported monolayer MoS2 photodetectors have obtained a responsivity of 880 AW-1 at a wavelength of 561 nm and a photo-response in the 400-680 nm range. Also, a hybrid 2D materials and quantum dots phototransistor has been reported to show very high gain and optical sensitivity determined by the property of the quantum dots. Here we present a quantum dots/MoS2 photodetector consisting of graphene quantum dots and multilayer MoS2 sheets. Graphene quantum dots and MoS2 hybrid films are characterized by Raman/PL spectroscopy, atomic force microscopy (AFM), and X-ray photoelectron spectroscopy (XPS). We measured electrical property of GQDs/MoS2 devices under varied light range at low temperature. Our results suggest that the MoS2 and graphene quantum dots hybrid structure can be promising as efficient photo-detecting devices and optoelectronic circuits.

Scalable Single Step Route to Produce 2D-MoS2 Composites Rebecca F. Albers1, Elson Longo1 and Edson R. Leite1, 2; 1Chemistry Department, Federal University of São Carlos, São Carlos, Brazil; 2Brazilian Nanotechnology National Laboratory, Brazilian Center for Research in Energy and Materials, Campinas, Brazil.

Two-dimensional (2D) materials have attracted much attention from the scientific community due to their unique properties, such as optical, magnetic and mechanical. For example, due to its high Young’s modulus (~270 GPa), 2D-MoS2 is highlighted as a great candidate for nanofiller in polymeric composites. However, although 2D composite materials can be applied in many fields, the quality and the yield of their fabrication process are a constant concern. MoS2 is the most studied transition metal dichalcogenide in the world and many techniques have been developed to obtain this material, such as chemical vapor deposition and mechanical exfoliation. Recently, liquid exfoliation using ultrasonication has been used to obtain MoS2 sheets and functionalized MoS2 sheets in a single step. The exfoliation in the presence of the polymer polybutadiene (PB) increases the yield of the process, since the PB bonds in the edge of the MoS2 sheets stabilize the 2D structure during the exfoliation. Accordingly, in this study we provide some fundamental insights into MoS2 exfoliation process and yield increasing. For this, 2D-MoS2 materials were prepared by exfoliation under ultrasonication by using a bath and a tip, with three different molar mass of PB (5k (PB5k), 200k (PB200k) and 200k-300k (PB300k)) and two different solvents to disperse the polymers (toluene and tetrahydrofuran). When the exfoliation was performed by using PB5k, MoS2 sheets with very similar quality were obtained, inasmuch as Raman spectroscopy showed a frequency difference between A1g and E2g bands around 25 cm-1 (value for bulk MoS2 is 26.3 cm-1), regardless of the solvent used. On the other hand, when the exfoliation was performed by using PBS, better results are obtained when no solvent was used to disperse the polymer, since this polymer is liquid at room temperature (i.e., its role occurs without the need of a new medium). Moreover, characterizations of the 2D-MoS2 materials by X-ray and electron diffraction showed a higher degree of exfoliation in the presence of the polymer than in its absence. Besides, although the nature of the used solvents to disperse the polymer did not influence the quality of the sheets, the yield of the process was quite enhanced when toluene was used (11.26 % for the exfoliation when PB200k was used). This methodology provides a promising avenue toward the producing 2D-MoS2 composites with high degree of exfoliation and yield.

We thank FAPESP (CDMF, proc. 2013/07296-2) for the financial support; FAPESP (2016/14493-7) for the scholarship; CNPq and CAPES.

Scalable and Highly Crystalline Chemical Vapor Deposition of Atomically Thin TMDs Using a Combinatorial Metal Foil-Gas Precursor Method Paolo P. Ferrari1, Apratim Khandelwal2, Mohammad A. Hossain1 and Arend Van Der Zande1; 1Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Transition metal dichalcogenides (TMDs), a branch of the family of 2D materials, offer a wide range of electronic properties that rival or complement those of traditional materials such as silicon and III-V semiconductors. However, growing high-quality monolayers of these materials in a robust, reliable, and scalable way remains a challenge. The majority of studies utilize solid precursors, which is an easy, but unreliable and nonuniform growth method. Two methods which have particular promise are to use metal-organic chemical vapor deposition or solid metal foils with sulfur powder. Using metal-organic chemical vapor deposition to grow 2D monolayers leads to large area and uniform films [1,2], but it proves to be a difficult method to optimize and, typically, it yields domain sizes in the sub-micron range. A more recent method uses foil in combination with soda-lime glass and sulfur powder to achieve large crystal grain size over large areas [3], however, it is subject to the same issues associated with the use of solid precursors. Here, we report a new method that combines the two disparate methods of MOCVD and foil growth with the goal of achieving high quality, large area, and highly uniform monolayers of different TMDs. In the new method, metal foil is used as a source of the metallic precursor of the TMD, including molybdenum and tungsten, and a gas for the chalcogenide component, including hydrogen sulfide H2S or selenide H2Se. The feasibility of the proposed method is demonstrated by growing monolayer MoS2 and WSe2 in the form of individual crystals with grain sizes up to 100 µm as well as continuous films. Using PL and Raman spectroscopy, the as grown WSe2 crystals display 1.62 eV bandgap and FWHM of 60 meV, while the intensity ratio between the photoluminescence and E2g Raman peak is typically 25, indicating quality comparable to the solid precursor and MOCVD growth methods. The influence of growth time and temperature, the presence of salt or soda-lime glass, and flow rate of different gases on the number of layers, domain size and areal coverage are investigated to elucidate the optimal conditions of growth. This robust method is a robust and versatile growth technique that competes with the quality obtained through MOCVD while being much more scalable than solid precursors.

EP03.11.20
Surface Functionalization and Property Correlations of MXenes Gregory Nehrer1, 2, James Hecker1, 2, David Lioi1, 2, Andrew Sharratt1, 2, Faisal Mehmood4, Dhiraj Nepal3, Ruth Pachter3, Richard Vaia2 and W. J. Kennedy2; 1Universal Technology Corporation, Beavercreek, Ohio, United States; 2Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio, United States; 3UES, Inc., Beavercreek, Ohio, United States.

MXenes are a new class of 2-D layered compounds that show promise as a highly-tunable material for next generation composites. In the last decade it has been demonstrated that these ceramic-derived materials can be easily processed into inks, aerosols, paints, and thin films via solution methods not available
to many other 2-D layered materials. Furthermore, they are inherently hydrophilic which is favorable for chemical functionalization. Prior work has demonstrated favorable applications in energy storage and electromagnetic shielding. However, a fundamental understanding of the intrinsic properties of MXenes is lacking, and methods for surface functionalization are needed.

To the purpose of developing tailored MXene bulk films for aerospace applications, we present fundamental electronic, chemical, and structural studies of individual MXene flakes utilizing experimental and theoretical methods. We have size-selected ultrathin sheets and verified their thickness using AFM and TEM and developed anaerobic protocols to surface functionalize individual particles using chemistries of catechols and silanes. Additionally, we confirmed modifications to the crystal lattice and local functional groups using XPS and Raman spectroscopies, as well as used EELS and ultralast transparent optical spectroscopy to extract microscopic electronic properties which were corroborated by theoretical calculations.

EP03.11.21
Understanding and Tuning Electronic Band-Offsets in Mixed-Dimensional van-der-Waals Heterostructures

computational analysis of the sulfurization process for molybdenum trioxide, through interactions with sulfur, still remains poorly understood and insufficiently investigated. Ab initio calculations and molecular dynamics simulations of the reaction of sulfur allotropes (S2-8) with molybdenum trioxide (MoO3) have been used to elucidate the mechanism of sulfurization pathway. These simulations show that the sulfurization process takes place through the formation of molybdenum oxysulfide rings, which can decompose into more sulfurized molybdenum species, oxysulfur molecules and/or smaller sulfur allotropes. As the sulfur allotrope is in a nanoscale sulfur distribution in a vapor phase, our approach can be adjusted to maximize the efficiency of the powder vaporization process.

Effect of Oxidation on the Raman and Photoluminescence Properties of Unpassivated and Novel-Passivated Layered GaTe

Large-area, high-quality two-dimensional molybdenum disulfide crystals have commonly been grown through powder vaporization because of its simplicity and cost-effectiveness. However, the sulfurization process for molybdenum trioxide, through interactions with sulfur, still remains poorly understood and insufficiently investigated. Ab initio calculations and molecular dynamics simulations of the reaction of sulfur allotropes (S2-8) with molybdenum trioxide and experimentally proposed molybdenum oxysulfide intermediates (MoO2S, MoO2S2) have been used to elucidate the mechanistic steps in the sulfurization pathway. These simulations show that the sulfurization process takes place through the formation of molybdenum oxysulfide rings, which can decompose into more sulfurized molybdenum species, oxysulfur molecules and/or smaller sulfur allotropes. As the sulfur allotrope is in a nanoscale sulfur distribution in a vapor phase, our approach can be adjusted to maximize the efficiency of the powder vaporization process.

Effect of Oxidation on the Raman and Photoluminescence Properties of Unpassivated and Novel-Passivated Layered GaTe

Emerging two-dimensional gallium chalcogenides, such as gallium telluride (GaTe), are considered promising layered semiconducting materials that can serve as vital building blocks in the field of nanoelectronics, optoelectronics and quantum photonics. Studies on the physical behaviors of layered GaTe are at early stages of fundamental research, and thus, are of significant interest from the scientific and technological point of view. However, oxidation-induced electronic, structural and optical changes observed in ambient-exposed gallium chalcogenides need to be further investigated and addressed. Herein, we report on the thickness-dependent effect of air and oxygen exposure on the Raman and photoluminescence (PL) properties of GaTe flakes, with thicknesses spanning in the range of a few layers to 65 nm. We have developed a novel chemical passivation that results in complete encapsulation of the as-exfoliated GaTe flakes in ultrathin siliconesquioxane (HSQ) film. A combination of correlation and comparison of Raman and PL studies reveal that the HSQ-capped GaTe flakes are effectively protected from oxidation in air ambient over the studied-period of 7 months, and thus, preserving their structural and optical characteristics. This contrasts with the behavior of uncapped GaTe, where we observe a significant reduction of the GaTe-related PL (~100×) and Raman (~4×) peak intensities. Furthermore, the time-evolution of the Raman spectra of uncapped GaTe is accompanied with the appearance of two new prominent broad peaks, at ~130 cm⁻¹ and ~146 cm⁻¹, which are associated to photo-induced effects, such as oxidation and amorphization, in GaTe. The oxidation of the uncapped GaTe is consistent with our Auger spectroscopy findings. Moreover, our surface-passivation has a dual role. Along with effectively protecting the flakes, it offers the capability to simplify the integration process of fabricating GaTe-based nanodevices, given HSQ is the most commonly used resist for electron beam lithography. Our holistic approach can help further explore and reveal the physical properties of few-layer GaTe, towards the practical realization of nanophotonic devices with structural, and photoluminescence stability.

obtained epitaxially aligned single-crystalline GaAs, GaN, and LiF through monolayer (1ML), bilayer (2ML), and trilayer (3ML) graphene, respectively. More interestingly, we discovered that such field penetration is substantially attenuated through hexagonal boron nitride (hBN) that contains polarity in its bonding. Thus, van der Waals epitaxy seeded from hBN and remote epitaxy seeded from graphene occur simultaneously when we perform epitaxy of GaN through 1ML hBN. Through 3ML hBN, complete transition from remote epitaxy to van der Waals epitaxy occurs. The excellent consistency between the theoretical and experimental findings unequivocally confirms that the ionic character of atomic bonding determines remote atomic interaction through 2D materials. Our work demonstrates that 2D materials can be sensitively probed at atomic scale by performing epitaxy through them. This transparency highly depends on the nature of substrate materials, while it can also be tuned by modulating the thickness and bonding chemistry of the 2D materials.

EP03.11.25
The Role of Oxygen as a Growth Catalyst in the Formation of MoS2 by CVD
Seong Soon Jo and Rafael Jaramillo; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

MoS2 transition metal chalcogenide (TMD) thin films are often made using MoO3 as a precursor. Directly converting metallic Mo to MoS2 would hold advantages for certain studies such as research on metal alloy TMDs, and for processes such as vacuum deposition in an oxygen-free environment. Recent work shows that although the thermodynamics of MoS2 formation in sulfur-rich environments may be favorable, the outcome is highly dependent on the chemical pathway taken and in particular on the oxidation state of the Mo precursor [1,2].

Here we report a study of the role of oxygen as a catalyst for the sulfurization of metal Mo thin films in chemical vapor deposition (CVD). We study the formation of MoS2 at high temperature from Mo and MoO3 films in the presence of S and H2S vapor and with different trace levels of oxygen. By systematically varying the reduction potential of the CVD furnace environment we demonstrate the essential role of oxygen in catalyzing MoS2 formation at relatively low temperature. Our results help to interpret the sizable literature on the growth of MoS2 thin films by CVD, and provide useful guidance for developing processes to make wafer-scale MoS2 films for applications ranging from photonics to catalysis.

EP03.11.26
Cleaning, Passivating and Doping Monolayer MoS2 by Laser Irradiation
Rahul Ban1, Victor Carozo2, Yuanxi Wang3, Ahmad E. Islam4, Nestor Perea-Lopez2, Kazumori Fujisawa2, Vincent Crespi3, Mauricio Terrones2 and Benji Maruyama1; 1Air Force Research Laboratory, WPAFB, Ohio, United States; 2The Pennsylvania State University, State College, Pennsylvania, United States.

Lattice defects such as chalcogen vacancies drastically affect the optoelectronic properties of monolayer transition metal dichalcogenides (TMDs) grown by chemical vapor deposition (CVD). They can be passivated through charge-transfer doping by laser irradiation in air. Here we perform a systematic in situ study to elucidate the passivation mechanism upon laser irradiation and show how to controllably n-dope monolayer MoS2. By combining resonance Raman and photoluminescence (PL) spectroscopy we show that an increase in defect density correlates with a red-shifted PL emission and hence an increase in electron density. Density Functional Theory (DFT) calculations identify chalcogen vacancies to be facilitators (not the source) of n-doping, and population of mid-gap levels upon doping lowers the activation barrier for O2 adsorption from 0.3 to 0.03 eV. Laser irradiation aids in the oxygen-passivation of chalcogen vacancies, manifested by an increase in PL intensity and blueshifted emission, and this blueshift is determined by the laser power density. The passivation occurs on two timescales, with the removal of surface adsorbrates first, followed by oxygen adsorption at the sulfur vacancy sites. Our systematic study provides valuable insights into the defect passivation process, and also demonstrates a practical way to modulate the carrier concentration of monolayer MoS2.

EP03.11.27
MXene Nanosheets—Electrochemical Etching, Oxidation Impediment and Morphology Alteration
Smit Alkesh Shah1, Wannmi Sun1, Touseef Habib1, Miladin Radovic2, Jodie L. Lutkenhaus1,2 and Micah Green1,2; 1Artie McFerrin Department of Chemical Engineering, Texas A&M University, College Station, Texas, United States; 2Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

MXenes are a relatively new class of nanosheets, and they have gained significant interest due to their unique chemical, dielectric and transport properties. Since their discovery in 2011, they have shown promise in a wide range of applications such as electromagnetic shielding, supercapacitors, batteries and water desalination. Typically, MXenes are made from layered carbides and/or nitrides called MAX phases, by selectively etching the A layer using hydrofluoric acid. Here, we successfully demonstrate the electrochemical etching of Al from porous Ti2AlC electrodes in dilute hydrochloric acid (no F ions) to form a Ti2CTx MXene layer on Ti2AlC. These MXenes possess chloride terminal groups, along with the common ones, such as –O and –OH. However, electrochemical etching can result in subsequent over-etching of parent MAX phases to carbide-derived carbon (CDC). We propose a core–shell model to explain electrochemical etching of Ti2AlC to Ti2CTx and CDC. The proposed model suggests that a careful balance in etching parameters is needed to produce MXenes while avoiding over etching. Our electrochemical approach expands the possible range of both etching techniques and resulting MXene compositions. We also demonstrate that colloidal MXene nanosheets encapsulated within spray-dried droplets can be scrolled, bent, and folded into 3D crumpled structures by capillary forces during drying. This morphological change was observed to be reversible upon rehydration. Finally, Ti2CTx MXenes are prone to oxidation, which causes them to chemically degrade to TiO2 over time and become impractical for desired applications. This makes processing of Ti2CTx MXenes difficult. We demonstrate that processing Ti2CTx MXenes in organic solvents and polymer composites leads to lower TiO2 content and higher conductivity compared to Ti2CTx MXenes processed in water. We monitored the oxidation content by measuring the conductivity of the processed films.

EP03.11.28
Ultraslimly-Exfoliated Layer-Controlled Black Phosphorus Nanosheets for Gas Sensing Applications
Ying-Hao Pai, Wang Wei Chien and Chun-Hua Chen; National Chiao Tung University, Hsin-Chu, Taiwan.

Atomically thin black phosphorus (BP), a new family member of the two-dimensional (2D) material, has attracted great attention in these years due to its exceptional electrical, mechanical, and surface properties offering great potential in a variety of applications. However, synthesis, dimensional control, particularly the thickness, and even the preservation of BP remain the challenges since the BP is extremely sensitive to humidity, which would lead to
serious structure damage. In this work, extremely-high-energy ultrasonic exfoliation was performed not only for effectively obtaining mass-produced dimension controlled BP nanosheets, but for greatly reducing the risk of overexposure to the aqueous solvents. A series of BP nanosheets with various dimensions were successfully obtained and subsequently applied as single-nanocrystal and nanoassembled chemical sensors for evaluating their sensing performance.

EP03.11.30
Understanding the Role of the Contact-Material Interface in a MoS2 Chemical Gas Sensor Using Directly Grown Graphene-MoS2 Lateral Heterostructures

Donna Deng1, Shruti Subramanian1, Kehao Zhang1, Keith Perkins1, Ke Xu2, Jun Li1, Randall M. Feenstra1, Susan Fullerton-Shirey1 and Joshua Robinson1

As the synthesis and material properties of 2D materials is better understood, new fronts of potential applications are opened, such as chemical and biochemical sensing. 2D materials offer many advantages in this field, including physical flexibility and large surface-to-volume ratio. While the mechanisms and factors affecting nanorods and nanotubes using conventional 3D materials have been well studied, such details in 2D transition metal dichalcogenide based sensors are not fully understood. In this work, we look at the role of the electronic contact in the sensing capabilities of directly synthesized MoS2 sensors for trimethylamine (TEA). Comparing MoS2 sensors with conventional metal contacts to graphene contacts, we find the band structure and corresponding charge transfer at the contact-channel interface plays a large role in the sensing characteristic of such devices. Devices with Ti/Au-MoS2 contacts, experimentally shown to have Schottky barriers with approximately twice the height of barriers across epitaxial graphene (EG)–MoS2 contacts, exhibit up to 5 orders of magnitude higher sensing amplitude (defined as a fractional change in the device conductance, $\Delta G/G_0$) compared to devices using EG contacts. In addition, effects of controlled defects, such as substitutional doping and plasma induced defects, on the MoS2 channel is studied. By incorporating 2 atomic % of Nb, for example, the TEA sensitivity threshold is reduced by more than an order of magnitude.

EP03.11.31
Electronic Structure and Strain Engineering of Layered Group IV Monochalcogenides

Baiyu Zhang and Xiaofeng Qian
Texas A&M University, College Station, Texas, United States.

Group IV monochalcogenides (MX, M=Ge or Sn, X=S or Se) have attracted a lot of attention very recently as MX are isoelectronic to black phosphorus. Monolayer black phosphorus, namely phosphorene holds high carrier mobility, optical absorbance, negative Poisson’s ratio (NPR), and a semiconducting gap. Monolayer group IV monochalcogenides MX exhibit large piezoelectricity, ferroelectricity, and degenerate structural ground state due to their noncentrosymmetric characteristics, and ultrathin MX have been successfully synthesized. Here we report a first-principles theoretical study of their negative Poisson’s ratio and electronic properties of group IV monochalcogenides with increasing strain and thickness. Our results show that, as number of layers increases, both direct and indirect band gaps decrease. Unlike MoS2, whose band gap transits from indirect to direct when thickness reduces down to monolayer, all four MX remain as indirect-gap semiconductors from monolayer to bulk phase. Furthermore, similar to few-layer black phosphorus, electronic structures, particularly band gaps, of MX can be tuned by strain along either armchair or zigzag direction. Different from auxetic black phosphorus, bulk MX possesses nearly zero Poisson’s ratio along the plane normal direction when elastic strain is applied in the zigzag or armchair direction. The present results shed light on the possibility of van der Waals and elastic strain engineering of group IV monochalcogenides for applications in optoelectronics and functional devices.

EP03.11.32
Raman Analysis of Liquid-Exfoliated Layered Nanomaterials

Matthew Large1, Aline Amorim-Graf2, Sean P. Ogilvie2, Alice King and Alan Dalton2
Physics and Astronomy, University of Sussex, Brighton, United Kingdom.

Raman analysis is a powerful technique for investigating the atomistic structure of materials by probing the vibrational behaviour of covalent bonds. In the field of nanomaterials science, Raman is frequently used to demonstrate quality of nanomaterials prepared through bulk techniques (plasma synthesis, liquid exfoliation). In many cases metrics based on peak ratios, positions and separations have been presented that allow properties such as layer number, defect density and lateral size to be determined from a range of nanomaterials. Single spot spectra at low magnification are often taken and stated to be “representative” of a sample, and used alongside metrics to describe population averages. We ask the question, can this approach ever be representative? It is intuitive that the interaction cross-sections of thicker particles are necessarily higher than thinner ones, and likewise for particles with a greater lateral size; therefore large particulates with high-layer number are likely to dominate spectra collected when a wide distribution of particles are present in the interaction volume of the excitation source. On the other end of the scale, if the platelets are very large, the number of particles in the spot is no longer statistically representative of the sample, except in the limiting case of macroscopic CVD-produced materials.

We propose that the solution to this measurement problem is the use of Raman mapping at high magnification, and statistical analysis of the pixel-by-pixel spectra to build a truly representative picture of the particle distribution in the sample. We demonstrate the approach using three layered materials commonly discussed in the literature, prepared by standard liquid-phase exfoliation processes; molybdenum disulfide (MoS2), graphene, and hexagonal boron nitride (h-BN).

EP03.11.33
Structural Characterization of Defects in Hexagonal Boron Nitride Using Scanning Probe Spectroscopy

Daichi Kozawa1, Ananth Govind Rajan1, Volodymyr Koman1, Kevin Silmore1, Pingwei Liu1, Albert T. Liu2, Daniel Blankschtein3 and Michael Strano2

Lattice defects formed in 2D hexagonal boron nitride (h-BN) have emerged as unique nanopores. Their most useful property is photoluminescence (PL) from the defects in the form of single-photon emission even at room temperature. Even though the defects exhibit PL at multiple wavelengths in a visible range, which vary from defect to defect, the static characterization and analysis have been limited attention. To systematically characterize individual defects of h-BN, we develop scanning probe spectroscopy system combined with an atomic force microscope and a time-correlated single photon counting module. This system allows us to automatically measure thousands of PL spectra at each point, and correlate with PL lifetime, PL excitation, and thickness from individual defects. The statistical analysis of these collected data provides us insight into physical and chemical properties of nanoscale defects in h-BN and potential for ultrasensitive sensing and quantum photonics.

EP03.11.34
Raman Enhancement of Blood Constituent Proteins Using Graphene

Shengxi Huang1, Rishikesh Pandey2, Ishan Barman3, Jing Kong1 and Mildred S.
Texas A&M University, College Station, Texas, United States.

Raman spectroscopy has drawn considerable attention in biomedical sensing due to the promise of label-free, multiplexed and objective analysis along with the ability to gain molecular insights into complex biological samples. However, its true potential is yet to be realized due to the intrinsically weak Raman signal. Here, we report a simple, inexpensive and reproducible signal enhancement strategy featuring graphene as a substrate. Taking key blood constituent proteins as representative examples, we show that Raman spectra acquired from biomacromolecules can be reproducibly enhanced when these molecules are placed in contact with graphene. In particular, we demonstrate that hemoglobin and albumin display significant, but different, enhancement with the enhancement factor depending on the Raman modes, excitation wavelengths and analyte concentrations. This technique offers a new strategy for label-free biosensing owing to the molecular fingerprinting capability, signal reliability, and simplicity of the enhancement method.

A Comparison of Isotope-Enriched Bulk Hexagonal Boron Nitride Crystal Grown from Nickel- and Iron-Based Solutions  
Jiahun Li, Lianjie Xue, Bin Liu and James H. Edgar; Kansas State University-Chemical Engineering, Manhattan, Kansas, United States.

The growth of 10B and 11B isotope-enriched hexagonal boron nitride (hBN) single crystals from molten metal solutions was carried out through a combined experimental and theoretical approach. Using elemental 10B or 11B and nitrogen as the source, the hBN crystal size and quality obtained in molten iron (Fe), iron and chromium (Cr), and mixed Ni-Cr solutions were compared. In this work, the Fe-based solvent is shown to provide a less expensive growth environment than the more established nickel and chromium solvent.

hBN crystals were grown at 1,550 °C and atmospheric pressure, under continuously flowing nitrogen, in pure iron, 50 wt% Ni and 50 wt% Cr, and 80 wt % Fe and 20 wt% Cr. For the crystals grown using a pure Fe solvent, the lateral hBN crystal size and thickness were 0.5 mm and 30 microns, respectively. The predominant crystal domain shapes were equilateral triangles, with edge lengths up to 200 microns. This solvent produced the smallest crystals, presumably due to multiple nucleation sites due to the high solubility of nitrogen in Fe. The crystals grown from the Ni-Cr solution produced larger crystals sheets, up to 2.0 mm laterally and 80-100 microns thick. The surfaces were covered in parallel steps, suggesting the hBN grains had similar orientations. Some metallic inclusions were seen in the hBN produced from the Ni-Cr solvent. The domain shapes were equilateral triangles, truncated triangles, and hexagons. The hBN grown from 80 wt % Fe and 20 wt% Cr solvent had a similar lateral size and thickness with less surface steps, compared to crystal grown from Ni-Cr. Within the sheet were large individual grains, with lateral dimensions up to 400 microns. The main shape of domains were equilateral triangle and parallelogram. The crystals were colorless and free from any inclusions. A critical requirement for successful hBN crystal growth is that solvent and boron nitrogen effectively. DFT was applied to determine the solubility of the nitrogen and boron in bulk Fe, a 50 at% Fe- 50 at % Cr mixture, and a 50 at% Ni-50 at% Cr mixture. At 1,550 °C, the calculated order of nitrogen solubility was: Fe>Fe-Cr>Ni-Cr. For boron, the order was: Fe-Cr>Cr-Ni-Cr. Thus, both Fe and Fe-Cr were predicted to be good solvents for hBN crystal growth. The DFT calculations and experimental results are consistent.

**EP03.11.36**

Molybdenum Vanadium Carbide—A New Tailorable Double-Transition Metal MXene for Electrochemical Applications  
David Pinto1, Babak Anasseri2, Hemesh Avireddy2, Juan R. Morante2, William Porzio3 and Yuriy Gogotsi1; 1Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 2Catalonia Institute for Energy Research, Sant Adrià de Besòs, Spain; 3Faculty of Physics, University of Barcelona, Barcelona, Spain; 4Istituto per lo Studio delle Macromolecole, Milan, Italy.

MXenes are a large family of 2D materials made by selective etching of the aluminum layers from Mn+1AlCn MAX phases into open-structures with single layers of Mn-Cn. These new highly-conductive materials present a remarkable capacitance (1500 F/cm²) in H2SO4. In 2015, the MXene family was extended to include double-transition metal (M) MXenes by introducing two different M types in separate atomic layers of a MXene single-flake, such as Mo5TiC3. The latter phase has already found use as electrode material in supercapacitor and battery-type devices. More than two dozen different compositions of the ordered double-M MXenes were predicted theoretically. Here, we present the synthesis and characterization of Mo5V4-xC3 MAX, and its resulting Mo5V4-xC3 MXene. Unlike Mo2TiC3, this phase is less ordered than previously reported double-M phases. Besides this, without having a dramatic change in its crystallographic structure, Mo5V4-xC3 can be produced with various ratios of Mo and V. This tailoring modifies the electronic and electrochemical properties, and surface terminations, making Mo5V4-xC3 a promising candidate for various applications. For example, in aqueous supercapacitors (1 M H2SO4), Mo5V4-xC3 has demonstrated one of the largest positive electrochemical window so far (up to 0.6 V vs. RHE, 0.75 V voltage window) with capacitance of 850 F/Cm². And, because of this, Mo5V4-xC3, positive electrode, can be coupled with TiC3, negative electrode, in a first full-MXene supercapacitor device producing 150 F/cm² device capacitance with a 1 V window. Besides the application in energy storage, Mo5V4-xC3 may be a promising electrocatalyst for hydrogen generation in water splitting devices.

Surfactant-Mediated Direct Patterned Growth of Atomically Thin Monolayers of Transition Metal Dichalcogenides  
Xufan Li1, Ethan L. Kahn2, Xiahao Sang3, Akina Oyede4, Kazunori Fujisawa2, Tianyi Zhang2, Raymond R. Unocic3, Kai Xiao3, Gugang Chen1, Mauricio Terrones2 and Avetik Harutyunyan1, 2; 1Honda Research Institute USA Inc., Columbus, Ohio, United States; 2Department of Physics, The Pennsylvania State University, University Park, Pennsylvania, United States; 3Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

To realize tremendous potential of two-dimensional (2D) monolayers of transition metal dichalcogenides (TMDs) requires high quality crystals with controllable morphologies and sizes, supported by various substrates, which in turn assumes deep understanding of the growth mechanisms. Moreover, these monolayers are particularly sensitive to surface contaminants associated with lithographical processes to create desired geometries. Here, we show that during the chemical vapor deposition growth of MoS2 monolayer single crystals from MoO3 and NaBr powder precursors, the presence of halide alters island growth (3D) mode of MoS2 to layer-by-layer growth (2D) mode. We found that alkali metal halide salt additive behaves as a surfactant in the growth of the TMD monolayers by chemical passivation of the edges that facilitates the strain and thereby kinetically suppresses 3D islanding growth. This insight enables us to enhance the growth of MoS2 monolayers on various substrates by preliminarily depositing a salt layer. Such a surfactant-mediated growth can also be applied to other 2D TMDs (e.g., WS2, MoSe2). Moreover, using various patterns of pre-deposited salt, we demonstrate direct growth of high quality MoS2 monolayers with corresponding patterns, which can be used for patterned 2D electronic devices. Our results open a perspective for direct patterned fabrication of pristine MoS2 monolayers on various substrates without lithography or transferring.

Substantial Impact of Charge on Electrochemical Reactions of Two-Dimensional Materials  
Junjian Shi, Donghoon Kim and Yuanyue Liu; The University of Texas at Austin, Austin, Texas, United States.
Two-dimensional (2D) materials have attracted great interest in catalyzing electrochemical reactions such as water splitting, oxygen reduction, and carbon dioxide reduction. Quantum mechanical simulations have been extensively employed to study the catalytic mechanisms. However, these calculations typically assume that the catalyst has a zero/constant charge for computational simplicity, while in reality, the catalyst usually has a varying charge as the reaction proceeds due to the match between its Fermi level and the applied electrode potential. These contradictions urge an evaluation of the charge effects.

Here using grand canonical density functional theory calculations, we show that the charge on 2D materials can have a much stronger impact on the electrochemical reaction than the charge on 3D metals, which arises from the unique electronic properties of 2D materials. Our work calls for reconsideration of some of the previously suggested electrocatalytic mechanisms of 2D materials by incorporating the charge effects. [1]

EP03.11.39
High-Performance, Flexible, Inkjet Printed Heterostructure Photodetector for Biosensing Applications
Ridwan Fayaz Hossain and Anupama Kaul;
University of North Texas, Denton, Texas, United States.

Age-related macular degeneration (AMD), a retinal degenerative disease that results in a continuous degeneration of photoreceptors in the retina which eventually leads to complete blindness [1]. One approach to combat AMD is through the use of artificially implantable photodetectors that are physically placed on the retina. The photodetector pixels allow the implantable photodetectors to be in intimate contact to retinal pigment epithelium. Interestingly, 2D materials such as photosensitive and semiconducting molybdenum disulfide (MoS₂) and electrically conducting graphene have recently received tremendous promise due to their unique photonic and optoelectronic properties and their potential in various types of micro and nano devices [2,3]. In this study, we have tested the biocompatibility of various 2D materials, such as graphene and MoS₂, in several organic solvents. A highly biocompatible photodetector on a flexible polyimide substrate was designed, fabricated using inkjet printing to form photosensitive pixels and tested as a function of photo intensity and strain.

Inkjet printed graphene and MoS₂ inks were characterized using techniques such as Raman Spectroscopy, PL, SEM and AFM. The inkjet printed 2D heterostructure devices were photoresponsive to broad-band incoming radiation in the visible regime, and the photocurrent scaled proportionally with the incident light intensity, exhibiting a photoresponsivity \( R \approx 0.30 \text{ A/W} \). This is \( 10^4 \) times higher compared to prior reports, and detectivity \( D \) was calculated to be \( 3.6 \times 10^{10} \text{ Jones} \) at room temperature. The strain-dependent measurements of photocurrent with bending showed a photocurrent of \( \approx 1.16 \mu\text{A} \) with strain levels for curvature up to \( \approx 0.262 \text{ cm}^{-1} \), indicating the feasibility of such devices for large format arrays printed on flexible substrate, unlike conventional Si implantable detectors that are rigid and nonconformable.

In conclusion, the inkjet printed, biocompatible 2D hetero-junction photodetector formed on flexible and conformable substrates was successfully shown to be photoresponsive to a wide range of light intensities and strain levels, making it a promising prospect for in vivo bio-sensing applications for AMD.

EP03.11.40
Two-Dimensional Topological Conduction in SnTe Thin Films
Stephen D. Albright1, Ke Zou2, F. J. Walker3 and Charles H. Ahn1; 1Department of Physics, Center for Research on Interface Structures and Phenomena, Yale University, New Haven, Connecticut, United States; 2Department of Physics & Astronomy, Stewart Blusson Quantum Matter Institute, The University of British Columbia, Vancouver, British Columbia, Canada; 3Department of Applied Physics, Center for Research on Interface Structures and Phenomena, Yale University, New Haven, Connecticut, United States.

The recently developed ability to manipulate one-dimensional edge states in conventional topological insulators (TIs) by selectively breaking time-reversal symmetry is a promising step towards developing TI-based devices. The same control of topological states is also possible in topological crystalline insulators (TCIs), such as SnTe, by selectively breaking crystalline symmetry. Large area quasi-two-dimensional TCI films have been difficult to achieve, however, making control of topological states challenging. This work presents structural and transport characterization of high quality ultrathin SnTe films grown by molecular beam epitaxy on single crystal SrTiO₃. Films thin enough to achieve edge state control are continuous and single domain in nature, and transport measurements show two-dimensional topological conduction through the protected SnTe/SrTiO₃ interface. Analysis of quantum effects observed in magnetotransport reveals the nature of topological states in the SnTe films, presenting a path to manipulating these states in devices.

EP03.11.41
Defect-Assisted Heteroepitaxial Growth of Monolayer Tungsten Diselenide Films with Preferential Orientation on Hexagonal Boron Nitride
Xiaotian Zhang1, Fu Zhang1,2, Yuanxi Wang1,2, Daniel Schulman1, Tianyi Zhang1,2, Anushka Bansal1, Nasim Alem1,3, Saptarshi Das4, Stephen D. Albright1, Ke Zou2, F. J. Walker3 and Charles H. Ahn1; 1Department of Physics, Center for Research on Interface Structures and Phenomena, Yale University, New Haven, Connecticut, United States; 2Center for Two Dimensional and Layered Materials, The Pennsylvania State University, University Park, Pennsylvania, United States; 3Department of Engineering Science and Mechanics, The Pennsylvania State University, University Park, Pennsylvania, United States; 4Department of Engineering Science and Mechanics, The Pennsylvania State University, University Park, Pennsylvania, United States; 5Department of Physics, The Pennsylvania State University, University Park, Pennsylvania, United States.

The rapid development of device technologies based on 2D transition metal dichalcogenides (TMDs) causes increasing demand for synthesis of high quality large area monolayer and few layer films. Our previous work demonstrated epitaxial growth of large area monolayer WS₂ films on c-plane sapphire using gas source chemical vapor deposition (CVD). However, the optical and electrical properties of coalesced monolayer films grown on sapphire are negatively impacted by the existence of anti-phase boundaries (APBs) resulting from a merging of an equal mixture of 0° and 180° orientated domains as well as non-uniformities arising from steps and charge-induced doping associated with the sapphire surface. Prior studies using powder source CVD demonstrated a preferred domain orientation for MoS₂ grown on hBN and first-principle calculations suggest this phenomenon originates from single atom vacancies on the hBN surface that act as nucleation sites. In this study, we further investigate the mechanism of defect-assisted domain alignment of 2D TMDs on hBN and demonstrate the growth of fully-coalesced WS₂ films on hBN with a reduced density of APBs and improved optical and electrical properties compared to films grown on sapphire.

WS₂ monolayer films were grown by gas source CVD at 800°C using W(CO)₆, and H₂S in a H₂ carrier gas employing a multi-step process to separately control nucleation density and lateral growth and coalescence of domains. Single crystal hBN flakes exfoliated from bulk crystals and transferred onto c-
plane sapphire were used as substrates. He plasma treatment and NH3 annealing were used to modify the surface defect density of hBN. Detailed studies of WSe2 deposition on hBN as a function of growth conditions and substrate pre-treatment confirm that domain nucleation is controlled by the surface defect density rather than the precursor concentration. Over 85% of WSe2 domains have consistent orientation via the defect-assisted growth. Through careful control of nucleation and extended lateral growth time, fully coalesced WSe2 monolayer films on hBN were produced for subsequent characterization. High resolution scanning transmission electron microscopy (S/TEM) analysis demonstrates the absence of APBs in coalesced regions formed by the merging of ¢0 oriented domains. The resulting Moï re pattern formed by the WSe2 on hBN indicates an epitaxial relationship of 3+3 WSe2 on 4+4 hBN. Temperature-dependent photoluminescence measurements show sharp and enhanced exciton and trion emission peaks, with no defect-related bound exciton emission from monolayer WSe2/hBN down to 80K. Backgated FET devices fabricated on WSe2/hBN films transferred to SiO2/Si substrates show an order of magnitude increase in room temperature carrier mobility (~5 cm2/V-s) compared to similar devices fabricated using monolayer WSe2 films transferred from sapphire. The results demonstrate the potential of hBN as a substrate for epitaxial growth of high quality monolayer TMD films.

EP03.11.42
Multifunctional In Situ Doping of Monolayer MoS2 for Electronic and Sensing Applications Kehao Zhang, Donna D. Deng, Shruti Subramanian and Joshua Robinson; The Pennsylvania State University, University Park, Pennsylvania, United States.

Substitutional doping has been demonstrated as an efficient way to tune the electronic and optoelectronic properties of 2D materials.1,2 Beyond the singular functionalization of 2D materials, multifunctional doping of 2D materials provides opportunities to realize great potentials to 2D materials by one dopant, which can be highly compatible to advanced technologies.3 Here, we report the multifunctional doping of monolayer MoS2; for electronic and chemical sensing applications. Niobium doped MoS2 with various doping concentration (0.5 at%–57 at%) is synthesized by metal organic chemical vapor deposition on c-plane sapphire. The Fermi level is tuned from 2.0 eV above valence band maxima (VBM) to 0.3 eV below VBM (degenerate doping) as doping concentration increases. Interestingly, this Fermi level tuning exhibits a significant shift from theoretical prediction. Evident from x-ray photoelectron spectroscopy and conductive atomic force microscopy, 0.5 at% can only slightly reduce the electron concentration in monolayer MoS2. –5 at% Nb concentration is needed to push the Fermi level to 0.2 eV above valence band maxima (p-doped) and >20 at% Nb doped MoS2 is degenerately p-doped, while <1 at% Nb for degenerate p-doping in theory. This unusual phenomenon is attributed to the strong electron doping from the sapphire substrate.4 Tunable Nb doping realizes multifunctionality of MoS2. 5 at% Nb doped MoS2 exhibits ~15× higher sensitivity (signal/noise ratio) to tetraethylammonium (TEA, a nerve agent) with <10ppb detection limit due to the enhanced conductivity and p-type conductance. Meanwhile, degenerate p-doped MoS2 provides an Ohmic contact between metals (Pt/Ir etc.) and both 2D (MoS2) and 3D (GaN) semiconductors, which may play an important role in contacting semiconductors. This work presents a promising route to cultivate the multifunctionality of doped 2D materials, enabling novel design of multifunctional electronic and sensing devices.

Composition-Tunable Synthesis of Large-Scale Mo1–xWxS2 Alloys with Enhanced Photoluminescence Juhong Park1, Min Su Kim2, Bumsu Park2, Sang Ho Oh3, Shrawan Roy3, Jeongyong Kim2 and Wonbong Choi1; 1University of North Texas, Denton, Texas, United States; 2Sungkyunkwan University, Suwon, Korea (the Republic of).

Alloying two-dimensional transition metal dichalcogenides (2D TMDs) is a promising avenue for band gap engineering. In addition, developing a scalable synthesis process and studying contributions of exciton complexes to the PL emission are essential for the practical application of these alloys with tunable band gaps in optoelectronic devices. Here, we report the synthesis of optically uniform single-layer Mo1–xWxS2 alloys by a two-step CVD method followed by a laser thinning process and investigations on their excitonic behavior with compositional changes. The amount of W content (x) in the Mo1–xWxS2 alloy is systematically controlled by the co-sputtering technique, and the post-laser process allows layer-by-layer thinning of the as-synthesized few-layer Mo1–xWxS2 alloys down to a single-layer. Photoluminescence (PL) and Raman mapping analyses suggest that the laser-thinning of the Mo1–xWxS2 alloys is a self-limiting process caused via heat dissipation to the substrate, resulting in spatially uniform single-layer Mo1–xWxS2 alloy films. As W content (x) increases, the single-layer alloys reveal controlled optical band gaps ranging from 1.871 to 1.971 eV. Furthermore, we found that the number of excessive charge carriers decreases as x increases, resulting in the change in the predominant component of the PL emission from trions for single-layer MoS2 to neutral excitons for single-layer WS2. Our findings present a promising path for the fabrication of large-scale single-layer 2D TMDs alloys and the design of versatile optoelectronic devices.

EP03.11.44
Superconductor-to-Insulator Quantum Phase Transition in Single Crystal LiMoS2 Nanosheets Ivan Verzhbitskiy1, Damien Voiry2, Manish Chhowalla3 and Goski Eda1; 1National University of Singapore, Singapore, Singapore; 2University of Montpellier, Montpellier, France; 3Rutgers, The State University of New Jersey, New Brunswick, New Jersey, United States.

Superconducting van der Waals ultrathin crystals have recently emerged as an excellent platform for studying the role of disorder and quantum fluctuations in reduced dimensions. Here we report our observation of two types of QPT in phase-engineered nanosheets of LiMoS2 having different contents of superconducting T’ phase and non-superconducting 2H phase. Our scaling analysis reveals that the as-synthesized samples with a predominantly T’ phase exhibit the ordinary QPT from superconducting to insulating state whereas the samples with a higher content of 2H phase display QPT with signatures of Griffiths phase evidenced by the diverging critical exponent. Our observations suggest that phase engineering allow formation of quenched disorder with a length scale suitable for the formation of rare superconducting puddles that lock the global superconducting phase above the mean upper critical field.
Large Enhancement of WS2 Photoluminescence in Two-Dimensional Perovskite—Transition Metal Dichalcogenide Heterostructure

Qin Yang1, Jean-Christophe Blancou2, Joeson Wong3, Yi-Rung Lin4, Hsinhan Tsai5, Wanyi Nie5, Deep M. Jarwala5, Aditya D. Mohite2 and Harry A. Atwater1; 1California Institute of Technology, Pasadena, California, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Rice University, Houston, Texas, United States; 4Department of Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Heterostructures constructed from two-dimensional (2D) van der Waals materials such as transition metal dichalcogenides (TMD), graphene, and boron nitride, have sparked wide interest in both device physics and materials science. Apart from these inorganic 2D materials, two-dimensional organic-inorganic hybrid lead halide perovskites (2D PVSKs) have recently emerged as promising materials for solar cells, with power conversion efficiencies over 12% and stability over 2000 hours, compared to 10 hours for traditional 3D PVSKs. 2D PVSKs also show higher photoluminescence quantum yield (~26%) than their 3D counterparts (~1%), suggesting their intrinsic optoelectronic quality may be much higher.

Fundamental photophysics of 2D PVSK materials can be further explored upon making their electronically active heterostructures with other van der Waals semiconductors. In this study we explore these heterostructures with semiconducting double layers of transition metal dichalcogenides built via exfoliation and dry viscoelastic stamping. We observed 116-fold enhancement in indirect transition occurring at 681-706 nm (1.76-1.82 eV) and 277-fold enhancement in trion emission peak at 658-666 nm (1.86-1.88 eV) of WS2 photoluminescence in double layer WS2 on (BA)2(MA)3Pb4I13 2D-PVSK heterostructure. We have also observed ~60meV blue shift in indirect transition (from 1.76eV to 1.82eV) in heterostructure comparing to bare WS2. The larger enhancement of photoluminescence intensity of trion emission in comparison to indirect transition and blueshift of indirect transition indicate increased carrier concentration in WS2 in heterostructure, due to either charge transfer from or defect passivation by 2D PVSK. Emission enhancement in WS2 by 2D PVSK shows promising features of the heterostructure, and may provoke further studies of Van der Waals heterostructures to understand fundamental photophysics of charge separation and novel, long lived excited states.

Manipulating 2D Materials with Light—From Crystalization to Enabling Flexible Electronic Devices
Nicholas Glavin1, Rafael Vita2, Richard H. Kim1, Michael Beebe1, Kimberly Gliice1, Rahul Rao1, Benji Maruyama1 and Christopher Muratore2; 1Air Force Research Laboratory, Dayton, Ohio, United States; 2University of Dayton, Dayton, Ohio, United States.

Altering local properties (< 10 micron length scale) of 2D materials with light has the potential to enable new and exciting devices that were previously very difficult to make. Moreover, by precisely controlling the transient temperature within the material through light-matter interactions, the manipulation and transformation can be done directly on flexible substrates. In this talk, we discuss manipulating amorphous and polycrystalline 2D materials to create and improve 2D crystal quality, control local chemistry, and to demonstrate device performance on flexible substrates. Experiments reveal the successful phase transformation of amorphous transition metal dichalcogenides (TMD) including MoS2 and WSe2 deposited on stretchable polymer substrates to their crystalline van der Waals layered structures. Detailed kinetic studies of crystal formation were accomplished via high throughput in-situ Raman spectroscopy at different surface temperatures and environmental conditions. With this technique, heterostructures were formed incorporating multiple TMD layers that were annealed simultaneously, and insights into the role of surface diffusion and activation energy for crystalization will be discussed. Laser writing within MoS2 exhibits controllable local heating and transformation to form various oxide phases with altering electronic properties. Additionally, large area, wafer-scale crystallization of stretchable 2D photodetectors with the use of a broadband pulsed lamp source demonstrate the feasibility of laser transformation as a means to create unique device constructs.

2D Perovskite for Optoelectronics
Hsinhan Tsai1,2, Reza Asadpour3, Jean-Christophe Blancou1, Jackie Evert1, P. M. Ajayan2, M. Ashraf Alam1, Mercouri G. Kanatzidis4, Aditya D. Mohite1 and Wanyi Nie5; 1Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 2Materials Science and Nanoeengineering Department, Rice University, Houston, Texas, United States; 3School of Electrical and Computer Engineering, Purdue University, West Lafayette, Indiana, United States; 4Fonctions Optiques pour les Technologies de l’Information, Rennes, France; 5Department of Chemistry, Northwestern University, Evanston, Indiana, United States.

Hybrid (inorganic-organic) perovskites have demonstrated an extraordinary potential for clean sustainable energy technologies and low-cost optoelectronic devices such as solar cells; light emitting diodes, detectors, sensors, ionic conductors etc. In spite of the unprecedented progress in the past six years, one of the key challenges that exists in the field today is the large degree of processing dependent variability in the structural and physical properties. This has limited the access to the intrinsic properties of hybrid perovskites and led to multiple interpretations of
Raman microscopy proved to be an extremely useful technique for characterization of 2D materials such as graphene, transition metal dichalcogenides (TMDs), black phosphorous, etc. Unfortunately, natural spatial resolution of confocal Raman microscopy, which is limited by the wavelength of the laser used (400-800 nm), is not sufficient for mapping heterogeneities and defects in these materials with characteristic dimensions of few – to few tens of nanometers.

Tip Enhanced Raman Spectroscopy (TERS) provides dramatically improved spatial resolution of Raman maps, down to few nanometers, and in addition provides dramatic enhancement of the Raman signal. Since TERS is a relatively new technique, peculiarities of the near-field Raman response of many 2D materials still remain to be discovered and explained.

We report an interesting observation we made during TERS imaging of thin (10-60 nm) flakes of MoO3 exfoliated to different metallic surfaces (Au, Cr, Al). Despite the fact that normal Raman spectra of this material feature at least 12 well distinguishable peaks within 100-1100 cm⁻¹ range, only one peak at 995 cm⁻¹ corresponding to out-of-plane Mo-O vibration was strongly enhanced in TERS spectra of MoO3 crystals. It should be expected and actually has been observed in TERS spectra of 2D semiconductors that out-of-plane modes get preferential enhancement, but the degree to which it happens in MoO3 is outstanding. Such mode selectivity in TERS spectra of 2D materials may be useful for mode assignment in case there are multiple possibilities for a
Exciton-Photon and Exciton-Photon Coupling Dynamics in Self-Assembled Hybrid Perovskite Quantum Wells

Email: ln295@cam.ac.uk

Self-assembled hybrid perovskite quantum wells have attracted attention due to their tunable emission properties, ease of fabrication and device integration. However, the dynamics of excitons in these materials, especially how they couple to phonons remains an open question. Here, we investigate two widely
used materials, namely butylammonium lead iodide (CH₃(CH₂)₃NH₃)₂PbI₄ and hexylammonium lead iodide (CH₃(CH₂)₅NH₃)₂PbI₄, both of which exhibit broadband photoluminescence since tails at room temperature. We performed femtosecond vibrational spectroscopy to obtain a real-time picture of the exciton phonon interaction and directly identified the vibrational modes that couple to excitons. We show that the choice of the organic cation controls which vibrational modes the exciton couples to. In butylammonium lead iodide, excitons dominantly couple to a 100 cm⁻¹ phonon mode, whereas in hexylammonium lead iodide, excitons interact with phonons with frequencies of 88 cm⁻¹ and 137 cm⁻¹. Using the determined optical phonon energies, we analyzed PL broadening mechanisms. At low temperatures (<100 K), the broadening is due to acoustic phonon scattering, whereas at high temperatures, LO phonon-exciton coupling is the dominant mechanism. Our results help explain the broad photoluminescence lineshape observed in hybrid perovskite quantum wells and provide insights into the mechanism of exciton-phonon coupling in these materials. Strong exciton-phonon coupling in 2D perovskites can be a benefit, for instance, it can accelerate polariton relaxation and realize polariton lasing with very low threshold. It could also provide interesting opportunities for the development of broadband, short-pulsed lasers.

I will also show our recent results on exciton-phonon coupling and polaritons in monolayer perovskite crystals in high-Q microcavities. We found out that the coupling strength and the Rabi splitting energy are affected by quantum well thickness.

Direct Correlation of Defects with Photoluminescence and Electrical Conductivity in Monolayer Transition Metal Dichalcogenides

Transition metal dichalcogenides (TMDs) are promising candidates for emerging applications such as transparent and flexible optoelectronics and electronics. Understanding the impact of defects on material properties, such as luminescence efficiency and charge carrier mobility, is essential for the advancement of these materials. However, it is challenging to observe discrete defects in monolayer TMDs at the nanometer-scale and to directly correlate defects with material properties. This is due to a lack of techniques capable of facile observation of defects in monolayers. Here, we demonstrate the ability to observe electronically active defects in monolayer TMDs using conductive atomic force microscopy (AFM) in ambient conditions, and we correlate defect density with local optoelectronic and electronic properties. We briefly discuss our AFM-based sample preparation technique which creates clean, homogenous samples that enable us to investigate the intrinsic optical and electronic properties. We find that CVD-grown WS₂ samples have up to an order of magnitude variation in defect density within a single triangular grain. We also find that the photoluminescence (PL) intensity is inversely proportional to defect density. We develop a model assuming non-radiative recombination occurs when excitons collide with defects, and we find good agreement between the model and experiments. To investigate electronic properties, we use kelvin probe force microscopy to obtain spatial maps of electrostatic potential in operating TMD transistors. The local potential gradient is proportional to the local resistivity, which allows us to observe variations in resistivity across the channel. We find that regions with low PL intensities exhibit large potential gradients. This suggests that the defects responsible for decreased PL intensity are also responsible for decreased electrical conductivity. In summary, we use a combination of conductive AFM, PL measurements, and kelvin probe force microscopy to understand the impact of defects on optoelectronic and electronic properties in monolayer TMDs. Our work demonstrates a simple and general methodology for correlating defects with various material properties in two-dimensional materials, which is essential for optimizing material and device performance.

SESSION EP03.13: Electronic Properties, Processes and Devices III

High Surface Area BN Coated Graphene Aerogel for Sensitive and Selective Gas Sensing
Hu Long1, 2, Sally DeMaio-Turner1, 2, Aiming Yan1, 2, Hossain M. Fahad1, HongMei Xu1, Wu Shi1, 2, Thang Pham1, 2, Zhen Yuan3, Ali Javey3, Marcus A. Worsley4 and Alex Zettl1, 2; 1Department of Physics, University of California, Berkeley, Berkeley, California, United States; 3Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, Berkeley, California, United States; 5Lawrence Livermore National Laboratory, Livermore, California, United States.

Two dimensional layered materials, such as graphene, and transition metal dichalcogenides (TMD) have great potential for gas sensing applications due to its high surface to volume ratio. Ultrasensitive chemical detection using single-layer graphene and single- and few-layer MoS₂ have been reported. Unfortunately, graphene based sensors without proper surface modification suffer from lack of selectivity; TMD sensors show good selectivity but not long term stability. Recently, hexagonal boron nitride (h-BN) nanomaterials, eg. nanosheets and nanotubes, have been predicted to be an effective material for reversible gas adsorption with high selectivity once charged. By modifying the charge state of the BN nanomaterials, adsorption and desorption of gas on BN can be controlled. This makes the whole process controllable and suitable for gas sensing. However, despite the encouraging theoretical discovery, sensing with h-BN is difficult to realize experimentally due to its electric insulating nature with large band gap (around 5.8 eV). In this research, we report on the controlled synthesis of high surface area h-BN coated graphene aerogel and its application for selective gas sensing. Hybrid BN/graphene aerogel is synthesized using graphene aerogel as a template and boric acid and ammonia as boron and nitrogen source, respectively. A thin layer of BN can be uniformly coated on graphene aerogel while maintaining the macro- and nanoscale morphologies and mechanical properties of the aerogel. With thin BN and graphene combination, charge transfer between BN and graphene can be greatly improved compared to bare h-BN alone. Sub ppm level detection limit for NH₃ is shown, while negligible cross sensitivity to ppm of NO₂, 2000 ppm CO₂ and 50000 ppm hydrogen. The low detection limit, high selectivity and high stability makes the sensor suitable for practical sensing application.

1:45 PM EP03.13.02
Integer and Fractional Quantum Hall Effect in Various Few-Layer Black Phosphorus Transistors
Jeanie Lai; The Ohio State University, Columbus, Ohio, United States.

Since its isolation in 2014, few-layer black phosphorus (BP) has been under intensive research efforts, due to its many interesting material properties such as the combination of high mobility and sizable band gap, in-plane anisotropy and band structure modulation by electric field or strain. Many of the predicted properties can only be revealed in high mobility samples, in which the intrinsic phenomena are not obscured by impurities, and which are essential for further applications in any quantum device structures. Here I will present our recent works on ultra-high quality few-layer BP transistors, including the creation of double quantum wells, Landau level gaps in samples with demonstrated strong in-plane anisotropy, high quality integer quantum Hall effect and the first observation of fractional quantum Hall effect in BP. These results pave the way to the study of even more fragile fractional
quantum Hall states or more complicated quantum structures in BP.

2:15 PM EP03.13.03
Black Phosphorus and Its Analogue—Electrical Transport and Device Applications
Lihong Bao1, Guocai Wang2, Tengfei Pei1, Shixuan Du1, Sokrates T. Pantelides2 and Hong-Jun Gao1; 1Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2Vanderbilt University, Nashville, Tennessee, United States.

As a young member in the family of two-dimensional materials, black phosphorus (BP) has attracted great attention due to its high hole mobility, and a sizable and tunable bandgap, meeting the basic requirements for logic circuits application. To realize a complementary logic operation, it needs to control the conduction type in BP FETs, i.e., the dominant carrier types, holes (P-type) or electrons (N-type). Absence of reliable substitutional doping techniques makes this task a great challenge, however. In this talk, I will demonstrate that capping the thin BP film with a cross-linked poly-methyl-methacrylate (PMMA) layer can modify the conductivity type of BP by a surface charge transfer process, converting the BP layer from p-type to n-type. Combining BP films capped by cross-linked PMMA to a standard BP, a family of planar devices can be created, including BP gated diodes (rectification ratio >10^5), BP barriers (on/off ratio >10^7), and BP logic inverter (gain ~0.75), which are capable of performing current rectification, switching, and signal inversion operations. Furthermore, the conversion of a bidirectional rectifier to a polarity-controllable transistor in black phosphorus (BP) by dual gate modulation can be realized. Employing cross-linked PMMA as a top gate and combining it together with the global back gate of the SiO_2 substrate, well-defined unipolar transport (n- or p-type) in BP could be get accessed. Inspired by the discovery of black phosphorus as channel material in FETs, the orthorhombic ones, such as GeS, GeSe, SnS, and SnSe, have attracted growing interest. I’ll also demonstrate ultrathin SnSe single crystals have been epitaxially grown on molten polydimethylsiloxane (PDMS) by the chemical vapor deposition (CVD) method. TEM characterization of octagonal SnSe nanosheets reveals a good crystalline nature and preferred crystalline orientations along the edges of the nanosheets. Thickness-dependent Ramans spectroscopy measurements result in a red shift of the A_{2g} mode and blue shift of the B_{1g} and A_{1g} modes, even when the thickness is over 10 nm, which is never observed in hexagonal Van der Waals structures. The octagonal SnSe nanosheets show an electrical anisotropic characteristic. Finally, the thermopower of SnSe nanosheets can be electrostatically tuned, and, when sweeping the gate voltage from -40 V to 40 V at 120 K, the thermopower can be tuned from 54 to 866 mVK^{-1}, indicating the unique advantage of gate modulation compared to chemical doping in thermoelectric applications.

MBE-Grown Transition-Metal Dichalcogenide Ultrathin Films and Heterostructures—Superconductivity, Ferromagnetism and Interface Transport Phenomena
Masaki Nakano1 and Yoshihiro Iwasa1, 2; 1University of Tokyo, Tokyo, Japan; 2CEMS, RIKEN, Wako, Japan.

Transition-metal dichalcogenide (TMDC) has become an invaluable material platform for condensed matter research owing to its intriguing properties and functionalities emerging at monolayer limit. There, conventional mechanical exfoliation plays an central role for sample fabrication, while bottom-up synthesis by molecular-beam epitaxy (MBE) has expanded a lineup of materials under investigation even to hardly cleavable compounds, providing a promising route to further exploration of novel quantum phenomena emerging at monolayer limit including heterostructures. However, those MBE-based approaches have been mostly focused on spectroscopic studies using conducting graphene substrates, whereas transport studied has been less performed despite its essential importance due to difficulties in growing high quality TMDC thin films on insulating substrates.

We have recently established a versatile route to layer-by-layer epitaxial growth of millimeter-scale single-crystalline TMDC thin films on insulating sapphire substrates by MBE [1], opening the door for exploration of transport properties of various TMDCs and their heterostructures at nanometer scale. In this presentation, we will introduce our growth recipe in detail, together with an interesting aspect of van der Waals epitaxy that is missing in conventional epitaxy with strong substrate-film interaction. We will also present our recent achievements in transport studies including realization of spin-momentum locked ‘island superconductivity’ in millimeter-scale ultrathin films based on group-V TMDCs that are suitable for further investigation of 2D superconductivity, observation of emergent ferromagnetism with anomalous Hall effect in strongly-correlated TMDCs that are missing in their bulk counterparts, as well as development of monolayer van der Waals heterostructures exhibiting intriguing interface transport phenomena in combination with a variety of TMDC thin films.

Large Magnetoresistance in a Topological Insulator/Magnetic Insulator vdW Heterostructure
Yingjie Zhang1, 9, Joseph Sklenar1, 9, Matthias Jungfleisch1, Youngseok Kim2, Yiran Xiao1, Gregory MacDougall1, 9, Matthew Gilbert4, Axel Hoffmann5, Peter Schiffer1 and Nadya Mason1, 5; 1Department of Physics, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 9Department of Physics, University of Delaware, Newark, Delaware, United States; 2Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 3Department of Electrical Engineering, Stanford University, Stanford, California, United States; 4Department of Applied Physics, Yale University, New Haven, Connecticut, United States; 5Materials Sciences Division, Argonne National Laboratory, Lemont, Illinois, United States; 9Beckman Institute, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 1Department of Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Department of Electrical and Computer Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 3Department of Electrical Engineering, Stanford University, Stanford, California, United States; 4Department of Applied Physics, Yale University, New Haven, Connecticut, United States; 5Materials Sciences Division, Argonne National Laboratory, Lemont, Illinois, United States; 9Beckman Institute, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Layered topological insulators (TIs), such as Bi_2Se_3 and Bi_2Te_3, host spin-momentum locked surface states that are inherently susceptible to magnetic proximity modulations, which can be utilized for nano-electronic, spintronic, and quantum computing applications. Here we present a strategy to fabricate TI-magnetic insulator (MI) heterostructures with high-quality interfaces, and experimentally measure the magnetoresistance (MR) at various temperatures. We observe rich hysteretic MR features including sharp MR switching and large, broad MR bumps (a few percent in magnitude), which we attribute to domain wall switching and out-of-plane anisotropic MR in the surface state, respectively. The out-of-plane magnetic anisotropy leads to band gap opening in the TI surface state, confirmed by an analytical diffusive transport model. These results provide both fundamental insights into the mechanism of magnetic proximity and spin exchange interactions in layered heterostructures, and a route towards energy efficient spintronic device applications.
We demonstrate direct writing of self-aligned 18 nm electrical circuitry with a scanning light probe on a two-dimensional (2D) van der Waals (vdW) semiconductor at the time scale of a minute. Light illumination over Au-electrode patterns on n-type MoTe₂ 2D channels locally convert them into p-type ones by creating adatom-vacancy clusters as electron acceptors in the host lattice. We provide direct evidence of such a microscopic doping mechanism by atomic scale imaging and spectroscopy. This real-time writing process is precisely controllable within a minute, in that diffusive doping profiles can be controlled at the sub-micrometer scale, and doping concentrations are tunable to vary the channel sheet resistance over four orders of magnitude. As such, we assembled both n- and p-doped channels within the same atomic planes to fabricate 2D device arrays of n-p-n (p-n-p) bipolar junction transistor (BiT) amplifiers and radial p-n photovoltaic cells in high performances. This doping method can be potentially used to fabricate designer 2D circuits based on atomically thin vdW semiconductors in arbitrary shapes.

The crystal orientation of an exfoliated black phosphorous flake is determined by purely electrical means. A sequence of three resistance measurements on the sub-micron level. Our results imply that the variation in the bandgap induced by dielectric disorder can be over 100 meV in monolayer WS₂ and WSe₂ samples that have not been encapsulated in hexagonal boron nitride (h-BN), but are supported on typical substrates like SiO₂. This variation decreases to the order of 10 meV upon h-BN encapsulation. While there is widespread interest to improve the underlying microscopic picture has not been fully explored. From our study, we suggest dielectric disorder as a mechanism likely to play a significant role.

**EP03.13.08**

The Influence of Dielectric Disorder on the Electronic Properties of Two-Dimensional Materials

**Archana Raja, Lutz Waldecker, Tony F. Hinez, and Alexey Chernikov**

The remarkably strong and environmentally sensitive Coulomb interaction at the atomically thin limit allows for modification of the quasiparticle bandgap and exciton binding energy of two-dimensional (2D) materials through modification of the dielectric environment. The change in the non-local or distance-dependent dielectric screening strongly modulates the free-carrier bandgap energy and excited exciton states compared to the ground state exciton transition. By probing the inhomogeneous linewidth broadening of the excited exciton transition using optical spectroscopy, we have identified dielectric disorder as a significant source of electronic disorder at the 2D limit.

We infer that within the diffraction-limited, sub-micron area of study there exists a spatially disordered dielectric environment. This in turn leads to spatially inhomogeneous quasiparticle bandgaps on the sub-micron level. Our results imply that the variation in the bandgap induced by dielectric disorder can be over 100 meV in monolayer WS₂ and WSe₂ samples that have not been encapsulated in hexagonal boron nitride (h-BN), but are supported on typical substrates like SiO₂. This variation decreases to the order of 10 meV upon h-BN encapsulation. While there is widespread interest to improve the optical and electronic properties of atomically thin materials by substrate surface passivation or encapsulation in a wide bandgap insulator like h-BN, the underlying microscopic picture has not been fully explored. From our study, we suggest dielectric disorder as a mechanism likely to play a significant role.

**EP03.13.09**

Electrical Determination of Crystal Orientation in Anisotropic 2D Materials—5-Point van der Pauw Method Demonstrated on Black Phosphorus

**Lintao Peng, Spencer Wells, Christopher Ryder, Mark C. Hersam, and Matthew Grayson**

The crystal orientation of an exfoliated black phosphorus flake is determined by purely electrical means. A sequence of three resistance measurements on an arbitrarily shaped flake with five contacts determines the three independent components of the anisotropic in-plane resistivity tensor, thereby revealing the crystal axes, with the help of simple geometric transformations including conformal mapping. The crystallographic orientation deduced from this all-electrical conformal five-contact method is confirmed with polarized Raman spectroscopy. The resistivity anisotropy ratio is observed to decrease linearly with increasing temperature T and carrier density reaching a maximum ratio of 3.0 at low temperatures and densities, while mobility indicates impurity scattering at low T and acoustic phonon scattering at high T. In addition, we examine the disorder-related transient conductivity, and observe that the commonly observed hysteresis in both electrical and photoluminescence studies of 2D materials can be characterized as a heavy-tail transient response to a step-function excitation. Dispersive diffusion equations successfully fit the transients in both the pristine and highly disordered sample limits, and a microscopic model for the response is provided, based on the continuous-time random walk model. Finally, we observe for the first time a generalized scaling behavior for the gated conductivity of 2D materials with disorder strength.

*PHYS. REV. LETT. 120, 086801 (2018).*
Two dimensional (2D) materials belong to a large family of anisotropic compounds which have strong, covalent bonds within a layer while between layers there are only weak van der Waals interactions that can be overcome, obtaining molecularly thin sheets. Such a dimensionality reduction has a profound impact on properties, that vary strongly with the number of atomic layers. From the moment of graphite exfoliation into an atomically thin monolayer, known today as graphene [1], two dimensional materials have been of main interest for a variety of electronic applications.

Whereas graphene applications in electronics has thus far been hindered by its non-existent band gap, layered semiconductors are studied as potential candidates for future devices. Many Transition Metal Dichalcogenides (TMDs) including MoS$_2$, MoSe$_2$, WS$_2$, WSe$_2$ have been thoroughly investigated, however in order to meet rising demands new families of 2D semiconductors are studied. One family of such is the transition metal phosphides, denoted MPS$_x$, for $x$=3 or 4; for example bulk crystals of CrP$_3$ - chromium thiophosphate – which has been examined in the past for applications in lithium batteries. Nowadays, this compound has once again gained scientific interest due to its optical anisotropic properties and the possibility to obtain and study its few- and monolayer systems [2].

In this research, bulk crystals of CrP$_3$ were obtained by vapor transport synthesis (furnace method), followed by structure and composition confirmation via different techniques, for example Scanning Electron Microscopy with Energy-Dispersive X-ray Spectroscopy (SEM/EDX), Powder X-Ray Diffraction (PXRD) and Raman spectroscopy. Optical properties, such as band gap and optical transitions were investigated by Solid State UV-VIS Spectroscopy, PhotoAcoustic Spectroscopy (PAS) [3] and Modulated Spectroscopy (MS) [3]. Then, bulk crystals of chromium thiophosphate (CrP$_3$) were exfoliated in liquid by ultrasounds to obtain few layers systems and photoconductivity measurements were used to ascertain photoactive properties, both of re-stacked films and bulk crystals.

EP03.14.06
Defect Mediated Growth of Transition Metal Dichalcogenides on Epitaxial Graphene

Layered 2D materials have garnered huge interest due to their inherent chemical, optical and electronic properties. In addition to the individual material property the weak inter-layer bonding, characteristic of 2D materials, allows for variable stacking of a combination of these materials; forming heterostructures. These heterostructures can provide pathways to develop all 2D electronics or enhancing the novel properties of the resultant stack. Current research using transferred exfoliated flakes has demonstrated the rich landscape of possible properties and applications of these heterostructures. However, to study these heterostructures without the hindrance of transfer process contaminants, bottom-up growth techniques which can provide pristine interfaces are needed. To understand and control the bottom-up assembly process, it is imperative to investigate the impact of defects on the growth of other 2D materials. The defects can act as nucleation sites, which in turn can be used to control the density and the domain size of the growing 2D films.

In this work we investigate the effect of defects in epitaxial graphene on the growth of transition metal dichalcogenides like WS$_2$. Epitaxial graphene was grown on on-axis 6H (0001) SiC substrate. The defect density of epitaxial graphene was controlled by exposing it to a helium plasma for different durations. The pristine and plasma treated graphene was exposed to a H$_2$S environment and subsequently to a WS$_2$ growth environment. The H$_2$S treatment and WS$_2$ growth was carried out at 50 Torr at temperatures ranging between 700-1000°C. The H$_2$S and W(CO)$_6$ precursor flow rate was maintained at 400 sccm and 5.7×10$^{-4}$ sccm, respectively. The results show that the defect generation, and subsequent sulfur incorporation was higher when the buffer layer was present between the SiC substrate and the graphene layers. The higher defect generation is attributed to the distortion in the bonds of the top graphene layer when the interfacial layer is partially bonded to SiC. In addition, the duration of plasma treatment directly controls the nucleation density of WS$_2$ domains, which is a crucial factor for controlling the domain size. Another key observation was that the plasma treatment modified the WS$_2$ nucleation sites from step edges to terraces. This impact on the nucleation site was, however, temperature dependent. Additional details about the role of the buffer layer, the interaction of the defects with the precursors and the impact on the nucleation site and density will also be presented.

EP03.14.02
Indium and Indium Alloys as Ultra-Clean Contacts for 2D Materials

Two dimensional (2D) transitional metal dichalcogenides (TMD) such as molybdenum disulfide (MoS$_2$) have been demonstrated to be excellent semiconductors for ultra-thin FETs. However, the main challenging for improving the performance is the contact resistance for all 2D materials. The direct deposition of metals can introduce substantial damage to ultra-thin TMD materials, which leads to high contact resistance. Studies have shown that creation of van der Waals contacts by dry transfer (graphene, hBN, metal) method reduces damage to the TMDs. Here, we report the realization of ultra-clean van der Waals contact between Indium and 2D materials. From scanning transmission electron microscopy images, we can see the interface is atomically sharp with no detectable chemical interaction. This ultra-clean van der Waals contact can also be translated to good device performance for 2D materials such as MoS$_2$, WS$_2$, WSe$_2$, and NbSe$_2$. Because Indium is a soft metal, we demonstrate that alloys of Pd, Pt, and other metals can be formed to vary the work function so that both hole and electron injection can be facilitated. We have measured the work function of the alloys using Kelvin force microscopy and correlated them with band offsets in WS$_2$ devices.
Using Hexagonal Boron Nitride and Its Composites to Reduce Friction on Steel

Alexander I. Marsden1, Martin King2, Mark A. Bissett3 and Ian A. Kimloch4; 1Materials, University of Manchester, Manchester, United Kingdom; 2Renold Power Transmission Ltd, Manchester, United Kingdom.

Reducing friction and wear is essential in industrial sliding applications. Layered materials like graphite and boron nitride are extremely effective as solid lubricants and have been extensively applied. More recently, exploiting these layered materials yields 2D materials that have surfaces with very low coefficients of friction. These materials show promise for reducing friction in nano- and micro-electromechanical systems. However, they could also benefit larger scale applications, and exploiting the thinnest and low friction properties of 2D materials requires further development.

Here we study the deposition of hexagonal boron nitride (hBN) onto steel using chemical vapour deposition from the solid precursor ammonia borane. We find that hBN forms nanostructured, multilayer films when using higher precursor temperatures. These films yield a lower coefficient of friction on the surface under lubrication than those with no coating. We also investigate the effect of pre-plating the surface with copper and nickel, as these are more well-defined hBN growth surfaces.

We also study composites made from the electrodeposition of hBN with nickel. These composites are examined using atomic force microscopy to understand how the surface wears under repeated sliding. The hBN incorporates into the nickel film, again reducing the surface coefficient of friction. These techniques could help guide industrialscaleable coating techniques to help reduce friction in sliding applications.

Ultrasonic and VOC-Selective Metallic Ti3C2Tx MXene Gas Sensors

Hyunsang-Kyung Kah1, Seon Joon Kim1,2, Yury Gogotsi2 and Hee-Tae Jung1; 1Chemical and Biomolecular Engineering, Korea Advanced Institute of Science and Technology, Daejon., Korea (the Republic of); 2A.J. Drexel Nanomaterials Institute, Philadelphia, Pennsylvania, United States; 3National Nanofab Center, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Developing highly sensitive solid-state chemical sensors for detecting biological, environmental and chemical agents is a very important issue. To obtain very high sensitivity, two factors are simultaneously required: (i) low electrical noise, which can be derived from high conductivity, and (ii) strong signal, originating from abundant analyte adsorption sites. However, as the introduction of reactive sites on the surface significantly degrades the electrical conductivity, these two factors are always in a trade-off relation. Thus, none of the previous sensor materials were able to simultaneously satisfy the two characteristics.

Here, we demonstrate state-of-the-art metallic Ti3C2Tx MXene gas sensors by employing a vacuum filtration method. The abundant surface functionalities and high conductivity of Ti3C2Tx enable the Ti3C2Tx sensor to overcome previous trade-off limitations, substantially outperforming typical two-dimensional (2D) material gas sensors in two important aspects. First, it has a very high sensitivity and shows a limit of detection (LOD) of 50~100 parts per billion (ppb) at room temperature, which is one of the lowest LOD ever reported. Second, the extremely low noise of metallic Ti3C2Tx yields a signal-to-noise ratio (SNR) that is two orders of magnitude higher than that of other 2D materials. In addition, we have observed that Ti3C2Tx sensors have higher selectivity toward VOC gases over acidic gases, which is a rare property. In-situ X-ray diffraction (XRD) measurements were used to verify that the intercalation of gas molecules into Ti3C2Tx layers plays a fundamental role in detecting gas molecules. The interlayer swelling induced by the intercalation of gas molecules can explain not only Ti3C2Tx sensors’ selectivity, but also their universal positive response for various gas molecules. It is noteworthy that more than 30 MXenes are now accessible, and we expect that this study will open the door for a large family of MXene sensors.

Chemical and Atomic Structure of Doped Transition Metal Dichalgonide Monolayers

Greg Stone and Daniel Kaplan; Precision Armaments Intelligent Sensors Division, US Army RDECOM-ARDEC, Picatinny Arsenal, New Jersey, United States.

Substitutional doping of the transition metal atoms in transition metal dichalcogenides monolayers offers an attractive route to modify the electronic and optical properties of these materials, as well as, introduce new properties. For example, the inherent p- or n-type nature of 2D crystals can be changed via doping. Furthermore, theoretical models indicate that the crystal structure may support a variety of possible defect dopant complexes, each of which modify the material properties differently. Currently, little is known about the distribution and defect structure of dopants in synthesized materials. In this work, V and Mn doped MoS2 monolayers are grown by chemical vapor deposition on gold foils. Using atomic resolution scanning transmission electron microscopy and x-ray photoelectron spectroscopy we report on the chemical and atomic structure of the V and Mn defect clusters.

Branching Ratio of Photothermal to Photoelectric Transduction in Suspended PtSe2

Hamza Z. Gul1,2; Wonkil S. Kong1,2, Hojyon Yi1,2, Byungwook Ahn1,2 and Seong Chu Lim1,2; 1SungKyunKwan University, Suwon-si, Korea (the Republic of); 2Center for Integrated Nanostructure Physics, Institute for Basic Science, Suwon, Korea (the Republic of).

In this study, the light interaction with PtSe2 is studied. The optically excited carriers in PtSe2 dissipate their energy as the heat to the lattice vibrations or electrical current to the electrons. In order to assess how the incident light energy is divided into the heat and the electrical current, PtSe2 is partially suspended on SiN substrate to eliminate the heat conduction from PtSe2 to the substrate. A focused laser illuminates the partially suspended PtSe2.

Studying the power-current relation using the power law we observe at low laser power the mechanism of photocurrent due to photoelectric effect. However as the laser power is increased, heat is generated in the sample due to photothermal effect, the photothermal effect results in a change in the coefficient of the power-current relation. Further analysis of the photocurrent as a function of laser power and electrical input will enable us to understand the contribution of photovoltaic and photothermal effect in our devices. Temperature dependent measurements allow us to estimate the rise of temperature in our sample at various laser power which show that at high laser power the temperature of the sample can increase to as much as 10K. The possibility of these mechanism coexisting at the same time or one being dominant over the other is being investigated. Understanding the interaction between the two processes will allow for more efficient device structure and performance from a highly promising material.

Novel Valleytronics in Bulk IV-VI Monochalcogenides

Shuren Lin1,2 and Jie Yao1,2; 1University of California, Berkeley, Berkeley, California, United
Valleytronics provide an additional degree of freedom in optoelectronic devices by having multiple non-equivalent “valleys” in the reciprocal k-space bandstructure of a valleytronnic material. Such valleys obey certain selection rules and can be selectively polarized by optical means. Until recently, research in valleytronics has mostly been conducted using two-dimensional transition metal dichalcogenides. However, such systems can only be probed at low dimensions and/or with the application of certain experimental conditions, such as cryogenic temperatures and/or strong electric or magnetic field. This inevitably poses a plethora of practical challenges that create a high barrier in advancing technology towards practical applications.

In our recent work, we show experimental evidences of the valley effect in a bulk, ambient, and bias-free model system of Tin(II) sulphide (SnS). We elucidate the direct access and identification of different sets of valleys, based primarily on the selectivity in absorption and emission of linearly polarized light, and demonstrate strong optical dichroic anisotropy of up to 600% and nominal polarization degrees of up to 96% for the two valleys with band-gap values 1.28 and 1.48 eV, respectively; the ease of valley selection further manifested in their non-degenerate nature. Such discovery enables a new platform for better access and control of valley polarization.

There are two non-degenerate local band gaps along two high symmetry axes, ΓY and ΓX, in the orthogonal crystal structure of SnS (and most IV-VI monochalcogenides). By looking at the compositions of the conduction and valence bands, we obtained the point groups that describe the k points along ΓY and ΓX, and the IrRs of the respective bands and show, via the electric dipole approximation, that the transitions at ΓY and ΓX will only occur with excitation using y and x-polarized light respectively. This forms the basis for valley selectivity.

Experimentally, we demonstrate that Tauc plots of absorption measurement results give band-gap values of 1.48 and 1.28 eV, clearly distinguishing the two sets of valleys. We also see that SnS is able to maintain a more than 200% for a range of more than 0.2 eV, and also possesses a maximum of more than 600%.

The polarization dependence of two PL peaks at 817 and 995 nm, respectively, is clearly observed; under parallel polarization, the 817 nm peak maximizes at the polarization that minimizes the 995 nm peak, and vice versa, demonstrating a 90° phase shift between the peaks and hence the orthogonality in polarization selectivity of the two sets of valleys responsible for such PL emissions.

Highly Efficient Solid-State Photoluminescence from Graphene Quantum Dots Incorporate ...nt Technology, Daejeon, Korea (the Republic of); 3Department of Convergence IT Device and Material Engineering, Korea Polytechnic University, Siheung, Korea (the Republic of).

Emerging graphene quantum dots (GQDs) have attracted great attention due to their excellent resistance to photobleaching and tunable band gap, making them promising candidates for future light-emitting devices. However, in the solid-state, n-interaction-induced aggregation-caused quenching (ACQ) of photoluminescence (PL) in GQDs makes realization of high performance device challenging. Here we propose application of GQD incorporated boron oxynitride (GQD@BNO), fabricated by a simple microwave-assisted method, on alternating-current powder electroluminescent device (ACPEL) as an active material. The BNO, comprising an interfacial, zone-joining boric oxide and tubrostratic boron nitrde, is an ideal matrix material for incorporating GQDs for three reasons: i) the presence of abundant surface oxygen functional groups facilitates intermolecular interaction with GQDs, ii) the relatively high refractive index (1.6-1.8) can enhance PL quantum yields (PL-QY’s), iii) the creation of a localized dielectric environment is advantageous for high-field induced electrical exicitation of GQDs. With these advantages, blue-luminescent GQDs were successfully incorporated into a BNO matrix via intermolecular hydrogen bonding to form GQD@BNO, which showed 8-fold enhanced PL-QY compared to that of the same amount of GQDs in water. The PL-QY enhancement results from the increase in the spontaneous emission rate of GQDs due to the surrounding BNO matrix, which provides a high refractive index environment and fluorescence energy transfer from the larger gap BNO donor to the smaller gap GQD acceptor. In addition, the size effect of GQD@BNO and the GQD loading ratio in BNO on the photo-physical properties shed light on the in-depth carrier dynamics of GQD in a BNO matrix. The robust solid-state PL properties made the GQD@BNO an ideal active material for ACPEL devices, whose lumiance exceeded 283 cd m⁻² for the first time. This successful demonstration shows great potential of GQDs in the field of low cost, eco-friendly EL devices.

Diverse Thermal Response of 2D Materials to Mechanical Strain Mine Hye; University of South Carolina, Columbia, South Carolina, United States.

Manipulation of thermal transport is in increasing demand as heat transfer plays a critical role in a wide range of practical applications, such as efficient heat dissipation in nanoelectronics and heat conduction hindering in solid-state thermoelectrics. It is well established that the thermal transport in semiconductors and insulators (phonons) can be effectively modulated by structure engineering such as external mechanical strain or materials processing. While three-dimensional bulk solid materials usually exhibit decreased lattice thermal conductivity upon mechanical stretching and enhanced thermal transport by compression, the thermal response of two-dimensional (2D) materials to mechanical strain is not that simple. Generally speaking, perfectly planar atomically-thin materials with graphene as representative have reduced thermal transport ability when tensile strain is applied. In contrast, some 2D materials with intrinsic buckled structure will possess enhanced thermal conductivity when being stretched. However, many exceptions exist in other 2D materials. For example, by performing comparative study of thermal transport in two-dimensional group III-nitrides (h-BN, h-AIN, h-GaN) and graphene, we found that the thermal conductivity of all three monolayer group III-nitrides is tremendously enhanced, especially for h-AIN and h-GaN (up to one order of magnitude). By deeply analyzing the orbital projected electronic structure, we establish a microscopic picture of the lone-pair electrons driving strong phonon anharmonicity in group III nitrides. We also found that the lone-pair electrons do not necessarily lead to enhanced thermal conductivity in strained penta-like 2D materials, which suggests the complexity of thermal response of 2D materials to mechanical strain. Our findings offer perspectives of modulating thermal transport properties of broad 2D materials for applications such as thermoelectrics, thermal circuits, and nanoelectronics.
Planck Institute for Solid State Research, Stuttgart, Germany; 2Korea University, Seoul, Korea (the Republic of); 3Sungkyunkwan University, Suwon, Korea (the Republic of).

Besides of graphene, two-dimensional (2D) van der Waals (vdW) layered materials have been intensively studied over the last eight years especially in the field of electronic and optoelectronic devices. Even though many interesting next-generation device physics such as spin transport, charge density wave, and topological insulator have been revealed in various 2D vdW materials, conventional device configurations like field-effect transistor, Schottky, and p-n diode implemented with the 2D vdW materials have also drawn researchers’ attention due to its similarity to the modern electronic and optoelectronic applications. Particularly, the Schottky and p-n junction based devices are essential elements of energy harvesting applications such as photovoltaic solar cell. In this sense, various surface doping methods have been used to tune the electronic and optoelectronic properties of the WSe2 sheets, but combination effects associated with different surface dopants and its detailed studies are still lacking.

Here, we have demonstrated a Schottky junction-based photovoltaic few-layer WSe2 device with an Al2O3 dielectric deposition near source electrode and a molecular doping (NDF-9) near drain electrode selectively. Scanning photocurrent microscopy (SPCM) with a 514-nm laser wavelength confirmed that a highly asymmetric photocurrent generation was occurred in the device, locally only at the WSe2/source electrode contact. Based on the SPCM and photoresponse results with various bias conditions from the devices, it was revealed that this asymmetric photocurrent was strong and its generation mechanism was originated from the enhanced Schottky junction at the WSe2/source electrode by the proper Al2O3 dielectric deposition and chemical doping. A peak photo-responsivity of ~20 mA W\(^{-1}\) as a photodetector and a peak external quantum efficiency of ~0.2 % as a photovoltaic power generator have been extracted. It is believed that our devices can pave the way for developing a van der Waals two-dimensional material-based Schottky junction solar cell.

**Origin of Trion Fluorescence at WS\(_2\): Monolayer Edges**

Zhenling Hu1, Junpeng Lu4, Xinyun Wang1, Jin Feng Long1, Qi Zhang1, Zehua Hu1,2, Junyong Wang1,2, Yanpeng Liu1,2, Wei Liu4, Chong haur Sow1,2, Antonio H. Castro Neto1,2 and Alexandra Carvalho2; 1Department of Physics, National University of Singapore, Singapore; Singapore; 2NUS Center for Advanced 2D Materials, Singapore, Singapore; 3Department of chemistry, National University of Singapore, Singapore; Singapore; 4Department of Physics, Southeast University, Nanjing, China.

For the frequently observed edge enhancement and spatial nonuniformities of photoluminescence (PL) of WS\(_2\) monolayer, even though tremendous effort has been put into, the fundamental physics behind remain elusive. Herein, we report that due to the chemisorption of oxygen atoms at the WS\(_2\) edges, and the much higher electronegativity of oxygen compared to that of sulfur and tungsten atoms, electrons accumulate at the edges, leads to the n-doping behavior and higher electron concentrations near the edges than that at the interior region, giving rise to the strong trion fluorescence. Using the first-principle calculations, it is proved that the edge exhibits n-doping semiconducting behavior instead of metallic behavior after oxygen adsorption at the edge.

**EP03.14.15**

**InSe Performance as a FET Sensor Device**

Badreyya A. AlShehhi and Irfan Saadat; Electrical and Computer Engineering Department, Khalifa University of Science, Technology and Research / Masdar Institute, Abu Dhabi, United Arab Emirates.

Indium Selenide (InSe) has attracted significant attention due to large tunability in the band gap, high carrier mobility and unique anisotropic optical properties compared to other two-dimensional (2D) graphene, based systems for chemical and gas sensing applications in the hostile environments. The expanded research requires integrating the chemical and gas sensing capability with optical sensing function. Therefore, in this work, we report the integration and characterization of this material as field-effect transistor (FET) device and as an optical sensor. High-quality InSe thin flakes were prepared using the Scotch-tape-based mechanical exfoliation method and then transferred to a cleaned 300 nm thermally grown SiO\(_2\) wafer. The InSe thin flakes were identified via color contrast by optical microscopy and Atomic Force Microscope (AFM). A direct laser writer was used for patterning while the deposition of electrodes (5 nm Cr /50 nm Au) was done by thermal evaporation. Results indicate that the measured output characteristics (I\(_{ds}\) vs V\(_{ds}\)) of the device exhibits ohmic behavior. Different current amplitudes have been observed with different flake thickness, which indicates the thickness modulated conduction path. Also within a fixed thickness, the channel current modulation can go up to more than 2% with increasing the gate voltage by 0.5 V (by accessing the substrate as a gate). In additional, the optical spectrometer studies shows that few layer of InSe flakes can absorb the light throughout the visible range. Conductivity assessment of InSe flakes and more gate modulation analysis will be reported in the conference.

**EP03.14.16**

**Study of Optical and Magnetic Properties of Transition Metal Doped MoS\(_2\): for Optoelectronic and Spintronic Applications**

Rosy Rahman, Amita Pathak and Tapan K. Nath; Indian Institute of Technology Kharagpur, Kharagpur, India.

The optical properties of MoS\(_2\) have been found to be vary with size and different doping concentration of transition metal (TM) ions as reported from first-principle calculations. The tuning of band gap in the optical range facilitates its application in optoelectronic devices. We have synthesized 2H phase pure MoS\(_2\) and Mo\(_2\)S\(_2\) with different Mn\(^{2+}\) and Co\(^{2+}\) doping (2%, 4%, 6% at. wt.) concentration using facile hydrothermal process. From the XRD analysis the highest intensity (002) peak at 14.2\(^\circ\) confirms the signature of formation of 2H MoS\(_2\) phase. The detailed morphological information of the as-synthesized Mn\(^{2+}\) and Co\(^{2+}\) doped MoS\(_2\), revealed by SEM and TEM technique provides the average length of the nanoflakes are of ~ 68 nm and width ~ 8 nm range. A single distinct peak at ~400 nm and two typical characteristic absorption peaks of undoped, Mn\(^{2+}\) and Co\(^{2+}\) doped MoS\(_2\) are clearly observed in the region of 600 - 690 nm. This corresponds to the A1 and B1 direct excitonic transitions of the MoS\(_2\) originated from the energy split of valence-band and spin-orbit coupling. The most interesting result which is seen from individual Tauc’s plot of undoped MoS\(_2\) and doped MoS\(_2\) is the red shift of peaks and decrease in band gap with increasing Mn\(^{2+}\) and Co\(^{2+}\) doping concentration. The maximum red shift obtained from undoped to 6% Mn\(^{2+}\) is ~ 30 nm with band gap variation of 0.4 eV. This indicates that the incorporation of TM ions lift the valence band edge causing decrease in band gap of 1T and 2H phases. It is confirmed from Raman spectroscopy having peak at 335 cm\(^{-1}\) along with characteristic peaks at 282, 379, 404, 452 cm\(^{-1}\) corresponds to the E\(_{1g}\), E\(_{2g}\), A\(_{1g}\) and A\(_{2g}\) phonon modes. MoS\(_2\) doped with different percentages of Mn\(^{2+}\) and Co\(^{2+}\) ions exhibits efficient fluorescence response although the fluorescence intensity gets quenched with increase in doping percentages due to incorporation of metal ions. Our results on MoS\(_2\), Mn\(^{2+}\) and Co\(^{2+}\) doped MoS\(_2\) nanoparticles can be used as better fluorescence probe as well as optoelectronic device applications in future. In addition we have also carried out magnetic (EPR, PPMS) measurements of the Mn\(^{2+}\) and Co\(^{2+}\) doped MoS\(_2\) samples from which we conclude the enhancement of temperature and structure dependent ferromagnetic signal with increasing doping concentration up to certain level (~ 6 at%). Such type of temperature, structural along with doping dependent variation of ferromagnetic moment in 2D transition metal dichalcogenides can offer a promising application in future spintronic device applications.

**EP03.14.17**

**Nonlinear Optical Spectroscopy of Two-Dimensional WSe\(_2\) Nanoflakes**

Sergey Lavrov, Arsenii M. Buriakov, Elena D. Mishina, Kirill Brekhov, Nikita Ilyin, Anastasia Sheskakova and Artur Avdzhian; RTU-MIREA, Moscow, Russian Federation.
Two-dimensional semiconductor graphene-like materials are currently extremely developing materials. This is primarily due to their unique properties, which make it possible to create on their basis a large number of effective devices of nano- and optoelectronics. A separate promising niche for the use of these materials is the creation of valleytronics devices on their basis. These materials are ideal candidates for studying the mechanisms of valleytronics and methods of its application. The charge carriers in these materials can be localized in two symmetric band valleys. However, optical absorption, carrier mobility, effective mass and other parameters of these materials directly depend on selected valley. Thus, valley selection may be accomplished by changing the parameters of the optical radiation excitation. This feature of these materials was the subject of presented work.

In this work we study two-dimensional flakes of transition-metal dichalcogenides - WSe₂. Flakes were obtained using a standard method of mechanical exfoliation on a Si/SiO₂ substrate, which ensured their uniformity and defectiveness. The substrate thickness was chosen on the basis of optimal conditions for the generation and detection of nonlinear optical processes in monolayer WSe₂ flakes.

To study the optical properties, a pump-probe technique combined with optical spectroscopy was used. Chosen technique allowed a complex analysis of the monomaterials to be studied with high spatial resolution (400 nm) and at low temperature (4K). Thus, characteristic relaxation times of these structures were established. An analysis of the valley lifetimes direct measurement in single-WSe₂ layer using circularly polarized light was made.

The second optical harmonic generation dependence on the excited radiation energy and its power and the temperature of the WSe₂ flakes are identified experimentally.

The work was supported by Ministry of Education and Science of Russian Federation (State task no. 3.7335.2017/9.10 and grant No. 14.Z50.31.0034).

EP03.14.18
Solving Mysteries in Contact Scaling for 2D FETs
Zhiliui Cheng¹, Hattan Abuzaid¹, Shreya Singh², Yifei Yu², Linyou Cao² and Aaron D. Franklin³-⁴. ¹Department of Electrical and Computer Engineering, Duke University, Durham, North Carolina, United States; ²Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; ³Department of Chemistry, Duke University, Durham, North Carolina, United States.

Atomically thin 2D crystals are promising channel materials for extremely scaled field-effect transistors (FETs). However, the challenge of contacting 2D materials, especially at the scaled contact lengths (L_c < 50 nm) required for future technologies, constitutes a major roadblock for realizing their full potential. Two mysteries have emerged from studying contact length scaling behavior in 2D FETs: the impact of 2D material thickness and contact gating.

It is unclear how the thickness of 2D materials impacts the transfer length (length over which the majority of carriers are injected at the metal-semiconductor contact). There are many incongruent claims around this mystery, from both experimental and theoretical studies. For example, some theoretical studies claim the transfer length is ~1 nm for monolayer MoS₂ FETs, whereas some experimental studies demonstrate a transfer length ranging from 30 nm to 100 nm. The second mystery is the influence of contact gating on contact scaling. Most 2D FETs demonstrated thus far use a back-gate configuration, which allows for electrostatic modulation of the metal-2D as the channel is gated, creating a contact-gating effect. Contact gating could induce stronger carrier injection, but conclusive evidence for its actual impact on the transfer length remains unknown. Unraveling these two mysteries is pivotal in order to understand how carriers are transported in scaled metal-2D contacts.

In order to investigate these mysteries, we fabricated 2D devices having identical channel length, but with different contact lengths (from 15 nm to 100 nm). The channel material is CVD-grown MoS₂ with the thickness ranging from 1 to 4 layers, allowing us to study the effects of 2D crystal thickness based on monolayer increments. For this range of MoS₂ thicknesses, we compared the devices in top and bottom gate configurations, to understand the impacts of contact gating on the transfer length and the contact scaling behavior. Furthermore, we benchmarked the contact scaling behavior of these various 2D FET configurations against the theoretical and experimental observations in the literature, providing a holistic picture of carrier transport at these metal-2D interfaces.

EP03.14.19
Understanding Interlayer Coupling in TMD-hBN Heterostructure by Raman Spectroscopy
Li Ding¹, M. Shoufie Ukhtry¹, Mikhail Chubarov¹, Tanushree H. Choudhury¹, Fu Zhang¹, Rui Yang,² Jonathan Fan¹, Mauricio Terrones¹, Joan M. Redwing¹, Feng Yang¹, Mingda Li⁶, Riichiro Saito¹ and Shengxi Huang¹. ¹The Pennsylvania State University, State College, Pennsylvania, United States; ²Stanford University, Stanford, California, United States; ³Tsinghua University, Beijing, China; ⁴Tohoku University, Sendai, Japan; ⁵Shenyang National Laboratory for Materials Science, Shenyang, China; ⁶Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

In two-dimensional van der Waals heterostructures, interactions between atomic layers dramatically change the vibrational properties of the hybrid system and demonstrate several interesting phenomena, which are present in individual 2D materials. In this work, we have investigated the vibrational properties of the heterostructure between transition metal dichalcogenide (TMD) and hexagonal boron nitride (hBN) on gold film at low and high frequency ranges by Raman spectroscopy. Nineteen Raman modes have been observed from the sample, including a new interlayer coupling mode at 28.8 cm⁻¹. Compared to reported experimental results of WS₂ on Si/SiO₂ substrates, the Raman spectrum for WS₂ on hBN/Au emerges a blue shift of about 8 cm⁻¹. Furthermore, a remarkable enhancement of Raman intensity can be obtained when tuning hBN thickness in the heterostructure. Through systematic first-principles calculations, numerical simulations and analytical calculations, we find that the 28.8 cm⁻¹ mode originates from the shearing motion between monolayer TMD and hBN layers. In addition, the gold substrate and hBN layers form an optical cavity and the cavity interference effect enhances the obtained Raman intensity. Our research demonstrates novel vibrational modes of two-dimensional van der Waals heterostructure as an effective tool to characterize a variety of such van der Waals heterostructure and reveals a new method to enhance the Raman response of two dimensional materials.

EP03.14.20
Realization of 2D Quasicrystals Through Liquid Exfoliation Approach
Thakur P. Yadav¹, Cristianos F. Woelkner²-³, Shyam K. Sinha², Tiva Sharifi³, Amey Apte², Nilay Makhopadhyay², Onkar N. Srivastava¹, Robert Vajtai⁵, Douglas S. Galvao¹, Chandra S. Tiwary⁵ and P. M. Ajayan⁵. ¹University of Campinas, Campinas, Brazil; ²Departamento de Física, Universidade Federal do Paraná, Curitiba, Brazil; ³Department of Physics, University of Houston, Houston, Texas, United States; ⁴Department of Physics, Institute of Science Banaras Hindu University, Varanasi, India; ⁵Materials Science and Engineering, Rice University, Houston, Texas, United States; ⁶Department of Metallurgical Engineering, Indian Institute of Technology, Varanasi, India; ⁷Materials Science and Engineering, Indian Institute of Technology, Gandhinagar, India.

The realization of quasicrystals has attracted considerable attention due to their unusual structures and properties. The concept of quasicrystals in the atomic thin materials is even more appealing due to the in-plane covalent bonds and weak interlayer interactions. Here, it is demonstrated that 2D quasicrystals can be created/isolated from bulk phases because of long-range interlayer ordered aperiodic arrangements [1]. An ultrasonication-assisted exfoliation of poly-grained icosahedral Al–Pd–Mn quasicrystals at room temperature shows the formation of a large area of mono- and few layers in threefold quasi-crystalline plane. The formation of these layers from random grain orientation consistently indicates that the threefold plane is most stable in comparison to the twofold and fivefold planes in quasicrystalline clusters. The above experimental observations are further supported by theoretical simulations. The mono- and few-layered aperiodic planes render plentiful active sites for the catalysis of hydrogen evolution reaction. In order to
understand the origin of structural stability of 3D metallic Al, Pd, and Mn atomic arrangement into 2D ones we carried out ab initio (DFT level, full structural (NMAXEELS) calculations). The structural models consisted of 2D layers initially in a threefold crystallographically icosahedral symmetry. These structures constitute the first demonstration of quasi-crystalline monolayer ordering in a free-standing thin layer without requiring the support of periodic or aperiodic substrate.

EP03.14.21 Equilibrium and Non-Equilibrium Free Carrier Dynamics in Two-Dimensional Ti3C2Tx MXenes—THz Spectroscopy Study
Lyubov V. Titova1, Guangjiang Li1, Kateryna Kushnir1, Yongchang Dong2, Sergii Chertopalov1, Apparao Rao2, Vadym Mochalin1 and Ramakrishna Podila1; 1Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2Physics and Astronomy, Clemson University, Clemson, South Carolina, United States; 3Chemistry, Missouri University of Science and Technology, Rolla, Missouri, United States.

MXenes is an emerging class of two-dimensional transition metal carbides, nitrides and carbonitrides which exhibit large conductivity, ultrahigh volumetric capacitance, high threshold for light-induced damage and nonlinear optical transmittance, which have been suggested as candidates for energy storage, optical modulation and THz detection, among other applications [1]. Successful implementation of photonic and optoelectronic devises based on MXenes such as Ti3C2Tx requires knowledge of intrinsic carrier mobility in these materials as well as of the effects of photoexcitation on conductivity and ultrafast nonequilibrium dynamics of charge carriers. We report on equilibrium and non-equilibrium free carrier dynamics of Ti3C2Tx investigated by THz spectroscopic studies [2]. We have studied intrinsic THz conductivity as well as photoinduced changes in conductivity of a 16 nm-thick film of Ti3C2Tx nanoplates. We find that a high, ~2×10^10 cm^3/s intrinsic charge carrier density and relatively high (~34 cm^2/Vs) mobility of carriers within individual nanoplates results in an exceptionally large, ~46 000 cm^2 absorption in the THz range, in agreement with prior theoretical predictions [3]. We also demonstrate that Ti3C2Tx conductivity and THz transmission can be manipulated by photoexcitation, as absorption of near-infrared, 800 nm pulses suppresses the conductivity for hundreds of picoseconds. Experimental observation of the control over THz transmission and conductivity by photoexcitation suggests the promise for application of 2D MXenes in THz modulation devices and variable electromagnetic shielding.

Evgeny Iakovlev, Petr Zhilyaev and Iskander Akhatov; Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

A two-dimensional (2D) material placed on an atomically flat substrate can lead to the formation of surface nanobubbles trapping different types of substances. In this paper graphene nanobubbles of the radius of 7-34nm with argon atoms inside are studied using molecular dynamics (MD). All modeled graphene nanobubbles except for the smallest ones exhibit an universal shape, i.e. a constant ratio of a bubble height to its footprint radius, which is in an agreement with experimental studies and their interpretation using the elastic theory of membranes. MD simulations reveal that argon does exist in a solid close-packed phase, although the internal pressure in the nanobubble is not sufficiently high for the ordinary crystallization that would occur in a bulk system. The smallest graphene bubbles with a radius of 7nm exhibit an unusual “pancake” shape. Previously, nanobubbles with a similar pancake shape were experimentally observed in completely different systems at the interface between water and a hydrophobic surface.

Leily Majidi, Poya Yasaee and Amin Salehi-Khojin; University of Illinois at Chicago, Chicago, Illinois, United States.

Energy has been one of the most challenging issues during the past decades. The necessity of research in overcoming current energy challenges is crucial because of various reasons such as: limited sources of fossil fuels and carbon emission which leads to global warming and pollution. Electrochemistry is one of the most promising technologies towards environment-friendly and sustainable energy systems. However, it has advanced much more slowly over the last two decades than many companion fields. Fundamental physical parameters such as catalysts’ activity and electronic properties are now hindering major developments in electrochemistry and electrocatalysis. Therefore, new generation of materials are necessary for future applications. In this study, we report on synthesis and characterization of 2D transition metal dichalcogenide (TMD) materials based on group V and VI of transition metals and their sulfides, selenides and tellurides. These materials demonstrate excellent catalytic performance and much higher activity in oxygen reduction and evolution reactions in an aprotic medium with Li salts compared to the reported catalysts. We believe these materials can be utilized as new generation of electrocatalysts for the future developments in catalysis and energy storage systems.

EP03.14.24 Graphene-Based Heterojunction and Its Photoelectric Conversion from Visible to Short-Wave Infrared Light
Xinming Li1,2,3, Hongwei Zhu2, Jian-Bin Xu1, Renzhi Ma1 and Takayoshi Sasaki1; 1International Center for Materials Nanoarchitectonics (WPI-MANA), National Institute for Materials Science (NIMS), Tsukuba, Japan; 2School of Materials Science and Engineering, Tsinghua University, Beijing, China; 3Department of Electronic Engineering, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

In the last few decades, the advances and breakthroughs in graphene and related two-dimensional (2D) materials have been witnessed both scientific fundamentals and potential applications. Graphene’s unique electronic and optical properties have made it an attractive material for developing optoelectronic devices, such as solar cells and photodetectors.[1]

In this talk, I will introduce the graphene-semiconductor heterojunction and its photoelectric conversion from visible light to short-wave infrared (SWIR) light. The graphene can form a Schottky junction with Si, wherein the graphene can function as the transparent electrode and carrier transport layer. In this Schottky junction, Si can absorb the sunlight and contribute photo-generated carriers, so that this heterojunction can be used as a solar cell and a photodiode. [2-3] This solar cell is considered to be a promising demonstration and the power conversion efficiency is raised to 15.6% with electrical and optical improvement.[4-5] Furthermore, this graphene-based heterojunction can be utilized for the photodetectors from visible to SWIR light through
Recent progress reveals the significance of metal dopants in transition-metal dichalcogenides (TMD) on reductive catalysis such as hydrogen evolution reaction. As the concentration of dopant increases, separately-distributed metal dopants tend to form energetically favored clustered structure. Higher concentration of dopant leads to phase separation and structural instability, demolishing the positive doping effect. As a result, the ideal performance of metal-doped TMD catalysts requires certain optimized doping concentration. In this work, we first realize controllable doping of various types of TMDs with desired concentration via a facile sulfurization process on homogenously mixed chloride precursors. The atomic structure of a series of doped TMDs was then unraveled by Raman and TEM techniques. Their catalytic performance was evaluated and the correspondence between atomic configuration, structural stability and catalytic activity was built to elucidate how doping booms the catalysis using TMDs to the greatest extent.

**Networks of Graphene Nanoribbons and Nanosheets Formed in Metals by the Electrocharging Assisted Process**

Lourdes G. Salamanca-Riba1, Xiaoxiao Ge1, Christopher Klingshirn1, Manfred Wuttig1, Oded Rabin1, Karen Gaskell1, Daniel Cole2 and Christopher M. Shumeyko2; 1University of Maryland, College Park, Maryland, United States; 2U.S. Army Research Laboratory, Aberdeen, Maryland, United States.

The incorporation of carbon nanostructures, such as graphene and carbon nanotubes, in the lattice of metals is desirable to take advantage of the superior mechanical and electrical properties of these graphitic nanostructures and the high density of electrons in metals. There have been numerous attempts to create composites of metals, such as copper or aluminum, with carbon nanostructures. These methods frequently require several steps and in aluminum produce the undesirable compound Al4C3. We use electrocharging assisted process which consist of the application of a high DC current to a mixture of liquid metal and carbon particles to incorporate carbon in the metal in a stable form. This method creates graphene nanoribbons and nanosheets in the metal lattice which form epitaxial nanostructures and grows to form a stable structure. The graphene structures bond with atoms in the metal lattice to form the composite very stable. We present a detailed investigation of the process and the effect on the properties of the composites. Raman spectra and mapping indicate that the carbon in the composite has sp2 character. Also, TEM imaging shows that the carbon forms graphene nanoribbons that extend along crystaline directions of the metal lattice. The improvement in electrical and thermal properties as well as the increase in tensile strength are due to the formation of the graphene nanoribbons.

This work is based upon work supported by the U. S. Department of Energy under Award No. DE-EE0008313. Dr. David Forrest is the Project Technology Manager and Debbie Schultheis is the Project Officer/Manager.

**High Performance Graphene Photodetector with van der Waals Heterostructure Through Tuning Carrier Tunneling**

Youngrae Kim and Woo Jong Yu; Sungkyunkwan University, Suwon, Korea (the Republic of).

In the present decade, graphene, which is one of the large number of possible two-dimensional (2D) materials, is considered as a remarkable material for photonics and optoelectrics due to its specific properties such as gapless band structure which enables to modulate optical properties, ultra-fast carrier mobility which makes a fast modulation, a wide absorption range from ultra-violet (UV) to far-infrared (FIR), transparency and flexibility. However, a weak absorption properties and small built-in potential in a monolayer of carbon atoms have limited the properties such as an external quantum efficiency (EQE) range of ~0.1 - 1 %. Also, existing graphene-based photodetector with the lateral structure which has a photo response near graphene-metal junction is not an ideal for the harvesting efficient photons. To increase optoelectronic properties in graphene, large number of devices integrating with 2D transition metal dichalcogenides (TMDs) materials and Quantum dots (QDs) materials which have high absorption properties were developed recently. However, integration with these materials limits the absorption range due to their own bandgap even graphene has advantages in large absorption range. Here, we developed large absorption range to infra-red (IR) range graphene photodetector with metal/insulator/graphene heterostructure by controlling the Schottky barrier. The absorption range can be controlled by utilize with different materials by controlling Schottky barrier. In visible range, we used Au/h-BN/graphene heterostructure which the existence of the h-BN tunneling layer makes extremely low dark current ~10^-13 A. As the result, our photodetector has the high IPH/IPD over ~20 contrast to reported lateral graphene photodetector which has under 5. Finally, we also show the possibility of the IR photodetector from Ni/NiO/graphene heterostructure.

**Torsional Instability in the Single-Chain Limit of a Transition Metal Trichalcogenide**

Thang Pham1, Sehoon Oh1, Patrick Stetz1, Seita Onishi1, Christian Kisielowski2, Marvin Cohen1 and Alex Zettl1; 1University of California, Berkeley, Berkeley, California, United States; 2Molecular Foundry, Berkeley, California, United States.

The scientific bounty resulting from the successful isolation of few-to-single layers of two-dimensional van der Waals materials suggests that related new physics resides in the few-to-single chain limit of one-dimensional van der Waals materials. In my talk, I will present our recent effort in the synthesis of the quasi-one-dimensional transition metal trichalcogenide NbS2 in the few chain limit, including the realization of isolated single chains. The chains are encapsulated in protective boron nitride or carbon nanotube sheaths to prevent oxidation and to facilitate characterization. Transmission electron microscopy reveals static and dynamic structural torsional waves not found in bulk NbS2 crystals. Electronic structure calculations indicate that charge transfer drives the torsional wave instability. Very little covalent bonding is found between the chains and the nanotube sheet, leading to relatively
unhindered longitudinal and torsional dynamics for the encapsulated chains.

**Fabrication of Size-Controllable Graphene Quantum Dot Array Embedded in Hexagonal Boron Nitride**

Zehua Huang, Qi Han and Jun Wang; School of Optoelectronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

Zero bandgap materials are suitable candidates for the preparation of broad-band photodetectors. As a novel three-dimensional Dirac semimetal, Cd$_3$As$_2$ has shown many outstanding features such as linear dispersion, ultrahigh carrier mobility and zero bandgap. Cd$_3$As$_2$ nanosheet has higher light absorption rate compared to the monolayer graphene. Here we report a kind of Cd$_3$As$_2$ nanosheet and perovskite quantum dots FaPbBr$_3$($\text{CH(NH}_2\text{)PbBr}_3$) hybrid photodetector from visible to near infrared. After coating the perovskite QDs, the current responsivity increases more than 30 times. At room temperature, the pure Cd$_3$As$_2$ nanosheet has a responsivity of 62.8 mA/W at 780 nm under 1mV bias voltage, and the current response rate reaches 1.89 A/W after coating the FaPbBr$_3$ QDs. The Cd$_3$As$_2$ nanosheet and FaPbBr$_3$ QDs hybrid photodetector exhibits broadband responses from 405nm to 780nm at room temperature. Our work shows that coating perovskite QDs can significantly improve the performance of broadband photodetectors based on 3D semimetal Cd$_3$As$_2$.

**Black Phosphorus—An Exciting Material for Electronics and Optoelectronics**

Sumeet Walia, Taimur Ahmed and Sruthi Kuriakose; RMIT University, Melbourne, Victoria, Australia.

Black-phosphorus (BP) has emerged as a material of interest owing to its high carrier mobility and the presence of an intrinsic direct bandgap. Its thickness-dependent energy gap and highly anisotropic properties make it an important material to investigate amongst the family of two-dimensional (2D) materials. Few-layer BP has been a focus of several studies and is promising for applications in electronics, optoelectronics, energy storage, gas sensing, catalysis and chemical/biosensing. However, the ambient instability of BP remains the biggest hurdle in its progress. The fact that the material has to be stored and handled in an inert environment renders it to be unfavourable for practical implementation. To date, the solution to avoid degradation has been capping BP to minimize its interaction with the ambient environment. Here, we present a systematic investigation of the origins of oxidative degradation in few-layer black phosphorus (BP). Subsequently, we also propose an ionic liquid based approach to prevent ambient degradation of BP.

First, we conducted an in-depth investigation into the origins of degradation revealing that oxidation due to light causes degradation whereas humidity on its own does not cause any material and acts merely as a facilitator of photo-oxidation [1].

Subsequently, we have designed a new chemical sequestration strategy which will enable the handling and operating of BP in standard laboratory environments.

Finally, we designed an approach that allows this sensitive material to remain stable without requiring its isolation from the ambient environment [3]. We employ imidazolium-based ionic liquids (ILs) as quenchers of damaging oxidative species on the BP surface. This chemical sequestration strategy allows BP to remain stable for over thirteen weeks, while retaining its key electronic characteristics.

Besides, fundamental studies on the degradation of BP, we have also explored plasma thinning and defect engineering of BP layers.

**Fabrication of Size-Controllable Graphene Quantum Dot Array Embedded in Hexagonal Boron Nitride**

Gwangwoo Kim$^1$, Kostya Novoselov$^2$, Byeon-Hyeok Sohn$^3$ and Hyeon Suk Shin$^2$; $^1$Ulsan National Institute of Science & Technology, Ulsan, Korea (the Republic of); $^2$School of Physics & Astronomy, University of Manchester, Manchester, United Kingdom; $^3$Seoul National University, Seoul, Korea (the Republic of).

Graphene quantum dots (GQDs) have received tremendous attention because their band gap can be controlled. Although many approaches have been developed to fabricate GQDs, they are time-consuming and costly, and furthermore, precise control over the morphology and size distribution of GQDs remains challenging. Here, we demonstrate spatially controlled conversion of hexagonal boron nitride (h-BN) to graphene on an array of Pt nanoparticles (NPs) to realize an array of uniform GQDs embedded in an h-BN sheet. A uniform Pt NP array was formed on a SiO$_2$/Si substrate with the aid of self-patterning diblock copolymer micelles, and the h-BN sheet was transferred on the Pt NPs array by the conversion of h-BN on Pt to GQDs. The size of the obtained GQDs corresponded with the sizes of the Pt NPs due to the selective conversion of h-BN on top of Pt NPs. Uniform and precisely controlled size of the GQDs ranging from 7 to 13 nm was achieved. Finally, we demonstrate electron transport by the size-controlled GQDs isolated by insulating h-BN like a Coulomb blockade, indicating that the splitting energy of the GQD is 80–160 meV, compatible with its dimension.

**EP03.14.32**

**Manufacture of Two-Dimensional Electrodes by Transition Metal Ditellurides Which Have High Electric Conductivity and Transparent Properties**

Taewon Yuk, Gyutae Jeon, Hakyu Kim, Byeonguk Min and Sukjun Kim; Korea University of Technology and Education, Cheonan, Korea (the Republic of).

Many two-dimensional materials show high electrical conductivity similar to Graphene. Especially, some of transition metal ditellurides has electrical conductivity as high as pure metals. Also, they can be transparent once they are in the form of a thin layer. Fortunately, they can be easily fabricated in the form of thin layer that consists of a few numbers of atomic layers. We attempt to fabricate thin films of nickel ditelluride in two ways (Intemmetallic Target, Co-sputtering). Both of fabricated thin film crystal structure is Ni$_2$Te$_2$, Melonite, 98-004-3293. Our results prove that nickel ditelluride are one of promising candidates for transparent electrodes (existing electrode/200 μm/cm, 80%). First, 2 inch-compound targets were prepared by fabricating the intermetallic followed by SPS. Thin film (thickness 9nm) was deposited by Radio frequency sputtering (PVD) using the Intemmetallic Target. Second, thin film (11nm) was deposited by co-sputtering a Ni and a Te target at Ni:Te=3:7. For two methods, we controlled sputtering power and deposition time and substrate heating conditions to maximize their electrical conductivity. Through TEM analysis proved that more grains with c-axis. Therefore, by after annealing and chemical exfoliation, Nickel ditellurides thin film grain size can be growth coarse and make more thin layer.

**EP03.14.33**

**A Solution-Processed Bi$_2$S$_3$ Photo-Sensing Film with High On-Off Ratio to Mitigate a Trade-Off Between Morphology and Electronic Properties**

Ryosuke Nishikubo$^1$ and Akinori Sacki$^{1,2}$; $^1$Osaka University, Osaka, Japan; $^2$JST-PRESTO, Tokyo, Japan.

Metal chalcogenides (MCs) with two-dimensional (2D) atomic layers have evolved as premier materials for functional devices, including WS$_2$-based field-
effect transistors, Bi$_2$Te$_3$-based topological insulators, and Bi$_2$Se$_3$-based thermoelectric converters. Despite being highly studied, MCs continue to be predominantly synthesized via solid-state reactions at high temperature (>1000 °C) or liquid-phase reactions, which afford microcrystal powders detrimental to low-cost processing of devices over large areas.

Bismuth sulfide (Bi$_2$S$_3$) is an attractive 2D-layered, visible light-absorbing semiconductor composed of non-toxic, abundant elements. However, improving the quality of a Bi$_2$S$_3$ thin film for device applications while maintaining its intrinsic electronic properties is a challenge, as conventional film fabrication processes require a trade-off due to the uncontrolled nucleation and growth steps. Herein, we report a novel procedure for Bi$_2$S$_3$ film formation involving spin-coating of a precursor solution of bismuth salt and sulfur-source organic molecule followed by crystallization under diluted H$_2$S gas. This two-step process produced a large-grained (<400 nm), smooth (surface roughness = 1.7 nm), and highly pure Bi$_2$S$_3$ film with a layer-stacked structure on a substrate. Most importantly, the thin film exhibited excellent photo-sensing performance as a phototransistor with improved photoconductance and on-off ratio compared to those prepared by conventional methods. The obtained high on-off ratio is a result of high photoconductance and low dark-current, supported by high crystallinity, morphology and purity. Our approach provides a versatile route for the development of metal sulfide semiconductors for optoelectronic devices.

**Green Integration of Layer-by-Layer 2D TMD Films on Arbitrary Substrates by Water-Assisted Layer Separation** Jung Han Kim$^1$, Tae-Jun Ko$^2$, Emmanuel E. Okogbue$^{3,4}$, Sang Sub Han$^2$, Mashiyat S. Shawkat$^2$, Kyu Hwan Oh$^1$, Hee-Suk Chung$^3$ and Yeonwoong Jung$^{1,2,4}$; 1Electrical and Computer Engineering, University of Central Florida, Orlando, Florida, United States; 2NanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 3Nanotechnology Program, University of Central Florida, Orlando, Florida, United States; 4Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Two-dimensional (2D) transition metal dichalcogenides (TMDs) exhibit unusually superior and tunable electrical, optical, and chemical properties unattainable in conventional inorganic thin films. The intrinsically layered van der Waals (vdW) crystallinity of 2D TMDs coupled with their extremely small thickness suggest that such property advantages can be further promoted by integrating them onto the substrates of novel functionalities and unconventional geometries. A prerequisite for the full exploration of such unprecedented opportunities is to precisely transfer larger-energy-scale 2D TMDs onto targeted functional substrates without compromising their intrinsic material quality as-grown. Herein, we present a water-assisted “green” approach to efficiently separate, transfer, and integrate 2D TMD layers onto virtually arbitrary substrates without using additional chemicals. We demonstrate the successful integration of 2D TMDs onto a variety of unconventional substrates including paper, wood, and plastics as well as their layer-by-layer integration with controlled morphology. The success of this facile 2D layer integration is attributed to the surface energy imbalance in between as-grown 2D TMDs and their growth substrates (i.e., silicon dioxide (SiO$_2$)), which efficiently facilitates the penetration of water underneath the grown 2D layers. We further extend this novel 2D layer integration approach to develop large-scale 2D/2D heterostructures as well as 2D flexible photodetectors, which confirms its versatility for a wide range of device applications.

**Centimeter-Scale Three Dimensionally-Ordered 2D MoS$_2$ Vertical Layers Integrated on Flexible Elastomeric Substrates** Md Ashrafal Islam$^{1,2}$, Jung Han Kim$^1$, Tae-Jun Ko$^1$, Shraddha Nehate$^2$, Md Golam Kaim$^1$, Kalpathy Sundaram$^2$, Minjee Ko$^2$, Chang-Hee Cho$^2$, Hee-Suk Chung$^3$ and Yeonwoong Jung$^{1,2,4}$; 1Nanotechnology Program, University of Central Florida, Orlando, Florida, United States; 2Department of Electrical and Computer Engineering, University of Central Florida, Orlando, Florida, United States; 3Department of Emerging Materials Science, DGIST, Daegu, Korea (the Democratic People's Republic of); 4Analytical Research Division, Korea Basic Science Institute, Jeonju, Korea (the Democratic People's Republic of); 5Department of Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States; 6Department of Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States; 7Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

The intrinsically anisotropic layered structure of two-dimensional (2D) transition metal dichalcogenides (2D TMDs) enables a variety of intriguing material properties which strongly depend on the physical orientation of constituent 2D layers. For instance, 2D TMDs with vertically-aligned 2D layers exhibit numerous dangling bonds on their 2D layer edge sites, offering tremendous opportunities for a wide range of applications which demand high physical/chemical surface reactivity. Moreover, such property advantages can be further promoted as far as 2D TMDs with controlled layer orientation can be integrated onto the unconventional substrates of tailored geometry and functionality while their structural integrity is well retained. Herein, we report large-area (>2 cm$^2$) three-dimensionally (3D) structured 2D MoS$_2$ layers with vertically-aligned layers integrated on mechanically flexible elastomeric substrates. We synthesized 2D MoS$_2$ with vertically-aligned layers on silicon dioxide/silicon (SiO$_2$/Si) 3D pillars-patterned substrates. The 3D-ordered vertical 2D MoS$_2$ layers were subsequently transferred and integrated onto flexible polydimethylsiloxane (PDMS) substrates, enabled by the water-assisted layer transfer method developed in our group. The structural integrity of the vertical 2D MoS$_2$ layers was characterized by extensive spectroscopy and microscopy before and after the transfer and was confirmed to well retain. We demonstrated mechanically flexible humidity sensors based on the 3D-ordered 2D vertical MoS$_2$ layers and identified their superior sensitivity, which is attributed to the combined effect of increased surface area and enhanced 2D edge density.

**EP03.14.36**

**Scalable Synthesis of Crystalline vdw MOF Nanosheets with Large Aspect-Ratio Through Ultimate Control Over Hydrogen Bond Formation and Reaction Rates** Yuxia Shen$^1$, Bohan Shan$^2$, Hui Cai$^1$, Ying Qin$^1$, Ashutosh Agarwal$^2$, Bin Chen$^1$, Lei Li$^1$, Houlong Zhuang$^1$, Bin Mu$^1$ and Seliaatin Tongay$^1$; 1Arizona State University, Tempe, Arizona, United States; 2Arizona State University, Tempe, Arizona, United States.

Large scale synthesis of van der Waals (vdW) metal organic framework (MOF) nanosheets with controlled crystallinity and interlayer coupling strength has been one of the bottlenecks in the development of 2D materials. This has limited not only our visibility to their fundamental properties, but also the industrial daily life applications. Here, we demonstrate scalable synthesis of mBDC (m=Zn and Cu) 2D MOFs at large scales through a bi-phase method. By replacing water molecules in the reaction with pyridine, hydrogen bonding at metal cluster sites and between the layers is largely eliminated. This sustains vdw MOFs growth and prohibits tightly coupled MOF structures. By adding controlled amount of TEA and formic acid in the reaction solution, we are able to regulate the proton concentration and reaction rates, which allowed us to control the nucleation density, growth speed, crystallinity, and material thickness, to achieve highly crystalline vdw MOF nanosheets with extraordinarily high aspect ratio. Described synthesis route can be easily scaled up for large-scale production in either crystal powder or depositing onto various substrates. Benefiting from its large lateral size, vdw nature, and high crystallinity, we are able to perform AFM, KPFM, and Raman measurements to establish their fundamental properties as novel material characterization tools, allowing a new perspective on the structural identification via lattice vibration, as well as the very first insight on their thickness-dependent properties. This work provides a scalable synthesis method for production of high quality 2D MOF nanosheets, and structural and physical insight into the material properties for the first time.

**EP03.14.37**

**Sodium Chloride Induced Heterogeneities in Epitaxial MoS$_2$** Kehao Zhang$^1$, Brian M. Bersch$^1$, Fu Zhang$^1$, Natalie Briggs$^1$, Ke Xu$^1$, Ke Wang$^1$, Mikhail Chubarov$^1$, Joan M. Redwing$^2$, Susan Fullerton-Shirey$^2$, Mauricio Terrones$^1$ and Joshua Robinson$^1$; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2University of Central Florida, Orlando, Florida, United States.

Sodium chloride induced intrinsic heterogeneities in the epitaxial growth of MoS$_2$ film onto a silicon substrate at high temperature (>1000 °C) or liquid-phase reactions, which afford microcrystal powders detrimental to low-cost processing of devices over large areas.
The realization of wafer-scale transition metal dichalcogenide monolayer films\(^1\) and the successful exploration of 2D TMDs library\(^2\) are two major milestones in the recent efforts on the synthesis of 2D materials. Interestingly, NaCl is used in both cases to reduce the nucleation density and melting points of oxides. However, the presence of alkali metals is detrimental in conventional silicon-based semiconductors due to high rates of ion diffusion through the bulk, leading to degradation in device performance and reliability. In 2D materials, like traditional dopants such as tinium and niobium, alkali metals, such as potassium K\(^+\), results in degenerate doping of MoS\(_2\). Therefore, it is critical to comprehensively evaluate the impacts of NaCl on the properties of synthetic 2D materials. In this work, we elucidate NaCl-induced heterogeneities in synthesis, photonic response and electrical performance of MoS\(_2\) films, and demonstrate that salt-assisted synthesis of epitaxial MoS\(_2\) monolayers degrades electrical device performance. First, we develop the NaCl-free large area (2+2 cm\(^2\)) epitaxy of MoS\(_2\) evident from in-plane X-ray diffraction (XRD) and utilize it to compare to the growth with NaCl. Atomic force microscopy (AFM), scanning electron microscopy (SEM), Raman, and photoluminescence (PL) indicate that growth of monolayer films without NaCl are crystalline and uniform across a wide range. Substrates without island growth, while two distinct growth modes (island and layer-by-layer) and rates are identified when NaCl is utilized. The heterogeneous growth kinetics due to NaCl leads to photonic heterogeneities related to non-uniform monolayer strain. Moreover, utilizing NaCl introduces a 1.5x decrease in mobility, 2x increase in subthreshold slope, and 100x reduction in on/off ratio due to electronic trap states. Finally, comparison of transport properties between devices fabricated using as-grown and transferred films reveals that interface coupling (charge transfer, trap states) can dominate the device performance, indicating the importance of substrate engineering to realize the high performance, synthetic 2D based devices.

Unveiling Growth Mechanisms in 2D/2D Layer-By-Layer Horizontal Epitaxy to 2D/3D Vertical Cross-Over in van der Waals Heterostructures

Nitin Choudhary\(^1\), Tae-Jun Ko\(^1\), Jung Han Kim\(^1\), Md Asriful Islam\(^1\), Hye Min Oh\(^1\), Kevin Coffey\(^1\), YounJoon Jung\(^1\) and Yeonwoong Jung\(^2\); \(^1\)University of Central Florida, Orlando, Florida, United States; \(^2\)Korea Basic Science Institute, Jeonju, Korea (the Republic of); \(^3\)Seoul National University, Seoul, Korea (the Republic of).

2D van der Waals (vdW) heterostructures composed of chemically distinct transition metal dichalcogenides (TMDs) exhibit exotic functionalities, projecting enormous opportunities for next generation semiconductor heterojunction devices. Despite the recent advances in developing 2D vdW heterostructures of various geometry and component, their fundamental growth principle, i.e. how 2D layers of one kind grow on top of the other, has not been fully clarified. In this work, we investigate the fundamental parameters that dictate the growth characteristics of 2D/2D heterostructures composed of vertically-stacked 2D MoS\(_2\)/W\(_{\text{S}}\). By employing tungsten trioxide (WO\(_3\)) nanowires as growth templates which enable the atomistic inspection of 2D/2D interfaces upon transmission electron microscopy (TEM), we observed a unique growth transition in these materials; i.e., 2D/2D layer-by-layer horizontal epitaxy to 2D/3D crossover akin to the Stranski-Krastanov (SK) growth of vertical layers. We further identified that this growth mode transition is driven by increasing the thickness of the seed metal films converted to 2D TMD layers. Molecular dynamics (MD) simulation confirmsthe formation of the internal strain that facilitates the 2D layer growth. The morphological characteristics of resulting 2D/2D heterostructures. Our finding is insightful for better understanding the growth principles behind generic 2D vdW heterostructures, thus pave ways for their utilization towards emerging 2D heterojunction devices.

EP03.14.39

Thermoelectric Properties of CVT-Grown Lithium-Intercalated Molybdenum Disulfide (Li\(\text{MoS}_2\))

Hong Kuan Ng\(^1\), Anas I. Abutaha\(^2\), Yi Liu\(^1\), Ivan Verzhbitskiy\(^3\), Goki Eda\(^4\) and Kedar Hippalgaonkar\(^5\); \(^1\)National University of Singapore, Singapore, Singapore; \(^2\)IMRE, A*STAR, Singapore, Singapore.

Thermoelectricity, based on the Seebeck effect, is an alternative for power generation and refrigeration due to its ability to directly convert thermal into electrical energy. Here, we study thermoelectric properties of exfoliated Li\(\text{MoS}_2\) grown using Chemical Vapour Transport (CVT), where a mixture of 1T’ and 2H phases coexist in a single sample due to the 2H to 1T’ phase transition induced by Lithium (Li) intercalation. We show that as-fabricated Li\(\text{MoS}_2\) devices are p-type in nature with high electrical conductivity due to its metallic 1T’ phase, and that in-situ thermal annealing of Li\(\text{MoS}_2\) in vacuum induces a p-type to n-type transition as a result of delithiation. A peak power factor of 18 uW/mK\(^2\) is observed in an effective medium of Li\(\text{MoS}_2\) with reasonable electrical conductivity is maintained by the metallic 1T’ phase and the Seebeck coefficient is controlled by the semiconducting 2H phase. By refining the thermal annealing temperature and annealing time that controls de-lithiation of LixMoS\(_2\), we hypothesize that a higher power factor can be achieved, showing an additional knob to tune energy dependent scattering in these novel materials.

EP03.14.40

Highly Enhanced Photoresponsivity of Monolayer WS\(_2\) Photodetector with Nitrogen-Doped Graphene Quantum Dots

Duc Anh Nguyen\(^1\), Hye Min Oh\(^1\), Ngoc Thanh Duong\(^1\), Seungho Bang\(^2,3\), Seok Jun Yoon\(^1,2\) and Mun Seok Jeong\(^1,2\); \(^1\)Department of Energy Science, Sungkyunkwan University, Suwon 16419, Korea (the Republic of); \(^2\)Center for Integrated Nanostructure Physics (CINAP), Institute for Basic Science (IBS), Sungkyunkwan University, Suwon 16419, Korea (the Republic of).

Monolayer (ML) transition metal dichalcogenides (TMDs) such as tungsten diselenide (WSe\(_2\)) are particularly interesting in the field of nanoscale optoelectronic devices because of its direct band gap, high carrier mobility and high ON/OFF ratio. However, atomically thin material layers have limited ability to absorb and emit radiation because of their low cross-sectional area. To enhance the photoresponsiveness of ML WSe\(_2\), a strong light absorbing material such as PbS quantum dots (QDs) or organolead halide perovskite were introduced. However, these materials are toxic and unstable under ambient condition because of the presence of Pb compounds or organic materials. Therefore, it is a huge challenge for finding a low cost, non-toxic and stable material to create a hybrid structure with ML WSe\(_2\) to improve its optoelectronic performance.

In this work, we report a facile method for fabricating a hybrid structure that consists of ML WSe\(_2\) covered with Nitrogen-doped graphene quantum dots (ML WSe\(_2\)/N-QGQDs). The PL intensity of ML WSe\(_2\) is enhanced drastically because of the reduction of the positive trion and enhancement of the neutral exciton formations through electron transfer from N-QGQDs. The improved photoresponsivity in ML WSe\(_2\)/N-QGQDs photodetector is attributed to strong light absorption and charge transfer from N-QGQDs to ML WSe\(_2\). The photogating effect also plays a key role in the improvement of hybrid photodetector performance. Notably, this hybrid photodetector exhibits good stability under ambient condition.
2-dimensional (2D) material field effect transistors (FETs) are promising devices to overcome the problems of conventional devices with their new attractive electrical properties. Since 2D material FETs have very similar structures to Junctionless transistors (JLTs) with no junctions requiring heavily-doped silicon as a channel, the analysis of the conduction mechanism of 2D material FETs based on the conduction mechanism of JLTs is considered as an effective method. JLTs are a special type of FETs that operate in accumulation mode using bulk conduction mechanism instead of conventional inversion mode.

Prior studies show that, in a 2D material FETs with a multi-layered channel, the conduction path is formed on the surface of the channel material if the electrodes are fabricated on the surface of the channel. In this study, multi-layered 2D material FETs with edge-contacted channel using molybdenum disulfide (MoS2) were fabricated to investigate the effect of bulk conduction. The changes of transfer characteristics with the electrodes structure of FETs were observed, which can be explained by carriers directly injected at the interface between electrodes and edges of the channel. For the further analysis, mobility degradation factors using transconductance ($g_m$) and Low Frequency Noise (LFN) of FETs were evaluated. FETs with electrodes on the edge of the channel show less decrease of $g_m$ curve than the ones with electrodes on the surface of the channel. The change of the current fluctuation was observed in case of edge contacted FETs, attributed to the contribution of bulk conduction.

These results indicate the reduction of surface roughness scattering from the bulk conduction mechanism in multi-layered structures. An enhancement of bulk conduction was also observed in FETs with electrodes on the edge of the channel in LFN Characteristics. Our study suggests an effective method to analyse the mobility degradation factors depending on conduction path in multi-layered channel regime.

**EP03.14.43**

*Excitonic Energy Transfer in van der Waals Heterostructure of 2D Hybrid Perovskite and Monolayer WS2* Qi Zhang, Eric Linardy and Goki Eda; NUS, Singapore, Singapore.

Two-dimensional (2D) organic-inorganic hybrid perovskite is a re-emerging material with strongly excitonic absorption and luminescence properties that are attractive for optoelectronics. Similar to other excitonic 2D semiconductors, the excitons in 2D perovskite nanosheets are expected to exhibit near-field coupling with nearby excitonic systems. Here we report on an experimental observation of excitonic energy transfer in van der Waals heterostructures consisting of 2D hybrid perovskite ([C6H5C2H4NH3]2 PbI4) and monolayer WS2. We prepared the heterostructure using the dry-transfer technique with the WS2 layer encapsulating the perovskite sheet to protect it from degradation. Photoluminescence excitation spectroscopy with WS2 exciton emission in the detection channel reveals a distinct ground exciton absorption feature of perovskite, evidencing energy transfer from perovskite to WS2. At the resonance peak of perovskite, the emission from WS2 was enhanced by a factor of 2–5. This observation suggests that the energy transfer occurs not only from the top-most layer but also from the lower layers of perovskite. We further discuss the emergence of a peculiar sub-gap low energy emission peak which may be attributed to the interfacial hybridization between WS2 and the organic moiety of perovskite.

*Simultaneous Synthesis and Integration of Ultrathin Electronic Components for Beyond Silicon Circuits* Qi Zhang and Liying Jiao; Chemistry, Tsinghua University, Beijing, China.

When the silicon metal-oxide-semiconductor field effect transistor (MOSFET) was first introduced in integrated circuits, it shows strong scalability and the complexity of circuits increases exponentially in the past several decades according to the Moore’s law. However, as the characteristic dimension of MOSFET reaches the thermal and quantum limit, scaling down the device from lateral and vertical directions becomes increasingly difficult and costly. Driven by the urgent demand for continuously shrinking the size of transistors, great efforts have been made on exploring low dimensional electronic materials, such as nanowires, carbon nanotubes (CNTs) and two-dimensional (2D) materials as building blocks for constructing smaller devices during the past two decades. Although electronic devices based on individual nanomaterials have exhibited high performance, there is still a huge gap towards integrating these single devices into practical circuits that can compete with state-of-the-art silicon chips. Here we present an alternative device manufacturing strategy in which the ultrathin electronic components in the active layer are chemically synthesized and integrated simultaneously in a single step and each component is connected via covalent bonds instead of physical interfaces. As a proof of the concept, we synthesized arrays of logic devices and radio frequency devices through the phase-patterned growth of ultrathin atomic layers. The obtained circuits composed of semiconducting phase as channels and metallic phase as contacts and interconnects were ready to work after the synthesis process and exhibited high performance. Moreover, we successfully constructed multilayered devices with vertical interconnections to show the potential of our strategy on fabricating three-dimensional (3D) integrated circuits (IC) with ultimate circuit densities in vertical space. This approach makes the design and optimization of electronic devices much more flexible and preserves the intrinsic performance of the materials to the largest extent and therefore, provides a new technology for manufacturing high performance integrated circuits beyond silicon.

*Visualizing and Understanding the Microstructure of Transition Metal Dichalcogenide Monolayers* Xiaomin Xu1, Thorsten Schultz1, 2, Ziyu Qin1, 4, Benedikt Haas1, 2, Nikolai Severin1, 2, 3, Jan N. Kirkchof6, Andreas Optitz2, 3, Christoph T. Koch1, 2, Kirill Bolotin5, Jürgen P. Rabie1, 2, Goki Eda1 and Norbert Koch1, 2, 3, 4; 1Department of Physics, Humboldt-Universität zu Berlin, Berlin, Germany; 2Integrative Research Institute for the Sciences (IRIS Adlershof), Berlin, Germany; 3Department of Physics, National University of Singapore, Singapore, Singapore; 4State Key Laboratory of Materials Processing and Die Mould Technology, Huazhong University of Science and Technology, Wuhan, China; 5Department of Physics, Freie Universität Berlin, Berlin, Germany; 6Helmholtz-Zentrum für Materialien und Energie GmbH, Berlin, Germany.

Probing the microstructure of transition metal dichalcogenide (TMDC) monolayers is of paramount importance to understand the optical and electrical properties, and to facilitate a controllable application in optoelectronic devices [1]. Industry-scale fabrication on TMDC monolayers seems within reach due to the rapid development of chemical vapor deposition (CVD) [2], yet visualization of spatial structure variations in nondestructive and high-throughput manner remains challenging [3,4].

Here we report how grain boundaries, strain fields, and grain orientation can be identified unambiguously with combined lateral force microscopy (LFM) and transverse shear microscopy (TSM) for CVD-grown tungsten disulfide (WSe2) monolayers. In LFM images, sharp line-shape contrasts appear and persist after sample transfer, and their locations coincide with regions having photoluminescence (PL) intensity fluctuation, corresponding to inherent structural defects, i.e. grain boundaries. Differently, diffuse-shape contrasts disappearing after sample transfer solely arise from changes of the friction coefficient under strain. TSM is demonstrated to be superior in identifying grain orientation since the shear stress signal varies with respect to the scan vector due to the elastic anisotropy of the crystalline sample. Further, angle-dependent TSM measurements enable us to acquire the fourth-order elastic constants of monolayer WSe2 experimentally.
Our study exemplifies a rapid and non-destructive approach to visualize the microstructure of TMDC monolayers, insights into their elastic properties, thus providing an accessible tool to support the development of advanced two-dimensional optoelectronic devices.

Temperature-Dependent Electrical Properties of Piezoelectric Monolayered MoS₂

Abstract:

Monolayered molybdenum disulfide (MoS₂) is one of the most promising materials for next-generation electronic/optoelectronic devices because of its prominent piezoelectric property that can modulate Schottky barrier height and control transport behaviors without applying any external gate bias. Although temperature dependency of current transport in monolayered MoS₂ has been predicted in a theoretical study based on 2D thermionic equation, experimental result about temperature dependences of piezoelectric/piezophotoelectric effect in monolayered MoS₂ has not been reported yet. Several researchers have studied piezoelectric properties of monolayered MoS₂ only at room temperature. Here, we focused on temperature dependence of the piezoelectric effect in CVD grown monolayered MoS₂. In this study, transport behaviors of monolayered MoS₂ on polyethylene terephthalate (PET) as a flexible substrate under strain from 0 to 0.3 % in generally accepted operating temperature region from 273 K to 333 K were examined. Thermocouple was used to directly measure the temperature of such MoS₂. We observed that strain-generated piezoelectric charges in our MoS₂ affected the transport behavior by modulating SBH at the interface between electrodes and MoS₂. In addition, we found that the current and SBH had different tendencies depending on sample temperature. A dominant effect of the current behavior with the strain used in our monolayered MoS₂ depending on sample temperature was also determined by measuring photocurrent under the strain. The piezoelectric effect was found to be dramatically increased when sample temperature was decreased from 320 K to 270 K.

Growth of WS₂ Nanocrystals and Nanosheets by a New Lithium Intercalation Method for Multifunctional Device Application

Abstract:

Transitionnal metal dichalcogenides (TMDC) such as WS₂ has drawn immense attention recently owing to their thickness dependend band gap energy which is missing among other two-dimensional materials like graphene or carbon nitride. However, widespread application of semiconducting WS₂ is hampered by their low yield production methods. Among the two-dimensional (2D) TMDC, WS₂ is very reluctant to undergo liquid exfoliation than other. So, it is a new challenge to synthesize mono or few layer WS₂ flakes or nanocrystals of controlled size in large scale and simple way. WS₂ shows similar kind of band gap modulation like MoS₂ with the layer number attractive for opto-electronic device application. Here, we have synthesized bi-to-few layers WS₂ in solution from bulk WS₂ by Li-ion intercalation technique using lithium halide. In brief, WS₂ bulk powders and LiX (anhydrous) were mixed in hexane. The mixture was sonicated for 50 minutes in an ultrasonic bath sonicator. The black mixture was washed several times with N, N-Dimethylformamide (DMF) to remove unreacted lithium halides and further sonicated for 15 minutes to obtain yellowish green solution. In addition, WS₂ nanocrystals of different sizes have been synthesized by sonication induced fragmentation method. The structural and morphological properties of the as synthesized WS₂ nanocrystals were investigated by different spectroscopic and microscopic techniques such as TEM, AFM, RAMAN, XRD, XPS. We have observed that the photoluminescent property of the nanocrystals changes dramatically compared to the 2D flakes of WS₂. We have employed ZnO as n-type and WS₂ nanocrystals of 2-3 nm as p-type to fabricate heterojunction light emitting diode. The fabricated device shows a broad band emission from 400 to 700 nm at 0.9 mA. In addition, charge storage ability of WS₂ nanocrystals is investigated by integrating flexible solid state symmetric supercapacitor using acetylene black as a conducting filler and PVA-H₃PO₄ mixture as gel electrolyte. The fabricated supercapacitor shows 28 mF/cm² areal capacitance at a current density of 0.1 mA/cm². This result paves the way to fabricate future optoelectronic devices.

EP03.14.49
Phase Transition of T-phase WS₂ Derived by Adsorption of ORR Intermediates and Its Applications as Carbon-Free Cathode for Li-Air Batteries

Abstract:

T-phase tungsten disulfide (T-WS₂) is firstly suggested as a potential candidate for carbon-free cathode of Li-air batteries (LABs) to replace conventional carbon-based materials. Using density functional theory calculations, it was revealed that the electron transfer caused by the adsorption of oxygen reduction reaction (ORR) intermediates (i.e. Li₂O₂ and Li₂O₃) enhances the W – W clustering due to the electronic instability induced by additional charge, and it causes a phase transition to the new phases of T-WS₂ (named as DT-WS₂ and ZT-WS₂). Moreover, in terms of electrochemical performances, DT-WS₂ and ZT-WS₂ have a small discharge overpotential of 0.84 V and 0.91 V, respectively. For this reason, DT-WS₂ and ZT-WS₂ are predicted to have comparable electrochemical performance with well-known carbon-based cathodes. In addition, it is found that the adsorptions of intermediates induce the semiconductor to metal transition in DT-WS₂ and the increase of carrier concentration in ZT-WS₂, resulting in high electrochemical performance. It is therefore confirmed that DT-WS₂ and ZT-WS₂ are strong candidates as a carbon-free cathode based on two-dimensional materials for LABs.

Two-dimensional materials having a van der Waals (vdW) gap have attracted considerable attention for future electronics and optoelectronics applications because of their ultimate thickness limit. One of the most intriguing properties of standard transition metal dichalcogenides (TMDs) is that they show a direct optical transition as a monolayer, while they possess an indirect band gap in the bulk counterpart. Even though they possess interesting properties, materials exploration of TMDs is limited to the composition of MX$_2$, where M is a transition metal and X represents a chalcogen element. In this study, we propose HfGeTe$_4$ as a new ternary transition metal dichalcogenide [1]. It was reported that bulk HfGeTe$_4$ was a layered structure having a zigzag vdw gap, which is a striking difference from a standard flat vdw gap. Therefore, it is expected that such the zigzag shape allows a higher cohesive energy between layers. The total energies were calculated by a density functional theory (DFT) code CASTEP as a function of inter-layer distances, and it was found that HfGeTe$_4$ has the highest cohesive energy than other typical TMDs like MoS$_2$ or MoTe$_2$. This would enable the stronger adhesion with metal or insulator layers that has advantage for industry. The band structures were calculated for bulk and monolayer HfGeTe$_4$ using a screened exchange (sx) hybrid functional. The bulk has a band gap of about 0.67 eV and a transition occurs from the $\Gamma$ point in the valence band maximum (VBM) to the $\Gamma$ point in the conduction band minimum (CBM), indicating an indirect semiconductor. On the other hand, the direct transition is realized at the $\Gamma$ point in ML with a band gap of 1.3 eV. Furthermore, it was also found that models more than 2ML show the indirect transition, demonstrating the same trend with TMDs. The band gap decreases with increasing number of layers toward the bulk limit. Based on the current study, the materials exploration of layered chalcogenides will dramatically extend from binary to ternary systems that may lead to the discovery of novel materials for future electronics applications.

However, traditional metal precursors like halides, oxides, and thiometallates implicate several disadvantages such as low solubility and volatility and the function modulation of BP. The heterojunction. Optoelectronic experiments on Esaki diode and Esaki diodes (peak to value current ratio ~ 4.4), backward-rectifying diodes and non-rectifying devices as a consequence of band-structure alignment at the heterojunction. Based on the findings, we have chosen BP/ReS2; van der Waals heterostructures due to following reasons: (i) In addition to opposite polarity of majority charge carriers i.e. p-type BP and n-type ReS2; BP/ReS2 forms type-II broken-gap alignment at the heterojunction and (ii) BP flakes show substantial dependence of work function on their respective thickness. In the Phosphorene (BP)/Rhenium disulfide (ReS2) heterojunction, we exploit BP work function tunability with varying flake thickness to demonstrate that BP-based broken-gap heterojunction could display diverse current-transport such as gate tunable rectifying p-n junction diodes (current rectification ~ 10^6), Esaki diodes (peak to value current ratio ~ 4.4), backward-rectifying diodes and non-rectifying devices as a consequence of band-structure alignment at the heterojunction. Optoelectronic experiments on BP diode and p-n junction diode clearly reveal that diversity of current-transport derives from the work function modulation of BP. The p'-n-p junction made of thick-BP/ReS2/thin-BP functions as multi-value inverters, and shows the behavior of bipolar junction transistor (BJT) with common-emitter current gain up to 50. Such tunability could be beneficial in the development of compact electronic circuits with devices of multifunctionality reducing the need of multiple materials. Current-transport tunability due to ΦBP modulation and p'-'n-p BJT with high gain, which benefits from the high hole-mobility of BP, demonstrates the high potential for a new class of scalable and multifunctional devices.

Tunable Current-Transport in Phosphorene Based Broken-Gap Heterojunction

At the few-atom-thick limit, transition metal dichalcogenides (TMDs) exhibit a host of attractive electronic, optical, and mechanical properties [1]. The possibility to pattern these properties may have a great impact on applied [2] and fundamental research [3]. In this work, we report on the effects of ionic hydrogen irradiation in multi-layer (number of layers greater than 10) TMDs. We found that production and accumulation of molecular hydrogen just one or few monolayers beneath the flake top surface are induced by proton irradiation. Molecular H2 therein produced coalesces to form bubbles, which lead to the localized swelling of prevalently one X-M-X plane. This results eventually in the formation of spherical domes on the basal plane of bulk WS2, WSe2, WTe2, MoS2, MoSe2, flakes. The domes contain highly-pressurized hydrogen (at around 10 atm), are prevalently one monolayer thin and are robust against aging and mechanical stress. Due to their single-layer peel, they emit light efficiently, also well above room temperature, display circular dichroism and feature second harmonic generation signal. The TMD membrane, which forms the domes, is subjected to both in-plane high biaxial-tensile strain (up to ~5% at the summit of the dome) and out-of-plane uniaxial compressive strain (up to about -1.6% at the summit of the dome). Finite-element calculations show that both tensile and compressive strains vary over the dome surface. More precisely, the absolute values of all the strain components decrease moving from the center to the edge of the domes. These results enable the unprecedented observation on a single dome of a direct-to-indirect band gap transition, due to the crossing of the Γ-K (indirect) and K-K (direct) optical transitions, as already predicted by theoretical calculations [4]. Furthermore, by means of electron-beam lithographic processing, all these features can be made spatially scalable [5]. Indeed, the domes can be produced with the desired density, well-ordered positions and size tunable from the nanometer to the micrometer scale, thus providing a template for the manageable and durable mechanical and electronic restructuring of two-dimensional materials.

An Efficient Approach to Atomic-Scaled 2D Chalcogenide Based Materials from a New Class of Single-Source Precursors

Heterometallic structures containing metal 4+ ions are interesting molecules for the creation of (multi)functional 2D materials such as high quality graphene-like 2D MX2 (M = transition metal, X= S, Se) structures, given their unique physical properties for optical, optoelectronic and electronic devices. However, traditional metal precursors like halides, oxides, and thionometallates implicate several disadvantages such as low solubility and volatility and the use of hazardous reactants such as H2S. Therefore, in this study, a novel class of [M4+(SE(N(Me)ESi)] single-source precursors was designed for a variety of tetravalent transition metal including tungsten(V), molybdenum(V), titanium(IV) and vanadium(IV). These complexes were formed by simple synthetic protocols and characterized by a combination of spectroscopic techniques, single crystal x-ray analysis and TG-DTA experiments. For instance, the controlled decomposition of the well-characterized [W(Se(N(Me)ESi]) complex during chemical vapor deposition (CVD) experiments resulted in the formation of highly crystalline 2D layered WS2 thin films without the necessity for further purification steps. As-prepared films were subjected to atomic scale imaging and x-ray analysis to confirm the synthesis of phase-pure MX2 materials. Dianionic, tridentate chelating pincer type XN2-ligands (X= S, Se) have thus opened up a new field of precursor engineering and allow an efficient approach towards the synthesis of scalable van der Waals heterostructured materials such as 2D transition metal dichalcogenides that are expected to play an important role for future energy applications.
Developing cost-effective high-performance catalysts for the hydrogen evolution reaction (HER) stands as a key issue for the utilization of hydrogen as a major energy carrier. While Pt may provide the best HER catalysis performance, it is too expensive and rare to be useful for massive production of hydrogen.

Here I will show our work on engineering two-dimensional transition metal chalcogenide materials to have even better HER catalysis performance than Pt. This includes the discovery of new fundamental understanding on the HER catalysis and optimization of numerous aspects of the catalysts. We rationally design the composition and structure as well as the materials following the guidance of the new understanding, and eventually develop HER catalysts with better than that of Pt.

Tailoring Material Properties of Nanostructured WS\textsubscript{2} During Plasma-Enhanced Atomic Layer Deposition for Enhanced Electrochemical Performance
Shashank Balasubramaniam\textsuperscript{1}, Longfei Wu\textsuperscript{2}, Vincent Vandalon\textsuperscript{1}, Marcel Verheijen\textsuperscript{1,3}, Wilhelmus (Erwin) Kessels\textsuperscript{1}, Jan Philipp Hofmann\textsuperscript{1} and Ageeth A. Bol\textsuperscript{1}; \textsuperscript{1}Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; \textsuperscript{2}Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, Netherlands; \textsuperscript{3}Phillips Innovation Laboratories, Eindhoven, Netherlands.

Non-noble metal catalysts such as transition metal dichalcogenides (TMDs) are being studied as alternatives to Pt for sustainable production of \textit{H}_2 through the electrochemical hydrogen evolution reaction (HER). Layered TMDs like WS\textsubscript{2} are promising candidates for HER catalysts when engineered into nanostructures with exposed reactive edge sites. In this work, we demonstrate a novel and highly reproducible approach based on plasma-enhanced atomic layer deposition (PEALD) to maximize the density of such reactive edge sites.

PEALD is a cyclic deposition technique based on sequential use of self-limiting precursor and plasma-activated co-reactant steps. Controlling the various parameters during the plasma exposure step of PEALD allows tailoring of material properties (morphology, composition etc.) which can significantly influence the HER performance. Sub-nanometer thickness control and low processing temperatures are some of the other key merits of PEALD.

In our work, two types of nanostructured WS\textsubscript{2} with distinct material properties were synthesized at a low temperature of 300 °C by using two different plasmas as co-reactant during PEALD. Transmission electron microscopy (TEM) studies revealed that the application of a H\textsubscript{2}S+Ar plasma resulted in the growth of WS\textsubscript{2} ‘nanosheets’ while the addition of H\textsubscript{2} to the plasma i.e. H\textsubscript{2}S+H\textsubscript{2} resulted in the growth of WS\textsubscript{2} ‘fins’, for the same tungsten precursor. The WS\textsubscript{2} nanosheets comprised of closely packed sheets with their edges predominantly terminating on the top surface, while the WS\textsubscript{2} fins comprised of high surface area open structures that tapered out on the top surface. Rutherford backscattering spectroscopy (RBS) studies indicated excess S content for the WS\textsubscript{2} nanosheets with a S:W ratio of 2.2, while a S deficiency was observed for the WS\textsubscript{2} fins with a S:W ratio of 1.9. Moreover, in line with TEM studies, X-ray diffraction (XRD) studies showed differences in preferential orientation of the crystals for WS\textsubscript{2} nanosheets and WS\textsubscript{2} fins.

The HER performance of WS\textsubscript{2} nanosheets was significantly better than of WS\textsubscript{2} fins when comparing the overpotential required to reach a current density of 10 mA/cm\textsuperscript{2}. A relatively lower overpotential of ~390 mV was sufficient for the nanosheets while a significantly higher overpotential of ~460 mV was required for the fins. In line with the HER results, copper underpotential depositions on the respective nanostructures revealed a higher number (3x) of reactive edge sites for the WS\textsubscript{2} nanosheets when compared with the WS\textsubscript{2} fins. To further enhance the HER performance, the catalytically superior WS\textsubscript{2} nanosheets were grown on top of the high surface-area WS\textsubscript{2} fins. This WS\textsubscript{2} layered stack (nanosheets on fins) showcased the best HER performance in our work (overpotential of ~365 mV). To summarize, we demonstrate how PEALD can be used as a new approach to nanoeengineer and enhance the HER performance of WS\textsubscript{2} by maximizing the density of reactive edge sites at low processing temperature (300 °C).

High-Throughput Identification and Characterization of Two-Dimensional Materials Using Density Functional Theory
Karnal Choudhary; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

We introduce a simple criterion to identify two-dimensional (2D) materials based on the comparison between experimental lattice constants and lattice constants mainly obtained from Materials-Project (MP) density functional theory (DFT) calculation repository. Specifically, if the relative difference between the two lattice constants for a specific material is greater than or equal to 5%, we predict them to be good candidates for 2D materials. We have predicted at least 1356 such 2D materials. In addition to structural and energetics, we compute electronic bandstructures with/without spin-orbit coupling, optoelectronic properties, dimension dependent elastic properties, topological invariant properties, thermolectric and phonon properties. The data is publicly available at the website http://www.ctems.nist.gov/~knc6/JVASP.html.

Revealing Strain-Induced Effects in Ultrathin Heterostructures at the Nanoscale
Ghazi Sarwat Syed and Harish Bhaskaran; University of Oxford, Oxfordshire, United Kingdom.

Atomic thick two-dimensional materials are being increasingly studied, particularly for flexible and wearable technologies because of their inherent thickness and flexibility. One aspect where our understanding is still limited is on the effect of mechanical strain, not on individual sheets of materials, but when stacked together as heterostructures in devices. In this talk, I will demonstrate the use of Kelvin probe microscopy in capturing the influence of uniaxial tensile strain on the band-structures of graphene and WS\textsubscript{2} (mono- and multilayered) based heterostructures at high resolution: a major advance in strain characterization tools through enabling a single-shot capture of strain defined changes in a heterogeneous system at the nanoscale, overcoming the limitations (materials, resolution, and substrate effects) of existing techniques such as optical spectroscopy. I will show that the strain-enhanced charge transfer with the substrate plays a dominant role, causing the heterostructures to behave differently from two-dimensional materials in their isolated forms.

**EP03.14.62**
Spectroscopic Appearance of Topological Nature in Two Weyl Semimetals
Chun-Liang Lin\textsuperscript{1}, Ryuichi Arafune\textsuperscript{1}, Emi Minamitani\textsuperscript{1}, Maki Kawai\textsuperscript{1} and Noriaki Takagi\textsuperscript{2}; \textsuperscript{1}Department of Electrophysics, National Chiao Tung University, Hsinchu, Taiwan; \textsuperscript{2}MANA, National Institute for Materials Science, Tsukuba, Japan; \textsuperscript{1}Department of Materials Engineering, The University of Tokyo, Tokyo, Japan; \textsuperscript{2}Institute for Molecular Science, Okazaki, Japan; \textsuperscript{1}Graduate School of Human and Environmental Studies, Kyoto University, Kyoto, Japan.

Topology in abstract mathematics has revolutionized our conventional understanding of solid state physics, resulting in the emergence of exotic quantum phases such as topological insulators (TIs). Recently the realization of the Weyl semimetals (WSMs) leads us to uncover the topological properties of materials beyond TIs. WSMs have gathered a deal of great attention because the quasiparticles in WSMs behave as Weyl fermions, massless chiral fermions long sought in particle physics. WSMs are classified into two types, Type I and II, according to the topology of the Weyl point, where the electron and hole pockets touch each other. In our experiment, the electronic structures of two transition metal dichalcogenides (TMD) type-II WSMs were studied
by quasiparticle interference with scanning tunneling microscopy (STM). The results have shown the evidence that both Td phase Tungsten Ditelluride (WTe2) and Molybdenum Ditelluride (MoTe2) are type-II WSM, agreeing with the prior theoretical predictions. Also, the difference in the topological nature (i.e. the positions of the Weyl points and the Fermi arc surface states) between two type-II Weyl semimetals is clearly revealed.

Preparation of Oxygen-Enriched Silicon-Oxy-Carboide/Carbon (O-SiOxCy/C) Lamellas via Carbothermal Conversion of 2D Siloxene Sheets and Their Use as a High-Performance Electrode for Supercapacitors Parthiban Pazhamalai, Karthikeyan Krishnamoorthy, Surjit Sahoo, Vimal Kumar Marippan and Sang-Jae Kim; Nano Materials and System Lab., Department of Mechatronics Engineering, Jeju National University, Jeju, Korea (the Republic of).

The development of silicon (Si) based electrode materials for supercapacitors (SCs) are rapidly increasing in recent years due to ease of tailoring the energy/power metrics of the SCs via controlling the nanostructures and their composition. Herein, we have demonstrated a novel carbothermal reaction route for the preparation of oxygen-enriched silicon-oxy-carboide/carbon (O-SiOxCy/C) lamellas (using 2D siloxene sheets and alginate as Si-O and C source). Physico-chemical characterizations such as X-ray photoelectron spectroscopy, Fourier-transformed infra-red spectroscopy, and laser Raman analysis revealed the formation of O-SiOxCy/C powders via carbothermal reaction. The high-resolution transmission electron micrographs and elemental mapping analysis revealed the formation of lamella-like structures with homogenously distributed of Si, O and C atoms in the O-SiOxCy/C lamellas. The fabricated SiOxCy/C-based symmetric supercapacitors (SSCs) using 1 M TEABF4 electrolyte operates over a wide potential window (3.0 V), delivered a high specific device capacitance (16.71 F g−1), and holds high energy density (20.89 Wh Kg−1), high power density (15,000 W Kg−1), low-equivalent series resistance (compared to other O-SiOxCy/C based SSCs) with excellent cyclic stability and superior rate capability. Further the experimental results demonstrating a novel preparation method involving the carbothermal transformation of 2D siloxene sheets into O-SiOxCy/C lamella and their excellent supercapacitive properties which will create new-horizons on the development of next-generation supercapacitor devices.

ACKNOWLEDGMENTS: This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (2016R1A2B2013831 and 2018R1A4A1025998).

Resonant Bonding Driven Giant Phonon Anharmonicity and Low Thermal Conductivity of Phosphorene Guangzhao Qin and Ming Hu; University of South Carolina, COLUMBIA, South Carolina, United States.

Two-dimensional (2D) phosphorene, which possesses fascinating physical and chemical properties distinctively different from other 2D materials, calls for fundamental understanding of thermal transport properties for its rapidly growing applications in nano-/opto-electronics and thermoelectrics. However, even the basic phonon property, for example, the exact value of the lattice thermal conductivity (κ) of phosphorene reported in literature, can differ unacceptably by one order of magnitude. More importantly, the fundamental physics underlying its unique properties such as strong phonon anharmonicity and unusual anisotropy remains largely unknown. In this paper, based on the analysis of electronic structure and lattice dynamics from first-principles, we report that the giant phonon anharmonicity in phosphorene is associated with the soft transverse optical (TO) phonon modes and arises from the long-ranged interactions driven by the orbital gated resonant bonding. We also provide a microscopic picture connecting the anisotropic and low κ of phosphorene to the giant directional phonon anharmonicity and long-ranged interactions, which are further traced back to the asymmetric resonant orbital occupations of electrons and characteristics of the hing-like structure. The unambiguously low κ of phosphorene obtained consistently by three independent ab initio methods confirms the phonon anharmonicity to the large extent and is expected to end the confusing huge deviations in previous studies. This work further pinpoints the necessity of including van der Waals interactions to accurately describe the interatomic interactions in phosphorene. To the best of our knowledge, it is for the first time proposed in 2D material that resonant bonding leads to low thermal conductivity, despite that it was originally found in 3D thermoelectric and phase change materials. Our study offers new insights into phonon transport from the view of orbital states, which would be of great significance to the design of emerging phosphorene based nano-devices.

EP03.14.65
Anomalously Temperature-Dependent Thermal Conductivity of Monolayer GaN with Large Deviations from the Traditional 1/T Law Guangzhao Qin and Ming Hu; University of South Carolina, COLUMBIA, South Carolina, United States.

Efficient heat dissipation, which is featured by high thermal conductivity, is one of the crucial issues for the reliability and stability of nanodevices. However, due to the generally fast 1/T decrease of thermal conductivity with temperature increase, the efficiency of heat dissipation quickly drops down at an elevated temperature caused by the increase of work load in electronic devices. To this end, pursuing semiconductor materials that possess large thermal conductivity at high temperature, i.e., slower decrease of thermal conductivity with temperature increase than the traditional 1/T relation, is extremely important to the development of disruptive nanoelectronics. Recently, monolayer gallium nitride (GaN) with a planar honeycomb structure emerges as a promising new two-dimensional material with great potential for applications in nano- and optoelectronics. Here, we report that, despite the commonly established 1/T relation of thermal conductivity in plenty of materials, monolayer GaN exhibits anomalous behavior that the thermal conductivity almost decreases linearly over a wide temperature range above 300 K, deviating largely from the traditional κ ∼ 1/T law. The thermal conductivity at high temperature is much larger than the expected thermal conductivity that follows the general κ ∼ 1/T trend, which would be beneficial for applications of monolayer GaN in nano- and optoelectronics in terms of efficient heat dissipation. We perform detailed analysis on the mechanisms underlying the anomalously temperature-dependent thermal conductivity of monolayer GaN in the framework of Boltzmann transport theory and further get insight from the view of electronic structure. Beyond that, we also propose two required conditions for materials that would exhibit similar anomalous temperature dependence of thermal conductivity: large difference in atom mass (huge phonon band gap) and electronegativity (LO-TO splitting due to strong polarization of bond). Our study offers fundamental understanding of phonon transport in monolayer GaN, and the insight gained from this study is of great significance for the design and search of materials superior for applications in nano- and optoelectronics in terms of high-performance thermal management.

Strain Engineering Valleytronic Materials to Preserve State Coherence Nina Leclere1,2, Jonah Haber1,2 and Jeffrey B. Neaton1,3; 1Cornell University, Ithaca, New York, United States; 2Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Department of Physics, University of California, Berkeley, California, United States.

Recent developments in valleytronic devices demonstrate that exceptional 2D transition metal dichalcogenides (TMDs) possess degenerate energy levels at
Density functional theory (DFT) is employed to compute the electronic structure of the 2D MoS2 material as the system evolves with strain. In synthesis over large-areas, as well as its electronic tunability, which is possible through intercalation of atomic species such as H, O, F, and Li to the widespread adoption of these materials in opto-electronic, catalytic, and device studies. However, methods offering explicit control over the Natalia Drichko, David H. Gracias, Mingwei Chen and Thomas J. Kempa; Johns Hopkins University, Baltimore, Maryland, United States.

The emergence of 2D materials has led to increased attention on correlating the structural, optical, and optoelectronic properties of atomically thin transition metal chalcogenides like MoS2. We demonstrate the tunability of the photoluminescence (PL) properties of bulk MoS2 via implantation of Nb ions. Raman spectroscopy is used to confirm the p-type doping. The PL intensity of MoS2 is drastically enhanced by the adsorption of p-type dopants. X-ray photoelectron spectroscopy (XPS) is used to study the change of MoS2 structure after annealing in oxygen. We also demonstrate a stronger PL enhancement through defect engineering and oxygen bonding realized by oxygen anneal. Our results provide a new route for modulating the optical properties of two-dimensional semiconductors. The strong and stable PL from defects sites of MoS2 may have promising applications in optoelectronic devices.

SESSION EP03.15: Novel Heterostructure Devices—Fabrication and Properties
Session Chairs: Feng Miao and Xiaofeng Qian
Friday Morning, November 30, 2018 Hynes, Level 2, Room 210

8:00 AM EP03.15.01
Low Dimensional Material Hybrid Structure for Optoelectronics Application Hyun-Soo Ra, A-Young Lee, Dohyun Kwak, Min-Hye Jeong and Jong-Soo Lee; Energy Science and Engineering, DGIST, Dalsunggun, Korea (the Republic of).

The low dimensional materials (0D-2D) are candidate to optoelectronics application with high performance. It has unique functionality, such as mechanically flexible characteristic and transparency, for new paradigm functional device research. Among the low dimensional materials, TMDCs family and black phosphorus among 2D materials have advantages of best charge mobility and good absorption properties, also. Recently, 2D stack n-p heterojunction and lateral p-n homo-junction for photovoltaic device application was emerging research field. Additionally, 0D materials have that of best luminescence and absorption properties due to especially high volume to surface ratio, but poor electrical properties due to the long organic ligand chain to prevent quantum confinement effect from coupling with around quantum dots.

Here, we introduce each 2D-0D materials hybrid structure with ligand engineering and device with mix advantage of each low dimensional materials. Through phototransistor measurement, we demonstrated overwhelm responsivity (A/W) of >10^5 A/W and Detectivity (J) of >10^10. Based on the results, we proved mechanism of charge transfer and photo-doping (n-type and p-type) effect in hybrid system. Also, we introduce structure of 2D-2D p-n hetero-junction and 2D p-n lateral homo-junction for photovoltaic application. In the case of 2D-2D heterojunction, the solar cell characteristic is dominated. In the other case, diode-like phototransistor as the new paradigm device is introduced.

8:15 AM EP03.15.02
Dimension and Morphology Control in Transition Metal Dichalcogenide Crystals Through Prescribed Substrate Interactions Tomojit Chowdhury, Natalia Drichko, David H. Gracias, Mingwei Chen and Thomas J. Kempa; Johns Hopkins University, Baltimore, Maryland, United States.

Chemical vapor transport is an extensively used method for synthesis of bulk and 2D transition metal dichalcogenides (TMD) and it has fueled the widespread adoption of these materials in opto-electronic, catalytic, and device studies. However, methods offering explicit control over the dimensionality, morphology, and crystalline phase of TMDs are rare. In this work, we demonstrate that prescribed substrate interactions can control the dimensionality and morphology of MoS2 crystals from the nano- to micron-scale. Si substrates bearing phosphide moieties were prepared in a high vacuum chemical vapor deposition reactor. MoS2 synthesis was carried out on these substrates using standard protocols. At low surface phosphide concentrations, 2D MoS2 crystals exhibit periodic serrated edges. At high surface phosphide concentrations, MoS2 crystals form high aspect ratio (~200 nm wide and 10 µm long) quasi-1D filaments. Detailed kinetic studies and surface energy calculations indicate that the chemical nature of the underlying Si–phosphide substrate surface is instrumental in transforming growth of MoS2 from conventional 2D triangular to quasi-1D crystal morphologies. A significant blue shift of the photoluminescence of these quasi-1D TMDs is observed at room temperature and ambient pressure. These new materials underscore the importance of rational synthesis in elaborating materials with unique and prescribed properties.

8:30 AM EP03.15.03
Two-Dimensional Monoelemental Materials via Confinement Hetroepitaxy Natalie Briggs1, 2, Brian M. Bersh1, Ana De La Fuente Duran1, 2, Yuanxi Wang2, Angping Li2, Carolina Navarro2 and Joshua Robinson1, 2; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2D Crystal Consortium Materials Innovation Platform, University Park, Pennsylvania, United States; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Epitaxial graphene grown on silicon carbide has played a key role in the field of 2-dimensional materials research to date, owing in part to its relative ease of synthesis over large-areas, as well as its electronic tunability, which is possible through intercalation of atomic species such as H, O, F, and Li to the
epitaxial graphene (EG)/silicon carbide interface. But while the primary focus of EG intercalation studies has historically been the controlled doping of EG layers, resulting intercalant layers alone are also of great interest, due to potential for phenomena such as superconductivity in the ultra-thin, ordered, intercalant layers. Here we discuss the realization of atomically-thin materials in EG/SiC systems through an intercalation-based process termed confinement heteroepitaxy.

To realize graphene/intercalant/SiC heterostructures via confinement heteroepitaxy (CHet), synthesized EG layers are first plasma treated. Plasma treatments serve to increase defect density in the layers, which can promote the process of intercalation. Following this treatment, samples of plasma-treated EG/SiC are placed over elemental or compound precursors and heated in an argon atmosphere in a tube furnace from 600-1100°C. Cross-sectional transmission electron microscopy (STEM) allows for direct imaging of the graphene/intercalant/SiC heterostructures. Additionally, x-ray photoelectron spectroscopy indicates a change in the carbon bonding environment of the EG/SiC following the CHet, suggesting the presence of intercalant layers at the EG/SiC interface.

To-date, gallium, indium, and tin have each been realized at the EG/SiC interface via CHet, where STEM shows predominant formation tri-layer gallium, bi-layer indium, and mono- to bi-layer tin between SiC and EG. The observed thicknesses are consistent first principles calculations of structural energetics performed for a range of chemical potentials. First-principles calculations also indicate covalency between SiC and the first intercalant layer of Ga, and decreasing covalency between each subsequent Ga layers. Further investigation of graphene/Ga/SiC structures has shown a superconducting gap at roughly 2.9K via scanning tunneling microscopy. Transport measurements of the structures have suggested superconducting gaps at higher temperatures, which could be due to differing phases or chemistries of the Ga intercalant. Ongoing work aims to investigate possible superconductivity in intercalated In and Sn, as well as the impact of plasma chemistry and intercalation temperature on superconducting Tc.

Controlled Synthesis of In-Plane Few-Layer 2H-1T′ MoTe2 Junctions for High-Performance 2D Electronics Youngdong Yoo1, Zachary P. DeGregorio1, Yang Su1, Steven J. Koester2 and James E. Johns3; 1Ajou University, Suwon, Korea (the Republic of), 2University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) have attracted much attention due to their emergent electronic and optical properties. Formation of in-plane junctions of the 2D TMDs could build in new functionalities that are practically useful, leading to new applications such as high-performance electronics and flexible optoelectronics. Here we report on the fabrication of in-plane 2H-1T′ MoTe2 junctions by flux-controlled phase-engineering of few-layer MoTe2 from Mo nanoislands. By changing Te atomic flux, we control the phase of few-layer MoTe2. Few-layer 2H MoTe2 is obtained with high Te flux, while few-layer 1T′ MoTe2 is formed with low Te flux. With medium flux, we synthesize few-layer in-plane 2H-1T′ MoTe2 junctions. As-synthesized MoTe2 is characterized by Raman spectroscopy and X-ray photoelectron spectroscopy. Kelvin probe force microscopy and Raman mapping confirm that in-plane 2H-1T′ MoTe2 junctions possess abrupt interfaces between 2H and 1T′ MoTe2 domains. In addition, we fabricate few-layer 2H-1T′ MoTe2 patterns using the phase-selective synthetic strategy. Our flux-controlled phase engineering method could be utilized for the large-scale controlled fabrication of 2D metal-semiconductor junctions for high-performance 2D electronics.

Atomic Reconstruction at van der Waals Interface in Twisted 2D Materials Philip Kim; Harvard University, Cambridge, Massachusetts, United States.

Control of the interlayer twist in the vdW interface has been widely used to engineer an artificial 2-dimensional (2D) electronic systems by the formation of a moiré superlattice. Many exotic physical phenomena occur associated with the incommensurability of the moiré superstructures; the fractal energy spectrum of Hofstadter butterfly and recently discovered Mott insulating and unconventional superconducting behavior of the ‘magic’ twist angle bilayer graphene have demonstrated the wealth of the nontrivial topology of electronic band structures. However, the atomic scale microstructures and electronic structures of vdW interfaces have been understood in the frame of rigid rotational moiré structures without atomic scale relaxation. In this presentation, we will discuss the engineered atomic scale reconstruction at twisted vdW interface. We find that the vdW interaction energy that favors interlayer commensurability competes against the intralayer elastic lattice distortion to form a quasi-periodic domain structure, inducing profound changes in electronic structure. Particularly, we show quantitative analysis of the engineered atomic-scale reconstruction completely controlled by the twist angle between two graphene layers and anomalous electron transport occurring in the network of topologically protected propagation modes along the domain boundaries. Interfaces between vdW materials are a crucial material platform for realization of novel quantum electronics. Our discoveries of atomic scale reconstruction at vdW interfaces will provide a new route to engineer the 2D materials for exceptional functionalities.

10:30 AM EP03.15.07

Transition metal dichalcogenides (TMDs) have attracted immense attention in recent times owing to their unique structure and layer dependent properties and have shown great promises in the field of electronics, optoelectronics and energy conversion.1-2 Heterostructures of TMDs have emerged as a
fascinating platform to explore both fundamental and device applications. However, controlled synthesis of layered 2D heterostructures still remains a challenge. Here we report a novel approach towards the synthesis of WO3/WSe2 heterostructures through electrophoretic deposition (EPD) onto a conducting substrate. A large area uniform coating on to a conducting substrate can be obtained using EPD with minimal restriction on the shape and size of the substrate. We found that these heterostructures can provide electrocatalytic sites with superior electrochemical activity towards Hydrogen Evolution Reaction (HER). We attribute this exceptional catalytic activity to various parameters such as (i) higher electronic conductivity, (ii) higher proton diffusion coefficient of tungsten partial oxides, (iii) induced defects in the lattice during EPD and also to (iv) the hydrogen spill over mechanism exhibited by the hybrid catalyst. These factors synergistically contribute in achieving enhanced catalytic activity for HER. The deposited heterostructure offers a high exchange current density of 75.85 µA cm⁻², lower onset potential of 83 mV and very low Tafel slope of 47 mV decade⁻¹, which makes it a highly promising candidate for electrocatalytic HER.

Synthesis of 2D Metal Carbides and Nitrides (MXenes) and Their Applications Babak Anasori, Kathleen A. Maleski, Patrick Urbankowski, Christine B. Hatter, Tyler Mathis, Kanit Hantanasirisakul, Arianna S. Levitt and Yury Gogotsi; Department of MSE and A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States.

MXenes are a large family of 2D transition metal carbides and nitrides, such as Ti₃C₂, Ti₃C₂Tₓ, NbC, TaC, Mo₂C, Mo₃Ticl₂, and W₁₃C. A MXene single flake can be composed of 2, 3, or 4 atomic layers, each layer built of a transition metal interleaved with layers of carbon or nitrogen, with a total flake thickness of ~1 nm. Additionally, significant control over physical and electrochemical properties can be achieved with the possibility of having more than two transition metals in the in-plane and out-of-plane ordered forms. Because of the wet etching synthesis methods, all of the MXenes reported to date have surface functionalities, such as hydroxyl, fluorine, and oxygen, which add hydrophilicity to their surfaces. Free-standing films of MXenes, made from their colloidal solutions, have a high metallic conductivity (e.g., 10,000 S/cm for Ti₃C₂ films), enabling their use in a diverse set of applications. In this talk, an overview of conditions used to synthesize MXenes from their bulk precursors and delaminate to single-layer flakes will be presented. In addition, MXene flake assembly into transparent as well as thick films, fibers, composites, and devices and their energy storage, sensor, and catalysis applications will be discussed. At the end, a general summary and outlook for the future research on 2D MXenes will also be presented.

Controlled Electron Beam Induced Doping in van der Waals Heterostructures Wu Shi¹,², Salman Kahrn³, Lili Jiang³, Sheng-yu Wang⁴, Hsin-Zon Tsai¹, Dillon Wong⁴,⁵, Takashi Taniguchi⁶, Kenji Watanabe⁶, Feng Wang⁴,², Michael Crommie¹,² and Alex Zettl¹,²; ¹Lawrence Berkeley National Laboratory, Berkeley, California, United States; ©Department of Physics, UC Berkeley, Berkeley, California, United States; ³Princeton University, Princeton, New Jersey, United States; ²National Institute for Materials Science, Tsukuba, Japan.

Spatial control of charge density in electronic devices is an essential tool to explore exotic physics and enable new device applications. Traditionally, this has been achieved using conventional lithographic techniques that define gated regions or the use of molecular self-assembles on surfaces to spatially modulate charge transfer. These techniques suffer problems such as limited spatial re-writability and lack of feasible topological designs due to technical limitations of the developing process. Recent work has demonstrated an alternative way to induce nanoscale rewritable doping patterns in vdW heterostructures without introducing impurities by optical illumination or applying an STM tip voltage pulse. In this work we further develop this simple but efficient local patterning technique by utilizing electron beam induced doping. With this new doping scheme, we realize precise tunability of carrier density as well as patterning of doping profiles with nanoscale spatial resolution while preserving the high quality of the vdW heterostructure device. Our results demonstrate distinct advantages over conventional local gates, making it an ideal approach to study a variety of superlattice physics in van der Waals heterostructures and to create on-demand circuits for device applications.

11:30 AM EP03.15.10
Low-Temperature Epitaxy of SnS on MoS₂ for 2D-2D p-n Junctions Jack N. Olding, Alex Henning, Michael J. Moody, Jason Dong, Emily Weiss and Lincoln J. Lauhon; Northwestern University, Evanston, Illinois, United States.

The stability of two-dimensional (2D) materials down to the monolayer limit, and the weak van der Waals bonding between monolayers, enables fabrication of heterostructures beyond the constraints of conventional heteroepitaxy. Though many novel heterostructures have been created by mechanical exfoliation and stacking, the ability to directly grow 2D chalcogenide heterostructures over large areas would create new opportunities for large-scale integration. Here, p-type tin sulfide (SnS) is grown on n-type molybdenum disulfide (MoS₂) in an atomic layer deposition (ALD) reactor at low temperatures (180 °C) to form vertical p-n 2D-2D heterojunctions. X-ray diffraction (XRD) and electron backscatter diffraction (EBSD) establish an axiotaxial relationship between the two crystals, with two preferred orientations rotated about the [001] axis normal to the (001) planes. The influence of precursor dose and purge times on lateral and vertical growth rates suggests that the growth is not strictly self-limiting, and is best described as pulsed chemical vapor deposition (CVD). Substrate preparations including annealing and exposure to a plasma indicate that rapid and reproducible nucleation is promoted by defects while preserving axiotaxial alignment. Kelvin probe force microscopy was used to establish a built-in potential as high as 0.9 eV, which is significantly larger than those previously measured in transition metal dichalcogenide heterojunctions (~0.2 eV). The photoresponse of heterojunctions was probed by photoconductive atomic force microscopy to further explore the potential for photodetection and photovoltic applications. This demonstration of direct growth at low temperatures is greatly enabling for fabrication (e.g. selected area growth of heterostructures using patterned resists) and characterization (e.g. fundamental studies of thickness dependent photophysics and device performance).

11:45 AM EP03.15.11

Two-dimensional (2D) materials have attracted tremendous attention since the advance of graphene. The field now has extended far beyond graphene with new exfoliation of the 2D family such as h-BN, transition metal dichalcogenides (TMDs), black phosphorus, etc. Assemblies of 2D materials into van der Waals heterostructures further exhibit many interesting properties in both fundamental research and practical applications. Herein, we report monolayer metal-organic frameworks (MOFs) as new 2D building blocks that can be assembled into van der Waals heterostructures with other 2D materials such as TMDS while at the same time maintain the versatility of MOFs. We develop a synthetic route based on liquid-liquid interface chemistry to produce several types of monolayer MOFs with high quality over an inch-scale. The growth mechanism has been characterized and studied through in situ optical measurements. The potentials of 2D MOFs are first demonstrated by generating van der Waals heterostructures with monolayer MoS₂ (ML-MoS₂) grown by metal-organic vapor deposition (MOVD). The resulting heterostructures can be laser patterned to selectively remove the 2D MOFs. Moreover, the 2D
MOFs and TMDs are assembled into vertical superlattices with controlled d-spacing and composition via a layer-by-layer vacuum stacking technique. The employment of versatile monolayer MOFs enables the incorporation of functional molecular moieties into two-dimensional electronic circuits. As a proof-of-concept device, we successfully demonstrate a photo-switchable tunneling junction by attaching photo-responsive ligands onto MOF layers in a MOF/MoS₂ heterostructure. These materials show promising applications in multifunctional 2D electronic devices.

The controlled growth of the conducting and semiconducting two-dimensional (2D) materials beyond graphene, represented by the transition metal dichalcogenides (TMDs), as well as the topological insulator Bi₂Se₃, is the necessary path towards the realization of their application prospects. The control of the thickness, in other word, the layer number of the 2D materials is one of the most important criteria, as their properties vary significantly with respect to the layer numbers. Ideally, the scheme of van der Waals epitaxy determines that the bottom-up synthesis of the 2D compounds should follow a layer-by-layer scenario, as strain does not accumulate in the direction normal to the layers, thanks to the van der Waals gap between the layers. However, in reality, layer-by-layer growth is rarely completely achieved. Multilayer growth still dominates the experimental observation in the laboratories. In addition, an island morphology is often observed, which strongly indicates a "wrong" stacking sequence in contrast to the more stable structure of mineral crystals. In this work, we developed multiscale simulation tools to investigate the morphology of island growth driven by combinations of screw dislocations, in order to shed light on the identification of the cause of such multilayer growth. With the phase-field model, we are able to reproduce all the spiral growth patterns previously reported in the experimental literature, and identify the morphology of the underneath driving defects, which cannot be easily revealed by experiments. More importantly, we discovered a type of defect that caused uncontrolled multilayer growth via a pair of screw dislocations, but the resulting domain showed no spiral lines, with the aforementioned "wrong" stacking sequence. This type of defect consists of a pair of opposite screw dislocations, which constitute a short step edge. The screw dislocations can be embedded in the substrate. They can also be generated within the film during epitaxy. The in-film step edges are generated from a linear accumulation of metal vacancies, via a lift-up mechanism due to the imbalanced growth rate of the adjacent edges. This mechanism was experimentally confirmed by us in the molecular beam epitaxy of Bi₂Se₃. In an atomistic perspective, we used first-principles calculation to show why this mechanism is likely to happen in the layered chalcogenides. We show that the lift-up mechanism is initiated by the dimerization of chalcogen elements, therefore it is expected to be transferable to other layered chalcogenides beyond the TMDs. Based on the mechanistic analysis, we are able to provide guidance for a better layer number control: targeted to avoid the growth scheme, experimental parameters should be tuned to prevent the generation of the initial defects. This work was supported by ASCENT, one of six centers in JUMP, a Semiconductor Research Corporation program sponsored by DARPA.

2:00 PM EP03.16.03 Exploring and Understanding Quantum Nonlinear Optical Effect in 2D Materials Hua Wang and Xiaofeng Qian; Texas A&M University, College Station, Texas, United States.

Recent experiments demonstrated that 2D materials not only exhibit strong linear excitonic behavior upon photoexcitation, but also have strong nonlinear optical (NLO) responses. The latter could be useful for many technologically important applications. Here we will present our first-principles theoretical development and understandings of giant NLO responses in a number of 2D materials including group IV monochalcogenides and transition metal dichalcogenides, and demonstrate that 2D materials provide perfect solid-state platform for exploring nonlinear nanooptics. We will also present very recent work on other 2D NLO properties and discuss the relationship between the NLO responses and topological nature. Our present findings open up new avenues for ultrathin nonlinear optoelectronics. References: 1) Giant Optical Second Harmonic Generation in Two-Dimensional Multiferroics. 2:15 PM EP03.16.04 Controlled Growth Mechanism of Bilayer TMD Homo- and Hetero-Structures—A Multiscale Simulation Approach Kamalika Ghatak and Dibakar Datta; New Jersey Institute of Technology, Newark, New Jersey, United States.

After the discovery of Graphene in 2004, the research based on possible findings of other 2D structures are at peak due to the absence of band gap in
Among the new generation 2D materials, TMDs are one of the rising stars due to its wide variety of electrical and mechanical properties in between the semiconductor and metal. Moreover, the bilayers of 2D materials are receiving more limelight due to its unique properties such as layer-dependent tunable optoelectronic and mechanical behavior. These bilayers are attached to each other by weak van der Waals force and the control over the experimental growth technique is required in order to synthesize desired stacked products. Among several existing growth techniques, epitaxial growth mechanism is the most preferred one due to its technological advantages such as reduction of defect density (e.g., tilt grain boundaries), consistency in the overall growth, final products with sharper interfaces. Computational analysis involving Density Functional Theory (DFT) and Molecular Dynamics (MD) simulation is necessary to gain deeper insight into the post-growth analysis. We, therefore, considered different bilayers such as, WS2-WS2, WS2-MoS2, MoS2-MoS2, and MoS2–Graphene and compared their properties (electronic and physical). We considered both the chalcogen and metal terminated edge as the initial TMD structure to grow and we have also considered the length effect and the orientation effect of the second layer towards the formation energy of the overall structure. We find that the growth temperature plays a crucial role in governing the growth mechanism. The difference of formation energies of different TMD leads to the reaction rate difference and the growth temperature of TMD layers. For example, we find that formation energies of MoS2 and WS2 are 2.48 and 2.70 eV respectively and hence growth temperature of the WS2 (~ 800-1050) are higher than MoS2 (~ 600-850). At the controlled growth temperature, for chalcogen termination, one-step growth mechanism is preferable where the second layer starts from the center (core) and grows outwards (edge). On the contrary, for the metal terminated edge, two-step growth is preferred where the second layer starts from the edge and grows inwards (core). Our results conclude that the evolution of various TMD homo/hetero-structures originates from the competition between the adsorption, desorption, and the diffusion of metal (Mo, W) and chalcogen (S, Se) atoms under various growth temperatures. Our computational work provides a more in-depth understanding and guidelines of design and fabrication of TMD heterostructures.

2:30 PM EP03.16.05
The Kinetics of Two-Dimensional Materials’ Growth Feng Ding1,2; 1Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 2Center for Multidimensional Carbon Materials, Institute for Basic Science, Ulsan, Korea (the Republic of).

After the discovery of graphene, research of two-dimensional (2D) materials attracted great attention. Until now, there are hundreds of 2D materials have been discovered and predicted but only very few of them, such as graphene, h-BN and MoS2, could be synthesized in large area and high quality. To achieve the industrial synthesis of various 2D materials in large area and high quality, understanding the kinetics of their growth is of crucial importance. In compare with the 3D crystals, 2D materials own their unique properties, such as the ultra-high flexibility and the strong edge-substrate interaction. Our research team has used various theoretical approaches, such as ab initio calculation, molecular dynamic (MD) simulation, kinetic Monte Carlo (KMC) simulation and phase field theory (PFT) simulation, to explore the kinetics of 2D materials' growth. Our studies have revealed a few key characteristics of 2D materials growth: (i) the growth and etching of an edge of a 2D material is reversible and the rate of the growth or etching is determined by the structure of the edge and a one-dimensional (1D) nucleation process; (ii) The shape of a 2D materials during growth or etching is determined by its symmetry, the interaction with the substrate and can be precisely described by the kinetic Wulff construction; (iii) By considering the structures of various edges of a 2D materials, our theoretical calculation can precisely predict the environment dependent edge structure and the shape evolution during a 2D material’s growth and etching. Our theoretical study has revealed that the key element of synthesizing 2D materials in large area and high quality is the selection of proper substrate.

2:45 PM EP03.16.06
Kinetics of Structural Phase Changes in Two-Dimensional MoS2; Aditi Krishnapriyan1, Qian Yang1, Yao Zhou2, Ekin D. Cubuk2 and Evan J. Reed1; 1Stanford University, Cupertino, California, United States; 2Google Brain, Mountain View, California, United States.

Predictive capabilities for kinetic processes in materials are in their infancy, but kinetics are critical for a spectrum of energy applications ranging from phase change materials, catalysis, materials synthesis, and combustion. The structural phase transition between the metallic 1T or 1T' and semiconducting 2H structures in two-dimensional transition metal dichalcogenide materials is important to understand for synthesis and may provide exciting new opportunities for energy-efficient electronic and optical devices. However, very little is known about the mechanisms and kinetics of these phase changes or how to engineer the kinetics. We propose a novel electronic structure based method to determine the nucleation kinetics and timescales of this phase change. Furthermore, we discuss the curious fact that the interface energies between phases for this challenging problem are mathematically ill-defined. We also point to strategies on the engineering of kinetics in these phase change materials that take into account nucleation barriers and nucleation time.

3:00 PM BREAK

SESSION EP03.17: Infrared and Thermal Properties of 2D Materials
Session Chair: Rui He
Friday Afternoon, November 30, 2018
Hynes, Level 2, Room 210

3:30 PM EP03.17.01

Achieving ultra-low thermal conductivity in solid-state materials is a grand challenge in nanotechnology, with applications in thermoelectric energy conversion and phase change memory. While a large majority of the best thermal insulators have low densities, there is a need to engineer materials that have excellent heat insulation properties while still being dense and mechanically stable. Van der Waals (vdW) materials offer a unique opportunity to achieve this goal, as heat conduction in the cross-plane direction is impeded by weak phonon transmittance at the interfaces. To do this, it is important to first understand the various factors that govern thermal transport at 2D material interfaces. This includes examining the role of phonon mismatch, which determines how the thermal boundary resistance (TBR) at “mismatched” interfaces between different 2D layers compares to that at “matched” interfaces between similar 2D layers. Furthermore, it is crucial to investigate the impact of interlayer coupling on phonon transmission and TBR at vdW interfaces.

To address these questions, here we study thermal transport in multilayer graphene/MoS2 (G/M) heterostructures. These samples are assembled layer-by-layer starting from large-area synthesized monolayers of each material using a residue-free transfer process [1,2]. We measure the cross-plane thermal resistance across various stacks of these layers (for example, G, G/G, G/M/G, G/M/M/G, and so on, sandwiched between Al metal and SiO2) using time-domain thermoreflectance (TDTR), an ultrafast optical pump-probe technique. Using a novel scanning approach, we produce quantitative maps of thermal resistance, connecting local variations in TBR with the underlying 2D-layer stacking sequence. The measured stack thermal resistance increases from ~10
to ~100 m²KGW⁻¹ as the number of inserted 2D layers is increased from 0 (direct Al to SiO₂ contact) to 4 (G/M/M/G stack). Importantly, we find that the thermal resistance at mismatched G/M interfaces is significantly higher than the matched G/G and M/M interfaces, pointing towards the important role of phonon mode overlap. In addition, we show that the strength of interlayer coupling has a strong influence on the cross-plane thermal resistance, which we tune via high-temperature vacuum annealing and monitoring using photoluminescence and Raman spectroscopy. Overall, our results show that heterogeneous stacking of atomically-thin layers has the potential to create “synthetic” solids with effective thermal conductivities falling below ~0.1 Wm⁻¹K⁻¹, approaching some of the lowest measured to date for dense solids.

Layer-by-Layer Temperature Probing Across 2D van der Waals Heterostructures
Sam Vaziri¹, Eilam Yalon¹, Miguel Muñoz Rojo¹, Saurabh V. Suryavanshi¹, Connor McClellan¹, Connor S. Bailey¹, Alex J. Gabourse¹, Victoria Chen², Sanchit Deshmukh¹, Kirby K. Smith¹ and Eric Pop¹,²,³
¹Electrical Engineering, Stanford University, Stanford, California, United States; ²Material Science and Engineering, Stanford University, Stanford, California, United States; ³Precourt Institute for Energy, Stanford University, Stanford, California, United States.

Van der Waals (vdW) heterostructures obtained by stacking different two-dimensional (2D) materials are known to exhibit tunable electronic and photonic properties [1]. However, their thermal properties have been relatively unexplored, whether such vdW interfaces could be tuned for thermoelectric applications [2] or could pose heat dissipation bottlenecks for 2D electronics [3]. In this work, we investigate cross-plane heat transport in layered vdW heterostructures by probing the temperature of individual 2D monolayers. We combine Raman thermometry and scanning thermal microscopy (SThM) to achieve monolayer cross-plane and ~50 nm in-plane temperature measurement resolution. vdW heterostructures are fabricated with a novel transfer process, achieving polycrystalline-free interfaces. The heterostructures consist of monolayers of MoS₂ and/or WSe₂ with graphene (Gr) on top as a transparent heater, all on SiO₂ substrates. We heat the graphene top layer electrically and probe the temperature of each 2D material in the heterostructure by its unique Raman signal. By measuring the temperature of each layer in the vdW stack, we can extract the thermal boundary conductance (TBCs) of all interfaces. As a result, we report here for the first time the TBCs at 2D/2D monolayer interfaces including Gr/WSe₂, Gr/MoS₂ and MoS₂/WSe₂ with values of 5±3 MWm⁻²K⁻¹, 11±3 MWm⁻²K⁻¹ and 9±3 MWm⁻²K⁻¹, respectively. However, measured 2D/3D interfaces exhibit somewhat higher TBCs of 15±4 MWm⁻²K⁻¹, 22±4 MWm⁻²K⁻¹ and 27±5 MWm⁻²K⁻¹ for WSe₂/SiO₂, MoS₂/SiO₂, and Gr/SiO₂, respectively. These interfaces correspond to an equivalent Kapitza thermal resistance ranging from 30 nm of SiO₂ (Gr/WSe₂ interface, lowest) to 200 nm of SiO₂ (Gr/WSe₂ interface, highest). The measured interface TBC trends can be explained by Landauer’s formalism, as a product of phonon density states overlap (modes) and area-mass mismatch (transmission) of the two materials forming the interface. These results are essential for understanding and tuning heat dissipation in 2D materials and their applications. In addition, the material-specific Raman thermometry measurement provides unprecedented (i.e. single-layer) temperature resolution, in the atomic scale limit.

Stacking-Dependent Interlayer Phonon Modes in 3R- and 2H-MoS₂
Eui He¹, Jeremiah van Baren², Gaihua Ye¹, Zhipeng Ye¹, Pouyan Rezaie¹ and Chun Hung Lui¹,²
¹Texas Tech University, Lubbock, Texas, United States; ²University of California, Riverside, Riverside, California, United States.

MoS₂ exhibits several stacking orders (polymorphs) with considerably different properties. The common 2H stacking order displays non-centrosymmetric crystalline structure for odd layer numbers, but centrosymmetry for even layer numbers. In contrast, 3R-MoS₂ is non-centrosymmetric for all layer numbers, and thus retains those properties that require a lack of inversion symmetry, such as the valley-selective optical rules. There is strong incentive to fully understand 2D materials of different stacking orders, as it may open the door to novel material and device applications. We study the interlayer phonon modes of the 3R- and 2H-MoS₂ polypeptides by ultralow-frequency Raman spectroscopy. In the spectral range of 5-60 cm⁻¹, we observe the Raman features of interlayer phonon modes, including the interlayer shear (S) and breathing (B) modes, which correspond to the lateral and vertical displacement of the atomic layers, respectively. The most intensive B modes have similar layer-thickness dependence for both 3R- and 2H-MoS₂. However, the most intensive S modes display opposite layer-dependent behavior for the two polytypes. Our experimental results are consistent with the predictions based on the linear chain model. In particular, the highest-intensity B mode corresponds to the lowest-band vibration for both polytypes, but the highest-intensity S mode corresponds to the lowest- and highest-frequency branches for 3R and 2H polytypes, respectively. Our results reveal a close relationship between the crystal structure and the Raman activity of interlayer modes in 2D materials, and provide insight into the materials’ optical and vibrational properties.

Artificially Stacked van der Waals Heterostructures for Enhancing and Broadening Resonant Second Harmonic Generation
Chinh Tam Le¹, Yong Soo Kim¹ and Joon Jung²
¹Physics, University of Ulsan, Ulsan, Korea (the Republic of); ²Physics, Sogang University, Seoul, Korea (the Republic of).

Noncentrosymmetric transitional metal dichalcogenides (TMDs) and their vertical heterostructures (HSs) provide an ideal platform for studying atomic-scale nonlinear optics, especially second harmonic generation (SHG). TMD monolayers with different bandgaps can be artificially stacked not only to enhance the SHG efficiency but also to broaden the spectral range for the excitation resonance. We produced well-aligned homo-bilayer, hetero-bilayer, and hetero-trilayer structures, comprised of monolayers of MoS₂ and its alloy MoS₂-Se₂(1-x), and studied their broadband SHG properties. Photoluminescence analysis on all the vertically stacked HSs showed clear A- and B-excitonic transitions from each constituent layer, thereby confirming the excellent optical quality of the HSs. Especially, wavelength-dependent SHG measurements on the hetero-trilayer yielded strong SHG response over the spectral range of 550 nm to 780 nm. Our proof-of-concept study indicates that the spectral range for efficient SHG can be engineered by controlling the Se concentration in the MoS₂-Se₂(1-x) layers in the well-aligned HS systems, tuning the spin-orbit-split A- and B-excitons as well as the bandgap of each constituting layer. The strengthening and widening effects of SHG are interpreted as the superposition of resonant SHG across the A- and B-exciton levels from the constituent layers. Our results demonstrate the feasibility of artificial strong second-order nonlinear optical materials working over a broad spectral range by combining MoS₂ with different MoS₂-Se₂(1-x) alloys.

Exciton-Phonon Interaction and Upconversion Spectroscopy in Monolayer MoS₂
Shivangi Shree¹, Bo Han¹, Marco Manca¹, Emmanuel Courtade¹, Cedric Robert¹, Thierry Amand¹, Xavier Marie¹, Takashi Tanguichi², Kenji Watanabe², Marina Semina³, Leonid Golub³, Mikhail Glazov³ and Bernhard...
Transition metal dichalcogenides (TMDs) are ideal for exploring fundamental physics and applied optics as they are semiconductors with a direct bandgap in the monolayer (ML) limit. Encapsulation in hexagonal BN results in narrow optical emission linewidth, which allows investigating crucial details of the exciton spectra.

First, in MoSe2 MLs reduced emission linewidth at T=4K of about 1.5 meV enables us to observe unusual high-energy tails in absorption and emission for the neutral A-exciton. We show experimentally and theoretically that the exciton-acoustic phonon interaction in MoSe2 MLs is responsible for the asymmetric lineshape at the high-energy side both in emission and absorption [1]. We develop an analytical theory using the deformation potential due to longitudinal acoustic phonons that explains the origin of the observed asymmetric broadening. We show that this interaction in ML TMDs is much stronger compared to III – V nano-structures. The strong exciton-phonon interaction also results in prominent resonant Raman features in the photoluminescence (PL) excitation experiments.

Second, we show that resonant excitation of the neutral A-exciton transition results in emission of the B-exciton 200 meV above the excitation laser energy. When generated efficiently through resonant excitation, exciton densities become high enough for exciton scattering to occur, which can lead to the disappearance (annihilation) of one exciton as the second exciton absorbs its energy and occupies a high-energy state (upconversion).

In this work we show experimentally and theoretically that these Auger-type exciton-exciton interactions are qualitatively different in TMD MLs as compared to conventional semiconductors. In our theory we go beyond the usual analysis of the four-body interaction (2 electrons, 2 holes) within a two-band approach (conduction and valence band) and show that due to the particular conduction band energy spacing and strong exciton binding energy in MoSe2 but also MoS2, WSe2, and MoTe2 monolayers exciton upconversion is an efficient, resonant process [2].

Circularly polarized light (CPL) exhibits enantioselective interaction with chiral molecules, providing a pathway toward all-optical chiral resolution. Compared to existing chemical schemes like chiral chromatography, this all-optical approach could be rapid, economical, and readily adaptable to a wide variety of chiral molecules. CPL alone has been shown to achieve enantiomeric excesses only up to 2% while maintaining yield higher than 40%; however, high index dielectric nanoparticles can increase separation efficiencies. Such nanoparticles support both electric and magnetic Mie resonances, which locally increase the electromagnetic density of chirality, C, as well as the rate of differential absorption between enantiomers, g. Here, we investigate Si metasurfaces for all-optical chiral resolution. We consider a metasurface consisting of nanoscale cylinders and optimize C and g by varying the cylinder aspect ratio. First, using finite-difference time domain simulations, we simulate a square array of Si cylinders that are 100 nm high with a lattice parameter of 1000 nm. As we vary the radius of the disk from 170 to 360 nm, the electric dipolar mode redshifts relative to the magnetic mode, providing the opportunity to independently tune the phase of the electric and magnetic dipoles. Accordingly, we can achieve both electric and magnetic field enhancement as well as perfectly circular near-fields (a phase lag of π/2 between electric and magnetic field), the ideal condition for enantioselective light absorption. Using this method, we demonstrate that a disk with radius 280 nm gives a 4-fold average enhancement in enantioselective absorption (g) at λ = 1550 ± 50 nm. The enhancement occurs over the entire cylindrical surface and local enhancements up to 11x in g and 130x in C are also observed. Using the molecule camphor as an example, we show how this enhancement can give rise to 20% separation efficiencies with 40% yield over a large volume region. Moving to experiment, we fabricate metasurfaces using electron-beam lithography and disperse the chiral molecule helicene-diketopyrrolopyrrole in the near-field. This molecule shows strong, circularly dependent absorption at 592 nm and photoluminescence at 610 nm. We show how photoluminescence of this molecule tracks with our calculated enhancements in g. Our results pave the way for full chiral resolution based on absorption dependent photionization or photolysis.

8:45 AM EP04.01.03 Enhanced Directional Emission of Incoherent Radiation from All-Dielectric Vogel Spiral Arrays Sean Gorski1, Ran Zhang1, Abdullk Gok1, Alan Lene2, Madis Raukas1 and Luca Dal Negro1, 2; 1 Electrical and Computer Engineering, Boston University, Boston, Massachusetts, United States; 2 CTO Materials, OSRAM Opto Semiconductors, Beverly, Massachusetts, United States; 3 Materials Science and Engineering, Boston University, Boston, Massachusetts, United States.

The development of scattering arrays of dielectric nanoparticles that can efficiently and directionally extract partially coherent radiation from high refractive index active materials poses significant challenges to traditional photonic approaches. In particular, the directional extraction of incoherent Lambertian radiation from dielectric interfaces, which is important to emerging lighting device applications, has not been systematically addressed so far. In our talk we experimentally address this relevant technological and scientific problem under realistic testing conditions by systematically studying directional emission enhancement from aperiodic arrays of dielectric nanorods atop light emitting LED materials. We prepared luminous materials with their surfaces functionalized by using transparent oxide nanorods arranged in the isotropically scattering golden angle Vogel spiral geometry and experimentally quantified the enhanced light extraction and directionality via Fourier-space photoluminescence imaging and microscopy. A variety of patterns were fabricated with varying nanopillar diameter and mean particle separations. The samples were excited with a 405 nm pump laser and directional emission was experimentally demonstrated comparing Fourier-space images of patterned and unpatterned regions of the samples. A total extraction enhancement of up to x2 times can be obtained with an angular directionality of ±30°. Our data have been compared with both numerical (FDTD) and analytical modeling of kinematic light scattering for incoherent radiation. Finally, based on our efficient analytical model we will also discuss general engineering design rules that enable directional extraction and enhancement using aperiodic scattering arrays with isotropic scattering.

9:00 AM EP04.01.04 All-Dielectric Materials Integration for Planar-Lens-Based Optical Beam Steering Josue J. Lopez1, Scott Skirlo1, Dave Khara2, Jamison Sloan1, Samuel Kim1, Sarur Baramhavar2, Jeffrey Herd3, Paul Juodvalkis3, Marin Soljacic1 and Cheryl Sorace-Agaskar1; 1 Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2 Lincoln Laboratory, Lexington, Massachusetts, United States.

Light Detection and Ranging (LIDAR) has attracted significant interest for autonomous navigation, imaging, and sensing. In particular, there is demand for compact, non-mechanically steered components with low size, weight, and power consumption requirements. Current leading LIDAR solutions use one-dimensional (1D) or two-dimensional (2D) phased-array antennas to steer a coherent beam bi-directionally. Interestingly, the RF Radar literature contains lens-based beam steering solutions (e.g. Rotman lenses) that overcome major challenges found in phased arrays. Their photonic analogs have not yet been investigated and are a viable solution for optical beam steering. Herein, we demonstrate the first planar-lens-based beam steering device that functions at λ = 1550 ± 50 nm and is fabricated with all-dielectric materials. The planar lens is fabricated with 25 nm of amorphous silicon on top of 195 nm of silicon nitride that allows for the design of a lens with a wide view in-plane of the lens. A grating made with the same dielectric stack allows for out-of-plane coupling in the far-field. We demonstrate this 2D beam steering through theory, simulations, and experimentally fabricated photonic components. The total angular range of this lens-based approach is an azimuthal range of φ = 41.0° and polar range of θ = 12.0°. In addition, we suggest new lens of-plane coupling in the far-field. We demonstrate this 2D beam steering through theory, simulations, and experimentally fabricated photonic components. A variety of patterns were fabricated with varying nanopillar diameter and mean particle separations. The samples were excited with a 405 nm pump laser and directional emission was experimentally demonstrated comparing Fourier-space images of patterned and unpatterned regions of the samples. A total extraction enhancement of up to x2 times can be obtained with an angular directionality of ±30°. Our data have been compared with both numerical (FDTD) and analytical modeling of kinematic light scattering for incoherent radiation. Finally, based on our efficient analytical model we will also discuss general engineering design rules that enable directional extraction and enhancement using aperiodic scattering arrays with isotropic scattering.

9:15 AM EP04.01.05 Digital Metasurfaces with Graphene Humeyra Caglayan, Mohsin Habib and Alireza Rashed; Tampere University of Technology, Tampere, Finland.

We have investigated graphene-gold metasurfaces to enhance light-graphene interaction in the MIR region and additionally, we demonstrate a new class of electrically controlled digital metadevices. In the first part, we will experimentally demonstrate that it is possible to increase and tune the optical transmission response of a graphene-based device substantially by applying less gate voltage compared to the back-gating methods via ionic liquid gating and nanoplasmonic antennas in the same device. Designing and utilizing V-shaped plasmonic structures enabled us to increase the interaction between the graphene layer and the incident field in the mid-infrared wavelengths. In this work, we have decided to use V-shaped plasmonic antennas. Among many candidates of plasmonic structures, V-shaped plasmonic nanoantennas have also proven useful in many applications including energy localization in nanosystems, unidirectional side scattering, and even sub-wavelength scale devices that can create abrupt phase changes and allows complete beam shaping. By using an ionic gating scheme, we are able to induce high electric fields near graphene to efficiently tune graphene’s Fermi level and control its carrier concentration, therefore shifting the transmission response of nanoantennas and the response of the device. In the second part, we will focus on the effect of the graphene supercapacitor. Graphene supercapacitor has been studied by different research groups for promising capacitor properties. In this work, we focused on its tuning effect. To understand the effect of the separation between graphene capacitor and metamaterial arrays on the performance of our metadevice, we measured near-field transmission spectrum in the forward direction at various separation values while sweeping the bias voltage between ±1.5 V. The fabricated active metadevices enable efficient control of both amplitude (< 50 dB) and phase (> 90°) of electromagnetic waves. In this hybrid system, graphene operates as a tunable Drude metal that controls the radiation of the passive metamaterials.
Furthermore, by integrating individually addressable arrays of meta-devices, we demonstrate a new class of spatially varying digital metasurfaces where the local dielectric constant can be reconfigured with applied bias voltages.

9:30 AM EP04.01.06
Active Infrared Niobium and Aluminum Oxide Plasmonic Metasurfaces Richard M. Osgood1, Lalitha Parameswaran2, Mordechai Rothschild2, Alkim Akyurtlu1, Yassine Air-El-Aoual1, Michael Okamoto1, Steven Koor1, Jimmy Xu1, Sergey Dichur1, Do-Joong Lee4 and Jin Ho Kim1; 1.U.S. Army NSRDEC, Natick, Massachusetts, United States; 2/MIT Lincoln Laboratory, Lexington, Massachusetts, United States; University of Massachusetts Lowell, Lowell, Massachusetts, United States; 3Division of Engineering Physics, Brown University, Providence, Rhode Island, United States; 4MIT ISN, Cambridge, Massachusetts, United States.

Rectification of GHz signals by diodes coupled to a surface of light-intensifying antennas has demonstrated optical-to-electrical (d.e.) power conversion efficiencies near 80%, an impressive achievement potentially useful for direct power beaming to charge batteries. In the infrared (IR) and visible, rectification occurs via quantum tunneling and/or hot-electron transport coupled to optically rectifying antennas, but IR rectennas are very challenging to investigate. Novel device concepts, including new metasurfaces, materials, and nanofabrication, must be employed. Because rectennas have absorption tuned by metamaterial dimensions, instead of by a band gap, they capable of light-harvesting and detecting broadband IR.

We designed microantenna arrays, consisting of plasmonic stripes that produce metamaterial and plasmonic resonances with near-perfect absorption [2], with teeth that induce a net asymmetric electric field driving electrons into the ground plane. The microrectenna is formed by these field-intensifying teeth and a vertical Metal-Insulator-Metal (MIM) diode (the metal-NbOx-Nb). The barrier layer NbOx, with thicknesses 5 – 30 nm, was ALD-deposited on Nb. Au stripes and symmetry-breaking stripe-teeth arrays were patterned atop the NbOx/Nb base layer with Ti and other adhesion layers. Ti adhesion layers did not provide sufficient asymmetry for rectifying diodes. Pt without an adhesion layer resulted in significantly asymmetric I-V curves as reported earlier [3], but required advanced patterning techniques since features are very small (hundreds of nm) and standard litho techniques don’t work well without good adhesion layers. We explore both front-side physical etching and forming the microrectenna arrays upside down on a Si handle wafer. In the latter case, IR illumination would pass through the wafer, shifting resonances such as the stripe arrays, making data analysis more challenging and requiring multiple excitation wavelengths. Nevertheless, we obtained good agreement between calculated and observed antenna resonances, large MIM diode asymmetry well-described by our advanced model of MIM diode conduction and rectification [4]. The short-wave IR reflectivity, polarized along the teeth, exhibits multiple peaks, whose positions depend on the separation between the teeth. Au stripes were also fabricated directly on the substrate using unique, "single-shot" electron-beam patterning. We also analyze Al/AlOx/Au microrectenna arrays and compare the resulting I-V curves under laser illumination with simulations. We compare the NbOx-based diodes, coupled to the Pt microantenna array, under SWIR illumination with the model, and predict the rectified signal, measured using a lock-in amplifier.

9:45 AM EP04.01.07
Amplitude and Phase Modulation of Femtosecond Pulses Using Silicon Metasurfaces Wenqi Zhu1,2, Shawn Divitt1,2, Cheng Zhang1,2, Henri Leze1 and Amit Agrawal1,2; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2University of Maryland, College Park, Maryland, United States.

Ultrafast optical science and technology depend on optical pulse shaping, which compliments pulse generation and characterization methods. Example applications for pulse shaping include pulse compression, dispersion compensation for fiber optic communications, coherent laser control of quantum mechanical processes, and spectrally selective nonlinear microscopy. Fourier-transform pulse shaping has emerged as the most successful and widely adopted technique, in which shaping is achieved by parallel modulation of spatially separated frequencies without requiring an ultrafast modulator. Here, we offer the first experimental demonstration of femtosecond pulse shaping using a centimeter-scale silicon metasurface acting as both amplitude and phase modulation mask. The deep-subwavelength silicon nanostructures, positioned with nanometer precision, provide accurate amplitude and phase modulations to each frequency component. Masks of this type offer a lower cost, larger size, higher resolution, high diffraction efficiency, high damage threshold method for controlling ultrafast pulses.

The experimental implementation is based on a Fourier-transform pulse shaping apparatus. A femtosecond optical pulse from a Ti:Sapphire oscillator covering the spectral range from 725 nm to 925 nm is angularly dispersed by the first grating and then focused by an off-axis parabolic mirror. A dielectric metasurface mask positioned at its focal plane can introduce amplitude and phase modulation to each spectral component. Our metasurface masks are composed of an array of polycrystalline silicon pillars resting on a fused-silica substrate. The rectangular pillars that form the metasurface are placed in a two-dimensional array. Each column of pillars along the y-axis introduces a designed phase to a narrow spectral range around a target wavelength. The cross-section of each pillar is chosen via an optimization algorithm to achieve the designed spectral phase shift while maintaining a large transmittance. The pillars provide a phase depth of 2π radians such that phase wrapping is necessary to impart the given phase function. As an example, we design a metasurface which imparts a pure quadratic phase (as a function of frequency). This design would generate enough dispersion to stretch a pulse from 15 fs to 40 fs. The measured spectral phase, group delay, and pulse shape applied by a representative, fabricated device match well with expected values. We have also achieved independent amplitude (through polarization) and phase shaping, as well as dynamic control, using metasurfaces.

In summary, we have designed, fabricated and tested an optical pulse shaper that uses a metasurface for spectral and amplitude phase modulation. The high precision with which metasurfaces can control polarization, amplitude, and phase point toward new, previously unrealizable applications in optical pulse shaping.

10:30 AM EP04.01.08
Hybridization of Localised Surface Phonon Polaritons via Symmetry Breaking in Dolmen Nanostructures Swathi Iyer G.R.1, Chase T. Ellis1, Alexander J. Giles1, Dmitry N. Chigrin2, Michael Meeker1, Joshua D. Caldwell4 and Joseph Tischler1; 1Naval Research Laboratory, Washington, District of Columbia, United States; 2Institute of Physics (IA), RWTH , Aachen, Germany; 3CNST NanoFab, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 4Mechanical Engineering , Vanderbilt University, Nashville, Tennessee, United States.

Phonon-mediated subdiffractional confinement of light, combined with low optical losses has made polar-dielectrics such as SiC attractive for Infrared (IR) nanophotonic applications. By utilizing a nano-dolmen architecture, we experimentally and theoretically demonstrate hybridization between localized,
Indium Tin Oxide (ITO) has been demonstrated to have a tunable ENZ condition in near-infrared spectral range. Using co-deposited RF magnetron functionality for a broad range of IR-based applications including surface enhanced sensing and detection; thermal imaging and nanophotonic circuitry.

Current OLED displays rely on a circularly polarised (CP) filter to enhance contrast by trapping ambient light inside the display. However, this means that 50% of the randomly polarised light emitted from each OLED pixel never leaves the screen, halving display efficiency and operational lifetime. One way to overcome this is to create CP light emitting OLEDs (CP-OLEDs). A potential route to fabricate such devices is to induce chirality in a normally achiral electroluminescent polymer by blending it with a chiral small molecule. Our approach uses polyfluorene copolymers blended with an intrinsically chiral helicene dopant, which allows for CP-dependent applications while retaining much of the performance properties of the original polymer. Previously circularly polarised polymer emission has been achieved via thick cholesteric stacks of liquid crystalline polymers, where linearly polarised light becomes circularly polarised. To date, people have focused on the high film thickness regime to investigate the cholesteric stacking inside the active layer and the properties of the liquid crystal structure. Here, for the first time, we show that it is possible via film thickness to control the competitive effect between cholesteric packing and local chiral emission, the latter originating from an induced asymmetry in the polymer electronic and magnetic transition dipole moments. Remarkably, we observe handedness inversion in a system containing only one sign of chiral dopant. We compare how the chemical structure of the non-chiral polymer and post-deposition thermal processing impacts the chiroptical response of the resulting thin films and OLED devices in an effort to provide a set of design rules for future high-performance CP-OLEDs. We demonstrate a liquid-crystalline light emitting polymer with a record high induced circular dichroism. The circularly polarised photoluminescence and electroluminescence both show thickness-dependent CP emission and handedness inversion. In our system, the energy level alignment between dopant and host polymer ensures no charge trapping effects. As a result, the CP-OLED shows minimal change in the device performance compared to the original undoped OLED in terms of turn-on voltage and brightness. This provides new design rules for creating efficient circularly polarised light emitting diodes with high brightness and a high electroluminescent dissymmetry.

Photonic Band Structure Engineering in Strongly Absorbing Materials for Narrow-Band Optoelectronics. Arlene Chiu, Botong Qui, Ebuka S. Arinze, Yida Lin, Minda Wagenmaker, Andrew Rauch and Susanna M. Thon; 1Electrical and Computer Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 2Mechanical Engineering, The University of Alabama, Tuscaloosa, Alabama, United States.

Inorganic materials with finite absorption bandwidths could find uses in many optoelectronic applications such as wavelength-selective photodetection, optical imaging, target recognition, chemical detection and solar energy harvesting. They would be of particular interest for multijunction photovoltaics to facilitate current-matching between different cells, by, for example, enabling one of the cells to absorb only in the infrared while maintaining transparency in the visible regime. However, in contrast to molecular materials that exhibit finite absorption bandwidths in the ultraviolet or visible wavelength ranges, inorganic semiconductors typically strongly absorb at all energies larger than their bandgaps.

Here, we introduce a new set of materials based on photonic band structure engineering in strongly absorbing media to demonstrate inorganic semiconductors with finite absorption bandwidths. Photonic crystals (PCs), materials with periodic variations in their refractive indices, are used to manipulate light flow in a wide range of dielectric structures; however, the extent to which features such as photonic bandgaps can be supported in absorbing materials is still an open question. We studied this question in order to use PCs to artificially induce spectral transparency windows in the visible range in infrared-responsive materials.

To study the effect of absorption on photonic band structure in periodically structured materials, we used the finite-difference time-domain method to simulate the well-studied 2D GaAs slab PC structure, which consists of a triangular lattice of air pillars in a semiconductor membrane, as a test-case. We gradually increased the value of the imaginary part of the refractive index while keeping the real part of the refractive index constant in our hypothetical material to study how adding absorption affects the band structure. We quantified how, as absorption in the medium increases, the number of photonic band decreases, the magnitude of the remaining bands and contrast in the photonic bandgap diminishes. However, the band structure is partially preserved even in the high-absorption case, with the low frequency photonic bands and associated bandgaps retaining approximately 40% of their magnitude when compared to the non-absorbing case.

Experimentally, we demonstrated spectral tuning via photonic band structure engineering in a strongly absorbing infrared-responsive thin film composed of PbS colloidal quantum dots (CQDs). Using nanosphere lithography to create the PC structure, our photonic material had both twice the transmittance at 400 nm and twice the absorption at 960 nm compared to a planar CQD film. Employing photonic engineering to tune the spectral responsivity in strongly absorbing media, as demonstrated in this study, could provide a viable pathway for optoelectronic applications requiring finite absorption bandwidths.

Novel Tunable ENZ Media in the Near- to Mid-Infrared Range. Wesley Britton, Ran Zhang and Luca Dal Negro; 1Division of Materials Science and Engineering, Boston University, Brookline, Massachusetts, United States; 2Department of Electrical and Computer Engineering, Boston University, Boston, Massachusetts, United States.

Dramatic advancements in areas such as electrical modulation, signal processing, and nonlinear frequency conversion have revitalized initiatives to develop more efficient nonlinear optical materials. In response, epsilon near zero (ENZ) media have emerged as a promising novel platform for nonlinear optical enhancement. However, ENZ materials operating in the near- and mid-infrared spectral ranges rely on metallic components with narrow wavelength tunability and high extinction losses. Likewise, they may require nano-manufacturing in three dimensions, which can severely limit device implementations and increase manufacturing costs. Heavily doped semiconductors are a common alternative. In particular, the transparent conductive oxide, Indium Tin Oxide (ITO) has been demonstrated to have a tunable ENZ condition in near-infrared spectral range. Using co-deposited RF magnetron
sputtering, we have developed an alternative material to ITO thin films, Indium Silicon Oxide (ISO). Upon post-deposition annealing this thin film material is found to extend the tunable ENZ condition into the mid-infrared with lower extinction losses. Moreover, the material is fully Si compatible, and has excellent surface smoothness properties that promised ease of scalability and device nanofabrication. We perform TEM and XRD measurements in order to correlate the structural and optical properties of this new material. In addition, we measure this material’s optical bandgaps and resistivity to determine and modulate charge carrier concentration. Our work significantly diversifies and expands the reach of ENZ medium and nonlinear optical materials in the infrared spectral range.

**11:45 AM EP04.01.13**

**Engineered Epsilon-Near-Zero Optical Nonlinearity of Al-Doped Zinc Oxide Thin Films Grown by Atomic Layer Deposition**

Subhajit Bej, Sudip Gurung and Howard Lee; Baylor University, Waco, Texas, United States.

Unusually large nonlinear optical properties of conducting oxide and metallic nitride materials in their epsilon-near-zero (ENZ) region (i.e. the region where the real part of their dielectric permittivity approaches zero), have been reported recently [1-4]. Processes involving nonlinear frequency conversion can be benefited from these ENZ regions due to relaxed phase-matching criteria. Moreover, nonlinear optical processes which do not require phase-matching, such as nonlinear refraction and nonlinear absorption, can also be largely enhanced in the ENZ region. This giant enhancement can be attributed to the hot free-carrier dynamics resulting from ultrafast laser assisted heating. Since the response time of such nonlinear processes can be ~100 fs, these ENZ materials could open distinct functionalities to the path to revolutionary nanoscale nonlinear optics and ultrafast on-chip optical applications.

In this work, we report an efficient method to engineer the nonlinear refraction coefficients ($n_2$) and the nonlinear absorption coefficients ($\beta_2$) of Al-doped zinc oxide (AZO) ENZ thin films. The AZO films with ENZ wavelengths ranging between 1500-1650 nm are synthesized on fused silica substrates by the atomic layer deposition (ALD) technique [5]. The properties of the ALD AZO films such as film thicknesses and ENZ wavelengths can be precisely controlled by changing the deposition conditions (e.g., number of deposition cycles and doping level of Al). Nonlinear optical properties of the fabricated films are measured using Z-scan technique using an ultrafast laser peaked at wavelength $\lambda_p$=1550 nm. Measured $n_2$ and $\beta_2$ values of the films are evaluated upon fitting the experimental closed-aperture and open-aperture data respectively. We also observed that the nonlinear refraction and the nonlinear absorption strengths can be engineered by controlling the ZnO to Al dopant layer ratios in the deposited AZO films even if they have similar thicknesses. The tunability of the ENZ nonlinearity can be attributed to the efficient control of free-carrier densities. Also, we experimentally demonstrate enhancement of the effective nonlinear properties of the films due to excitation of ENZ modes at oblique incidence while illuminating with TM polarized light. Measured values as large as $n_2=10^{-18}$ cm/Watt and $\beta_2=10^{-9}$ cm/Watt are obtained with a 216 nm thick ALD-fabricated AZO film for TM polarized light incidence at 60°. The results of this work provide an understanding about engineering nonlinear optical properties of AZO ENZ materials for nanophotonic applications.

This work is supported in part by the YFA Program from DARPA (grant number N66001-17-1-4047).
For what applications are plasmonic materials better than all-dielectric materials, and vice versa? Or 2D materials versus their bulk counterparts? How does the requisite bandwidth affect materials selection? Known material-based fundamental limits to optical response work at one of two extremes — a single frequency, or all-frequency sum rules — with no incorporation of bandwidth and no useful quantitative measure for all-dielectric approaches. Here, we use the complex-analytic properties of certain optical-response functions in conjunction with novel energy-conservation constraints to derive fundamental limits to near-field optical response for any material, over any bandwidth. We show that certain canonical geometries can approach the bounds at specific frequencies, while at many others there is significant opportunity for structured materials to surpass them by orders of magnitude. We map out a frequency-bandwidth phase space in which we identify optimal materials among plasmonic, all-dielectric, and 2D-material candidates and we put forward a quantitative material figure of merit to stimulate new-materials discovery.

A Comparative Study of Materials for Refractory Plasmonic Applications
Peter K. Petrov1, Matthew P. Wells1, Ryan Bower1, Rebecca Kilmurray1, Bin Zou1, Andrei Mihal1, Neil Alford1, Rupert F. Oulton1, Lesley Cohen1, Stefan A. Maier1 and Anatoly Zayats2; 1Imperial College London, London, United Kingdom; 2King's College London, London, United Kingdom.

Materials such as W, TiN, and SrRuO3 (SRO) have been suggested as promising alternatives to Au and Ag in plasmonic applications owing to their refractory properties. However, investigation of the reproducibility of the optical properties after thermal cycling at high operational temperatures is so far lacking. Here, thin films of W, Mo, Ti, TiN, TiON, Ag, Au, and SrRuO3 are investigated to assess their viability for robust refractory plasmonic applications. Films ranging in thickness from 50 - 180 nm are deposited on MgO and Si substrates by RF magnetron sputtering and, in the case of SrRuO3, pulsed laser deposition, prior to characterisation by means of AFM, XRD, spectroscopic ellipsometry, and DC resistivity. Measurements are conducted before and after annealing in air at temperatures ranging from 300 - 1000°C for one hour, to establish the maximum cycling temperature and potential longevity at temperature for each material. It is found that SrRuO3 retains metallic behaviour after annealing at 800°C, however, importantly, the optical properties of TiN and TiON are degraded as a result of oxidation. Nevertheless, both TiN and TiON may be better suited than Au or SRO for high temperature applications operating under vacuum conditions.

Synthesis of Transition Metal Dichalcogenide Thin Films as Very High Refractive Index Materials for Photonics
Christopher T. Chen1, Jacopo Pedroni2, Ashley Gaulding1, Christoph Kastl1, Tevye R. Kuykendall1, Francesca Maria Toma1, Adam Schwartzberg1 and Shaul Aloni1; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Università degli Studi di Milano-Bicocca, Milano, Italy.

New materials for conventional photonic index are predicated on high refractive index contrast for enabling high performance. Fabrication of nonphotonic devices also relies on the ease of pattern formation through lithographic templating and/or etching. Layered transition metal dichalcogenides are an area of intensive focus due to their emergent properties at the monolayer limit. Bulk transition metal dichalcogenides possess very high refractive index. One convenient synthetic route for large area coverage of transition metal dichalcogenides is the deposition of transition metal oxides, e.g. MoO3 and WO3, and subsequent conversion into transition metal dichalcogenides at elevated temperatures in the presence of reactive chalcogenide species.

In this presentation, we demonstrate a scalable method for producing high refractive index WS2 layers by sulfidation of WO3 synthesized via atomic layer deposition (ALD). High index of refraction is achievable through multiple synthetic procedures. With careful control of synthesis conditions, we can produce high refractive index WS2 thin films and conformal coatings by short high temperature (800°C) or prolonged moderate temperature (650°C) annealing in hydrogen sulfide. Although this process yields highly polycrystalline films with grain sizes on the order of 10 nm or less, the optical constants are in agreement with those reported for single crystal bulk 3R-WS2. The conformal nanocrystalline thin films demonstrate a surprisingly high index of refraction (n > 3.9), and structural fidelity compatible with lithographically defined features down to ~10 nm. Subsequently, we demonstrate three photonic structures - first, a two-dimensional hole array made possible by patterning and etching an ALD WO3 thin film before conversion, second, an analogue of the 2D hole array first patterned into fused silica before conformal coating and conversion, and third, a three-dimensional inverse opal photonic crystal made by conformal coating of a self-assembled polystyrene bead template. These results can be trivially extended to other transition metal dichalcogenides, thus opening new opportunities for photonic devices based on high refractive index materials.

Heteroepitaxy of Titanium Nitride for Plasmonic Applications
Amber N. Reed1, Hadley A. Smith1, 2, Zachary J. Biegler1, 2, Rachel L. Adams1, 2, Madelyn J. Hill1, Krishnamurthy Mahalingam1, Kurt Eynk1, Brandon M. Howe1 and Augustine Urbas1; 1Air Force Research Laboratory, WPAFB, Ohio, United States; 2University of Dayton, Dayton, Ohio, United States.

High temperature stability, chemical stability, low surface energy and mechanical robustness, combined with a zero-crossover wavelength in the visible region make titanium nitride (TiN) a promising plasmonics material. In this work we demonstrate the heteroepitaxial growth of TiN on (0001)-Al2O3, (001) MgO, (001) - LiNbO3 substrates using controllably-unbalanced reactive magnetron sputtering. Additionally, we discuss the relationship between TiN crystalline quality and optical properties. Coupled x-ray diffraction (XRD) of our TiN show high quality epitaxial growth on all three substrates, however, further structural characterization reveals differences in crystal defects, strain and surface morphology based on substrate crystal structure and lattice mismatch. Pendellosung fringes on the (111)-TiN diffraction peak for the coupled XRD of TiN on c-plane sapphire and LiNbO3 indicate uniform d-spacing and a pristine interface. Pole figure XRD show 6-fold symmetry for the TiN grown on sapphire, indicating the presence of stacking faults. These domains, which are further evident in atomic force microscopy (AFM) of the TiN surface, are attributed to different stacking within the TiN domains. XRD of the TiN on MgO show Pendellosung fringes on the (001)-TiN diffraction peak. Cross-hatching features similar to those on the bare MgO substrate seen in the AFM of the TiN surface. Variable angle spectroscopic ellipsometry (VASE) shows that TiN behaves metallic on all substrates with a zero crossover wavelength between 470 nm and 490 nm. Differences in the real (ε1) and imaginary (ε2) permittivity for TiN on the different substrates are also seen in the VASE measurements. From the ellipsometry measurements we calculate aquality factor (QLSPR = - ε2/ε1) of 3.34, 3.9 and 4.2 for TiN on LiNbO3, MgO and Al2O3 respectively, for a wavelength of 1550 nm. The differences in ε1 and ε2 become more pronounced at longer wavelengths.

New Materials for Photonics Beyond Noble Metals
Marina S. Leite; University of Maryland, College Park, Maryland, United States.

Steel is an alloy primarily formed by iron, carbon, and chromium that have transformed our society. Today, it is implemented in applications spanning from building construction to surgical tools. This disruptive material results from alloying, which provides superior mechanical properties. In analogy to steel, we propose the alloying of metals (Ag, Au, Cu, Al), which can enable the development of optical materials with unprecedented permittivity values, not found in its pure counterparts. Our paradigm overcomes the limitation imposed by the pre-defined permittivity of metals [1]. We demonstrate he unique
near- and far-field optical properties of these alloys for energy harvesting devices [2], and how they are correlated with the alloys band structure [3]. Further, we show perfect absorbers using Al-Cu semiconductor with near-unity (> 99%) and omnidirectional absorption in the visible and NIR range of the spectrum, formed by a simple dual-layer thin film stack [4]. Beyond coin-age metals, we introduce the use of earth-abundant materials for the realization of devices with on-demand response, including reconfigurability and transient behavior.

Tunable Fano-Resonance Alloy Metasurfaces Hauhua Li and Ji Zhou; Tsinghua University, Beijing, China.

Fano resonances are made of asymmetry components, which are either of different sizes or various shapes. In optical range, these kinds of nanostructure have strict requirements both for the design and the fabrication of each unit cell. Here, we put forward an alloy-made metasurface, which is composed of two kind of unit cells with different ingredients. In such a case, the properties of each counterpart can be adjusted gradually by changing the ratio of the alloy, which gives us a way to shift the phase of the metasurface, inducing the shift of asymmetry.

Single Crystal and Bicrystal Metal Growth on Amorphous Insulating Substrates Jonathan Fan and Lucia Gan; Electrical Engineering, Stanford University, Palo Alto, California, United States.

Metallic structures on insulators are essential components in advanced electronic and nano-optical systems. Their electronic and optical properties are closely tied to their crystal quality, due to the strong dependence of carrier transport and band structure on defects and grain boundaries. Here we report a general method for creating patterned single crystal metal microstructures on amorphous insulating substrates, using liquid phase epitaxy. In this process, the patterned metal microstructures are encapsulated in an insulating crucible, together with a small seed of a differing material. The system is heated to temperatures above the metal melting point, followed by cooling and metal crystallization. During the heating process, the metal and seed form a high melting point solid solution, which directs epitaxial metal growth. High yield of single crystal metal with different sizes is confirmed with electron backscatter diffraction images, after removing the insulating crucible. Unexpectedly, the metal microstructures crystallize with the direction normal to the plane of the film. This platform can readily extend to the growth of bi-crystals, by specifying two seed structures at each end of the metal stripe, thereby enabling the detailed study of single grain boundaries in microscale devices. This platform technology will enable the large scale integration of high performance plasmonic and electronic nanosystems.

3D Printed Metamaterials for High-Frequency Applications Aydin Sadeqi, Hojatollah Rezaei Nejad and Sameer Sonkusale; Tufts University, Medford, Massachusetts, United States.

We present a facile, low-cost and cleanroom-free technique for the fabrication of metamaterials using computer-aided 3D printing, metal deposition and wet etching. This hybrid approach enables realization of complex 2D and 3D geometries, which require multiple steps in conventional lithography. As an example we show innovative Mushroom-type metamaterials which consist of metamaterial unit cells standing on a thin pedestal. Such metamaterials are first designed in 3D CAD software (SolidWorks) and the entire 3D structure is first printed using a stereolithography (SLA) based printer (Formlabs Incorporated, Somerville, MA, USA). The printed device is then washed with Isopropyl alcohol (IPA) and distilled water. Then the device is fully cured with Form cure (by Formlabs). We use two approaches for metal deposition of the metal resonators on the top surface of 3D printed design. In our first approach, we stamp the top surface of the mushroom-type printed device with silver paste (AG-510 Silver conductive ink, Applied Ink Solutions; Westborough, MA, USA). We measure the transmission spectrum of the device with continuous wave THz spectrometer (Topoint Photonics, Munich, Germany). Unit cells show disk geometry with 250μm and periodicity of 1mm and the height of the pedestals are 8nm. The silver sputtered metamaterial shows resonant frequency at 222GHz matching with the simulation results. In our second approach, we sputter the printed device with 100nm of gold by NSC-3000 Magnetron sputter tool. Then we use gold etchant type TFA (TRANSENE Company, Incorporated; Danvers, MA, USA) to etch away gold from the whole device except the top surface of the disk resonators. Plasma treatment was used before etching so that the gold etchant would flow easily in between the pedestals of the mushroom-type metamaterials. The gold sputtered metamaterial shows a resonant frequency in 248GHz matching with the simulation results. We also characterized variability in fabrication by measuring the surface area of disks. The variability ranges from 235μm to 270μm showing a Gaussian distribution centered at 250μm. The coated areas by stamping method show high variability in the coated surface area with similar Gaussian distribution. We also extended our fabrication method for different types of metamaterials to show its versatility. As a second design we also implemented split ring resonator (SRR) geometry in a mushroom-type structure. The transmission spectrum of SRR shows a resonant frequency at 55.8GHz matching with the simulation result. In summary, our hybrid approach combining 3D printing, metal deposition and wet etching enables low cost realization of complex 3D metamaterials with unique electromagnetic functionalities.

4:45 PM EP04.02.10

Conductive transition metal nitrides (TMNs) have recently been suggested as viable alternatives to the noble metals gold and silver for plasmonic applications. Ceramic TMNs offer increased thermal stability [1] whilst also providing broad spectral tunability and CMOS compatibility. One such material, niobium nitride (NbN), has previously been suggested as a possible candidate for plasmonic devices at visible and near ultraviolet wavelengths, despite increased electronic losses [2].

We present an experimental investigation of the growth mechanism and optical properties of reactively sputtered NbN thin films grown at a range of deposition temperatures. Thin films of NbN have been demonstrated to display tunable double epsilon-near-zero behaviour, the mechanism of which will be discussed. Furthermore, in order to assess the viability of TMNs for inclusion within future plasmonic and optoelectronic devices it is essential to understand their optical properties and thermal stability when patterned on the nanoscale. We present an investigation of the plasmonic performance of NbN nanoparticles and nanodisc arrays fabricated by colloidal lithography and e-beam lithography.
An Actively Controlled Terahertz Metamaterial Based on Digital Microfluidics

Peiyi Song1, Leimeng Sun1, Kai Luo2, Kai Zhang1, Fangjing Hu1 and Liangcheng Tu1; 1MOE Key Laboratory of Fundamental Physical Quantities Measurement, Huazhong University of Science and Technology, Wuhan, China; 2School of Electronic Information and Communications, Huazhong University of Science and Technology, Wuhan, China.

Terahertz metamaterials (MMs) have shown their powerful capabilities in manipulating THz waves. By tailoring the unit cell’s properties and optimizing their arrangements, different functionalities such as filtering, absorption, focusing, and anomalous reflection of THz waves have been achieved. In the approaching to multi-functional THz MMs, reconfiguration at the unit cell level is of important. As one type of reconfigurable MMs, digital and programmable metamaterials have been experimentally validated in the microwave range, but not yet available in the THz regime. Therefore, finding the tuning mechanism at the unit cell level to achieve at least a 180° phase difference (for 1-bit) is the key for THz digital and programmable metamaterials. Once the digital states have been realized and controlled in a programmable manner, THz digital and programmable MMs can be realized.

Digital microfluidics has been developed recently based upon the manipulation of microdroplets. The size, spacing and flowing speed of microdroplets can be precisely controlled. Microdroplets in variety of materials, such as water, oil and liquid metal, can be generated and manipulated. More importantly, digital microfluidics possesses the capability to determine the locations of microdroplet within a small region of the device. This technique gives us an idea to design a very specific microfluidics device that integrates with carefully patterned microchannels to form an array of MM unit cells for THz manipulation. Channel in each unit cell then can be actively filled or unfilled by liquid material to obtain two digital states with a 180° phase difference, representing a reconfigurable operation of a 1-bit MMs unit cell.

In this paper, the idea of creating THz digital metamaterials using digital microfluidics technologies is investigated. A reflective-type 1-bit THz digital metamaterial based on a digital microfluidic system is designed for proof-of-concept purpose. A T-junction microfluidic setup is used to generate liquid metal microdroplets “train”. Next, the microdroplets train is delivered to the THz MM area with 9×9 subarrays, where each subarray contains 3×3 unit cells. By determining the size of each droplet and the spacing between them, each subarray can be set to be filled or unfilled with liquid metal for two digital states. It is worth noting that, the patterns of microdroplets train can be quickly and precisely created and modified by adjusting the pressures over the T-junction. Numerical simulation results show a ~180° phase difference for the two digital states within a 67% bandwidth. Radar cross-section (RCS) reduction is also demonstrated by optimizing the coding sequence of the microfluidic-based THz digital MM, giving a minimum 20 dB RCS reduction in the ±45° phi cuts. Methods and materials used in fabricating the THz microfluidics chip are discussed in the last part.

Development of Graphene Combined Terahertz Metamaterials for Biomolecule-Specific Sensing

Minah Seo1, Sang-Hun Lee1, Jong-Ho Choe2 and Chulki Kim1; Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Korea University, Seoul, Korea (the Republic of).

Various optical technologies for discrimination of biochemical molecules have been actively studied and steadily developed for medical diagnosis, pharmacuetics, mutagenesis, phylogenetics, and so on. In particular, terahertz (THz) electromagnetic waves have shown substantial promise for such applications since intrinsic vibrational, rotational, inter-molecular, and intra-molecular modes of many small molecules exist at broad THz frequency regime. Despite of such availability, it has been quite limited to obtain a reasonable signal from diluted molecule samples directly, since absorption cross section of the molecule is too small at THz frequency range. To increase sensing efficiency and absorption cross section of such target molecules, various types of nano metamaterial structure based sensing platform have been introduced [1, 2, 3]. Here, we performed THz time-domain spectroscopy (THz-TDS) using nanoscale metamaterial based sensing chips for discrimination and detection of small molecules including various types of nucleotides. This enables us to detect even very small quantities of sugar molecules sensitively and even selectively. Moreover, several extremely pathogenic types of viruses were also discriminated in terms of the THz optical characteristics [4]. Finally, by combining of high quality factor of resonance structure and suspended graphene mono layer can provide unprecedentedly increased sensitivity in sensing of such small biomolecules even with enormous size ratio between THz wavelength and DNA nucleotide. Our suggested THz transmission model modified by THz field enhancement at nano-slot resonances and molecular plate capacitor model show an excellent fitting curve to the measured THz transmission changes in terms of used DNA quantity. With this report, THz spectroscopy research can go beyond the absorption cross-section limit with enormously enhanced sensitivity. Two new major areas of research might emerge with our study:

1) Ultrasensitive label-free type sensing of biomolecules even in aqueous state
2) Contact-free investigation of electro-optic characteristics for suspended 2D materials

Acknowledgements
This research was supported by the Global Frontier Program CAMM-2016M1A6B3936653, and KIST intramural grants (2E28280 and 2V05880).
Metal-semiconductor metamaterials make it possible to enhance the light-matter interaction, due to resonant absorption and scattering of light by plasmon excitations in a system of metallic nanoparticles embedded into a semiconductor medium. The condition of such a resonance is \( \text{Re}(\epsilon_m + 2\epsilon_s) = 0 \), where \( \epsilon_m \) and \( \epsilon_s \) are the permittivities of the semiconductor and metal components of the metamaterial, respectively. The goal of this work was to develop and investigate new metamaterials based on the AlGaAs semiconductor matrix containing random or periodic systems of metallic AsSb nanoinclusions.

The 1 μm thick AlGaAs films were grown by molecular beam epitaxy at low temperature (200°C) on semi-insulating GaAs substrates with (001) orientation. The concentration of the Al was 30%. The low growth temperature provided incorporation of the excess As into the epilayer in the form of antisite defects As\(_{\text{Ga}}\), with concentration of 1%. During the grown process, AlGaAs epilayer was additionally doped with isovalent Sb impurity. The samples were subjected to annealing at temperatures of 400–700°C, which provided self-organization of the metallic AsSb nanoinclusions in the bulk of the AlGaAs epilayer. The volume fraction of the nanoinclusions was 0.17%. This value was determined by transmission electron microscopy and via measuring the concentration of arsenic antisite defects in the as-grown sample. Periodically arranged systems of layers of AsSb nanoinclusions were formed via periodic δ-doping of AlGaAs epilayer with Sb. The distance between δ-layers was 100 nm while their number was 12 and 24. The post-growth annealing at temperatures of 400–700°C provided formation of the periodic systems of layers of AsSb nanoparticles near the δ-layers of Sb.

The experimental study of AsSb-AlGaAs random system for various post-growth annealing temperatures was carried out by the investigation of optical extinction coefficient spectra. We observed significant absorption and scattering of light in the random system of plasmonic AsSb nanoinclusions in the transparency window of the AlGaAs matrix. However, the plasmon resonance peak corresponds to the energy within the fundamental absorption band of AlGaAs.

Investigation of the periodic system of AsSb-AlGaAs layers was carried out by optical reflection spectroscopy for light incidence angles up to 85° for s- and p-polarizations. In optical reflection spectra we observed resonant reflection peaks, accompanied by satellite oscillations. The magnitudes of the resonant peaks increased with the increase of average size of AsSb nanoinclusions and reached 19% and 31% for the 12 and 24 AsSb-AlGaAs periods, respectively. Resonance wavelengths corresponded to the expected values in accordance with the Bragg law. We relate these significant reflection magnitudes to the high dielectric contrast between the AsSb nanoinclusion layers and surrounding semiconductor medium, which is caused by the proximity of the plasmon and Bragg resonances.

**Switching the Extrinsic Chirality in Achiral Metasurfaces Using Magnetic Fields** 
Lei Bi\(^1\), Jun Qiao\(^2\), Tongtong Kang\(^1\), Huili Wang\(^2\), Bo Peng\(^1\)

Chiral plasmonic nanostructures have attracted great research interest due to their strong light-matter interaction in the subwavelength scale, leading to strong chiral optical response potentially applicable for enantiomer sensing, imaging or data communication. Active tuning the chiral optical response of chiral plasmonic devices can be realized by modulating the plasmonic modes at the nanoscale. Several methods have been proposed to effectively switch the optical chirality of such devices, including using phase change materials\(^{[1]}\), DNA origami\(^{[2]}\), mechanical deformation\(^{[3]}\) and magneto-optical effects\(^{[4]}\).

However, to achieve efficient chirality control is still a challenge. Here, we demonstrate switching of the extrinsic chirality of an achiral plasmonic metasurface at glancing incidence angles by using low magnetic oxide thin films. Upon switching the applied magnetic field direction, the metasurface shows sign reversal of the far field optical chirality in a wavelength range of 900 to 1100 nm. The device is composed of a thin film stack of perforated Au/Cu/YIG/YIG/SiO\(_2\)/TiN multilayers fabricated by sputtering and pulsed laser deposition (PLD). The periodic nanohole structure is fabricated by polystyrene (PS) sphere self-assembly in large areas. We experimentally demonstrate the circular dichroism (CD) of 0.15 rad induced by extrinsic chirality at an incident angle of 65°. Under an applied magnetic field of -3500 Oe to +3500 Oe out-of-plane, the far field CD can be switched with a dynamic range of -0.1 to 0.32 rad. Modal simulation also revealed a significant superchiral field modulation in the near field, which is about one-order of magnitude higher compared to previous work of magnetic chiral nanostructures. The effective modulation of optical chirality in our devices is due to a much higher field intensity enhancement in low loss magneto-optical oxide thin films. Our device provides a new method to realize efficient tuning of chiral metasurfaces using applied magnetic fields.

**Active Beam Scanning via Ge\(_2\)Sb\(_2\)Te\(_5\): Phase-Change Metasurface Employing Mie-Resonance**
Ali Forouzmand and Hossein Mosallaei;
Northeastern University, Boston, Massachusetts, United States.

Nonuniform graded-pattern metasurfaces as flat and compact realizations of conventional bulky optical elements have attracted immense interest with the opportunity of miniaturization and highly-densed integration in photonic/optical devices. So far, lack of reconfigurability and real-time phase/amplitude modulation has been a tremendous challenge that prevents realization of active spatial light modulation and dynamic beam steering. To surmount this obstacle, metasurfaces hybridized with functional materials can offer an ideal platform to create ultracompact modulators which enable a strong light-matter interaction and allow for introducing dynamic spatially-varying optical properties. Although various kinds of dynamic controllable paradigms have been introduced, they suffer from low reflection efficiency and limited phase shift due to high dissipative loss, short interaction length, and ineffective physical mechanism (e.g., hybridization with plasmonic nanoantennas with single on-resonance operation).

In order to attain highly efficient tunable optical design with simultaneous high reflection level and wide phase shift, a non-volatile optically controllable metasurface consisted of geometrically-fixed chalcogenide nanobars is theoretically investigated where the refractive index of each nanobar can be effectively tuned under assumption of multi-level partial crystallization and structural amorphous-to-crystalline transition. This can be accomplished through careful selection of a state-of-art tunable phase-change material (PCM) coupled with a unique physical mechanism. We utilize a recently emerged PCM called Ge\(_2\)Sb\(_2\)Te\(_5\) (GST) with a strong resonant bonding, large bandgap, and low carrier concentration leading to large index contrast between amorphous and crystalline states (\(\Delta n=1.8\)) and low optical loss (\(\Delta \kappa=0.4\)) compared to the classical GST alloys. In addition, the GST nanobars as all-dielectric building blocks can support both the magnetic and electric resonances whose spectral positions and strength can be governed by varying the crystallization level. This gives us the possibility to take into account the contribution of both supported Mie-type dipolar modes and operate at the middle of them (off-resonance operation). By preventing from the concurrence of high field confinement and large extinction coefficient inside the PCM integrated element (known as the origin of an inevitable efficiency degradation), significantly large phase modulation of 270° is achieved while the reflection efficiency is not only high but also exhibits minimal changes between 0.6 and 0.8 for all the intermediate crystallization states. As a potential application, we leverage from phased-array concept and progressive phase-delay of nanoantennas in an array to achieve continuous steering ability when each GST nanobar is individually crystallized.

As a potential application, we leverage from phased-array concept and progressive phase-delay of nanoantennas in an array to achieve continuous steering ability when each GST nanobar is individually crystallized.
Optical metasurface is an artificial optical interface capable of controlling the flow of light by bending, scattering, absorbing or filtering electromagnetic waves [1]. Metasurface is usually composed of periodic metallic components for their sub-wavelength scale response, but high refractive index based dielectric metasurface using Mie scattering is also desirable to integrate with dielectric circuit as well as the view of optic loss [2]. On the other hand, two-dimensional (2D) transition-metal dichalcogenides have emerged as a new class of active medium with atomic layer thickness [3]. 2D exciton-polaritonic state can play an important role in many optical properties such as enhancing emitting, lasing and modulating of light. However, light coupling such a dielectric metasurface with 2D material is still in lack of work. Here we report such a system in consisting of MoS2 and dielectric metasurface to engineer light-matter coupling. The MoS2 sample was grown by chemical vapor deposition (CVD) method. The nature of MoS2 was confirmed by both of AFM and Raman characterization, where by the thickness of typical ~5nm. The multi-layer MoS2 exhibit exciton emission centering at 1.95 eV, with narrow line width of 60 meV. Dielectric metasurface was precisely designed by amorphous silicon nanoblock in order to have first-order Mie scattering corresponds to the magnetic dipole in a range of MoS2 exciton emission. To enter the magnetic mode induced strong coupling regime, we investigate scattering spectra with various coupling strength by detuning its quality factor and distance of each layer. The spectral evolution of the composite system shows a spectral mode splitting phenomenon to depend on the energy detuning based on Si-nanoblock geometry. To understand the strong coupling effect properly, coupled mode theory is utilized, which can describe splitting energy of the coupled system. Calculated spectrum corresponding the 72meV (Si-nanoblock width=150nm, height=150nm, thickness =100nm) splitting energy shows the strong coupling condition above the vacuum Rabi splitting criterion. This strong coupled state of the composite system occurs when the energy exchanges between the MoS2 and Si-nanoblock is faster than their individual energy dissipation rate. As a result, we have systematically studied the geometry dependence of coupled state, demonstrating the validity of strong coupled state of the composite system. The occurrence and utilization of the strong coupling condition can be tailored by proper structural design and its related harmonic mode condition. These results could provide important clues to integrate 2D material on a chip level circuit, and also quantum optics devices.

**EP04.03.08 Light Trapping in Perovskite Solar Cells with Non-Resonant Metasurfaces**

Mohammad I. Hossain1, Nivedita Yumnam2, Md Waysheh Qarony3, Veit Wagner4, Dietmar Knipp1 and Yuen H. Tsang1; 1Applied Physics, The Hong Kong Polytechnic University, Kowloon, Hong Kong; 2Physics and Earth Sciences, Jacobs University Bremen, Bremen, Germany; 3Geballe Laboratory for Advanced Materials, Department of Materials Science and Engineering, Stanford University, Stanford, California, United States.

Non-resonant metasurfaces were investigated as potential light trapping structures in perovskite thin film solar cells. The short-circuit current and energy conversion efficiency of thin-film single and tandem solar cells can be improved by light trapping while lowering the material consumption. Light trapping is commonly achieved by texturing the solar cells or at least texturing the contacts of solar cells. In the first part of the study periodically arranged metal oxide nanowire arrays were realized by electrodeposition. The zinc oxide nanowires were prepared by templated growth through a mask of photoresist. The subwavelength large zinc oxide nanowires can be used to texturing building blocks in controlling the phase of the incident light. In a second part of the study, optical simulations were used to design non-resonant metasurfaces with optical properties comparable to commonly used light trapping structures like pyramids or inverted pyramids. A comparison of the metasurfaces with the pyramid textured perovskite solar cells, exhibiting almost identical quantum efficiencies and short circuit currents. For thick perovskite solar cells, the incoupling of light in the solar cell is improved, and the short-circuit current and energy conversion efficiency is increased by approx. 15%. For thin perovskite solar cells the incident light is diffracted and scattered, and gain in the short-circuit current and energy conversion efficiency of 20-30% is observed. Guidelines for the design of the non-resonant metal oxide metasurfaces will be provided.

**EP04.03.09 Characterizing Optical Effects of Metasurfaces Using Photoelastic Modulators—Advantages and Limitations**

Ioan-Augustin Chioar1, Richard M. Rowan-Robinson1, Paolo Vavassori2 and Vassilios Kapaklis1; 1Physics and Astronomy, Uppsala University, Uppsala, Sweden; 2CIC nanoGUNE, San Sebastian, Spain; 3Ikerbasque, Basque Foundation for Science, Bilbao, Spain.

Metasurfaces are nanostructured interfaces designed to induce abrupt changes to light wavefronts and polarization by means of arrays of sub-wavelength scatterers acting as optical antennas [1]. This tailoring largely depends on the size and shape of the scatterers, as well as on the choice of material, all of which can be designed to a high degree using modern fabrication techniques. Such flat metasurfaces offer a vast and exciting playground for both fundamental studies related to light-matter interaction at the nanoscale, as well as technological opportunities for designing a new generation of flat optical components.

Given the large freedom in design, appropriate characterization methods and tools need to be developed, thus enabling access to various optical parameters for such metasurfaces. Photoelastic modulators (PEM) are typically employed to quantify optical effects, such as linear and circular dichroism/birefringence. However, we have observed that conventional PEM-based methodology is quite challenging for determining such quantities [2] can be affected by artifacts and spurious effects, particularly when dealing with anisotropic and chiral metasurface architectures. We will present and discuss advantages, limitations, and different analysis methods that can still facilitate access to certain properties of such metasurfaces using PEM-based characterization techniques.

**EP04.03.10 Toroidal Resonances in Graphene-Based Planar Core-Shell Terahertz Metasurfaces**

Nazmin Akter, Mustafa Karabiýik, Fahmida Alam and Nezih Paşa; Electrical and Computer Engineering, Florida International University, Miami, Florida, United States.

Toroidal multipoles are one of the fundamental excitations which are considered as the third family of electromagnetic multipoles in addition to the electrical and magnetic multipoles. These multipoles have recently become an attractive area in metamaterials research. However, detection of this type of resonant moments is highly challenging since they do not efficiently couple to the free space. The toroidal dipole resonance possesses magnetic moments that are aligned head-to-tail and form a dynamic vortex in the shape of a torus' surface due to induced currents. Existence of toroidal multipolar modes in
planar 2D structures has received growing attention recently due to their easy fabrication and characterization. Devices based on toroidal modes have recently been used in practical applications such as biological sensing and microwave antennas. Resonant modes in complex structures such as core-shell structures can be explained by hybridization of elementary plasmons supported by nanostructures of elementary geometries. In such cases, the electromagnetic interaction between the elementary plasmons leads to mixing, splitting, and shifts of the plasmon energies of the entire structure. However, these changes have not been investigated for toroidal modes yet.

THz wavelengths have several advantages that could promote their use as sensing and imaging tool. THz radiation can penetrate non-metallic materials such as fabric, leather, plastic which makes it useful in security screening for concealed weapons. The THz frequencies correspond to energy levels of molecular rotations and vibrations of DNA and proteins as well as explosives, and these may provide characteristic fingerprints to differentiate biological tissues in a region of the spectrum not previously explored for medical use or detect and identify trace amount of explosives. Graphene with its exquisite material, electronic and optical properties, particularly with its potentially very high carrier mobility is an excellent material for THz applications.

In this paper, we report on a theoretical and experimental investigation of the hybridized toroidal plasmonic modes in metasurfaces composed of graphene core-shell resonators with different configurations. Spectral characteristics of the metasurfaces with core-only, shell-only and core-shell designs with various geometrical variations have been investigated using a finite-difference-time-domain (FDTD) tool. Selected structures have been fabricated using PDMS-based graphene transfer method and standard microfabrication tools and techniques on a high-resistivity Silicon substrate. Transmission spectra of these fabricated metasurfaces have been measured using backward wave oscillator (BWO) and THz time-domain spectroscopy (TDS) systems. We discuss the hybridization of the toroidal modes in core-shell resonators due to the coupling of the fields on individual core and shell components and their dependence on geometrical parameters.

EP04.03.11
System Level Considerations for Tunable Metasurface Designs
Artur R. Davoyan and Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

Optical phased arrays are important ingredients for beam forming in sensing, imaging and ranging applications. Electrically tunable metasurfaces comprised of elements where phase and/or amplitude may be addressed individually offer a highly integrated and versatile platform for beam shaping. However, addressing electrically a large number of metasurface elements may seem a substantial practical limitation. Here, we report a novel architecture of control for phased array antennas and metasurfaces. In contrast to previous schemes utilized for beam forming in phased array antennas and metasurfaces, our design involves a reduced number of control elements, is efficient and compact. A typical metasurface employed for beam forming contains periodic arrays of emitters and/or scatters, each having its own phase and amplitude. Coherent superposition of the fields scattered by each of the emitters forms a narrow beam, direction of which may be controlled by an applied voltage. However, current architectures assume individual control (e.g., by an applied voltage) of each of the scatter. While for a small number of elements this architecture works well, with increase of the number of array elements the control becomes complex and power inefficient. For instance, a square array with N elements on the side would require N2 of control voltages. Hence, for large aperture arrays, e.g., with 1000 elements on the side – that are operated at optical frequencies, 106 control elements are needed.

In contrast here we propose a different control scheme. Beam forming relies on a fundamental relation of independent phase progression along two orthogonal directions (e.g., x and y) and a constant phase gradient along these directions. It is this superposition of phase gradients along orthogonal planes that allows us to implement a perimeter control architecture. Control signals are applied along the orthogonal axes on the perimeter of the array superimpose at any given element inside the array. For the case of a linear voltage phase relation this voltage superposition directly corresponds to phase superposition. Such a control scheme in contrast to a previously mentioned one requires only 2N controls. We note that our architecture may also utilize nonlinear gradients and phase relations with a proper design. Our approach is generalizable to different frequency domains, including optics, infrared, terahertz, microwave and RF, as well as acoustics.

EP04.03.12
Anapoles in Disk Nanoantennas Fabricated from III-V Nanowires for Enhancement Second Harmonic Generation
Maria Timofeeva1, Lukas Lang1, Claude Renaut1, Flavia Timpu1, Igor Shtrom2, Alexei Bouravlev2, George Cirlin3 and Rachel Grange1; 1ETH Zurich, Zurich, Switzerland; 2Saint-Petersburg National Research Academic University of the Russian Academy of Sciences, Saint Petersburg, Russian Federation; 3ITMO University, Saint Petersburg, Russian Federation.

Nonlinear optics is a fast-developing research field with a high potential of applications with new types of metamaterials, nanoantennas, lasers and versatile photonic devices. Nanophotonics is usually associated with metallic nanostructures and nanoparticles due to their optoelectronic and plasmonic properties. Despite successful applications of such kind of structures, it is well known that plasmonics suffer from ohmic losses, heating and incompatibility with standard CMOS technology. However, recent research follows a new route of light manipulation at the nanoscale by employing optically induced Mie resonances in dielectric and semiconductor materials with high refractive indexes, for example silicon or germanium, as an alternative to metallic nanostructures to overcome these issues. In our work, we utilized the electromagnetic properties of III-V semiconductor nanowires to design building blocks for nonlinear all-dielectric metamaterials and devices. We developed a new concept of fabrication standing disk nanoantennas by slicing epitaxially grown nanowires with focused ion beam milling. This method allows us to create nanodisk configurations on any substrate and it significantly expands the possible applications of III-V disk nanoantennas.

In the fabricated standing disks from GaAs/AlGaAs nanowires, we studied nonradiating current distributions, called anapoles modes. The nonradiating current distributions have two essential features that make them very promising structures for photonic devices: first, lack of energy losses and second invisibility to the propagating electromagnetic field. We demonstrated in III-V standing disk nanoantennas the suppression of the far field radiation and strong electromagnetic field confinement inside the disk structure that lead to the strong enhancement of the second harmonic generation. We experimentally shown the drop in the linear scattering in the region of 800-900 nm and simultaneous enhancement around 5000 of the second harmonic generation from these disks in comparison with a layer of AlGaAs. For the theoretical analysis we developed a full model that allows us to calculate linear scattering, second harmonic generation and perform the multipole expansion of the electromagnetic field inside studied disks. Using this multipole expansion in both spherical and Cartesian coordinates, we confirm that the demonstrated nonradiating configurations are anapoles.

In the future, we believe that this approach of nanowires slicing can form a new branch of nanotechnology to fabricate different chains of disk and rod nanoantennas on different substrates. Such type of chains could become a core element for lasers and sensors with low power consumption based on lossless nonlinear photonic components supporting anapoles and compatible with CMOS technologies.

Following Polaritonic Chemistry with Photo- Switchable Molecules Using Optical Nanoantennas in the Strong Coupling Regime
Esteban Pedreauza Villalmanzo1, Valeria Suavedra1, Evgeniya Smetanina1, Mehdi Keshavarz Hedaya1, Mohsh Abdestayl Mahmoud Abedaliz8, Timur Shega1, Joakim Andreas1, Mady Elbuhri1 and Alexandre Dmitriev1; 1Department of Physics, University of Gothenburg, Gothenburg, Sweden; 2Chalmers University of Technology, Department of Chemistry and Chemical Engineering, Chemical Physics, Gothenburg, Sweden; 3Department of Micro and Nanotechnology,
Optical resonant molecular systems often display what is called a strong coupling to the nanoplastic systems. This is primarily explored for the nanophotonic active control and in the studies of quantum optics [2]. At the same time, the strong coupling of the molecular resonances to the nanoplasmonic resonances has not been addressed to follow the light-induced molecular processes. Here we combine an exemplary molecular photo-switch, from spiropyran to photochromic family, with anisotropic nanoplasmonic antennas to earn the monitoring tool for the light-activated processes using molecular and nanoplasmonic resonances strong coupling regime [3]. We follow the reversible photo-isomerization of the spiropyran photoswitch from the spiro form to the merocyanine form by tuning in the nanoplasmon antenna to the excitonic state of the merocyanine form (at 570 nm), prompting the formation of a hybrid excitation-plasmonic state. Our anisotropic nanoantenna provides two polarization-dependent spectrally separated resonances in the visible region, allowing for separate monitoring of the plasmon-exciton strong coupling and the conventional enhanced optical near-field refractive index sensing. This system uncovers a new modality in polaritonic chemistry and optical label-free monitoring of the photo-activated processes and can find applications in photocatalysis, biosensing and in hybrid molecular-nanoantenna actively modulated systems.

EP04.03.14

Multiresonant Composite Optical Nanoantennas

Junyeob Song and Wei Zhou; Virginia Tech, Blacksburg, Virginia, United States.

Optical nanoantennas can concentrate light and enhance light-matter interactions in subwavelength domain, which is useful for photodetection, light emission, optical biosensing, and spectroscopy. However, conventional optical nanoantennas operating at a single wavelength band are not suitable for multiband applications. Here, we propose and exploit an out-of-plane plasmonic engineering strategy to design and create composite optical nanoantennas that can support multiple nanolocalized modes at different resonant wavelengths. These multiresonant composite nanoantennas are composed of vertically stacked building blocks of metal-insulator-metal loop nanoantennas. Studies of multiresonant composite nanoantennas demonstrate that the number of supported modes depends on the number of vertically stacked building blocks and the resonant wavelengths of individual modes are tunable by controlling the out-of-plane geometries of their building blocks. In addition, numerical studies show that the resonant wavelengths of individual modes in composite nanoantennas can deviate from the optical response of building blocks due to hybridization of magnetic modes in neighboring building blocks. Using Au nanoplate arrays as deposition masks to fabricate arrays of multilayered composite nanoantennas, we experimentally demonstrate their multiresonant optical properties in good agreement with theory predictions. These studies show that out-of-plane engineered multiresonant composite nanoantennas can provide new opportunities for fundamental nanophotonics research and practical applications involving optical multiband operations, such as multiphoton processes, broadband solar energy conversion, and wavelength-multiplexed optical system.

EP04.03.15

2D Surfaces as a Handle to Engineer 3D Photonic Nanostructures

Sadan Fu1, Xiaoxiong Wang1, Haoze Wang2, Jing Kong3 and Jifeng Liu1; Dartmouth College, Hanover, New Hampshire, United States; 2Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Two-dimensional (2D) materials, such as graphene and hexagonal Boron Nitride (h-BN), have been attracting the eyes from the materials research society, especially for their photonic and electronic applications. In addition to their own 2D material functionality, in recent years 2D materials are also being investigated as a template to engineer the growth of 3D photonic structures and devices. Here, we show that the drastic change in surface energy on single-layer 2D materials can be effectively applied to engineer self-assembled 3D photonic nanostructures, including Sn-SnO core-shell nanoneedles and Sn nanodot arrays. The wetting angle analysis reveals that the 2D layer, though only with atomic-scale thickness, can already modify the surface properties of the 3D nanostructures. Furthermore, for example, the single-layer graphene (SLG) lattice is enough to make it hydrophobic (~100° wetting angle of water). In contrast, h-BN seems to be wetting-transparent to the surface, i.e. it retains the original surface properties of the substrate. It’s observed that such a surface properties variation leads to clear geometric differences of the Sn and Sn-SnO core-shell nanostructures grown on the top, and thus greatly influences the optical properties at 2D interfaces. The Sn nanostructure on SLG/quartz always tends to be more continuous than that on quartz directly; while the Sn nanostructure on h-BN/quartz and quartz directly show identical geometries. We derived the effective refractive index change of 3D Sn and Sn-SnO core-shell nanostructures on SLG vs. on silica, which can be further engineered to achieve other novel 3D photonic structures on SLG utilizing 2D materials as a template. An example is the highly effective light trapping in 2D materials contributed by the 3D photonic nanostructures, which has been revealed by direct optical absorption measurement and confirm by strongly field-enhanced Raman signals from the 2D materials. With Sn-SnO core-shell nanoneedles, the absolute absorption of SLG can reach up to 17% from the wavelength of 500 nm to 1200 nm; with Sn nanodot arrays, the absolute absorption of SLG can be up to 20% from the wavelength of 500 nm to 4500 nm. Furthermore, these structures can also be used as deposition masks to fabricate arrays of multilayered composite nanoantennas, we experimentally demonstrate their multiresonant optical properties in good agreement with theory predictions. These studies show that out-of-plane engineered multiresonant composite nanoantennas can provide new opportunities for fundamental nanophotonics research and practical applications involving optical multiband operations, such as multiphoton processes, broadband solar energy conversion, and wavelength-multiplexed optical system.

EP04.03.16

Fabrication of Gold Nanostructures Using Wet Lift-Off without Adhesion Promotion

Mengjie Zheng1, 2, Yujia Yang1, Huigao Duan3 and Karl K. Berggren1; 1Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2School of Physics and Electronics, Hunan University, Changsha, China; 3College of Mechanical and Vehicle Engineering, Hunan University, Changsha, China.

Adhesion layers are often needed in the fabrication of metallic nanostructures. For example, Ti and Cr layers facilitate the adhesion of Au nanostructures on various dielectric and semiconductor substrates, which is essential for many applications such as plasmonics, metamaterials, and nanoelectronics. However, despite providing mechanical stability, adhesion layers sometimes have detrimental effects in certain applications. It has been reported that in plasmonics, metallic adhesion layers for Au nanostructures cause damping of surface plasmon resonances, and lead to a decreased field enhancement and plasmon lifetime. Hence, there has been a quest for fabricating Au nanostructures with an alternative adhesion layer or even without an adhesion layer. In our previous work, we have shown Au nanoparticle arrays can be made free from adhesion layers. Here we systematically investigate the effect of adhesion layers on Au nanostructures made from electron beam lithography and a wet lift-off process.

In this work, Au nanoparticle arrays and nano-gratings were fabricated via electron beam lithography on a silicon or Au-coated silicon substrate. A single
layer PMMA resist was exposed and developed. Electron beam evaporation deposited the Au nanostructures with or without a Ti adhesion layer. Wet lift-off was performed in hot NMP without sonication. The samples were gently rinsed intermentally with flowing NMP. Experiments showed Au nanostructure adhesion was affected by several factors, including nanostructure size and geometry, lithographic dosage, and the substrate being used. Au nanoparticle arrays have an almost perfect yield even without an adhesion layer. Hence, an adhesion layer is not indispensable in the fabrication of isolated Au nanostructures. However, a higher lithographic dosage is required to achieve a high yield in the absence of an adhesion layer, which shows the adhesion layer increases the tolerance to residual resist scum after development. As for Au nano-gratings, the adhesion layer is not necessary for short grating lines, but is essential for achieving a high yield for long grating lines. Longer grating lines could have more defects and cracks at the Au-substrate interface, leading to a greater vulnerability to delamination. Furthermore, we find an adhesion layer is also necessary when making Au nano-gratings on top of a Au-coated substrate. This observation indicates the adhesion layer is needed not only for the adhesion between the metallic nanostructures and the substrate, but also for the adhesion between the metallic overlayer to be removed and the resist layer. The latter adhesion is crucial for removing unwanted metal pieces from the samples in the wet lift-off process.

**EP04.03.17**

**Metal-Halide Perovskite Confined in Nanoporous Oxide Thin Films for Light Emitting Applications**

Stepan Demchyshyn, Serdar Sariciftci, Markus Schrerber, Siegfried Bauer and Martin Kaltenbrunner; Johannes Kepler University, Linz, Austria.

Halide perovskites are inexpensive and easily processable next generation semiconductors. We here demonstrate perovskite solid-state confinement in nanoporous oxide matrices as a general strategy to control the size of the nanocrystals (<10 nm) in the strong quantum size effect region. Photoluminescence tuning between near infrared and ultraviolet is achieved by manipulating the size of perovskite crystals through confinement in nanoporous alumina (npAAO) or silicon (npSi) scaffold [1].

Our novel method of nanocrystalline perovskite preparation within a porous oxide matrix results in device-relevant structure that requires no colloidal stabilization. Low-voltage LEDs with narrow, blue-shifted emission fabricated with perovskite nanocrystals confined within npAAO thin films support the general concept for next-generation photonic devices. The template-controlled size of the perovskite crystals is quantified in npSi with microfocus high-energy X-ray depth profiling in transmission geometry, verifying the growth of perovskite nanocrystals throughout the entire thickness of the nanoporous films. We study in detail exciton recombination, exciton-phonon interactions and energy trap states in confined and bulk semiconductor films using low temperature photoluminescence spectroscopy down to 3.8 Kelvin.

Further areas of application include photon detectors, (polarized) electroluminescent devices, single-photon sources and metasurfaces. Future developments will include increasing the efficiency of the LEDs, exploring their applications in flexible devices and in depth study of the fundamental properties of the confined structures.

**EP04.03.18**

**Hierarchical Nanodisk Arrays Inspired by Diatom Frustules as Near Infrared Metamaterial Absorbers**

Aobo Li1, Xiaoguang Zhao2, Guangwu Duan3, Stephen Anderson2 and Xin Zhang2; 1Boston University, Boston, Massachusetts, United States; 2Boston University Medical Center, Boston, Massachusetts, United States.

The design and fabrication of electromagnetic metamaterials have been extensively studied given their unique engineered electromagnetic properties. A broad array of applications has enabled the development of metamaterials such as invisibility cloaking and perfect absorbers, among others. In order to achieve IR absorption, subwavelength structures are required on the nanometer scale. Diatoms, a type of photosynthetic microalgae, feature silica exoskeleton structures that enclose their cytoplasm. The abundant hierarchical micro and nanopores on the diatom frustules have been employed in a range of bio-inspired and bio-mimetic studies. In this study, we mimicked the cribrum pores (diameter ~224 nm) on diatom frustules in order to design a hierarchical gold nanoresonator array that can be used as a near-IR metamaterial absorber. The design was validated with preliminary simulations and measurements, which demonstrate the potential for future applications in IR sensing and thermal emitter applications.

Diatoms (Coscinodiscus Species) were initially cleaned with concentrated sulfuric acid to remove organic contaminations. The extracted frustules were subsequently washed with DI water. Pore sizes and pore distributions on the frustules were measured and measurement data were used to design and fabricate the nanodisk arrays. An n-type 100 silicon wafer was used as the substrate, on which a 200 nm gold layer was deposited as the ground plane and 200 nm of SiNx was deposited as the spacer. On top of it, the bio-inspired nanodisk arrays were deposited through e-beam lithography (EBL) and a subsequent lift-off process. Finite difference time domain (FDTD) analysis was conducted to study the proposed structure’s characteristics. A Bruker Vertex 70v Fourier transform IR (FTIR) spectroscopy was used to obtain the reflectance of the structure.

The abundant micro- and nanopores are seen on both sides of the diatom frustule. Specifically, we are interested in mimicking the cribrum pore sizes, and corresponding measurements were conducted. The nanodisks’ size and hierarchical arrangements mimicked the cribrum pores on the frustules. The simulation result demonstrates that there is a strong absorption peak in the IR range. We found that the nanodisks are resonant at the peak frequency and the surface electric field patterns show a clear dipole resonance. Subsequently, we evaluated the frequency peak shift as a function of nanodisk diameter. We demonstrate that the absorption becomes stronger as the disk diameter increases, and the peak shifts towards longer wavelengths. The measurements of the structures show similar tendency of the peak shift as a function of disk diameter. The disagreement between the simulation and experimental measurements may be a result of material property mismatches. The results demonstrate a potential use of the hierarchical patterns as a novel route to design and fabrication of metamaterial absorbers.

**EP04.03.19**

**Dispersionless Wavefront Engineering of Light Using Time-Modulated Metasurfaces**

Mohammad Mahdi Salary, Samad Jafar-Zanjani and Hossein Mosallaei; Northeastern University, Boston, Massachusetts, United States.

Optical metasurfaces have provided a great flexibility in shaping the wavefront of light by engineering the phase response of constituent building blocks. In the conventional metasurfaces, the required phase profile is achieved through changing structural parameters of a resonant element or rotation of a half-wave plate element around its axis. Recently, an extensive effort has been put into post-fabrication tuning of geometrically-fixed metasurfaces by incorporating different mechanisms to tune the spectral shift of the resonance and modulate the phase response of the elements in real-time. Despite the real-time tunability of these actively controlled metasurfaces, their operation has been mostly studied in the quasi-static case where the temporal variations are disregarded. Introducing time-modulation in a metasurface leads to generation of higher-order frequency harmonics and breaks the reciprocity constraint. In this work, we demonstrate that time-modulated metasurfaces can extend the degree of light manipulation and wavefront engineering through a non-resonant
modulation-induced phase shift. It is rigorously established that the light picks up a dispersionless phase shift regardless of incident angle and polarization, upon undergoing frequency conversion in a time-modulated metasurface which is determined by the modulation phase delay and the order of generated frequency harmonic. The efficiency of frequency conversion is independent of modulation phase delay and merely depends on the modulation depth and resonant characteristics of the metasurface building blocks, with the efficiency being maximal near the resonance, and decreasing away from the resonance. This creates a new design paradigm which allows for realization of tunable spatial phase discontinuities within the time-modulated metasurface in the terahertz frequency regime implemented using graphene-wrapped silicon microcavities electrically biased with radio-frequency signals. Several different functionalities such as tunable beam steering and focusing of frequency harmonics are investigated and the broadband wide-angle performance of the metasurface in manipulation of higher-order frequency harmonics is verified. The proposed paradigm is a departure from the previous metasurface design rules and enables realization of multifunctional tunable metasurfaces with wide angular and frequency bandwidth.

EP04.03.20
Transient and Flexible Hyperbolic Metamaterials on Freeform Surfaces Hung-I Lin1, Kun-Ching Shen2, Shih-Yao Lin1, Golam Haider1, Yao-Hsuan Li1, Shu-Wei Chang1 and Yang-Fang Chen7; 1National Taiwan University, Taipei, Taiwan; 2Academia Sinica, Taipei, Taiwan.

Transient technology is deemed as a paramount breakthrough for its particular functionality that can be implemented at a specific time and then totally dissolved. Hyperbolic metamaterials (HMMs) with high wave-vector modes for negative refraction or with high photonic density of states to robustly enhance the quantum transformation efficiency represent one of the emerging key elements for generating not-yet realized optoelectronics devices. However, HMMs has not been explored for implementing in transient technology. Here we show the first attempt to integrate transient technology with HMMs, i.e., transient HMMs, composed of multilayers of water-soluble and bio-compatible polymer and metal. We demonstrate that our newly designed transient HMMs can also possess high-κ modes and high photonic density of states, which enables to dramatically enhance the light emitter covered on top of HMMs. We show that these transient HMMs devices loss their functionalities after immersing into deionized water within 5 min. Moreover, when the transient HMMs are integrated with a flexible substrate, the device exhibits an excellent mechanical stability for more than 300 bending cycles. We anticipate that the transient HMMs developed here can serve as a versatile platform to advance transient technology for a wide range of application, including solid state lighting, optical communication, and wearable optoelectronic devices, etc.

EP04.03.21
Large-Area and Flexible All-Dielectric Metasurfaces via Templated Dewetting of Optical Glasses Tapajoyti Dasgupta, Louis Martin-Monier, Wei Yan, Arthur Lebris, Das Tung Nguyen, Alexis Page, Yungkin Qu and Fabien Sorin; EPFL, Lausanne, Switzerland.

Dielectric and plasmonic metasurfaces require the integration of materials with accurate control over position, size and shape for high optical efficiency. They are typically fabricated by the well-established lithographic or chemical processes. Hence, it remains difficult to scale to large-area and unconventional substrates. Here, we propose the template dewetting[3-5] of thin chalcogenide glasses[6,7] as a novel approach to self-organize a variety of large index contrast all-dielectric metasurfaces[8]. Given the right dewetting temperature settings, initial film thickness and underlying pattern, the breakup of the film can occur at prescribed locations resulting in nano-objects of tunable position and sizes. This control over the dewetting of chalcogenide glasses paves the way towards simple fabrication route of advanced 2D and quasi 3D photonic devices over large area, flexible and stretchable substrates. Low processing temperatures enable large-scale use of rigid but also unconventional flexible and stretchable substrates. This bears a particular importance as lithographic processes today are limited by cost, and also in terms of area and substrate rigidity. The structures we realize are shown to have a very large and tunable absorbance in the visible range opening up possibilities for photo-detecting applications. Such structures also enable strong electromagnetic field confinement, and will be shown to have a variety of application in sensing, light management and second harmonic generation. By dewetting increasingly thick layers, inter-particle gap down to 10 nm could be achieved in such metasurfaces. This leads to a Fano resonance in transmission, due to the interference between a sharp electric gap mode and a broad magnetic mode due to the particles in the lattice. We will demonstrate in particular monolayer protein detection with high sensitivity, with an LOD down to around 0.5mg/ml.

EP04.03.22
Deep-Learning-Enabled On-Demand Design of Chiral Metamaterials Wei Ma, Feng Cheng and Yongmin Liu; Northeastern University, Boston, Massachusetts, United States.

Chirality refers to the structural property of an object that cannot be superposed onto its mirror image. Due to its universal existence in nature, chirality has attracted immense research interest with important applications in spectroscopy, sensing, imaging, and pharmaceutical synthesis. However, limited by the small electromagnetic interaction volume, the chiroptical response of natural materials is usually very weak and thus difficult to be detected with high sensitivity. The advent of metamaterials offers an elegant and effective solution to this problem. So far, various intrinsic and extrinsic chiral metamaterials have been demonstrated.[1] Although a set of symmetry requirements derived from Jones matrices can guide the design of chiral metamaterials,[2] these guidelines are insufficient when we want to quantitatively design a metamaterial structure given a desired chiral response, or even to simply predict the trend of chiral response as the structure transforms. Currently, the prediction task heavily relies on iterative, time-consuming numerical simulations to solve Maxwell’s equations on a case-by-case basis, while the retrieval task remains extremely challenging with no general close-form solutions. Inspired by the remarkable progress and success of the deep learning technology in processing images, speech and videos, very recently we developed a purpose-designed deep learning architecture to automatically model and optimize three-dimensional chiral metamaterials.[3] Different from numerical optimization approaches, data-driven methods based on deep learning can represent and generalize complex functions or data, to uncover unknown relations among a huge number of variables. The proposed deep-learning model is composed of two bidirectional neural networks aiming to solve three basic tasks simultaneously. In the forward modeling, it is a fast prototyping tool with high accuracy comparable to numerical simulations, to predict the full optical responses of a chiral structure. On the other hand, given the full optical responses, the network can be used to retrieve the geometric parameters of
the chiral meta-atom to solve the inverse problem. Moreover, starting from some basic requirements on the frequency, amplitude and polarity of the circular (nonlinear) mode, the deep model can produce suitable geometric parameters of the meta-atom. Our results demonstrate that such a data-driven model can be applied as a very powerful tool in studying complicated light-matter interactions, and accelerating the on-demand design of novel nanophotonic devices, systems and architectures for real-world applications.

Metasurfaces Enabled by Locally Tailoring Disorder in Phase-Change Materials Martin Hafermann, Philipp Schöppe, Jura Rensberg and Carsten Ronning; University of Jena, Jena, Germany.

Phase-change materials, such as Ge,Sb,Te (GST), exhibit drastic changes of their optical and electrical properties, which is related to different bonding mechanisms in their respective crystalline and amorphous states. This is not only already used in non-volatile memristors and optical data storage devices, but is also of enormous interest for optical metasurfaces. Other than applying a heat stimulus, such as thermally, optically or electrically, to induce the change of state, we demonstrate that ion irradiation can be used to trigger the phase change from crystalline to amorphous utilizing the creation of irradiation defects.

First, we performed homogenous ion irradiation of thin GST layers. Crystalline and amorphous phases coexist after low ion fluence irradiations, because of the statistical nature of ion irradiation. Thus, homogeneously irradiated GST has gradually tunable optical properties with increasing ion fluence, and thus behaves like a disordered metamaterial. This new degree of freedom will open new horizons: the combination of conventional metasurfaces made of noble metal antennas with GST as a switchable dielectric will thus be expanded by gradually tunable optical responses of such systems.

Additionally, we used a focused ion beam system to irradiate a thin GST layer in defined areas with structure sizes down to 100 nm, which is below the diffraction limit of direct laser writing. The local triggering of the phase change in sub-wavelength dimensions can be used to design metasurfaces operating in the near-IR. Because of the simplicity of our approach, we can easily create optical elements that can be reconfigured and inherently flat. We will demonstrate the design and characterization compared with FDTD simulations of our optical devices, e.g. reflector polarizers, Fresnel zone plates and beam steerers.

EP04.03.24
Applicability of Effective Medium Approximation for Hyperbolic Metamaterials with Period 20 Times Smaller than the Wavelength of Light Anubhav Sukham1, Osamu Takayama1, Maryam Mahoodi2, Andrei V Lavrinenko1 and Radu Malureanu1;1Photonics Engineering, Technical University of Denmark, Kgs.Lyngby, Denmark; 2Laser and Plasma Research Institute, Shahid Beheshti University, Tehran, Iran (the Islamic Republic of).

Hyperbolic metamaterials (HMMs) [1] consisting of alternating dielectric and metal layers are playing a key role in the field of nanophotonics due to its wide range of applications in super resolution [2], bio sensing [3,4], enhancing spontaneous decay rate [5]. To realize HMMs in the visible to near-infrared regime of operation, gold is a practical plasmonic material due to its good optical properties and high chemical stability. In these wavelength range, the thickness of the metal layer is generally between 10 and 20 nm [6,7]. However, gold does not adhere well onto oxides or Si, thereby leading to discontinuous and rough films for thicknesses below 15 nm. This imposes the need of an adhesion layer, most commonly Ti or Cr. Recently our group has shown that silane based adhesion layer (3-Aminopropyl)trimethoxysilane (APTMS) eliminates the need for metallic adhesion layers and it allows the existence of surface plasmon modes with properties similar to the theoretically predicted calculations [8]. In this work, we have successfully fabricated and characterized structures composed of Au and alumina multilayers with up to 10 layers of Au. The gold and alumina layers were 10 nm thick, thus allowing for hyperbolic dispersion in the visible to near-infrared range. APTMS adhesion layer was used on each interface between Au and alumina to provide better adhesion and therefore to obtain high quality smooth layers. The Au and alumina layers were fabricated using sputtering and atomic layer deposition techniques, respectively. The use of these techniques helps to obtain a high quality HMMs with a RMS roughness of 0.80 nm after the tenth period. Using these structures, we show that the effective medium approximation (EMA) can be used for structures with as little as 4 periods. The optical characterization shows very good agreement with the theoretically predicted EMA after 4th period and onwards. As a quantitative measure, we calculated the mean squared derivation (MSD) of the measured reflectance compared to the EMA predicted one. After the 4th period, the MSD is below 4%.

EP04.03.25
Transmission Enhancement of Subwavelength Metasurface Lens by Tapered Nanostructure Ya Sha Yi, Mao Ye, Dachuan Wu, Wei Guo and Yueheng Peng; University of Michigan, Dearborn, Michigan, United States.

Metasurface microlens is one of the emerging planar micro-optical devices with great potential in a variety of applications. Among this field, high refractive index contrast nanostructures show great advantages in areas such as spectral modification of optical wave front. These advantages have enabled the microlens to be designed in a scale ranging from micrometers to several millimeters with focus size less than a micrometer. Based on the subwavelength nature of phase shifters, the physical realization of the microlens relies on nanofabrication techniques. To be specific, it can be either fabricated through reactive ion etching (top-down process) or deposition then lift-off (bottom-up process). Despite the difference in the process details, both of the two techniques have one common challenge that it is extremely difficult to fabricate structures with a high aspect ratio (e.g., a ratio higher than 5:1 thickness versus width). For planar grating lens that is designed under linearly polarized incidence (e.g., utilization of propagation phase, not Pancharatnam–Berry phase), the different phase shift is created by altering the effective refractive index. To achieve enough phase shift in visible wavelength with limited thickness (e.g., low aspect ratio), researchers have looked into high refractive index materials such as GaN and TiO2. While high refractive index materials are enabling phase shifters more phase shift with comparatively low aspect ratio, their transmission may experience a significant drop. To design an optimum planar microlens, one should either increase the phase coverage of low-index material nanostructures or increase the transmission of high-index material nanostructures. While the most effective way of increasing phase coverage of nanostructures is to increase its thickness (increase single-mode propagation length inside the structure), this idea may not be practical, as we already approaching the limit of current
In this work, we have discussed possible transmission enhancement mechanisms and their feasibilities with the application of planar microlens. In addition, we have proposed the subwavelength-tapered nanostructure to enhance the transmission of TiO2 nanostructure as phase shifters of metasurface lens under the linearly polarized light. The enhancement effect is then numerically demonstrated.

**Achromatic Subwavelength Metasurface Lens Over Whole Visible Bandwidths**

Ya Sha Yi, Miao Ye, Dachuan Wu, Yuecheng Peng and Wei Guo; University of Michigan, Dearborn, Michigan, United States.

Metasurface lens is one of emerging planar nanophotonic devices that promises unprecedented control of the light at nano scale and have potential applications in highly multidisciplinary fields including imaging, sensing, spectroscopy and photovoltaics. Typically, for concentrating micro grating lens utilizing 0th diffraction mode, a high index contrast grating is used as individual phase shifter to satisfy the lens focusing requirements, as it can provide relatively large phase shift from 0 to 2π so that the light focusing condition can be met. However, the high index contrast gratings give rise to a significant chromatic behavior and achieving achromatic focusing over certain bandwidth turns out to be very challenging. The achromatic focusing capability is critical for a variety of applications, as light sources (e.g., light emitting diodes) or the signal (e.g., photoluminescence and fluorescence signals) has a substantial bandwidth, especially in the visible wavelength range. For refractive lens such as Fresnel lens, achromatic behavior requires hybrid design to compensate for chromatic loss, thus significantly increase the device’s complexity and cost. For emerging micro lens designed based on subwavelength phase shift units, metalens based on circularly polarized incidence is reported with achromatic behavior achieved through special dispersion control of Pancharatnam-Berry phase elements. While for linearly polarized incidence, only several wavelengths can be achieved in telecommunication range, lens with a notable focal shift or very narrow bandwidth has been achieved.

In this work, we have demonstrated the achromatic all-dielectric metasurface lens covering the whole visible wavelength based on relatively low index contrast gratings. Supported by the unique chromatic phase shift of polymer nano structure, we are able to demonstrate a broadband subwavelength achromatic micro lens which can cover 250 nm of visible bandwidths (from 435 nm to 685 nm) with focal shift less than 5% with linearly polarized incidence. Our work is a critical step further to achieve the promises made by the flat metasurface lens that is comparable with image qualities obtained by the commercial objective.

**EP04.03.27**

**Dielectric Metasurfaces with the Kerker Effect as Narrowband Absorbers in NIR**

Chi-Yin Yang1, Jhen-Hong Yang2, Zih-Ying Yang1, Zhong-Xing Jhou1, Viktoria Babicheva1 and Kuo-Ping Chen1; 1National Chiao Tung University, Tainan, Taiwan; 2Arizona State University, Tempe, Arizona, United States.

High-refractive-index (HRI) dielectric metasurfaces have attracted a lot of attention recently. Silicon is one of feasible HRI materials that has been widely used in solar cells, photonic waveguides, and photon detectors. However, the band-gap ~ 1 eV makes the quantum efficiency of silicon low at near-infrared (NIR) wavelengths. In this work, a high absorptance device is proposed and realized by using amorphous silicon nanoantenna arrays (a-Si NA arrays) that suppress backward and forward scattering with engineered lattice resonance with Kerker effect. The overlap of electric dipole and magnetic dipole resonances is experimentally demonstrated. The absorptance of a-Si NA arrays increases 3-fold in the near-infrared (NIR) range in comparison to unpatterned silicon films. Nonradiating a-Si NA arrays can achieve high absorptance with a small resonance bandwidth (Q = 11.89) at wavelength 785 nm.

**EP04.03.28**

**Shaping Terahertz Beams with High-Efficiency All-Dielectric Metasurfaces**

Cheng Zhang1, Erik Isele1,2, Wenqi Zhu1, Jared Strait1, Shawn Divitt1, Amit Agrawal1 and Henri Lezec1; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Due to its wide-bandwidth and transparency to many optically opaque dielectric materials, Terahertz (THz) wave plays a key role in the areas of telecommunications and national security. Moreover, THz technology is also critical for spectroscopic applications in the areas of chemistry, biology, and material science by its ability to measure optical properties (both amplitude and phase) over a broad spectral range simultaneously. However, despite significant progress in the generation and detection of THz radiation over the last couple of decades, one of the current bottlenecks has been the availability of high-efficiency and compact free-space optical elements for spatial manipulation of THz wavefront. As an example, one of the most common (and possibly the only) way to very tightly focus a THz beam is still using bulky hyper-hemispherical Si lenses which also inconveniently requires samples to be in contact with the lens surface. Only in the last few years, there has been significant developments in the ability to arbitrarily manipulate the spatial properties of optical beams in the visible and near-infrared regime using wavelength-scale thickness flat-optical elements, referred to as “metasurfaces”. Metasurfaces are typically composed of laterally shaped nano-scale optical elements (either metallic or dielectric) arranged in a sub-wavelength lattice, and are able impart spatially variant phase (amplitude) modulation to an optical wave-front. They can thereby achieve almost arbitrary control over wave-front shaping (analogous to refractive optics), however only with sub-wavelength-scale-thickness elements. Similar efforts have recently been extended to the THz frequency regime, although high operational efficiencies can only be achieved with reflection-type devices. Both low-efficiency and device operation in the reflection-mode of these devices remains a concern since most practical applications require a transmission geometry and high throughput efficiency.

In this work, we discuss design, fabrication, and characterization of all-dielectric THz metasurfaces exhibiting high throughput efficiencies and operating in the transmission mode. We utilize commercially available high resistivity silicon and fused silica wafers, as well as standard semiconductor manufacturing techniques to fabricate metasurfaces with high-throughput efficiencies, making our approach both practical and readily accessible to other researchers and industry users. As a proof of concept to demonstrate the versatility of our approach, we show high numerical aperture (NA ~ 0.9) focusing of THz radiation as well as generation of cylindrical vector THz beams with metasurfaces.
Silica-Coated Plasmonic TiN Particles for Photothermal Killing of Cancer Cells

Pascal Gieshwend, Simona Conti, Caroline Maake and Sotiris E. Pratsinis

Photothermal therapy (PTT) using plasmonic nanoparticles for cancer treatment is on the verge of clinical application. Titanium nitride nanoparticles[1] are a promising alternative photothermal agent compared to commonly used gold-based systems: Besides lower materials costs by a factor of 10⁵, TiN also exhibits a tunable localized surface plasmon resonance in the near-infrared (NIR) region for spherical particles in contrast to gold, where more complex structures are required to shift the LSPR from visible wavelengths to the NIR.[2]

Little is known, however, of the relationship between TiN particle characteristics and their optical properties in colloidal systems. Here, a detailed study on the synthesis of TiN nanoparticles by nitridation of TiO₂ and their use as PTT agents is reported. Special emphasis is laid on the oxygen content on the particle surface and bulk, which dictates the TiN optical properties. Colloidal suspensions were studied through UV-Vis and with NIR laser irradiation and correlated to particle characteristics. Higher nitridation temperatures and longer residence times are beneficial for increased NIR light absorption, while too high temperatures lead to aggregation of particles and deteriorated optical properties. This was overcome by the use of SiO₂-coated TiO₂ nanostructures as a starting material: The resulting SiO₂-coated TiN particles exhibited increased plasmonic properties compared to bare TiN, which was attributed to reduced plasmonic coupling effects. The optimized SiO₂-coated TiN had a photothermal efficiency of 58.5% and mass extinction coefficient of 31.5 Lg⁻¹cm⁻¹, outperforming commercial gold nanoshells that are used in clinical trials. Finally, the potential of SiO₂-coated TiN for PTT was successfully demonstrated in vitro by controllably killing HeLa cells.

Modification of Chemical Reactivity via Vibrational Strong Coupling Woonmi Ahn1, Igor Vurgaftman2, Adam Dunkelberger3, Jeff Owratsky3 and Blake S. Simpkins3; 1National Research Council Postdoctoral Associate, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2Optical Science Division, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 3Chemistry Division, U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

Polaritons, bosonic quasiparticles that result from strong photon-exciton coupling inside microcavities, have shown unique non-linear quantum phenomena such as Bose-Einstein condensation, superfluidity, and enhanced conductivity. Less well-known but equally intriguing is the strong coupling of molecular vibrations with resonantly-matched cavity modes, also referred to as vibrational strong coupling (VSC). The delocalized nature of hybrid polaritonic states opens up a new exciting route for modifying a material’s physical and chemical character including chemical reactivity. In this talk, we first demonstrate the strong relationship between cavity mode profile and spatial distribution of vibrational absorbers by systematically varying the location of a slab of vibrational absorbers within a Fabry-Perot microcavity. Both experiment and modeling showed a strong dependence of vacuum Rabi splitting on molecular distribution within the cavity, suggesting the possibility of controlling coupling strength, and potentially chemical reactivity, of a given region in the cavity through modification of the cavity field profile. We also examine cavities containing two remotely located slabs of vibrational absorbers that jointly couple to the cavity field and thus increase vacuum Rabi splitting by a factor of ~1.3. Finally, we examine a model reaction in pursuit of chemical reaction rates that can be modulated by VSC in a Fabry-Perot microcavity. Our results will further extend the knowledge of cavity-modified material properties, particularly chemical reactivity, which will have important implications for chemical synthesis and catalysis.

Nano-Plasmonic Metamaterials Composed of Self-Assembled Metal Nanoparticles and Their Bio-Application Kaoru Tamada; Institute for Materials Chemistry and Engineering, Kyushu University, Fukuoka, Japan.

A collective excitation of localized surface plasmon resonance (LSPR) has been studied extensively on 2D crystalline sheet composed of metallic nanoparticles [1]. The particle sheets are fabricated by self-assembly at air-water interface and deposited on solid substrates by Langmuir-Schaefer method. Both the experimental and the FDTD simulation data revealed a unique optical property of the 2D sheet, where the homogeneously coupled LSPR in 2D sheet exhibits not only a significant red-shift of LSPR band but also an additional amplification of electric field at the interface. Recently, a drastic reflection color change of Ag and Au nanoparticle multilayers was found on metal substrates [2, 3]. This phenomenon originates from the peak splitting of extinction spectra due to the electromagnetically induced transparency (EIT), occurring specifically on metal substrates [4]. The layer number dependent light confinement was critical, which resulted in such strong colors.Here the Ag nanosheets act as a nano-plasmonic metamaterial light absorber with a large oscillator strength. These optical data were well reproduced by the calculation with the Transfer-Matrix method by employing the effective medium approximation. This EIT related phenomenon was applied to colorimetric sensing devices, to detect a molecular level of reaction by naked eyes [5]. The 2D crystalline sheet was also an effective tool for high sensitive, high resolution fluorescence imaging of nanoflare [6]. The test experiments of actin filaments-labeled rat basophilic leukemia cells (RBL-2H3) and Paxilin-labeled NIH3T3 cells revealed high axial and lateral resolution even under a regular epifluorescence microscope, which held even better quality compared with the images taken under total internal reflection fluorescence (TIRF) microscopy [7, 8]. This non-scanning type, high speed imaging method will be quite useful to study dynamics of biomolecules.

10:30 AM EP04.04.07
Near Field Thermophotovoltaic Energy Conversion Linxiao Zha1, Anthony Fiorino1, Dakota Thompson1, Rohith Mittipally1, Pramod Sangi Reddy1, 2 and Edgar Meyhofer1; 1Mechanical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Materials Science and Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Heat-to-electricity conversion using solid-state devices is technologically important for electricity generation in remote locations, and waste heat recovery. In thermophotovoltaics, photons radiated from a hot thermal emitter are absorbed by a photovoltaic cell, exciting electron-hole pairs and generating electricity. A very hot thermal emitter is usually required for thermophotovoltaics to operate well. However, the temperature of the emitter is typically relatively low (~1000 K) such as in waste heat recovery, severely limiting the power output. Recent theories have proposed that when the gap size between the emitter and cell is much smaller than the thermal wavelength, the power output can potentially be dramatically enhanced by photon tunneling. Demonstration of such near field thermophotovoltaics has been elusive due to the difficulty in achieving a nanoscale gap between parallel surfaces of the emitter and the cell. In this talk we will describe how we experimentally demonstrated a 40 fold enhancement in power output, compared to the far-field, when the gap size between the emitter and the PV cell is reduced from ~10 µm to ~60 nm. Further, we will describe the dependence of performance on the temperature of the thermal emitter, and the bandgap of the PV cell. Our experimental results are supported by modeling based on fluctuational electrodynamics. Our work allows for systematically studying near field thermophotovoltaics towards high performance.

10:45 AM EP04.04.08
Unity Absorption in PbS Quantum Dots via Critical Coupling for Photonic Upconversion Michelle C. Sherratt, Mengfei Wu, Ting-An Lin, Marc Baldo and Vladimir Bulović; Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.
Solid-state infrared-to-visible photonic upconversion is a promising technique for improving the efficiency of optoelectronic devices such as photovoltaics and image sensors by generating additional above-band gap photons from sub-band gap ones that otherwise cannot be harvested. Previous works have demonstrated upconversion of near-IR (850 nm – 1010 nm) to visible (peaked at 610 nm) light utilizing PbS quantum dot absorbers and rubrene doped with 0.5 volume% of dibenzo[tetraphenyl]perilithene (DBP) as an annihilator/emitter layer. However, one of the primary limitations to realizing efficient devices based on this scheme is the low absorption of thin-film quantum dots in the near-infrared, typically less than 0.5%. In prior work, a 5-fold enhancement of PbS absorption (to ~1.5%) was demonstrated by introducing an Ag back-reflector, enabling an upconversion efficiency of 1.6% as compared to 0.51% as a result of the mirror effect.

In this work, we extend these studies to realize unity absorptance in the PbS quantum dot layer. We design a nanophotonic structure based on a critically coupled TiO₂ photonic crystal slab backed by a SiO₂/SiNₓ Distributed Bragg Reflector (DBR) to enhance the quantum dot absorption at 960 nm by ~200-fold. We assemble our upconversion structure of 5 nm PbS quantum dots/50 nm rubrene/DBP on a 70 nm thick TiO₂ photonic crystal slab infiltrated with spin-on glass (SiO₂). A pitch of 565 nm and hole diameter of 264 nm results in critical coupling to a guided mode in the TiO₂ slab, thereby enhancing the absorption into the PbS layer. By adding an 8-pair lossless DBR of quarter-wavelength SiO₂/SiNₓ (163 nm/123 nm), transmission is fully suppressed, allowing us to realize unity absorption into only the quantum dot layer in simulation. We additionally note that by designing a purely dielectric structure to enhance the QD absorption, reabsorption of the visible-wavelength light emitted by the rubrene/DBP is minimized. This will allow us to significantly improve the overall upconversion efficiency.

High Efficient Metallic Heat Sink Supported by Radiative Cooling Photonic Structures
Gil Ju Lee, Se-Yeon Heo and Young Min Song; School of Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology (GIST), Gwangju, Korea (the Republic of).

The advanced electronic devices such as portable and wearable devices have been widely spread, and the size of these handheld devices have decreased considerably while their power density has increased, therefore raising concerns about self-heating of devices. The undesired heat generation in the small electronics increases the surface temperature compared to skin temperature, resulting in thermal damage to epidermis layer. In addition to skin burn issues, the functionalities of the devices are deteriorated regarding operation speed, working time, and battery life. For the thermal management of these devices, a thin metal layer has been used as a heat sink element based on heat conduction and convection. Although such metallic film provides an excellent heat dissipation capability due to the high thermal conductivity, the thermal reduction path exists only convection effect with air.

Here, we propose the strategy of a high efficient metallic heat sink (HE-MHS) by introducing additional thermal reduction route, i.e. thermal radiation, therefore it boosts the cooling capacity remarkably. The overall configuration consists of a thin-metallic heat sink element and the engineered photonic structures that selectively emit the thermal infrared wave in atmospheric window (i.e. 8 – 13 μm). Aluminum was selected as the candidate of metallic layer for heat sink, with 30 μm-thick thickness allowing flexibility. The selective emitter (SE), which is photonic structure emitting thermal infrared wave, was formed on the metal film and composed of SiNₓ, SiO₂, and polydimethylsiloxane (PDMS). The simulated and measured emissivities were over 70% on average value in the wavelength of 8 – 13 μm.

The cooling performance was characterized with the handheld heater was used. The maximum surface temperature was increased depending on the supplied current to the heater, varying as 0.30, 0.35, 0.40, and 0.45 A, and the resulting temperatures were measured as follows: 1) the heater without the HE-MHS registered 42.3, 52.0, 55.1, and 64.7°C, respectively; 2) heater with the HE-MHS registered 28.1, 30.4, 32.6, and 35.6°C, respectively. This experimental result proves that the passive radiation-based cooling strategy is effective to suppress the heating of small electronics under solar irradiation.

11:15 AM EP04.04.10
Paint-Like Structured Polymer Coatings for High-Performance Passive Daytime Radiative Cooling
Jyotirmoy Mandal, Nanfang Yu and Yuan Yang; Columbia University, New York, New York, United States.

Passive daytime radiative cooling (PDRC) is a highly promising and sustainable way to cool structures ranging from buildings to vehicles, reduce carbon-footprints, and mitigate heat-island effects. Research over the years have yielded many designs for PDRC. On one end are common cool-roof paints, which, while inexpensive and easy to apply on surfaces, lack the high solar reflectance (R) and low long-wave infrared emittance (ε) required for PDRC. At the other end are multilayer photonic structures and metamaterials, which are efficient, but require silver mirrors to reflect sunlight and come as sophisticated and expensive sheets that are difficult to apply on rooftops. Therefore, a radiative cooler with performance comparable to such designs, but with the convenience of paints, remains sought after.

In our presentation, we will describe a simple, inexpensive and solution-based method for fabricating structured polymer coatings with an exceptional PDRC capability. Coatings fabricated by the process are hierarchically porous, which, due to the polymer's lossless behavior in the solar wavelengths and intrinsic emittance in the thermal wavelengths, yields remarkably high, substrate-independent hemispherical R (as high as 0.99) and hemispherical ε (as high as 0.97). The values are among the highest known in literature, and allow even completely exposed coatings to achieve sub-ambient temperature drops of ~0°C and cooling powers of ~96 W m⁻² under strong solar intensities of 800 and 750 W m⁻² respectively. The optical performance surpasses those of state-of-the-art PDRC designs, while the technique offers a paint-like applicability on diverse surfaces by techniques like painting, spraying and dip-coating. Furthermore, the process is compatible with a range of polymers, and can also incorporate dyes to achieve a desirable balance between color and radiative cooling. The performance of the coatings, along with the versatility of the technique, makes it attractive as a practical way to achieve high performance PDRC.

11:30 AM EP04.04.11
Hundred-Fold Enhancement in Far-Field Radiative Heat Transfer Over the Blackbody Limit
Dakotah Thompson1, Linxiao Zhu1, Rohith Mittapally1, Seid Sadat1, Zhen Xing2, Patrick McArdle2, Mumtaz Qazilbash2, Pramod Sangi Reddy1 and Edgar Meyhofer1; 1University of Michigan, Ann Arbor, Michigan, United States; 2Electrical Engineering and Computer Science, Gwangju Institute of Science and Technology (GIST), Gwangju, Korea (the Republic of).
Recent studies have shown that the radiative heat transfer rate between surfaces separated by nanometer gaps can greatly exceed Planck’s blackbody limit due to evanescent modes which are present in the near-field, i.e. gap separations below the peak thermal wavelength. However, achieving dramatic enhancements in radiative heat transfer in the far-field, when surfaces are separated by gaps much larger than the peak thermal wavelength, has not been explored experimentally. Here, we present experimental work demonstrating that the radiative heat transfer rate between appropriately designed nanostructures can exceed the blackbody limit by two orders of magnitude in the far-field. Our experimental platform comprises of aligned dielectric nano-membranes with embedded thermometers that allow the radiative heat transfer rate between the nano-membranes to be quantified. Large enhancements in heat transfer compared to the blackbody limit were observed for membranes with sub-wavelength thickness over a wide temperature range. The observed heat transfer rates are found to be in good agreement with our calculations based on the framework of fluctuational electrodynamics, which provide additional insights into the far-field radiative heat transfer between nanoscale objects in terms of enhanced emissions and absorption cross-sections in the infrared. This work highlights the potential of employing nano-membranes for controlling thermal absorption, and may have important ramifications for thermal to electric energy conversion.

11:45 AM EP04.04.12
Enhanced Forward Thermal Emission Enabled by Cascaded Particle Phonon-Polaritons Stavroula Foteinopoulou1 and Ganga Chinna Rao Devarapu2; 1ECE, University of New Mexico, Albuquerque, New Mexico, United States; 2Cork Institute of Technology, Bishopstown, Cork, Ireland.

Phonon-polariton materials have been largely overlooked as the material of choice to control infrared light-matter interactions as in bulk form they are near-perfect reflectors. However, recently they have emerged as one of the most prominent candidates for infrared “plasmonics” showing all the capabilities for light-confinement and enhancement as noble metals do in the visible spectrum. In particular, just as noble metal nanoparticles support particle plasmons for visible frequencies, sub-micron-sized particles made of a phonon-polariton material support particle phonon-polaritons which are localized resonances for infrared light. The operational frequency for such particle phonon-polaritons depends on the phonon-polariton material used and lies within its corresponding reststrahlen band in the broader infrared spectrum.

We show here that a judiciously designed micro pyramid array comprising SiC, exhibits a highly asymmetric cascaded coupling effect between such particle phonon-polaritons corresponding to each structural block [1]. We demonstrate how this asymmetric cascaded coupling effect leads to enhancement of thermal emission in one direction and its suppression in the opposite propagation direction [1,2]. We show that this highly asymmetric thermal emission can exist over a broad spectral range and over a wide angular range, of more than 45 deg. from normal incidence. In other words, this SiC platform behaves as a highly efficient forward thermal emitter [3]. This behavior is highly relevant to many application domains of infrared photonics such as one-way THz/infrared sources, thermal management and passive radiative cooling devices.

Analog Optical Computing Using Silicon Metasurfaces Albert Polman; Center for Nanophotonics, AMOLF, Amsterdam, Netherlands.

We present Si-based optical metasurfaces with suitably engineered spatial dispersion that perform mathematical operations on optical input fields in the visible and near-infrared spectral range. The nanopatterned surfaces, made by electron beam lithography and etching, are designed to sustain propagating leaky modes that interfere with a Fabry-Perot continuum to form Fano resonances with a line shape that creates a transfer function in Fourier space corresponding to first or second derivative. We present analytical theory, numerical modeling and experimental data using a broad range of input fields. Second-derivative metasurfaces create efficient edge detection with applications in image recognition as we will show. An outlook will be given for the emerging potential of analog optical computing using optical metasurfaces.

2:00 PM EP04.05.02
Photonic Crystal Fiber Metalens Enabled by Geometric Phase Optical Metasurfaces Jingyi Yang1, Indra Ghimire1, Pin Chieh Wu2,3, Sudip Gurung1, Catherine Arndt1, Din-Ping Tsai2 and Howard Lee3; 1Physics, Baylor University, Waco, Texas, United States; 2Research Center for Applied Sciences, Academia Sinica, Taipei, Taiwan; 3Thomas J. Watson Laboratories of Applied Physics, California Institute of Technology, Pasadena, California, United States; 4The Institute for Quantum Science and Engineering, Texas A&M University, College Station, Texas, United States.

Optical fiber is a well-established and efficient way to guide and manipulate light1. Although optical fiber is efficient for transmitting light, its functionality is limited by the dielectric properties of the constituent materials. The light exiting an optical fiber is typically diverging. Furthermore, the numerical aperture is determined by the refractive index of the fiber materials. Thus, the light intensity decreases significantly upon exiting the fiber. The emergence of metasurfaces provide the opportunity to tailor light’s properties for advanced light manipulation and to develop novel optical applications. For example, a specific profile using spatially-varied nano-antenna elements allow metasurfaces to control the wavefront of the light enabling novel ultrathin optical components such as flat lenses (i.e., metalens) 2-3. In this work, we experimentally demonstrated an ultrathin optical metalens, cascaded on the facet of large mode area photonics crystal fiber (LMA-PCF), that enables light focusing upon the fiber in the telecommunication regime. Our PCF metalens is designed to have a focal length of 30 µm and numerical aperture of 0.37 at operating wavelength of 1550 nm when fabricated on the core of LMA-PCF with diameter of 25±1 µm. A rectangular groove in the gold nano-layer is employed as a unit element (dimension: 489 nm x 134 nm; period: 602 nm). The large core area of PCF allows more fabricated unit elements (total 1261) on the core while maintaining single mode guiding, thus...
providing a smooth phase profile. To fabricate the PCF metalens, we first deposit a 40nm thick gold layer on the end facet of LMA-PCF by magnetron sputtering and fabricate desired pattern by focused ion beam milling. To verify the focusing effect, we capture the mode profiles along the propagation direction using a z-scan setup that consisting of objective lens, quarter waveplate, linear polarizer, and infrared camera. The right-handed circularly polarized light is launched to the PCF metalens and the left-handed circularly polarized output component is collected. Output light focusing is observed at the focal length of ~25.3 to 28 µm with wavelength between 1500 -1630 nm, which is close our designed focal length of 30 µm. The full-width at half-maximum of our observed focus spot ranges between 2.4 to 2.6 µm. Our maximum operating efficiency is 16.4%, which approaches the theoretically-predicted level for flat metasurfaces. Our integration of metalens and optical fiber will be significant in the miniaturizing of optical fiber devices with multi-functionalities and pave the way for in-fiber optical imaging and sensing applications.

Flat and Flexible—New Multi-Functional Metamaterials for the Far- and Near-Field Nanophotonics Yoichiro Tsurimaki1, Yi Huang1, Marcelo Lozano1,2, Seong Don Hong1,2, Gang Chen1 and Svetlana V. Boriskina1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Tecnologico de Monterrey, Escuela de Ingeniería y Ciencias, Monterrey, Mexico; 3Defense Agency for Technology and Quality, Seoul, Korea (the Republic of).

Emerging nanophotonic applications often rely on the use of 3D nano-structured materials, which require intricate low-throughput fabrication, are costly, and limited to the microscopic device footprints. I will discuss our work on the development of smart multi-functional nanophotonic structures, which can be fabricated by high-throughput techniques without the need for nano-patterning. These include single- and multiple-wavelength super-absorbers with flat surfaces designed via topological engineering of the layered material bulk (1,2), flexible polymer-based materials for solar energy harvesting and passive thermoregulation (3–5), and meso-porous network metamatals for solar-thermal energy harvesting, colorimetric sensing and security (6).

Metamaterials at the Extreme, Waves at the Limits Nader Engheta; University of Pennsylvania, Philadelphia, Pennsylvania, United States.

We have been exploring how the “extreme” light-matter interaction can be achieved using specially designed materials and metastructures. Several scenarios have been investigated, including near-zero-index photonic platforms, extreme quantum optics, geometry-independent “flexible” resonant cavities, ENZ electric-dipole levitation, coherent thermal emission, photonic bound states in the continuum, and more. Moreover, we have been working on materials platforms that would achieve functionalities useful for informatics, e.g., materials that “do the math”, structures that “solve equations”, etc. In a separate paradigm, we have also investigating how 4-dimensional metamaterials can give us more functionalities. I will discuss our most recent results for some of the above topics.

3:45 PM EP04.05.05
Harnessing Evanescent Waves by Metasurfaces Lin Li, Bo Xiong and Yongmin Liu; Northeastern University, Boston, Massachusetts, United States.

Evanescent waves are oscillating fields with energy spatially concentrated in the vicinity of an illuminated or emitting object. Evanescent waves are widely exist in nature, ranging from the non-radiative emission of nano emitters (e.g., quantum dots, N-V centers, and fluorescent dyes), to optical surface waves such as surface plasmon polaritons, and to near-field optical waves induced by moving charged particles. Evanescent waves carry rich non-radiative energy and important information about sub-wavelength features of the object. They have been extensively studied in many areas, such as super-resolution imaging/lithography, biomedical sensing, electron-driven light sources and energy harvesting, thanks to their unique spatial confinement properties.

However, the exponentially decaying nature of evanescent waves renders it difficult to capture, extract and engineer the wealth of energy and information that they can carry.[1,2]. In this work, we propose and experimentally demonstrate an innovative method to overcome this fundamental challenge by using a novel metasurface that consists of C-aperture resonators, so that we can efficiently convert evanescent waves to the far field emission. Meanwhile, the phase and polarization of the emission can be well controlled with the metasurface. Both electric and magnetic dipoles are utilized by changing the orientation of the C-aperture resonators[3] to achieve a complete control of the phase and polarization of optical waves. This approach is distinctly different from most previous metasurface works that only utilize electric dipole resonances. As a result, we can manipulate the near-field to far-field radiation with desired functionalities, such as the focusing, holography and polarization switching, without any additional, bulky optical components. In the experiment, we generate evanescent waves with total internal reflection scheme and the evanescent waves are modulated by the designer metasurface. The experimental results rigorously show focusing, holography and polarization switching as the theoretical designs, clearly confirming the new metasurface strategy. Our findings offer a versatile platform to extract and explore the near-field energy carried by evanescent wave and manifest promising applications in integrated optics. It will also further inspire studies related to evanescent waves, such as near-field energy harvesting, electron induced emission, subsurface sensing, and so on.

Magneto-plasmonic Sub-Nanometer-Multi-layer Nanoantennas for the Dynamic Magnetic Chiroptics and Structural Color Evgeniya Smetanina1, Irina Zubritskaya1, Esteban Pedrueza Villalmanzo1, Nicolò Macciaferri2, Paolo Varvassori3,4, Alexander S. Roberts2, N. Asger Mortensen5,6 and Alexandre
Optical platforms enabling the dynamic real-time control of the fundamental properties of light at visible and near-infrared frequencies are the essential components for the future optoelectronic devices. Combining materials with magnetic and plasmonic properties gives a possibility for a simultaneous enhancement of the chiro-optical and magnetic-optical properties [1-4]. Here we examine nanoantennas consisting of noble metal-ferromagnet sub-nanometer multilayers to employ it as an element in magnetically-controlled chiroptical surfaces and in plasmonic color printing. We design a nanodisk antenna comprising 15 interchanging Co (0.5 nm)/Au (1.5 nm) layers and perform a careful tuning of the layers to ease the strong perpendicular magnetic anisotropy [5] and the low magnetic saturation field to ease the magnetic control. By this we reach the magnetization switching at 0.7 Koe with the strong magnetic signal despite the insignificant amount of Co (7.5 nm of pure Co (15 Co layers x 0.5 nm thickness) in the multilayer nanodisk of the total thickness 31.5 nm). We propose using the developed Co/Au magnetoplasmonic element to control with the markedly low magnetic fields the chiroptical transmittance [6] and to be implemented as a dynamic color pixel in the plasmonic color printing. For the latter we show numerically that such Co/Au nanoelement provides a color-selective reflection [7-9] that could be potentially modulated by the external low magnetic fields.

electric dipole and electric quadrupole lattice resonances allows achieving significant reflection suppression and observation of a generalized lattice Kerker effect. Full-wave numerical simulations with a finite-difference time-domain method agree well with analytical calculations based on coupled dipole-quadrupole equations. One can engineer nanostructures of TMDC, transition metal oxides, and many other commonly occurred materials with HIPP to enhance the performance of plasmonic devices based on such HIPP materials.

Enhanced Plasmonic Optical Tweezer via Synergistic Effects of AuNPs/ZnONRs Structure So Yun Lee1, Jae Ryoun Youn1 and Young Seok Song2; 1Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of); 2Department of Fiber System Engineering, Dankook University, Yongin, Korea (the Republic of).

An enhanced plasmonic optical tweezer is investigated by utilizing hybrid gold nanoparticles/zinc oxide nanorods structure (AuNPs/ZnONRs) and the localized surface plasmon resonance (LSPR) phenomena. The structure is selected based on the numerical prediction which confirms the synergistic effects of AuNPs/ZnONRs on the LSPR-induced near-field enhancement and plasmonic heating. Finally, the plasmonic substrate is fabricated and indeed exhibits enhanced trapping performance compared to a control sample consisting of only gold nanoislands (AuNIs). The 3D numerical simulation of the electromagnetic field (EM) and coupled temperature-velocity fields (T-V) are conducted by using COMSOL Multiphysics®. First, the EM is solved to obtain the near-field enhancement around the nanostructures with the time-independent wave equation. Then, the coupled T-V are solved to obtain the temperature field, temperature gradient and velocity field with the steady-state coupled momentum-energy equations. The hybrid nanostructure was fabricated by the hydrothermal growth of ZnONRs followed by the photochemical reduction of AuNPs on the surface of ZnONRs3. For the trapping experiment, 1 μm PS particle suspension was used and a linearly polarized 532 nm laser of 1 mW was focused on the substrate through a 40×-objective lens. Maximum value of near-field enhancement factor and temperature of AuNPs/ZnONRs increase by about 107 % and about 160 %, respectively, compared to those of AuNIs. Moreover, AuNPs/ZnONRs results in steeper temperature gradient and faster fluid velocity than AuNIs, which are expected to be the main factors for enhancing the particle trapping performance.

The results of the scattered electric field and the pointing vector reveal that ZnONRs guides the enhanced incident light along the nanorod via leaky waveguide modes2. High dielectric constant of ZnO and the nanorod geometry result in efficient dipole scattering at the nanorod surface and wave guiding of the enhanced light, respectively.

In the experiment, the steeper temperature gradient and better multiple-trapping ability of AuNPs/ZnONRs than that of AuNIs are verified. All AuNPs/ZnONRs samples show better particle trapping performance than AuNIs. The material and structural effects of metal-dielectric hybrid nanostructure on LSPR and the plasmonic tweezer performance were investigated. We expect that this study will provide a useful way for designing the power-efficient device in various fields such as photovoltaics and photocatalysis, etc. where they can take advantage of the LSPR-induced photophysical processes.

Coupling Pyrromethene Dye Excitons to Plasmonic Surface Lattice Resonances Robert Collison2, 3, 4, Jacob Trevino3, Vinod Menon3, 1 and Stephen O'Brien2, 1; 1The City University of New York, New York, New York, United States; 2Ph.D. Program in Chemistry, The Graduate Center of the City University of New York, New York, New York, United States; 3The City College of New York, New York, New York, United States; 4The Advanced Science Research Center, CUNY, New York, New York, United States; 5Electrical Engineering, Columbia University, New York, New York, United States.

For the past ten years, plasmonic surface lattice resonances (SLRs) have been a growing topic of interest for photonic and plasmonic devices. We report on the fabrication of SLR-supporting arrays of aluminum nanodisks on glass, and the coupling of these SLRs to organic dye excitons on arrays coated with dye or dye-doped polymer films. In particular, the interaction of the SLRs with the excitons of the pyrromethene laser dye P580 is examined via angle-resolved transmission, reflection, and photoluminescence spectroscopy. Through variation of the concentration of the dye, the plasmonic particle diameter, and the spacing of the particles in the periodic lattice, the wavelengths of the relevant resonant modes and the Rayleigh anomaly are varied to determine the strength of the interaction between these modes, as well as the wavelengths and dispersions of the resulting SLR-exciton hybrid modes. The effects of coupling between the SLRs of various arrays with dye excitons, including angle-dependent emission, are reported.

EP04.06.03
Large Diffracted Transverse Magneto-Optic Kerr Effect in Magnetoplasmic Crystals Mikko Kataja, Rafael Cichelero and Gervasi Herranz; CSIC-ICMAB, Bellaterra, Spain.

Surface plasmon resonances confine light into subwavelength dimensions which results in a corresponding increase in electric field intensities near plasmonic nanostructures. Phase-matching conditions are exploited to enable nonreciprocal optical propagation and enhanced magneto-optic responses in magnetoplasmic systems [1]. Here we show that exploiting diffraction in conjunction with plasmon excitations adds further versatility and flexibility in
the design of photonic systems. As a testbed we analysed transverse magneto-optic Kerr (TMOKE) responses in magnetoplasmonic gratings etched into gold-cobalt multilayers. The grating coupler was chosen as the simplest system where we can combine the three distinct phenomena: magneto-optics, diffraction and plasmonics. The presence of transverse magnetization modifies the propagative conditions of the SPPs along the grating and lifts the degeneracy between the forward- and backward propagating modes. Angular resolved measurements revealed narrow line-shape plasmon resonances that were accompanied by large magneto-optical intensity effects in the diffracted beams. We show that exploiting plasmon resonances in diffraction gratings allows unexpectedly large diffracted TMOKE responses that exceed 3% - up to one order of magnitude larger than reported diffracted magneto-optical effects in systems where plasmon resonances are not present [2,3]. Our results pave the way towards using magneto-optical modulation of SPPs to build non-reciprocal diffraction components that could be used to control the direction of propagation of light beams.

**Zirconium Nitride Shells for Plasmonic Cloning of Visible Photodetector Nanowires**

Katherine Hansen1 and Chen Yang2,1; 1Chemistry, Boston University, Boston, Massachusetts, United States; 2ECE, Boston University, Boston, Massachusetts, United States.

One of the most critical challenges to high-performance nanowire (NW) photodetectors is the detectability of weak signals that noise obscures; the signal to noise ratio is critical in nanowire photodetectors due to nanoscale devices typically operating at lower voltages. Cloning is a proposed method to reduce the noise generated due to the probed field being disturbed by light scattered by the photodetector itself. It has been shown that for a silicon NW a gold shell can be engineered to support a polarization vector antiparallel to the original vector of the core, canceling the scattering response and effectively cloning the visible part of the electromagnetic spectrum without affecting the absorption.

Alternative plasmonic materials, such as zirconium nitride (ZrN), have permittivity values similar in magnitude to common dielectric components, an ideal condition for generating an antiparallel polarization vectors in the shell and core, and are in general considered easier for fabrication and integration. Here we propose and study theoretically zirconium nitride plasmonic cloaks as a plasmonic cloak for silicon nanowire photodetectors, using Mie formalism for scattering and absorption efficiency and near-field contours of the electric field. We have predicted ZrN cloaks to produce a significant decreasing the scattering, greater than 10 times compared to a bare wire, over a broad wavelength range for a broad range of shell thicknesses, with the greatest decrease being 28 times at 710 nm. We also predict the ZrN cloak to decrease the absorption of the photodetector across the visible spectrum without significantly decreasing the absorption within the silicon core compared to a bare silicon wire. By decreasing the scattering efficiency while simultaneously increasing the absorption efficiency of the nanowire, a ZrN cloak results in a 300 times increase in the ratio between the absorption cross-section and the scattering cross-section compared to a bare wire, thus making ZrN a excellent cloak better than traditional plasmonic materials.

**Nanoscale Artificial Plasmonic Lattice in Self-Assembled Vertically Aligned Nitride—Metal Hybrid Metamaterials**

Jiujie Huang1, Xuejing Wang1, Nicki Hogan2, Shengxiang Wu2, Ping Lu1, Zhe Fan1, Yaomin Dai1, Beibei Zeng4, Ryan Starko-Bowes1, Jie Jian1, Han Wang1, Leigang Li5, Rohit Prasankumar4, Dmitry Yarotski6, Matthew Sheldon2, Hou-Tong Chen2, Zubin Jacob1, Xinghang Zhang1 and Haiyan Wang2; 1Purdue University, West Lafayette, Indiana, United States; 2Texas A&M University, College Station, Texas, United States; 3Sandia National Laboratories, Albuquerque, New Mexico, United States; 4Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Nanoscale metamaterials exhibit extraordinary optical properties and are proposed for various technological applications. Here, a new class of novel nanoscale two-phase hybrid metamaterials is achieved by combining two major classes of traditional plasmonic materials, metals (e.g., Au) and transition metal nitrides (e.g., TaN, TiN, and ZrN) in an epitaxial thin film form via the vertically aligned nano composite platform. By properly controlling the nucleation of the two phases, the nanoscale artificial plasmonic lattices (APLs) consisting of highly ordered hexagonal close packed Au nanopillars in a TaN matrix are demonstrated. More specifically, uniform Au nanopillars with an average diameter of 3 nm are embedded in epitaxial TaN platform and thus form highly 3D ordered APL nanoscale metamaterials. Novel optical properties include highly anisotropic reflectance, obvious nonlinear optical properties indicating inversion symmetry breaking of the hybrid material, large permittivity tuning and negative permittivity response over a broad wavelength range, and superior mechanical strength and ductility. The study demonstrates the novelty of the new hybrid plasmonic scheme with great potentials in versatile material selection, and, tunable APL spacing and pillar dimension, all important steps toward future designable hybrid plasmonic materials.

**EP04.06.06**

**Plasmonics-Nanofluidics Hybrid Device—An Ultra-Sensitive Infrared Spectroscopic Platform for Bioanalysis and Study of Nanoconfined Molecules**

Thu H. Le1,2 and Takuo Tanaka2; 1Department of Applied Chemistry, The University of Tokyo, Tokyo, Japan; 2Innovative Photon Manipulation Research Team, RIKEN Center for Advanced Photonics, Wako, Japan.

Infrared (IR) absorption spectroscopy is one of the most powerful analysis tools, as it extracts essential information of chemical bonds and molecular structures in a label-free fashion. However, the low sensitivity which is originated from the intrinsically low absorption cross sections severely limits their practical applications. Plasmonic metamaterials-based IR spectroscopy has emerged as an promising approach that improves the sensitivity by exploiting the localized enhanced electromagnetic field (i.e., hot-spots) in plasmonic materials. This effect, however, is only effective when target molecules are located at the enhanced electromagnetic fields. It is thus of significance to control the spatial overlapping of molecules and hot-spots, yet it is a long-standing challenge.

Here we propose a plasmonics-nanofluidics hybrid device that enables the controllable delivery of molecules into the enhanced field of the plasmon modes. The device consists of a nanofluidic channel with a depth of several tens of nanometers sandwiched between a metal film and a batch of periodic nano square-disks. The structure forms a quadrupole resonant mode that traps the plasmonic energy inside the gap between two metal layers. This feature is exploited for ultra-sensitive detection and quantitative measurement of biomolecules. Furthermore, taking the advantage of precisely controlling the confinement of plasmonic fields inside the nanofluidic gap, we have also succeeded in characterizing the molecular structures of nanoconfined water. The performance of our device in ultra-sensitive detection of molecules and protein in aqueous solution were demonstrated. The device was purposely designed to spectrally overlap with the vibrational modes of the target molecules. When the analyte solution is introduced into the nanofluidic channel, the reflectance spectrum of the device reveals the signals of molecular vibrational modes as distinct peaks in the broad reflectance dip of the plasmonic structure. Our method confirmed the enhancement of sensitivity up to two orders of magnitude, with respect to previous reports.

Our device was also applied to measure the infrared absorption characteristic and elucidate the molecular structures of water confined in a 10 nm gap. It reveals the presence of a strong H-bond network with respect to bulk water, and the scaling behavior of confined water in the several tens of nanometer size regime. This effect is also found not being driven by the interaction with the interfaces; yet the constrained geometry itself promotes the intermolecular interactions of water and results in the modification of the H-bond network.

In conclusion, a plasmonics–nanofluidics hybrid device was proposed and demonstrated by employing top-down fabrication techniques. Our device has
offered an ultrasensitive platform for detection of molecules and in-situ probing of molecules or chemical reactions beyond the nanoconfinement.

**EP04.06.07**

**Versatile Top-Down Magnetoplasmonic Nanocone Optical Antennas**

Richard M. Rowan-Robinson1, Agne Čiučiulkaitė1, Ioan-Augustin Chioar1, Oleg Lysenko2, Matteo Pancaldi3, Paolo Vavassori4, Alexandre Dmitriev5 and Vassilios Kapaklis2; 1University of Gothenburg, Gothenburg, Sweden; 2CIC nanoGUNE, San Sebastian, Spain; 3IKERBASQUE, Bilbao, Spain.

Nanoscale confinement of light with the aid of plasmonics has stimulated research towards a number of future technologies including nanophotoniccircuit,s on-chip micro- and nanosensor arrays, super-resolution imaging and designer flat-optics. Within this field, active plasmonics, for which the optical properties can be tuned in real time by an external stimulus are of great interest. Here, magnetoplasmonics provides a promising avenue for real-time dynamic plasmonic devices with the use of an external magnetic field [1,2].

Here, we use a top-down approach to fabricate large area ordered arrays of magnetoplasmonic nanocone antennas. Using electron beam lithography a nanodiskhard-mask is patterned on the Au/TbCo film. By tuning the mask diameter, either complete or truncated nanocones are produced after the Ar+ ion milling process. The base diameters range between 100 to 200nm with the plasmonic body of Au and TbCo nanocone tip. The latter is ferromagnetic at room temperature exhibiting perpendicular magnetic anisotropy. We characterise the magneto-optical enhancement as a function of wavelength and incidence angle. An enhancement of the Faraday rotation and ellipticity is observed at the plasmon resonance.

Varying the incidence angle alters the contributions of vertical and base plasmon modes of the nanocone antenna, which could enable the generation of circularly-polarized electromagnetic near-fields in the vicinity of the nanocone tip. Preliminary simulations indicate that the nanocone geometry can sustain the input circularly polarisation, with an optical spin, generated at the tip. Note that amorphous TbCo is known to exhibit helicity-dependent all-optical magnetization switching [3]. The combination of the TbCo tip and the Au plasmonic antenna capable of enhancing the opticalspin could therefore pave the way for the plasmon-assisted optical magnetization switching at the nanoscale.

**Negative Optical Torque Arising from Mesoscopic Assembly of Plasmonic Nanoparticles**

Fei Han and Zijie Yan; Clarkson University, Potsdam, New York, United States.

Novel photonic materials not only rely on the properties of individual components, but also depend on the integration approach and structure of the building blocks. Here we report a new type of material assembly with emergent photonic properties: mesoscopic optical matter clusters self-assembled from silver nanoparticles under laser illumination. These nanoparticles are discrete in space yet behave as a rigid body due to strong mesoscale electrodynamic interactions. The clusters rotate opposite to the direction of the incident beam’s angular momentum, i.e., a negative optical torque behavior. Normal materials, e.g., the individual Ag nanoparticles, will only show positive optical torque. We will discuss the rich experimental phenomena observed in the optical matter system and reveal the mechanism for the emergence of negative optical torque.

**EP04.06.09**

**Electrochemical Doping of Conjugated Polymer Thin Films for Infrared Plasmonic Behavior**

Hemanth Maddali; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

The application of conjugated polymers for various purposes is expanding due to the introduction of pronounced electro-active behavior by doping. Some of these polymers include polyacetylene, polyaniline, polypyrrole, polythiophene as well as their various derivatives. Doping can switch a polymer from an insulator or a semi-conductor to a metal-like conductor and, is crucial for various electronic and optoelectronic applications. In particular, doped conjugated polymers can behave like disordered metallic materials and can exhibit conductivities ranging from ~10 S/cm to ~10,000 S/cm. We hypothesize that the afore-mentioned conductivities could result in a plasmonic frequency similar to that of metals, but in the mid- or far-infrared spectral region. Conventionally, heavily-doped inorganic semiconductors and metals are used as infrared plasmonic materials, but they are energy-intensive to produce due to high process temperatures and vacuum-based deposition. Utilizing conjugated polymers that are solution and room-temperature processable as infrared plasmonic materials would reduce the process energy and associated costs. However, a detailed study is required to prove that highly-doped polymers are suitable infrared plasmonic materials.

In this study, we prepare conjugated polymer (polythiophene) thin films on an indium-tin oxide (ITO) coated glass substrate using spin coating followed by electrochemical doping using tertbutylammonium perchlorate. A three-electrode setup is employed using the polymer-coated ITO-glass as the working electrode, a platinum counter electrode and a non-aqueous reference electrode. There was an immediate change in the color of the films from a bright pink (undoped film) to dark blue (doped film) upon electrochemical doping. The surface morphology of the undoped film was smoother when compared to the doped film which exhibited local micron-sized clusters and increased roughness due to dopant inclusion. The electrical properties are compared between the doped and undoped polythiophene films using four-point probe conductivity measurements. Preliminary measurements show a clear increase in the conductivity because of doping. However, contributions from the underlying ITO must be deconvoluted from the data before conductivity can be accurately quantified. Both transmission and reflection-mode infrared spectroscopy are used to measure changes in the infrared absorption of the doped and undoped polythiophene films and to determine the plasma frequency. A relation between conductivity (controlled by doping concentration) and plasma frequency can be established using the Drude model which allows us to identify the doping concentration required for a maximum plasmonic response. If optimum doping concentrations can be obtained, doped conjugated polymer materials could be a class of low-embodied-energy plasmonic material used for sub-wavelength waveguides, gratings and nano-particles with strong infrared optical responses.

**EP04.06.10**

**Imaging Enhanced Upconversion Luminescence from Single NaYF₄:Yb³⁺,Tm³⁺ Nanoparticles on Plasmonic Substrates**

Anahita Haghighadeh1, Amy Hor1, Jon Fisher1, Paul S. May2 and Steve Smith1; 1Nanoscience and Nanoengineering, South Dakota School of Mines and Technology, Rapid City, South Dakota, United States; 2Chemistry, University of South Dakota, Vermillion, South Dakota, United States.

We use single particle spectroscopic imaging and statistical analysis to assess the plasmonic enhancement of NIR-to-visible upconversion luminescence (UCL) from single B-NaYF₄:Yb³⁺,Tm³⁺ upconverting nanoparticles (UCPNs) supported on substrates consisting of random arrangements of Ag nanowires (NW) and Au nano-cavity arrays. We measure both apparent luminescence enhancement, which is power dependent due to the nonlinear kinetics of energy transfer upconversion (ETU), and the excitation enhancement, defined as the ratio of the excitation intensity needed to produce a given UCL emission,
Plasmonic-based sensors exploit sensitivity of plasmon resonance conditions to the dielectric constant of the local environment. However, the resonances are usually broad; in order to enhance the sensitivity, the presence of sharp features in angular or spectral behavior of the plasmon resonance is very desirable. In our work we explore two approaches, involving such features. All optical approach uses the extra-sharp peak observed in the reflection from gold nanostrips. The reflectivity from the gold nanostrips immersed in an ethanol-water solution demonstrates a very high sensitivity to small variations in ethanol concentrations at the angle of the sharp reflection peak. The second approach involves electrical detection which does not require a bulk optical setup, and is based on strong enhancement and polarity switching of the photo-induced voltages (plasmon drag effect) under plasmon resonance conditions observed in the strongly nanostructured systems. We show that the presence of an additional polymer layer deposited on the top of the structure significantly shifts the angular position of the signal. Further studies are in progress.

**EP04.06.12**

**Strong Coupling Under Gap Plasmon Mode in a Film-Gold Nanopyramid Array Structure**

Suvin Phani Kumar Kasani1, Peng Zheng2 and Nianqiang Wu1;
1Department of Computer Science and Electrical Engineering, West Virginia University, Morgantown, West Virginia, United States; 2Department of Mechanical & Aerospace Engineering, West Virginia University, Morgantown, West Virginia, United States.

Development of surface plasmon polaritons (SPPs) based optoelectronic devices is restricted mainly because of a high metallic energy loss and a weak nonlinearity of SPPs. This issue can be potentially addressed by making them work in the strong-coupling regime where the coupling strength outcompetes the energy loss. One way to achieve strong coupling is to couple a nonlinear material such as quantum emitter with the metallic nanostructure. In this work, the nanosphere lithography technique is used to fabricate a large area two-dimensional film-coupled gold nanopyramid array which supports gap plasmon mode. By incorporating a layer of quantum emitters at the gap, strong coupling is demonstrated between quantum emitters and the gap plasmon mode. This study has strong implications in designing state-of-the-art optoelectronic devices.

**EP04.06.13**

**Phosphorus Doped Diamond for Quantum Applications**

Shannon S. Nicley1, 2, 3, Paulius Pobedinskas2, 3, Rozita Rouzbahani2, 3, Sam Johnson1, Ken Haeneri1, 3 and Jason M. Smith1;
1Materials, University of Oxford, Oxford, United Kingdom; 2Institute for Materials Research (IMO), Hasselt University, Diepenbeek, Belgium; 3IMEC, IMEC vzw, Diepenbeek, Belgium.

The negatively charged nitrogen-vacancy (NV) centre in diamond is extremely promising as an optically addressable defect for quantum applications. Only the NV- state can be optically polarised and read out, however NV centres normally undergo photoionised charge-state conversion between NV- and a neutral state. A 532 nm laser pulse can be used to repump the centre into the desired state; but the repumping can also change the electrostatic environment of the NV centre, shifting the optical transition frequency by several linewidths. Improvements in spectral stability have been shown by repumping at 575 nm, however this still relies on laser pumping to maintain the NV state. The recent demonstration of the state-of-the-art in quantum entanglement in diamond, with entangling rates of up to 39 Hz [1] also illustrates the limitations posed by repumping to maintain the NV- state. Of their total ~75.5 μs protocol, ~50 μs is used for checking that the NV remains in the NV- state and is on-resonance, and if the neutral state is detected, an additional 300 μs is needed to repump into the NV-, which can be repeated many times before the entanglement experiment can begin. A novel solution to minimise repumping involves doping single crystal diamond (SCD) material n-type, so excess electrons stabilise the NV- charge state, without initialisation. A recent study [2] using the n-type dopant phosphorus (P) in CVD grown SCD demonstrated NV centres that remained stable in the NV- charge state. The precise control of the P concentration is critical for achieving long spin coherence (T2) times, with T2 = 0.8 ms already demonstrated for P-doped diamond [3]. Achieving controllable levels of P is an area of significant current interest [4-6] and so controlled parameter studies of the growth of P-doped diamond for quantum applications are needed.

We have grown a series of thick SCD samples with varying P/C in the plasma feedgas on (111) oriented Sumitomo substrates in a series of 24 h deposition experiments at 1000 °C. We have also grown a second series of 24 h deposition P-doped growth experiments with 0.5% oxygen in the plasma feedgas with varying concentrations of methane, for comparison of NV properties across a wide parameter space. FTIR and Hall effect results confirm the P-incorporation at the high growth temperature studied (1000 °C). We will present photoluminescence mapping and spectroscopy results, and assess the factors affecting the quality of the grown films for NV- stability and performance, to give strategies for achieving the growth of high quality n-type single crystal diamond for quantum applications.

**First Principles Approaches to Strongly Coupled Light-Matter Systems**

Johannes Fleck and Prineha Narang; Harvard University, Cambridge, Massachusetts, United States.
In recent years, research at the interface of chemistry, material science, and quantum optics has surged and now opens new possibilities to study strong light-matter interactions at different limits [1,2].

Combining theoretical concepts from the fields of material science and quantum optics presents an opportunity to create a predictive theoretical and computational approach to describe cavity correlated electron-nuclear dynamics from first principles. Towards this overarching goal, we introduce a general time-dependent density-functional theory to study correlated electron, nuclear and photon interactions on the same quantized footing [3].

In this talk, we demonstrate how Rabi splitting under strong light-matter coupling emerges in the absorption spectra and analyze cavity-modulated molecular motion of CO₂ molecules in optical cavities. Further, we use this novel framework to study how the potential-energy surfaces (PES) of a CO₂ molecule change under light-matter interaction.

Our work opens an important new avenue in introducing ab initio methods to the nascent field of collective strong light-matter interactions.

EP04.06.15
Towards Ab Initio Theory of Ultrastrong Coupling Photonics and Plasmonics
Nicholas Rivera1, Johannes Flick2 and Prineha Narang2; 1Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Applied Physics, Harvard University, Cambridge, Massachusetts, United States.

Recent experimental advances in materials science have engendered the ability to reach ultrastrong coupling regimes of light-matter interactions in the IR-Vis spectral band. The ability to find new ways to create hybrid states of light and matter may allow for new ways to achieve low-loss confinement of electromagnetic energy on the extreme nanoscale, which is critical for the development of optical technologies. To this end, it is critical to study how ultrastrong coupling of light and matter alters the real-space properties of electrons and photons, such as photon mode profiles, which encode the quantum fluctuations of the electromagnetic field, their coupling to matter, and their propagation properties.

Inspired by electronic-structure methods such as Hartree-Fock theory and self-consistent Born approximations, we develop a self-consistent field method for finding ground and excited states of coupled systems of matter and electromagnetic fields. This is the first formalism can allow us to assess the change in both electronic wavefunctions and photonic modes, as well as electronic energies and photonic energies, as a result of ultrastrong light-matter coupling. We apply this method to a relevant model problem in quantum plasmonics: an emitter coupled to a continuum of plasmonic modes in a two-dimensional electron gas such as doped graphene, whose extremely confined plasmonic modes may allow ultrastrong coupling with a single IR emitter.

For an emitter of dipole moment 0.5 e*nm on the order of 1 nm away from the graphene sheet, our method reveals several new features that break with the conventional theory of emitter-plasmon interactions. We find that the well-known scaling of plasmon-induced van der Waals forces for an atom near an electron gas breaks down, even in a local description, due to the strong renormalization of electronic energies and wavefunctions by the plasmonic modes. For an emitter 1 nm away from graphene, the energy gap between two-levels in an emitter can be decreased by over a factor of two compared to the predictions of van der Waals theory.

We further find that for the photons that a treatment of the electromagnetic modes based on linear-response theory with bare emitter states does not accurately predict the dispersion and mode profile of the resulting polaritonic modes, leading to deviations of up to an order of magnitude from linear response theory, due to the aforementioned renormalization of the electronic polarizability and resonance shifts self-consistently induced by plasmonic modes. This implies even in a fully local framework, ultrastrong coupling leads to a breakdown of typical macroscopic electrodynamics treatments that cannot be captured classically.

These results provide not only insight into photon modes induced by ultrastrong coupling, but also qualitatively new effects in light-matter interactions at the extreme nanoscale, distinct from other large-wavevector corrections like quantum nonlocality.

EP04.06.16
Plasmonic Core-Multi-Shell Nanowire Phosphors for Light Emitting Diodes
Amartya Dutta1, Sarath Ramadurgam1 and Chen Yang2; 1Boston University, Boston, Massachusetts, United States; 2Purdue University, West Lafayette, Indiana, United States.

White LEDs (WLEDs) compared to traditional illumination have higher efficiencies, longer lifetimes and are also environment-friendly. Commercial technology uses yellow-emitting cerium-doped yttrium aluminum garnet [(Y1-xCex)3Al5O12 or YAG:Ce] phosphor which is excited by a InGaN-based blue LED. However, such phosphors suffer from the following disadvantages: (1) limited phosphor performance due to thermal degradation, (2) significant backscattering losses, and (3) poor absorption. Current commercial WLEDs have a luminous efficacy around 140 lm/W, with research prototypes showing 170-180 lm/W.

Our work opens an important new avenue in introducing ab initio methods to the nascent field of collective strong light-matter interactions.

Towards Ab Initio Theory of Ultrastrong Coupling Photonics and Plasmonics
Nicholas Rivera1, Johannes Flick2 and Prineha Narang2; 1Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Applied Physics, Harvard University, Cambridge, Massachusetts, United States.

Recent experimental advances in materials science have engendered the ability to reach ultrastrong coupling regimes of light-matter interactions in the IR-Vis spectral band. The ability to find new ways to create hybrid states of light and matter may allow for new ways to achieve low-loss confinement of electromagnetic energy on the extreme nanoscale, which is critical for the development of optical technologies. To this end, it is critical to study how ultrastrong coupling of light and matter alters the real-space properties of electrons and photons, such as photon mode profiles, which encode the quantum fluctuations of the electromagnetic field, their coupling to matter, and their propagation properties.

Inspired by electronic-structure methods such as Hartree-Fock theory and self-consistent Born approximations, we develop a self-consistent field method for finding ground and excited states of coupled systems of matter and electromagnetic fields. This is the first formalism can allow us to assess the change in both electronic wavefunctions and photonic modes, as well as electronic energies and photonic energies, as a result of ultrastrong light-matter coupling. We apply this method to a relevant model problem in quantum plasmonics: an emitter coupled to a continuum of plasmonic modes in a two-dimensional electron gas such as doped graphene, whose extremely confined plasmonic modes may allow ultrastrong coupling with a single IR emitter.

For an emitter of dipole moment 0.5 e*nm on the order of 1 nm away from the graphene sheet, our method reveals several new features that break with the conventional theory of emitter-plasmon interactions. We find that the well-known scaling of plasmon-induced van der Waals forces for an atom near an electron gas breaks down, even in a local description, due to the strong renormalization of electronic energies and wavefunctions by the plasmonic modes. For an emitter 1 nm away from graphene, the energy gap between two-levels in an emitter can be decreased by over a factor of two compared to the predictions of van der Waals theory.

We further find that for the photons that a treatment of the electromagnetic modes based on linear-response theory with bare emitter states does not accurately predict the dispersion and mode profile of the resulting polaritonic modes, leading to deviations of up to an order of magnitude from linear response theory, due to the aforementioned renormalization of the electronic polarizability and resonance shifts self-consistently induced by plasmonic modes. This implies even in a fully local framework, ultrastrong coupling leads to a breakdown of typical macroscopic electrodynamics treatments that cannot be captured classically.

These results provide not only insight into photon modes induced by ultrastrong coupling, but also qualitatively new effects in light-matter interactions at the extreme nanoscale, distinct from other large-wavevector corrections like quantum nonlocality.
Increased local electric field can be created by surface plasmon polaritons (SPPs) excited from Au NPs on c-Si, which enhances light absorption and increases the photocurrent of the solar cell. The Au NPs on the surface of the c-Si wafer act as hotspots to increase the local field strength, thereby improving the performance of the solar cell. The enhancement in photocurrent is observed in CuO/Au NPs/n-cSi compared to CuO/n-cSi from I-V measurements under AM 1.5 illumination by the help of solar simulator. Under consideration of plasmonic effect of Au NPs on bulk c-Si SCs, this enhancement can be resulted in change in absorption within the junction and so that increase in photocurrent response of heterojunction device. The findings on the most suitable plasmonic interface and also to the other kinds of device structures in the ultimate quest for attaining affordable high efficiency SCs.

Spatial Mapping of Multipolar Surface Plasmons in Ti₃C₂Tx MXene Nanosheets with Tunable Energy Distribution

Jehad K. El-Demellawi1, 2, Sergei Lopatin3, Omar F. Mohammed2 and Husnam N. Alshareef4; 1Materials Science and Engineering, King Abdullah University of Science and Technology, Thuwal-Jeddah, Saudi Arabia; 2KAUST Solar Center, King Abdullah University of Science and Technology, Thuwal-Jeddah, Saudi Arabia.

The prospering family of two-dimensional (2D) transition metal carbides/nitrides, known as MXenes, have exhibited a variety of unique optical and optoelectronic properties, making them attractive for many potential sensing and photonic applications. Recently, nanosheets of the most studied MXene by far; i.e., Ti₃C₂Tx (Tₐ denotes surface functional groups such as =O or -F), were shown to exhibit intense surface plasmons (SPs) when excited by electron beams. However, their spatial variation over individual Ti₃C₂Tx nanosheets remains undiscovered. In this work, we used scanning transmission electron microscopy (STEM) combined with ultra-high resolution electron energy loss spectroscopy (EELS) to investigate the spatial and energy distribution of SPs (both optically-active and -forbidden modes) in mono- and multi-layered Ti₃C₂Tx nanosheets. By means of spatially resolved STEM-EELS mapping we were also able to directly visualize the inherent inter-band transition in addition to a variety of SP modes (both transversal and longitudinal), and correlate them with the shape, size and thickness of nanosheets. The independent polarizability of Ti₃C₂Tx nanosheets is unambiguously demonstrated, and attributed to their unusual weak interlayer coupling. This characteristic makes engineering a new class of nanoscale systems possible, where each monolayer in the multi-layered structure of Ti₃C₂Tx has its own set of SPs with distinctive multipolar characters. Furthermore, we probed the tunability of the SP energies by conducting in-situ heating STEM to monitor the change in the surface functionalization of Ti₃C₂Tx through annealing at temperatures up to 900°C. At temperatures above 500°C, fluorine (F) desorption multiplies the metal-like free electron density of Ti₃C₂Tx flakes, resulting in a monotonic blue-shift in the SP energy of all modes. Our results highlight the great potential of Ti₃C₂Tx for photonic applications, ranging from visible to MIR ranges, such as broadband photodetectors and plasmonic waveguides.

Surface-Engineered Plasmonic Nanostructures for Diagnosis and Therapeutic Applications

Qirong Xiong, Derong Lu, Yonghao Chen and Hongwei Duan; Nanyang Technological University, Singapore, Singapore.

The optical properties of plasmonic nanostructures, originating from localized surface plasmon resonance (LSPR), are of tremendous potential across many disciplines spanning chemistry, materials science, photonics, and medicine. The development of plasmonic nanostructures with precisely controlled spectroscopic properties and/or multifunctional characteristics is key to their use in diverse applications. In particular, tailored LSPR of plasmonic nanostructures allows for spatially confining photons at sub-wavelength scales and controlling light-molecule interactions at specific wavelengths. Excited LSPR dissipates energy of incident light by the combination of Mie scattering and absorption-mediated thermal conversion, making plasmonic nanostructures compelling photoabsorbers and imaging agents. This talk summarizes our recent work in developing tailored plasmonic nanostructures and well-defined assemblies that were not easily accessible by traditional colloidal chemistry. We have shown that our strategies based on the use of reactive polymers offers new opportunities in addressing some fundamental challenges in surface enhanced spectroscopy, diagnostic microfluidic biosips, and photothermal therapy.1, 5

Amplitude-modulated light signals were obtained by the third-order nonlinear optical response exhibited by hierarchical plasmonic nanoparticles interacting in a two-wave mixing configuration. Within this work is described a preparation method for fabricating nanostructured concentric rings samples by rotating nanoparticles in a nanofluid. The processing route is based on the evolution of the free falling of rotating nanoparticles in an ethanol suspension with a strong dependence on the elemental composition and nanoparticle size. Anisotropic bimetallic nanoparticles integrated by gold and platinum or gold and silver were numerically and experimentally analyzed. The nonlinear optical behavior of the resulting concentric rings was explored by employing a Nd:YAG laser system featuring nanosecond pulses at 532 nm wavelength for the measurements. High-Resolution Transmission electronic microscopy, UV-vis spectroscopy and Energy-dispersive X-ray spectroscopy studies were undertaken in order to characterize the samples. The inhomogeneous nature of the nanoparticles gives origin to an optically anisotropic response related to nonlinear optics enhanced by plasmonic excitations. The orientation of the samples produced important changes in the ratio between the real and imaginary parts of the third-order nonlinear optical susceptibility. Gyroscopic properties of the samples confirmed the possibility to control energy transfer effects induced by birefringence and multi-photonic absorption. Nonlinear optical interactions for performing ultrafast all-optical switching and instrument function can be contemplated. The authors kindly acknowledge the financial support from Instituto Politecnico Nacional and CONACYT.

EP04.06.21
Optoelectrically BiFunctional Plasmonic Color Filter Embedded in OLEDs Min Ho Lee, Dong Jun Jeong, Seonil Kwon, Hyunchul Kim and Kyung Cheol Choi; School of Electrical Engineering, KAIST, Daejeon, Korea (the Republic of).

Plasmonics utilizes surface plasmons that are generated when light enters the interface between metal and dielectric materials, resulting in new optical properties not seen in nature. Using plasmonic materials such as metals and dielectrics, various studies have been intensively performed to control optical characteristics. Among them, a plasmonic color filter that selectively extracts light from the visible spectrum by inserting a nanostucture into a plasmonic material has been reported.[1] In plasmonic color filter research, improving the transmission and color reproducibility are the main issues.[1,2] In addition, using a transparent conducting oxide, there was an attempt to produce a plasmonic color filter with good electrical conductivity as well as high transmittance. As a result, plasmonic color filter electrodes (PCEs) that function at the same time as conductive electrodes as well as a color filters have been developed as a new type of color filter.[3]

Most plasmonic color filters have been fabricated through patterning methods such as nano-imprinting or e-beam lithography. In terms of cost and processing time, such patterning methods have disadvantages for large areas; this has limited their application to display devices. However, in our previous research, PCEs were implemented with laser interference lithography, which is beneficial for large area patterning and allows for practical large-area applications such as displays and lightings.

In this study, we first proved the feasibility of fabricating PCES embedded in organic light emitting diodes. Each PCE for red and green light filtering was applied to a light-emitting device, instead of using an ITO electrode, which is used in counterpart devices as an anode. Fabricated devices showed diode operation characteristics, which verifies that PCES performed electrically in a stable manner. Also, the broad electroluminescent spectra in the above devices, ranging from 500nm to 700nm, were selectively filtered into red and green light, demonstrating the optical performance of the PCES.

Consequently, these results confirm that PCES function as color filters and electrodes simultaneously. The optimized PCE structure has a height of within some hundreds of nm. This thin and metal-based structure is advantageous for malleable devices that are flexible, stretchable, and etc. In addition, since PCE is based on metal, it can overcome the drawbacks of conventional color filters, e.g. dyes and pigments, which have poor thermal and chemical stability. Therefore, the PCES in this work, are not simply used to reduce device structure by integrating two functions (color filter and electrode). We expect this work will open new opportunities to develop and expand the use of novel plasmonic nanostructures.

Plasmonic Gold Nanosphonges Thomas A. Klar, Cynthia Vidal, Dmitry Sivun and Calin Hrelescu; Institute of Applied Physics, Johannes Kepler University Linz, Linz, Austria.

The quest for alternative plasmonic materials is vital for further progress in plasmonics-based photonics. Nanostructures, which can act simultaneously as optical detectors, stimulators, or photocatalysts are crucial for many applications in the fields of chemo- and biosensing, electro- and photocatalysis, electrochemistry, and biofuel generation. Plasmonic materials with a huge surface-to-volume ratio as well as a high density of active surface sites and electromagnetic hot spots, are desirable. In many cases, however, a large surface-to-volume ratio is counterproductive due to surface damping of the plasmonic resonances. We will discuss the plasmonic properties of sponge-like, in other words, fully porous, nanoparticles, so-called nanosphonges.1 In such sponges, both the gold and the air phase are fully percolated in three dimensions, providing a huge surface area but still sufficiently sharp plasmonic resonances.

We correlate, on a single nanoparticle basis, their optical scattering spectra (using dark field microscopy) with their individual morphology (using electron microscopy).2 The scattering spectra of such gold nanosphonges depend only weakly on their size and outer shape, but they are decisively influenced by their unique inner percolation pattern, in good qualitative agreement with numerical simulations.

In addition to scattering, we investigate the photoluminescence (PL) from gold nanoparticles due to electron-hole recombination4-5 in the specific case of gold nanosphonges. We find that the polarization anisotropy is much larger in the scattering spectra than in the PL spectra for individual gold nanosphonges. We interpret this finding that the excitation of local plasmons by a plane wave from the far field (scattering) and the local creation of plasmons via electron hole recombination with subsequent radiation to the far field (PL) are not reciprocal. We interpret this finding by the causality principle and the existing of a “plasmonic horizon” of less than 60 nm,3 given by the limited lifetime of plasmons (less than 1 femtoseconds) and by the finite speed of information.

EP04.06.23
Remote Activation of Emission by Surface Plasmon Polaritons Propagating in Silver Nanowires Aneta Prymaczek1, Kamil Wiwatowski1, Karolina Słowski1, Justyna Grzelak1, Joanna Niedziolka-Jonsson2, Dawid Piatkowski1 and Sebastian Mackowski1,2, Nicolaus Copernicus Univ, Toruń, Poland.
Hybrid nanostructures containing plasmonically active metallic nanoparticles exhibit many effects interesting from both fundamental and application perspectives. For instance, silver nanowires (NW) with submicron diameters and lengths of about tens of microns can act as energy propagators, by employing surface plasmons polaritons (SPP). These quasiparticles can not only propagate along a metal-dielectric interface for distances extending tens of microns, but also can remotely activate luminescence of emitters located in the closest vicinity of the NW.

The ability to remote activation of emission is demonstrated using both Stokes and anti-Stokes emitters. For this purpose we constructed a two-objective confocal fluorescence microscope, where the top objective is used for excitation of SPPs in a NW, while the detection of fluorescence is facilitated with the second one. The experimental setup allows for probing both stationary and time-resolved fluorescence of the photosynthetic proteins (Stokes emitters) and up-converting nanocrystals (anti-Stokes emitters).

The results indicate that the efficiency of SPPs propagation and luminescence activation depends strongly on the length of the nanowire as well as polarization of the laser beam. In addition, we show that the substrate affects the efficiency of the remote activation, which is less effective on graphene. Systematic analysis of many nanowires characterized with different lengths allowed to study the influence of the graphene substrate on the damping efficiency, which originates from polariton-graphene interactions. The efficiency of this process is also found to depend on the laser polarization and is more efficient for laser polarized along the nanowire.

Terahertz Radiation Transport Regimes in Three-Dimensional Disordered Media
Silvia Gentilini1, Neda Ghofraniha1, Claudio Conti1, 2, Mauro Missori1 and Davide Pierangeli1; 1CNR-ISC, Rome, Italy; 2Physics, Università La Sapienza di Roma, Rome, Italy.

The growing interest in Terahertz (THz) radiation in a wide range of applications is due to recent technological advances that have made emitters and detectors available in this spectral range. The THz radiation is particularly suitable for the study of systems, ranging from textiles to biological tissues, whose structural complexity makes unavoidable understanding how scattering affects its propagation [1].

On the other hand the propagation of electromagnetic (em) waves in random media is itself a topic of considerable interest in many research fields, since it can lead to a plethora of phenomena. With respect to standard techniques in the visible range, the detection technology available in the THz spectral range provides the advantage to easily access the amplitude and the phase of the em field.

The samples are made by dispersions of 1 mm diameter Silica spheres in a Paraffin matrix with refractive index nSi=1.95 and np=1.5 respectively, prepared at filling fraction, υ, ranging from 0.05 to 0.5. These dispersions are then solidified in cylindrical molds with 15mm diameters and variable thickness L. We collected the temporal signal E(t) transmitted by the sample over 800 ps at different filling fractions. By taking the Fourier transform of these signals, we can extract the spectral amplitude, E(o), and phase, φ(o), in a frequency range between 0.2 and 2 THz. We analyzed these quantities by following the paradigm [2] of light diffusion in order to explore the various transport regimes of THz radiation.

At low filling fractions, the spectral amplitude E(o) shows signatures of Mie scattering that is gradually washed out by the increasing de-coherence effect introduced by the increasing number of scatterers. In order to provide a quantitative approach to resolve the photon transport regime, we estimate the group delay τg=d[φ(ω)]/dω. This quantity provides the product between the inverse of group velocity and the propagation length L inside the sample. We then compare τg with the phase delay τp obtained as the ratio between the speed of light and the mean refractive index of the samples, τp=λ/2πn. The discrepancy between τg and τp increases for υ >0.1 denoting a transition from a ballistic to a diffusive transport regime. At υ >0.25, τg reaches a plateau, signature of the onset of photon trapping mechanism.

EP04.06.25
High-Contrast Optical Modulation with Asymmetric Plasmonic Metamaterials
Yuyi Feng1, Ruizhe Zhao1, Clayton Nemitz2, Tianyou Li1, Johannes Boneberg2, Deswen Cheng1, Lingling Huang1, Yongtian Wang2, Lukas Schmidt-Mende2 and Paul Leiderer2; 1School of Optics and Photonics, Beijing Institute of Technology, Beijing, China; 2University of Konstanz, Konstanz, Germany; 3Department of Physics and Astronomy, University of North Carolina, Chapel Hill, Chapel Hill, North Carolina, United States.

Metamaterials, artificial media with sub-wavelength structures, have received increasing attention due to their unique properties which cannot be found in nature. In particular, arrays of metallic or dielectric nanostructures with varying sizes and orientations are of great interest due to their ability of modulating the optical wave-fronts in a controllable manner. Here we fabricate a large-scale asymmetric gold nanostructure embedded into an aluminum oxide template on a glass substrate (1.4 cm x 1.4 cm). We show experimentally and theoretically that the orientation of the sample plays a crucial role in the optical response leading to controlled switching between transmitted and stopped light propagation. This could be useful for the future design and fabrication of optical modulators, which have applications in optical information systems.

3D Tapered Nanofocusing Plasmonic Nanocavity for Probe-Size-Independent Targeted Single-Molecule Detection
Shailabh Kumar1, Haeri Park1, Hyunjun Cho2, Radwanul H. Siddique1 and Hyuck Choo1, 2; 1Medical Engineering, California Institute of Technology, Pasadena, California, United States; 2Electrical Engineering, California Institute of Technology, Pasadena, California, United States; 3Samsung Institute of Advanced Technology, Suwon, Korea (the Republic of)
Enhancement of optical fluorescence has enabled breakthroughs in areas such as fluorescence-driven DNA sequencing, rapid disease detection, and other numerous biological studies. While several plasmonic nanostructures eliciting strong fluorescence enhancement have shown promise for these applications, they have been restricted to detection of small dye molecules due to their shallow and relatively flat 2D electromagnetic (EM) enhancement profile. However, bioassays in general utilize small dye molecules conjugated to larger proteins, and small dye molecules alone are rarely used in research and clinical diagnostics. Therefore, successful application of nanoplasmonics-enhanced bioassays requires that the devices exhibit excellent EM enhancement with a 3D volume that could accommodate molecular probes of all sizes.

Here, we have demonstrated a 3D tapered nanofocusing plasmonic nanocavity for fluorescence enhancement using probes of all sizes and targeted single-molecule detection. Our device focuses propagating surface plasmon polaritons (SPP) into a 3D tapered metal-insulator-metal (MIM) cavity that provides extreme volumetric enhancement for visualization of single molecule fluorescence. We fabricated our device on a silicon substrate with gold and silica layers to form a 3D-tapered Au-SiO₂-Au plasmonic cavity. The plasmonic nanocavity achieves strong EM-field confinement while the channel-like geometry of the nanocavity and attached waveguide provides test-fluid access and host surface functionalization for capturing molecules. A large, spatially uniform plasmonic hotspot plane at the tip of the 3D-tapered MIM gap allowed uniform visualization and molecular-specific capture of diversely-sized molecules diffusing in solution, including single-stranded DNA, streptavidin and anti-biotin antibodies with calculated fluorescence enhancement close to 1500. Appropriately optimizing the tip geometry also allowed individually capturing and detecting single antibody molecules at the tip.

EP04.06.27 Metal-Insulator-Metal Plasmonic Absorber with High Loss Metals and Dielectric Ahmad Khayyat Jafari, Texas Tech University, Lubbock, Texas, United States.

Achieving maximum absorption in a broadband range is one of the main goals of metal-insulator-metal metasurfaces. Meanwhile, decreasing the effective thickness of the device and keeping its configuration as simple as possible are other key criteria. There have been some approaches to attain the highest absorption with the maximum bandwidth. In this research, we demonstrate a new approach for this goal. We use lossy metal plus lossy dielectric as the building blocks of our structure. We expect that these two factors together elevate the absorption level. We expect that our device will have applications as a microbolometer in the mid-infrared region and could also be used as a powerful directional emitter in apparatuses such as Fourier Transform Infrared Spectrometers.

EP04.06.28 Porous Alumina—Building Block of Future Scalable Plasmonic Device, Light Source and Beyond Jinghua Fang; University of Technology Sydney, Ultimo, New South Wales, Australia.

Plasmonic metamaterials offer the unique ability to control subwavelength light propagation, thus achieving unprecedented sensing sensitivity and emerging nanophotonics phenomena. However, fabrication challenges and high losses hamper their applications, especially due to scalability issues. Here we will demonstrate that self-assembly of highly ordered porous alumina as one of best candidates will hold the key to unlocking this potential of scalable plasmonic metamaterials for the cost-efficient, practical devices.

Moreover, due to natural defects existing in porous alumina, formulating these point defects or line defects in this porous alumina will become very attractive as it can achieve integrated nanophotonic systems which require the coupling of emitters to optical cavities and resonators. In this work, we will report that porous alumina as an emitter is enhanced in the deep UV region by its own photonic-like crystal band edge. Also we will demonstrate hybrid systems of gold coated porous alumina in which the Cr³⁺ center emission from porous alumina is coupled to plasmonic nanocavities hence showing a random lasing effect.

Last but not least, I will report on several examples for growing and functionalization of nanometamaterials by exposing porous anodic aluminum oxide templates to a low-temperature plasma. With plasma, our environmentally-friendly process is simple, fast and does not involve any pre-treatment for the samples. This novel fabrication and functionalization technique constitutes another interesting application of alumina templates to different nanometal-materials growth and other possible applications.

EP04.06.30 Polaritonic Hybrid-Epsilon-Near-Zero Modes—Beating The Plasmonic Confinement vs Propagation-Length Tradeoff with Doped Cadmium Oxide Bilayers Evan L. Runnerstrom, Kyle Kelley, Thomas G. Folland, Joshua R. Nolen, Nader Engheta, Joshua D. Caldwell and Jon-Paul Martins, North Carolina State University, Raleigh, North Carolina, United States; Vanderbilt University, Nashville, Tennessee, United States; The Pennsylvania State University, University Park, Pennsylvania, United States; University of Pennsylvania, Philadelphia, Pennsylvania, United States; The Pennsylvania State University, University Park, Pennsylvania, United States.

Polaritonic materials that support epsilon-near-zero (ENZ) modes offer the opportunity to design light-matter interactions at the nanoscale through extreme sub-wavelength light confinement, producing phenomena like resonant perfect absorption. However, the utility of ENZ modes in nanophotonic applications has been limited by a flat spectral dispersion, which leads to small group velocities and extremely short propagation lengths. In this talk, I will describe a strategy to overcome this constraint by hybridizing ENZ and surface plasmon polariton (SPP) modes in doped cadmium oxide epitaxial bilayers. This results in strongly coupled hybrid modes that are characterized by an anti-crossing in the polariton dispersion and a large spectral splitting on the order of 1/3 of the mode frequency. These hybrid modes simultaneously achieve modal propagation and ENZ-mode-like interior field confinement, adding propagation character to ENZ-mode properties. It is additionally possible to tune the resonant frequencies, dispersion, and coupling of these polaritonic-hybrid-epsilon-near-zero (PH-ENZ) modes by tailoring the modal oscillator strength and the ENZ-SPP spectral overlap. PH-ENZ modes ultimately leverage the most desirable characteristics of both ENZ and SPP modes, allowing us to overcome the canonical plasmonic tradeoff between confinement and propagation length.
The ability to confine light now routinely to of order 10 nm\(^3\) volumes enables new functionalities for optoelectronic switching at ultralow energies. We present a range of devices in which an active polymer is sandwiched into nm-scale plasmonic gaps that can deliver fast and reversible actuation. Using the thermo-responsive polymer PNIPAM combined with directed nano-assembly using Au or Ag nanoparticles, allows high densities of nano constructs to be created, that change colour either in response to light or heat. High throughput synthesis allows the scale-up of these actuating nano-transducers (ANTS), opening up video-rate large area display technologies. We show measurements on single ANTs which confirm that n\textsuperscript{th} forces are developed, and discuss their application for optically-driven microfluidic valves. Close-packed films of ANTs act to pump water in and out of permeable membranes using light, and produce a switchable metamaterial. The integration of these devices with DNA origami machines is demonstrated for the first time. We also show that lithium can be optically-pumped in and out of perovskite materials, making light-rechargeable batteries.

Low-Voltage LWIR Tunable Transmission Filters Leveraging Graphene Plasmons

Thomas Beechem, Michael Goldflam, Michael Sinclair, Isaac Ruiz, Anna Tauke-Pedretti, Joel Wendt and David Peters; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Dynamically tunable infrared filters open pathways to multifunctional optical components needed for hyperspectral applications. Capitalizing upon this technology requires directing the filtered light to a detector. Overwhelmingly, however, tunable infrared filters operate in a reflective geometry that necessitates a complex optical path. Tunable transmission filters, on the other hand, can be placed immediately in front of the detector or can even be monolithically integrated with the sensing element to allow for independent pixel-by-pixel tuning. For these reasons, we have developed wafer-scale tunable infrared filters operating in transmission based on graphene plasmonics that simultaneously offer >75 cm⁻¹ tuning while maintaining >40% transmission and requiring biases less than 10V. This technology is amenable to direct monolithic integration with LWIR detector technologies for which we have developed a proof of concept demonstration.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia LLC, a wholly owned subsidiary of Honeywell International Inc. for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

Gate-Tunable Multifunctional Metasurfaces

Ghazaleh Kafaie Shirmanesh, Ruzan Sokhoyan, Pin Chieh Wu and Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

In the last several years, metasurfaces have demonstrated promise to control constitutive properties of light via interaction with nanoscale elements. To date, the functional performance of metasurfaces has typically been fixed at the time of fabrication. However, active control of metasurface properties would enable the realization of novel low-profile optical components, which can be used in numerous technologically relevant applications. These applications include but are not limited to dynamic holograms, focusing lenses with reconfigurable focal lengths, and beam steering, a key requirement for future chip-based light detection and ranging (LiDAR) systems.

In the present work, we report a multifunctional electrically-tunable metasurface, which may act both as a beam steering device and a focusing lens with reconfigurable focal length, depending on the voltage application configuration. The proposed multifunctional metasurface is actively controlled by incorporating a material with voltage-tunable optical properties, into the metasurface. In our work, we use indium tin oxide (ITO) as a voltage-tunable material. First, we experimentally demonstrate an electrical control of the phase of the metasurface unit element at telecommunication wavelengths. By carefully choosing the properties of the ITO and gate dielectric layers, we show that the phase shift of the metasurface unit element can be actively changed from 0° to 300°. Our design enables independent electrical control of each metasurface element via individual application of the DC voltage. Next, using this property, we show that the same metasurface can exhibit multiple functionalities, acting both as a beam steering device and a reconfigurable lens.

Schemes for Non-Volatile Phase Shifters for Large-Scale Photonic Integrated Circuits Based on Phase-Change and Shape-Memory Materials

Uttara Chakraborty, Jacques Carolan, Yifei Zhang, Juejun Hu and Dirk R. Englund; 1Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Photonic integrated circuits (PICs) provide a platform to control a large number of electromagnetic modes with high phase stability for applications including beam formation, quantum photonic technologies, and optical neural networks. A central challenge in scaling such applications is the ability to provide, or trim large numbers of phase shifters in a non-volatile fashion to reduce power consumption and enable cryogenic compatibility. For example, to program an arbitrary linear-optics unitary transformation on N input/output modes, it is necessary to set O(N²) phase shifters, a number which can be in the hundreds ([1], [2], [3], [4]). Here, we investigate two schemes for non-volatile phase shifters to solve these scaling challenges in silicon-on-oxide (SOI) PIC platforms. These rely on (1) phase-change chalcogenide glasses and (2) shape-memory ceramics.

1. For phase modulators based on chalcogenides [5], we consider germanium-antimony-selenium (GSSe) deposited over an exposed waveguide section in the SOI PIC platform. We consider the use of built-in silicon heaters to control the phase of the GSSe through tailored heating-cooling curves. As shown previously, there is a strong index difference between the amorphous (n=2.99) and crystalline (n=3.60+0.0398i) states of GSSe [6]. Through eigenmode expansion simulations, we find an effective index shift on the order of 10⁻³ for the fundamental mode of a silicon ridge waveguide, a corresponding length of 8.5 µm required for a π phase shift, and a loss of < 0.3 dB per phase shifter.

2. We also introduce a new concept for phase modulation based on the photoelastic effect in silicon, controlled via strain through nonvolatile actuators. In particular, we propose the use of shape-memory ceramics [7], such as ceria-doped zirconia, to strain SOI waveguides through transformations between the austenite (tetragonal) and martensite (monoclinic) states. We explore this non-volatile phase shifter concept through finite-element simulations based on experimentally measured material properties, and show that the shape-memory effect in polycrystalline zirconia can produce an effective index shift on the order of 10⁻³ for the fundamental mode of a silicon ridge waveguide. A corresponding length of 40.4 µm is required for a π phase shift.

Metasurfaces utilize strong interactions between light and two-dimensional nanostructured interfaces to control light at will, and enable us to break away from the reliance on light propagation by transferring an optical interface into functional devices. In this talk, I will describe my lab’s work on flat lenses and holograms based on metasurfaces. I will show you how we can control phase dispersion, i.e., phase as a function of wavelength, to create metatens triplets that correct both chromatic and monochromatic aberrations. I will describe how we can realize independent and complete control of optical phase and amplitude for multiple colors of light and demonstrate colorful holographic objects with realistic surface qualities.

Stable and Repeatable Multilevel Storage Using Phase Change Photonics

Here, we experimentally demonstrate a single multilevel phase change photonic storage cell with up to 34 non-volatile levels with high stability. Using a Ge\(_2\)Sb\(_2\)Te\(_5\) thin film to tune the transmission of light through a waveguide, we develop a single-pulse method to encode arbitrary storage levels regardless of the previous state of the material. With this technique, we show an order of magnitude reduction in both time and energy consumption which is a significant improvement over previous demonstrations of photonic phase-change memory. Furthermore, we develop three different methods to program multiple levels in the memory cell and investigate influence of different pulse parameters on the process of amorphization/recrystallization. This research is a significant step forward in the development of integrated photonic storage devices, demonstrates the possibility and advantages of all-optical storage network, and provides a potential platform for novel computing architecture like neuromorphic computing.

Reversible Phase Transformation of Silicon Nanoresonator for Optical Memory and Reconfigurable Metasurfaces

Recently we reported laser induced amorphization of silicon nanoparticle and demonstrated its optical response shift. In this presentation, we demonstrate that nanosecond pulsed laser can readily crystallize and amorphize different size of silicon nanoresonator at Mie resonance. Due to the switch of the optical dielectric constant, the resonance peak of nanoresonator can be shifted significantly. Raman mapping and SEM validated the phase transformation can be carried out reversibly. Melt-induced phase transformation of nanostructures usually suffers from the deformation and dewetting process. The first demonstration of reversible phase transformation is enabled by an abnormal geometry pinning effect, where we found the silicon thin disk melts but not dewets. We further demonstrated single “bit” writing and erasing with a sub-diffraction feature size. Combined with motion stage, arbitrary patterns can be written, including structural coloring and optical elements.

Dynamic Plasmonic Displays and Holograms

In this talk, we discuss dynamic plasmonic displays and holograms based on catalytic magnesium (Mg) metasurfaces in the visible range. Through the unique hydrogenation and dehydrogenation between Mg and magnesium hydride (MgH\(_2\)), different information components on the plasmonic metasurfaces become fully addressable in space and can be individually switched on/off. This results in dynamic plasmonic displays and holograms with designated multiple states, giving rise to high-level information control with unprecedented dynamic performance. Our work outlines the inevitable transformation from metasurfaces to metadevices, opening the door to a futuristic research horizon. Such dynamic plasmonic devices will allow for a wealth of applications for high-resolution displays, advanced security labels, high-density data storage and information processing.

Magneto-Optical Bi and Ce-Substituted Terbium Iron Garnet Thin Films for Nonreciprocal Photonics

In this presentation, we demonstrate the reversible phase transformation of a Bi-substituted terbium iron garnet thin film, which exhibits a significant change in optical properties upon cooling. This effect is attributed to the coupling between magnetoelastic and magnetostrictive contributions, leading to a nonreciprocal optical response. The demonstration of this behavior in thin films provides a pathway for the development of compact and efficient devices for nonreciprocal optical applications.
These transparent meta-photodetectors pave a new way for the next-generation transparent on-chip optoelectronic devices. To demonstrate this experimentally, we fabricate deep sub-wavelength arrays of nanowires in c-Si on a sapphire substrate using electron-beam lithography. funded by the City of Gdynia, Poland

Characterization revealed the growth of single phase polycrystalline TbIG films on Si without any secondary phases. Faraday rotation of TbIG/Si films measured at a wavelength of 1550 nm was ~600°cm⁻¹ and the spectral dependence of the Faraday rotation, optical absorption and refractive index was characterized. The Faraday rotation can be increased significantly by Ce or Bi substitutions in the garnet. The sidewall growth of doped TbIG films on SOI waveguides was investigated for fabrication of TE mode isolators. Moreover, performance of these garnets in lithographically patterned TE and TM mode on-chip optical isolators based on ring resonators and Mach-Zehnder interferometers have also been studied.

KEYWORDS: magneto-optical garnets, terbium iron garnet, optical isolators, magneto-optics, sidewall growth.

In this communication we use plasmonically active silver nanowires (AgNWs) as building blocks of an ultrasensitive sensing platform for single photodetective proteins. The nanowires were synthesized by wet chemistry and have diameters and lengths around 100 nm and 50 μm, respectively. For achieving enhanced functionality, we attach biotin molecules to their surface. Next they were deposited on a glass substrate, forming thus a sensor chip. The sensing potential of the nanowires was tested using Peridinin-Chlorophyll-Protein (PCP) equipped with a streptavidin linker. It is important to realize that PCP is roughly 4 nm in size, which is much less than diameters of the AgNWs. Upon depositing AgNWs on a glass surface, we first determine their positions using transmission mode of a wide-field microscope. Next, a 2 μl droplet of protein solution was deposited on the substrate with simultaneous acquisition of fluorescence images of the same sample area. The concentration of the protein was changed from millimolar down to picomolar in order to determine the limit of detection. Using this approach, we are able to monitor protein attachment to AgNWs in real-time. For highly concentrated sample the attachment is so efficient that within couple of seconds the nanowires are flaring, forming thus a distinct contrast to the background. Careful analysis shows that this contrast originates not only from the presumably higher concentration of the PCP complexes on AgNWs, but also from strong plasmonic enhancement of the PCP emission. Both effects are crucial for detecting the emission of single PCP complexes when the concentration of the sample deposited on the substrate is reduced by 6 orders of magnitude. In fact, we are able to observe single protein attachment to AgNWs in a real-time mode.

We analyzed the influence of several key factors that determine the detection efficiency of our platform. These include: surface coverage by AgNWs, acquisition parameters, and additional functionalization of the substrate itself. The approach presented here is rather universal and can be applied for detecting variety of analyte molecules with essentially ultimate sensitivity.

Extraction of multidimensional information carried by optical beams has a wide range of applications including photography, optical communication, and augmented reality. To date, photodetector systems based on homogeneous materials have limited abilities to measure more complex information beyond light intensity distribution, since these systems typically exhibit limited sensitivity to the polarization, wavelength, or phase of the incident light. Moreover, extracting desired information from the broadband optical signals is necessary for both the broadband and high-speed photodetectors. As a result, photodetectors with polarization- and wavelength sensitivity are combined with a polarization-insensitive anti-reflection at designed wavelengths in a single-layer structure. To demonstrate this experimentally, we fabricate deep sub-wavelength arrays of nanowires in c-Si on a substrate using electron-beam lithography. The NWs are 110 nm high, and the widths are 30 nm, 55 nm, and 110 nm for efficient photodetection and suppression of reflection of blue, green, and red light, respectively. The measured reflection at resonant wavelengths is as low as 2%, with a transmission /reflection ratio larger than 40. Spectrally-resolved photocurrent measurements show a clear single peak at the three design wavelengths, behaving effectively the same as RGB color filters in front of a bulk Si substrate. The measured photocurrent ratio peaks are 2.4 at 470 nm (B/G), 2.1 at 540 nm (G/R), and 4.9 at 680 nm (R/B) with a bandwidth of ~80 nm, enabling color detection. Finally, to improve the spatial homogeneity of photocurrent generated in the NWs, we fabricate a Si/ITO inter-digitated photodetector with ITO contacts sitting between Si NWs. The device optically functions as a NW array but electrically behaves like a homogeneous film because photo-excited charge carriers are extracted transversely across the NWs. The spatially-resolved photocurrent measurement shows only 10% signal fluctuation over 80% device area, revealing a reliable detection process for real applications. Altogether, these results demonstrate the first single-layer and single-material detection system which can detect color, polarization as well as intensity information in the whole visible regime. A 60% overall average transmittance is observed experimentally, enabling in-situ beam monitoring applications. These transparent multi-photodetectors pave a new way for the next-generation transparent on-chip optoelectronic devices.

Photonic Solutions for Stable Laser Beam Propulsion

The stability of the laser beam during the entire acceleration phase is regarded as one of the major obstacles to realizing laser-propelled spacecraft technology. In this work, we provide a comprehensive study of dynamical stability and consider several shapes that may be good candidates for stable beam riding. We analyze stability maps and basins of attractions for a range of beam intensity profiles and sail shapes which satisfy the stability criteria. We further find designs with the use of real materials, such as Si and SiO2, that provide suitable optical properties in the infrared frequency range and which satisfy the stability criteria. Then, we consider the mechanical stability of the sail by relaxing the assumption of sail rigidity. We present first-order finite-element simulations of the thermal and mechanical behavior of free-flying sails undergoing optical acceleration. Hence, for the sail shapes and beam profiles identified in our stability analysis, we study numerically the whether the sail materials are capable of maintaining their shape under intense laser acceleration, and consider methods of shape reinforcement such as structural framing and spin-stabilizing. We analyze conditions and thresholds for materials stiffness that are required for stable sail beam riding.

Revisiting the Photon-Drag Effect in Thin Metal Films Henri Lezec1, Glenn Holland1, B. Robert Ilic1, Cheng Zhang1,2, Wenqi Zhu1,2, Amit Agrawal1,2, Domenico Pacifici1,2 and Jared Strait1; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2Maryland NanoCenter, University of Maryland, College Park, Maryland, United States; 3School of Engineering, Brown University, Providence, Rhode Island, United States.

Current flow in metal films can be induced by the photon momentum carried by an obliquely-incident electromagnetic wave, a phenomenon known as photon drag. The prevailing intuition for the sign of this current assumes that the absorbed light transfers momentum to the free electrons of the metal, either directly or indirectly via plasmon excitation, ultimately generating electron flow in the direction of the in-plane incident photon momentum. However, the direction of this photon-drag (PD) current, has been reported to puzzlingly vary with polarization state, surface morphology and excitation of surface plasmons [1,2]. In particular, measurements to date have typically been carried out with the illuminated surface facing ambient air, yielding, for smooth films, PD currents of opposite sign for illumination with s- and p-polarization, respectively, where only the sign in the p-polarized case is consistent with the standard hypothesis of free-electrons pushed in the direction of the incident momentum. Here, we demonstrate that for smooth metal films (including Au, Cu, and Ni-doped Ag) with illuminated surface facing vacuum, the PD current displays the same sign and nearly the same magnitude for both s- and p-polarized incident light, consistent with the expectation that light with different polarization states carries the same momentum. However, the shared sign of the observed current is always opposite to that implied by the intuitive model above, requiring reimagination of the microscopic processes of the light-metal interaction. We propose a new model for the PD phenomenon in which the bound electrons of the metal – far more numerous than the free electrons - are the primary recipients of the quantum momentum kicks from the incident light, leading to a net polarization of the metal to which the free electrons respond to yield a PD current of the observed counterintuitive sign. The sign flip of the p-polarized signal upon subsequent exposure of the sample to air correlates with adsorption of ambient H2O molecules, and is proposed to result from generation of an extra polarization field induced by the intrinsic dipole moment of the molecules upon Lorentz-force induced rotation. Plasmon Drag in Strongly Nanostructured Systems David Keene1, Tejaswini Ronur Praful1, Natalia Noginova1 and Maxim Durach2; 1Norfolk State University, Norfolk, Virginia, United States; 2Georgia Southern University, Statesboro, Georgia, United States.

Giant enhancement of photoinduced electric currents in thin metal films under surface plasmon resonance conditions presents interest for various applications in plasmonic electronics and optoelectronics. In order to better understand the mechanism of the effect and explore possibilities to control and enhance it with nanoscale geometry, we study the photoinduced electric signals in strongly nanostructured systems, such as square-wave profile-modulated silver and gold films. Longitudinal and transverse photoinduced voltages are recorded as a function of incidence angle for various orientations of the grooves and are observed at both p and s polarizations. The angular dependence of the signal is found to have a shape reminiscent of Fano resonance, with a significant enhancement in magnitude in the range of plasmon resonance. A sharp switching of polarity is observed at p-polarization only, corresponding to efficient electron drag in the direction of plasmon propagation at smaller angles and against it at higher angles. Such a behavior is tentatively attributed to a coupling between the propagating surface plasmon polariton and localized surface plasmons excited at the sharp corners of the square-wave grating. Theoretically we estimate the effective forces acting on electrons and compare them with the experiment. We also demonstrate sensitivity of the polarity switching angle to the local dielectric environment, which makes the effect of interest for plasmonic based sensors with electric detection.

Photonic Solutions for Stable Laser Beam Propulsion Artur R. Davoyan, Michael D. Kelzenberg, Joeseon Wong, Ognjen Ilic, Cora Went and Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

Interstellar space exploration requires the development of novel propulsion systems. Among the potential candidates, beamed energy propulsion of ultratrace, nano-meter-thick lightsails is regarded as one of the key candidates for unmanned exploration of neighboring star systems. A high-power phased-array laser capable of producing ~10 GW/m2 illumination intensity will produce enough radiation pressure and thrust to accelerate a gram-scale spacecraft to relativistic speeds (up to ~0.2c). Among the many challenges facing such a propulsion system, dynamic stability of the sail, i.e., the ability to stay atop a laser beam during the entire acceleration phase, is regarded as one of the major obstacles to realizing laser-propelled spacecraft technology. In this work, we provide a comprehensive study of dynamical stability and consider several shapes that may be good candidates for stable beam riding. First we consider a generic scenario of a laser beam interaction with various rigid, perfectly reflecting geometric shapes. We show that certain mutual configurations of beam intensity profile and sail shape may enable dynamically stable solutions. We analyze stability maps and basins of attractions for these regimes. We further find designs with the use of real materials, such as Si and SiO2, that provide suitable optical properties in the infrared frequency range and which satisfy the stability criteria. Then, we consider the mechanical stability of the sail by relaxing the assumption of sail rigidity. We present first-order finite-element simulations of the thermal and mechanical behavior of free-flying sails undergoing optical acceleration. Hence, for the sail shapes and beam profiles identified in our stability analysis, we study numerically the whether the sail materials are capable of maintaining their shape under intense laser acceleration, and consider methods of shape reinforcement such as structural framing and spin-stabilizing. We analyze conditions and thresholds for materials stiffness that are required for stable sail beam riding.

Tuning the Anomalous Optical Dispersion of TiN Films via Si and O2 Dopants

EP04.10.02

Conventional amorphous multi-component metal-oxide semiconductors with high-mobility, large-area processing feasibility, and environmental stability have UV-level wide optical bandgap (> 3 eV), the photoinization of oxygen vacancy (Vo) defects under energetic blue-light spectrum introduces restrictive spectral photosensitivity. However, Vo-defect-induced photocurrent generation under visible-light stimulus has several disadvantages for visible-light detection using oxide photo-TRs: 1) insensitive performance, 2) narrow spectral/une selective color detection, and 3) slow dynamic photosresponse speed and severe persistent photocurrent (PPC) behavior. We designed all-solution-processed multi-stacked metal oxide/chalcogenide semiconductor-based visible-light phototransistors via thermal-activation defect-healing process, multi-stacked functional materials, and chemically-stable stacking. Here, multi-stacked structure consist of high-mobility a-ZTO (interface), high-efficiency visible-light passivated-crystalline CdS (Cc-CdS) absorber, and defective passive surface passivation a-ZTO (surface) for high-efficiency photo-carrier generation, spontaneous separation, and defect-free transport. Here, thermal-activation defect-healing process were performed for defect suppression of hetero-interfaces (ZTO/CdS and CdS/ZTO) with rapid phase change and crystalline CdS bulk film. Next, artificial engineering of gate-terminal (VGs condition) facilitate to tune and optimize photo-detection performance such as photo-sensitivity and dynamic photo-response (photo-rise/dark-recovery) speed.

All-Solution-Processed Metal Oxide/Chalcogenide Hybrid-Structure Based Phototransistor for Full-Color Detection and Fast Dynamic Response

EP04.10.01

Conventional amorphous multi-component metal-oxide semiconductors with high-mobility, large-area processing feasibility, and environmental stability have UV-level wide optical bandgap (> 3 eV), the photoinization of oxygen vacancy (Vo) defects under energetic blue-light spectrum introduces restrictive spectral photosensitivity. However, Vo-defect-induced photocurrent generation under visible-light stimulus has several disadvantages for visible-light detection using oxide photo-TRs: 1) insensitive performance, 2) narrow spectral/une selective color detection, and 3) slow dynamic photosresponse speed and severe persistent photocurrent (PPC) behavior. Ultrafast Real-Time Holography with an Epsilon-Near-Zero Material

EP04.09.05

Ultrafast Real-Time Holography with an Epsilon-Near-Zero Material M. Zahirul Alam1, Robert Fickler2, Orad Reshef2, Enno Giese1, Jeremy Upham1 and Robert Boyd1,2; 1Department of Physics, University of Ottawa, Ottawa, Ontario, Canada; 1Institute of Optics, University of Rochester, Rochester, Ontario, Canada.

Since the pioneering introduction of holography [1], optical holography has been used for data storage, signal processing, sensing, security, etc. However, applications of real-time holography have been limited by the slow write and erase times which can be up to a minute for a typical holographic material. The implementation is further complicated by the needs for widely different wavelengths for writing (UV light) and reading (visible or near IR) the holograms. Furthermore, holographic materials are bulk crystals and thus not suitable for integrated optics.

We experimentally demonstrate that an epsilon-near-zero [2,3] material can be used to overcome these long-standing barriers. Specifically, we implement an efficient and broadband real-time holographic system using a highly nonlinear epsilon-near-zero material [4 - 7] which is four orders of magnitude thinner and which exhibits up to twelve orders of magnitude larger refresh rate than those of a typical holographic material. Our findings have significant implications in ultrafast signal processing and multimode communication.

EP04.10.02

Tuning the Anomalous Optical Dispersion of TIN Films via Si and O2 Dopants Wesley Britton1 and Luca Dal Negro2,3; 1Division of Materials Science and Engineering, Boston University, Brookline, Massachusetts, United States; 2Department of Electrical and Computer Engineering, Boston University, Boston, Massachusetts, United States.

Realistic material employment in the emerging field of metaphotonics, the convergence of plasmonics, metamaterials, and nonlinear optics, requires
extensive control of material optical properties, a large nonlinear optical response, and robust mechanical stability. The transition-metal nitride material 
titanium nitride (TiN) has shown promise to fit these requirements at visible wavelengths, however it suffers from a larger than ideal imaginary 
permittivity and limited tunability. In this work, we develop a novel platform based on titanium silicon oxynitride (TiSiON) thin film optical ceramics of 
varying stoichiometry grown by reactive DC and RF co-magnetron sputtering and discuss its linear and nonlinear optical properties. Spectroscopic 
ellipsometry measurements reveal a decrease in imaginary permittivity, a tunable metallic behavior that can be extended to longer wavelengths, and 
evolution towards the value of real permittivity of a single material condition equal to zero at multiple wavelengths (i.e., multiple ENZ behavior). Consequently, we identify a novel class of materials with a double epsilon-near-zero (DENZ) character. It was found that that vacuum post-deposition 
annealing allows for further tuning of these materials’ structural and optical properties. We show that these thermal annealing treatments can largely 
modulate charge carrier concentration by measuring their optical bandgaps as a function of annealing temperature. In addition, XRD and TEM 
measurements were performed to correlate the observed material structure and optical properties. DENZ materials have the potential to be especially 
relevant for advancing the field of optical modulation, and this development of Si compatible materials DENZ materials along with materials with potential 
for a tunable nonlinear response and decreased optical losses in the visible spectrum, will extend the engineering feasibility of implementing integrated 
metamorphic devices. Nonlinear optical characterization based on Z-scan measurements will also be presented.

EP04.10.03

Slow-Light Mesophotonic Waveguides—Theoretical Insights for Practical Designs  Stavroula Foteinopoulou; ECE, University of New Mexico, 
Albuquerque, New Mexico, United States.

Being able to tame the speed and confinement of light is of immense important in a range of current photonic applications, such as on-chip all-optical 
circuitry, photonic neuromorphic computing, higher harmonic signal generation etc. Waveguides that support slow-light propagation have therefore been 
the subject of intense investigation efforts in the last decade. Different designs of mesoscale-patterned features had been realized primarily inspired by 
thoretical calculations relying on time-independent modal analyses.

We discuss here why such analyses are not appropriate for real systems, leading to erroneous predictions for the actual light propagation speed. We will 
show why a theoretical analysis based on the time-evolution of the wave is needed for the proper design of slow-light mesophotonic waveguides that can 
be high performing in the practical realm. In particular, we will present a counterexample demonstrating that when two modes are compared it is actually 
the mode with the higher group-velocity, as predicted from time-independent analysis, that ends-up effectively slowing-down light more. Our results 
contradict the widespread notion that the group-index is generally a good measure of the light’s speed effective slow-down factor in practical waveguide 
systems.

Our results suggest that in order to realize robust platforms for slow-light, waveguiding systems should be designed to exhibit simultaneously a large group 
index and a large modal index bandwidth. These results are important to inspire new slow-light waveguide designs that can break current performance 
limitations, enabling its applicability in optical signal manipulation devices.

One-dimensional hybrid Distributed Bragg Reflector (DBR) with high reflectivity is constructed using Tris (8-hydroxy) quinoline aluminum (Alq3) 
molecules and Titanium dioxide (TiO2) nanoparticles via spin coating process. Light emission Alq3 thin film is dominated by excitons. This material has 
been widely used as a superior emitter for organic light emitting diodes. Titanium dioxide (TiO2) is an inorganic semiconductor with a high band gap. 
Photoluminescence (PL) of thin films of Alq3 showed a broad PL peak at 532 nm. In DBR structures, PL quenching is observed but there is no shift in the 
PL peak of the Alq3. The PL quenching is tentatively attributed to energy transfer via sensitization to wide band gap TiO2 layers. The observation can be 
explained using an excitonic model. Fabrication process and optical properties of the structure are presented.

Model-Free Precision Control of 808nm Pulses  Brady Simon, Joshua Dupaty and Makhin Thitsa; Mercer University, Macon, Georgia, United States.

We proposed a method for precision control of 808 nm ultra short pulses in Er-doped fluorindate crystals. The infrared laser of 808nm wavelength is 
widely used in medical applications such as laser therapy for pain management, inflammation reduction and orthodontal procedures. Even though its initial 
use was mainly for wound healing and pain relief, the medical applications of low-level laser therapy have broadened to include diseases such as stroke, 
myocardial infarction, and degenerative or traumatic brain disorders. Such medical applications require these laser pulses to be precisely controlled. This 
partial wavelength is also highly applicable as the infrared light source for military night vision targeting tools and weapons. Moreover, it is a 
commonly used pump source for producing other popular wavelengths such as diode pumped 532nm green laser. Frequency up-conversion in rare earth 
doped crystals have been studied extensively. Previously, authors have reported the model based controller design, in which the controller varies and 
controls the pump rate in real time through the pump power resulting in the enhanced emission of 808nm wavelength in Er-doped fluorindate crystals 
under 1.48 μm pump. In model-based design, the performance of the resultant controller depends on the accuracy of the mathematical model used to 
represent the device in the design process. Therefore, this method is sensitive to modeling errors. In this paper a more robust control scheme using model-
free approach is presented. In this recently developed model free approach the controller design is independent of the mathematical model and hence any 
modeling error have no effect on the device performance. Both theoretical analysis of the control methodology and simulation results will be presented.

Excitation Intensity and InAs Thickness Dependent Luminescence Properties of Ultrathin InAs Layer in GaAs Matrix  Rahul Kumar, Yurii 
Maidaniuk, Andrian Kuchuk, Samir K. Saha, Pijush K. Ghosh, Satish Shetty, Yuriy Mazur, Morgan E. Ware and Gregory J. Sálamó; University of 
Arkansas, Fayetteville, Arkansas, United States.
Highly strained ultrathin InAs layer in GaAs has attracted much interest because of its use for study of fundamental physics as well as its application in electronics and optoelectronics devices. Recently submonolayer (SML) InAs deposition has been proposed as an alternative method to the extensively used Stranski-Krastanow (SK) mode of quantum dot (QD) growth. Moreover, both theoretical and experimental works have added interested for InAs single quantum well (QW) for efficient excitonic lasing applications. Here, we discuss results from a set of samples containing a single ultrathin InAs layer with varying thickness from 0.5 to 1.4 ML in a GaAs matrix grown by molecular beam epitaxy on GaAs (001) substrate at low temperature and investigated by low temperature excitation power dependent photoluminescence (PL). We will discuss results, including observed asymmetric PL spectra having a low-energy-tail at low and moderate excitation power for non-integral ML samples. We will also discuss the observed linear change in emission energy with InAs thickness a PL line shape from InAs/GaAs heterostructures that is excitation power and InAs thickness dependent. The discussion will be based on the interplay of uncorrelated electron hole pairs, free excitons and localized excitons with excitation power and its effect on the optical properties of the InAs layer.

Deterministic Fabrication of Quantum Dots for Quantum Light Sources Using Selective Photocathodo-electrochemical Etching
Ganapathi Subramania, P. Duke Anderson, Arthur Fischer and Daniel Koleske; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Semiconductor quantum dots (QDs) have become particularly important for quantum information science. Due to their atomic-like discrete energy spectrum they can behave as quantum light sources. Such sources operating at room temperature can be invaluable and can be enabled using III-nitride materials due to their large exciton binding energy. Here we demonstrate a quantum size controlled photo-electrochemical etch (QSC-PEC) approach toward the integration and deterministic placement of quantum dots (QDs) within prepatterned nanostructures. An array of III-nitride nanowires containing a single InGaN quantum well is first fabricated using electron-beam lithography (EBL) patterning followed by inductively coupled plasma reactive-ion etching (ICP-RIE). Next, QD is formed within the prepatterned nanowires using a bandgap-selective, wet-etching technique. Here the nanowires are immersed in acidic etch solution with laser illumination of specific frequency above the energy gap of the SQW. The illumination enables the etching of the SQW within the nanowire from the sides until quantum size effects causes increase in energy gap to ultimately stop the etch process, resulting in a quantum dot within the wire. The size of the QD can be tuned by the illumination frequency. Low-temperature microphotoluminescence (μ-PL) measurements of individual nanowires reveal sharp spectral signatures, indicative of QD formation. Further, internal quantum efficiency (IQE) improves an order of magnitude following QSC-PEC etching. Finally, second-order cross-correlation ($g(2)(0)$) measurements of individual QDs exhibit antibunching behavior indicating nonclassical behavior. Our results illustrate an exciting approach toward the top-down integration of nonclassical light sources within nanophotonic platforms.

Angle-Independent Photonic Pigments by Mie Resonances from Dielectric Colloidal Aggregates
Yu Naoi, Yukikazu Takeoka and Takahiro Seki; Department of Molecular and Macromolecular Chemistry, Nagoya University, Nagoya, Japan.

Photonic pigments, which is color materials using photonic materials, show fadeless colors caused from resonances, scattering and interferences of visible lights. Angle-independent photonic pigments especially are important for application of reflective displays and color materials. In our previous work, colloidal amorphous arrays, where monodispersed colloidal particles form an aggregate with short-range order, were found out as angle-independent structural colored materials under the conditions where a sample is illuminated from all directions. Although they usually appear whitish due to the contribution of multiple scattering of visible lights, we succeeded in taking on brilliant colors of the arrays by adding black particles such as carbon black diminishing the multiple scattering lights. However, the colors from the arrays exhibit angle-dependence under a directional light. We have to seek alternative photonic materials to improve the angle-independence.

Recent studies have revealed that in the reflection spectra observed from colloidal aggregates, the peaks due to different mechanism appear on the lower wavelength side than the scattering peak caused by the aggregates. The positions of the peaks don’t change at all even when changing the irradiation direction of light or the observation direction. These peaks are thought to be due to the phenomena called “Mie resonances”. Mie resonances are known as phenomena that light waves comparable to particle diameter are enhanced by circumnavigating of the light waves in dielectric spherical materials such as silica particles. In this research, we prepared photonic pigments displaying angle-independent colors by Mie resonances.

Silica particles from 200 nm to 500 nm in diameter mixed with carbon black particles to absorb multiple scattering lights are pressed into colloidal aggregates as pellets. In order to evaluate the angle dependence of the color observed from the prepared pellets, diffuse scattering was measured by injecting white light onto the flat surface of the pellets and changing the angle of the detector. The peaks derived from Mie resonances occurs in the visible region, and the pellets become photonic pigments without angle dependence when a colloidal particle having a diameter of 350 nm or more is used. Fine tuning of scattering lights is achieved by just changing the particle diameter, because the scattering lights of Mie resonances shift depending on the particle size. The color saturation of the photonic pigments due to Mie resonances can be controlled by adding amount of carbon black particles.

In summary, we succeeded to prepare angle-independent photonic pigments by Mie resonances even under a directional light. The results are useful for making energy-efficient color materials, optical devices and reflective displays having low viewing angle dependence. We are now investigating the contribution of the aggregation structure of the particles to the color development of this aggregates.

EP04.10.09
CMOS-Compatible Direct Bandgap Light-Emitting Germanium by Design
Linding Yuan, Shu-Shen Li and Jun-Wei Liu; Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China.

The microelectronic integrated circuits (IC) is approaching the physical limits of Moore's Law. The optoelectronic integrated circuit (OEIC) is a promising alternative to continue the Moore’s Law. Complementary-metal-oxide-semiconductor (CMOS) compatible high efficient on-chip optical functionalities has long been pursued for manufacturing monolithic integrated silicon-based photonic. Given the indirect bandgap nature of Si, which precludes the efficient emission and absorption of light, various Si-based systems has been proposed over past four decades. Despite intensive research efforts has been made, yet no applicable group-IV laser has been implemented, which becomes the last roadblock towards the OEIC. Because the direct bandgap is only 140 meV above the indirect bandgap in Germanium (Ge), it is well established that a tiny (~2%) extensile strain could render an indirect-to-direct bandgap transition
and makes it direct bandgap. However, there is no feasible way to create such extensive strain on Ge since the lattice parameter of Ge is even 4.3% larger than Si. Here, we propose inserting external atoms into interstitial sites of Ge, which grows on Si substrate through SiGe buffer layer, to induce an effective tensile uniaxial strain on Ge, a new pathway toward direct band gap Ge. By performing the first-principles calculations, we find that atom implantation in Ge are metastable and are effective ways to engineer the indirect band gap to direct band gap. We predict that the optical dipole transition of atom (Li, He, Ne, or Ar) implanted Ge ($E_g$ ~ 20 eV) is comparable to GaAs ($E_g$ ~ 28.8 eV), indicating an excellent optical property of our designed system. Significantly, we find with a low concentration (0.78%) of Ar atom implanted in Ge, direct band gap of 0.73 eV (~ 1700 nm) can be achieved. Because our proposed scheme is fully compatible with CMOS technology, our new concept would be a solution for on-chip lasers and paves the way towards Si-based OEIC.

EP04.10.10 Application of Large-Scale Flexible Selective Emitter for Deception of IR Detector
Namkyu Lee, Joon-Soo Lim, Injoong Chang and Hyung Hee Cho; Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of).

Research highlights
- Application of large-scale flexible infrared emitter for IR camouflage
- Suggestion of flexible infrared emitter without flexible dielectric materials considering mechanical stress
- Verification of flexible infrared emitter in the various conditions to apply for IR camouflage

Abstract
During several decades, the enhancement of survivability of ally has been one of issues on the modern battlefield. In particular, the infrared regime is important for the increase of survivability because the infrared emission from target occurs continuously from target, which makes the late recognition of target compared to the microwave based on radar using reflection signal. To control the infrared signal, we can control the temperature and emissivity on the surface based on the radiative heat transfer equation. In terms of manipulating emissivity, metamaterials have also superior potentials to apply for the military applications because it can realize the exotic properties contrary to natural resources. Especially, the selective emitter, which is one of metamaterials, has ability to manipulate the emissivity for modifying the emissive power from target. In addition, the IR detector has the limited range of detection wavelength because the atmospheric transparency window exists the range of 3–5 and 8–14 μm due to the existence of molecules to cause high infrared absorption. For this reason, via infrared selective emitter, we can match the infrared emission from target with the consideration of atmospheric transparency window. Furthermore, to apply the arbitrary surface on aircraft, military clothes and others, the selective emitter should have the material flexibility.

Here, we present the large-scale flexible infrared selective emitter for IR camouflage for ally’s survivability. To achieve the material flexibility of selective emitter, we use metal-dielectric-metal (MDM) structures. We adjust the flexible substrate of polyimide. And, contrary to the past research, the discrete dielectric material considering mechanical stress is applied for the selective emitter. In addition, we change the dielectric material to silicone dioxide and nitrile which are common materials to use MEMS fabrication process. The emissivity is measured by FT-IR (Bruker) using Kirchhoff’s law. The results showed that we can achieve the selective emitter with single peak to deceive the emissive power from target. In addition, the presented emitter is high reliability against temperature and peel&stick test. The maximum curvature of presented emitter is down to 250 μm, and the high machinability applies for the various surfaces and sizes. Furthermore, we attach the replicated aircrafts and confirm the performance of IR camouflage in the supersonic flowfields (Ma = 3) with the most severe condition of the aircrafts. This study will be helpful for the enlargement of applications using metamaterials.

EP04.10.11 Laser Micropainting in Visible Regime—Thin Film Interference of Iron (III) Oxide on Platinum Substrate
Younggeum Lee1, Wooseop Shin1, Saewoong Park1, Seongje Park1, Jaemook Lim1, Junyeob Yeo2 and Sukjoon Hong1; 1Optical Nanoprocessing Lab, Department of Mechanical Engineering, Hanyang University, Ansan, Korea (the Republic of); 2Novel Applied Nano Optics Lab, Department of Physics, Kyungpook National University, Daegu, Korea (the Republic of).

Thin film interference is one of the well-known optical phenomena that can be found in many places around us, and numerous optical coatings that utilizes thin film interference are already available in the market at the moment. In general, these optical coatings largely rely on Fabry-Perot interference that occurs between one or more films of dielectric or metallic materials. On the contrary, optical coating that consists of highly absorbing film on a substrate with finite optical conductivity has been investigated recently as a new type of optical coating. In the previous related studies, reflective optical coating at visible frequencies have been successfully achieved by coating Germanium (Ge) film at subwavelength thicknesses on gold (Au) substrate using conventional lithographic techniques. We found that iron oxide film (Fe2O3) on platinum (Pt) substrate, having similar refractive indices trends as Ge and Au, exhibit similar interference effect as the Ge film on Au substrate. In this study, Fe2O3 thin film is grown directly on Pt substrate by laser-induced photothermal reaction and applied as an absorbing dielectric for the optical coating. In brief, Pt substrate is immersed in aqueous Fe2O3 precursor solution and 532 nm continuous wave (CW) laser beam is focused on the substrate at 5 to 10 mW power. It is observed that the reflected spectrum from the substrate varies in full visible regime according to the resultant thickness of Fe2O3 film, which is easily controlled by changing the irradiation time. While on the other hand, the film thickness, and hence the reflected color, can be also altered by the scanning instead of changing the irradiation time. By choosing the proper scanning speed in the range of 10 μm/s to 30 μm/s, continuous line of Fe2O3, which exhibits the designated color in the visible frequencies, is created along the scanning path at microscale width. By utilizing the proposed laser process, thin Fe2O3 absorbing media is easily and selectively created on Pt substrate without any photolithographic techniques. It is also worth mentioning that Fe2O3 films at numerous thicknesses can be created on the same substrate with a single step, while it requires multi-step complex photolithography process with careful alignments to achieve the identical result with the conventional techniques.

Another virtue of the proposed laser process comes from the in-situ measurement of the thin film thickness in real time. The incident laser is absorbed by the substrate at 5 to 10 mW power. It is observed that the reflected color from the substrate varies in full visible regime according to the reflected spectrum from the substrate varies in full visible regime according to the reflected spectrum from the substrate. The laser beam is focused on the substrate at 5 to 10 mW power. It is observed that the reflected spectrum from the substrate varies in full visible regime. The laser beam is focused on the substrate at 5 to 10 mW power. It is observed that the reflected spectrum from the substrate varies in full visible regime. The laser beam is focused on the substrate at 5 to 10 mW power. It is observed that the reflected spectrum from the substrate varies in full visible regime.
The development of devices that can modulate and guide light using electrical stimuli has advanced phase change materials quite recently for beyond data-storage technologies, ranging from high resolution displays to smart windows. Despite the interest, the fundamental understanding of light-material interaction in these materials remains limited to photo-thermal induced crystallization. In this paper we report our observation of strong photovoltaic effect in phase change materials, both their amorphous and crystalline states using opto-electronic measurements on nano-scale crossbar devices; which we attribute to the interplay of photo-crystallization, photo-conductive and thermoelectric effects. We show that through device engineering the contribution of these individual effects to the photo-response can be tuned. We also show that the photo-voltaic effect plays a strong role in the photoreponse of the device, which can potentially make the phase change materials based photonic technologies self-powered, and even enable newer platform such as tunable photodetectors. We find phase change materials are stable under strong irradiance and show strong dependence on irradiance, independent of their states, each providing significant advance to understanding the materials science and photo-physics of these materials. As a demonstrator application we also illustrate the working of phase change materials based artificial retinas.

**Phase Dependent Photoconductivity in Chalcogenide Phase Change Materials**

Ghazii Sarwat Syed, Jan Mol and Harish Bhaskaran; University of Oxford, Oxfordshire, United Kingdom.

Solid-state microchip lasers attract attention because of their compact size (~cm), high stability, and high efficiency. Giant pulse power and high repetition rate can be realized with active modules and used in proliferation applications. However, these modules are large in size although Q-switches should be small to obtain shorter and higher output pulse. To overcome these issues, we have suggested the use of magnetooptical (MO) materials as Q-switches. Since the rare-earth iron garnet (RIG) film has the similar crystal structure and thermal expansion coefficient as the ones of Nd:YAG, we expected that the combination of RIG and Nd:YAG is suitable for realizing MO microchip lasers, and reported a MO Q-switch laser using Nd:YAG with the output peak power of 1.1 kW[1]. However, the cavity length was 10 mm at the previous report although the physical length limit is 5 mm. Because of the large size of the component holders of the laser optics, there were air gaps between the components and they limited the cavity length. In order to achieve a microchip MO Q-switch laser, the air gaps must be eliminated. In this report, the design and implementation of MO on the RIG film to remove the air gap between the RIG film and output coupler are discussed, and the Q-switching is demonstrated.

We used a matrix approach method to design the BM onto a single crystalline RIG [(Tb, Bi3(Gd, Fe)2O12] film, and SiO2 and Ta2O5 were used as a low and high reflectivity mirror, respectively. The optical constants of the materials were numerically estimated from their transmittance spectra using a simulation software (SCOUT) based on Fresnel interference. Reflective indexes of the RIG, SiO2, and Ta2O5 were 1.70, 1.43, and 2.02, and extinction coefficients of the RIG, SiO2, and Ta2O5 were 1.57×10-4, 2.79×10-3, and 1.48×10-3, respectively. The BM was designed to have a partial reflection of 50%. The BM was coated onto the RIG film via radio frequency ion beam sputtering. The atmosphere was filled with O2, and the ion beam power and voltage were 114 W and 1200 V, respectively. The fabricated structure of the BM was RIG/SiO2/Ta2O5/SiO2/Ta2O5, and the thicknesses of the films were 190 μm, 102 mm, 141 mm, 167 mm, and 129 mm, respectively. Two three-turn coils with diameters of 5.3 mm sandwiched the RIG film. A single crystalline 1 at.% Nd-doped YAG has which has a high reflection BM at the wavelength of 1064 nm on its input surface was used as a lasing material. The cavity length was 7 mm, which is 3-mm smaller than the one of our previous report[1]. The pumping power was 27.4 W and the repetition rate was 1 kHz at the wavelength of 808 nm, and the pulsed current with 2.3 μs width was applied to the coil for Q-switching. The output pulse had the pulse width of 25 ns, and the obtained pulse energy was 40 mJ corresponding to the peak power of 1.6 kW, which is 1.4 times larger than the previous report[1].

**EP04.10.15**

**Enhanced Photoluminescence from Multilayered Quantum Dots 2D Sheet**

Haruka Takekuma1, Junfu Leng1, Kazutaka Tateishi1, Yang Xu1,2,3, Y. Yin T. Chuang1,2,3, Soh Ruyazi1, Pangpung Wang1, Koichi Okamoto1 and Kaoru Tamada1; Chemistry, Kyushu University, Fukuoka, Japan; 1Institute of Materials Research and Engineering (IMRE), Singapore, Singapore; 2Agency for Science, Technology and Research (A*Star), Singapore, Singapore; 3Chemistry, National University of Singapore, Singapore, Singapore; 4Institute for Materials Chemistry and Engineering (IMCE), Kyushu University, Fukuoka, Japan; 5Institute of Systems, Information Technologies and Nanotechnologies (ISIT), Fukuoka, Japan; 6Osaka Prefecture University, Osaka, Japan.

Colloidal quantum dots (QDs) are one of the favorable nanomaterials having outstanding optical properties such as narrow emission bandwidth with high quantum yield. These properties can be useful for optical or optoelectronic device applications like solar cells or flat panel displays. Recently, there are several reports for QDs combining with metal structures, expecting enhance photo-luminescence (PL) by surface plasmon resonance (SPR) [1, 2]. There is another report mentioning that the thickness is an important factor for the PL from QDs spin-coated films [3]. In this study, we controlled the QDs layer thickness precisely by use of layer-by-layer deposition on glass and gold substrates, and compared their emission properties. A self-assembled monolayer composed of colloidal CdSe/ZnS QDs was fabricated by Langmuir-Schaefer (LS) method. The CdSe/ZnS crystal size is 5 nm in diameter and the thickness of organic ligand layer is 1 nm. The sheet was transferred to hydrophobized glass and gold substrates. To avoid a quenching by a Förster Resonance Energy Transfer (FRET), a 10 nm of SiO2 layer was deposited on gold substrate prior to the fabrication of multilayered QDs. The PL images and spectra of the multilayered QDs were taken under an epifluorescence microscope. The PL intensity of the multilayered QDs sheet on glass substrate increased monotonically against the number of QDs layer. However, it showed a different feature on gold substrate. Neither the mirror effect nor SPR effect can explain this layer-number-dependent PL intensity on gold substrate. If SPR is the main reason of PL enhancement, the maximum should appear at 10 to 20 nm layer thickness on gold in consideration of SPR and FRET [2]. Hence, the light confinement effect in the “optical resonator” composed of multilayered QDs sheet needs to be considered. We assume that a similar phenomenon to our previous study with multilayered silver nanoparticle sheets [4] was induced in the multilayered QDs sheet as well (although electromagnetically induced transparency (EIT) was not found in this case). The detailed data analysis with Finite-Difference Time-Domain (FDTD) simulation provides an overall picture of the layer-number-dependent PL profile, which includes three independent contributions of mirror effect, SPR enhancement, and light confinement.

Amorphous Si (a-Si) is used for fabrication of commercial low-cost flat panel image detectors for radiographic applications such as computed tomography (CT) imaging. a-Si photodiodes are known to exhibit a rapid decrease in quantum efficiency near 750nm. While crystalline Si does not suffer from such an early decline, the large-area and low-cost constraints of medical imagers make it challenging and costly to use crystalline Si for such devices. In this work, we report on the development of a sensitive layer for upconversion from 785 nm to green region of the spectrum, which nearly matches the peak quantum efficiency of a-Si detectors. Various host materials have been extensively studied in literature with rare earth ions such as Er³⁺ (emission: green+red), Tb³⁺ (emission: blue), Ho³⁺ (emission: red+green) along with Yb³⁺ as a sensitizer for upconversion to the visible regime at high incident optical power (~100 mW) for colloidal solutions. We carried out a thermal decomposition synthesis of NaYF₄:Yb/Er(18%)/Er(2%)/Gd(15%) at moderate temperature (~320°C), resulting in a nearly pure hexagonal phase material. This is confirmed by powder X-ray diffraction (PXRD) of the unannealed sample with a lattice constant (~5.17 Å). High-resolution transmission electron microscopy (HRTEM) measurements reveal the formation of nearly spherical nanoparticles. The observed plane ([100]) inferred from lattice fringes in TEM data with a visibly estimated interplanar distance (4.4±1.6 Å) is in reasonable agreement with standard data (~5.17 Å) for comparable NaYF₄-based materials. Excitation (785 nm) of the deposited thin films of Gd-doped unannealed material at relatively low incident power (~0.4 mW) exhibits a PL response in green (539 nm) and red (665 nm) region of the spectrum. Gd-based upconversion material based thin films are thus a feasible photonic material for potential effective extension of high quantum efficiency range in a-Si for flat panel image detectors.

Quantum dot light-emitting diodes(QD-LEDs) that allow emission from porous host materials with high color purity can be driven by low power. We can control their wavelength and the full width at half maximum (FWHM) of the emission spectrum by using abilities of size control, therefore, QD-LEDs are expected to be applied for displays with a wide color gamut. Recently, Cd-based QD-LEDs have been reported to show high color purity and external quantum efficiency (EQE). However, because of the toxicity and restrictions on the use of these Cd-based materials, their substitution with Cd-based materials such as InP is highly desired. In this study, we developed QD-LEDs using high-performance Cd-free QDs composed of core/shell spheres of ZnInGaP/ZnS. The Zn added to the InP core improved the crystal growth and the Ga helped control the lattice matching between the core and shell, increasing the stability in air. This is because the interfacial state of the core/shell has a huge impact on the deterioration mechanism. The photoluminescence (PL) emission peak, FWHM and quantum yield (QY) of this material are 521nm, 60.9nm and 73.8%, respectively. We fabricated a QD-LED with an inverted structure using these Cd-free ZnInGaP/ZnS QDs then the relationship between the hole transport materials and EQE. Some of these materials exhibited low EQEs, partially because electrons and holes were not efficiently able to recombine in the light-emitting layer. In other words, electrons were not fully blocked by the hole transport layer and penetrated through it. Therefore, a material with a high Lowest Unoccupied Molecular Orbital (LUMO) level to block and confine more electrons in the light-emitting layer was desired. We found that TCTA (4,4',4"-Tri(9-carbazoyl)triphenylamine) was effective for blocking electrons. The device fabricated with TCTA for the hole transport layer showed an EQE of about 3.4%. This value is comparatively high for common Cd-free QD-LEDs, and a better charge balance was achieved and the recombination probability between electrons and holes was increased compared with those of previously reported Cd-free QD-LEDs. We found that the combination of ZnInGaP/ZnS and TCTA was effective for realizing high-efficiency QD-LEDs.

There is an ever growing interest in organic electro-optic (EO) polymers as the active material in a range of applications from broadband terahertz emitters and detectors [1] to ultrafast electro-optic modulators [2]. Large electro-optic response [3] and ease of tethering on varying device platforms make EO polymers desired over conventional EO crystals (e.g. LiNbO₃) [4]. Push-pull chromophores with large first hyperpolarizability (β) are the key constituent of EO polymeric materials. The translation of their second order molecular nonlinearity into a macroscopic nonlinear optic effect (Pockels effect) depends on their alignment in an acentric orientation. This is achieved by a so called poling process, in which the chromophores dipoles are oriented with a strong external electrical field at elevated temperature [2-5]. One of the challenges of this technology is the long-term stability of the poled arrangement associated with a high EO response [4,5]. Poling efficiency and stability relies crucially on the host polymer and the degree of chromophore mobility after poling. Strategies widely being employed to stabilize the poling induced acentric order include, use of high glass transition temperature host polymers, cross-linking the chromophores with the host after poling, covalently bonding chromophores to the polymeric chain, adding site-isolation groups to the chromophores [4-6]. Presently, there is an intense research interest to achieve a high EO activity together with long-term thermal and photochemical stability.

In this work we focus on the study of host-guest polymeric materials and their EO performance with the purpose of understanding the mechanisms leading to a stable EO activity. We used known polyene-type push-pull chromophores with adequate molecular nonlinearity [4,5]. Miscible amorphous polymeric host materials with different glass transition temperatures were selected. Thin films of host-guest EO materials were poled using contact electric field poling and their EO coefficients were measured using Teng-Man modulation ellipsometry[7]. To understand the mechanism behind change in persistence of poling state with different host, thermally stimulated discharge studies were conducted and parameters governing the relaxation of the chromophores were obtained. The role of the host polymer on the poling efficiency and stability will be discussed. In-device figure of merit of selected materials will be presented for silicon-organic-hybrid (SOH) EO modulators [2,3].
The planar waveguide modes \( T_E \) or \( T_M \) show \( n \) nodes, i.e. positions where the mode intensity equals zero. Within symmetric waveguides one node of all odd modes (odd \( n \)) is situated in the center plane of the waveguide. Remarkably, this accounts for the entire spectral range where the modes exist, which paves the way for tailoring large bandwidth light matter interactions. For instance, light scattering inside a waveguide strongly depends on the filling factor of the scattering film. Placed in the node plane the scattering is strongly suppressed. On the contrary, only slight detuning of the waveguide could efficiently switch that scattering, which paves the way for new display concepts. In planar solar concentrators a diffracting layer placed in the node plane will hardly interact with the excited waves. As a consequence, by exploiting the node plane the same concentration factor and acceptance angle are reached at a much lower thickness of the concentrator.

**Studies of Morphological Changes Under Electron Beam Irradiation in Cesium Iodide Film**

Puspita Ray1, Radhakrishna V.2, Basishali Garai2 and Rajanna K.2

1Department of Instrumentation and Applied Physics, Indian Institute of Science, Bangalore, India; 2Space Astronomy Group, U R Rao Satellite Centre, Bangalore, India; 3Department of Physics, Dayananda Sagar University, Bangalore, India.

Remarkable properties of gaseous UV photon detectors make them attractive for relativistic particle identification in high energy physics, sky observation in position and admission emission topography in medical physics. Photocathode used to convert UV photons into electrons play a key role in deciding detection efficiency of these photon detectors. Cesium Iodide (CsI) is one of the most efficient UV photon converter among other alkali halides because CsI has the highest quantum efficiency in the UV wavelength range and is relatively stable in air. However, a major drawback of the photocathode material is ageing process which limits their life time and hence performance of these photon detectors. UV photon detectors used in high energy physics, suffer from a high radiation background. High radiation fluences of electrons or protons are continuously hitting on the detector photocathode surface. Such high flux would significantly affect the morphological, structural and photo-emission properties of the photocathode film.

In this work, we demonstrate the impact of electron bombardment on 50 nm thermally evaporated CsI film. It has been studied by SEM, XRD and HRTEM. A severe modification in surface morphology is observed under high energy electron beam exposure. This surface modification involves the creation of void areas which coalesce upon further exposure. Effect of exposure time and energy of incident electron beam on film continuity will be presented here.

Band-engineered Ge has become a promising candidate for monolithically integrated light sources on Si. The direct bandgap of Ge at 0.8 eV corresponds to the most technically important wavelength for telecommunications (1550nm), making Ge an ideal candidate for large scale photonic integration on Si chips for photodetection/optical sensing [1], modulation, and lasing [2]. Even though Ge is an indirect bandgap semiconductor, the energy difference between its direct and indirect bandgaps is only 136 meV [1], which can be compensated by tensile strain and n-type doping. However, growing high quality n+ Ge for efficient light emitters remain a significant challenge. Existing delta-doping approach in chemical vapor deposition (CVD) tends to adversely affect the direct and indirect bandgaps [3,4]. Delta-doping approach results in a low threading dislocation densities of ~10^6 cm^-2 [3], two orders lower compared to 10^8 cm^-2 from as-grown MOCVD samples with n=1x10^19 cm^-3 show a low threading dislocation densities of ~10^8 cm^-2 [3], two orders lower compared to 10^8 cm^-2 from as-grown MOCVD samples with n=1x10^19 cm^-3. Correspondingly, compared to delta-doped samples with a similar doping level, the MOCVD n+ Ge PL intensity is 5-10x higher at room temperature. In fact, their PL intensity is similar to delta-doped samples with 4x higher n-type doping level. Furthermore, the MOCVD samples also show no out diffusion of phosphorus or arsenic dopants upon annealing, in contrast to the delta doping approach. Finally, after annealing the PL intensity of devices decreases by a factor of 2-3 for the MOCVD samples, compared to ~100x for delta-doped samples. However, the PL intensity of the high-temperature annealed MOCVD samples decreases at the PL peak blueshifts mainly due to Ge-Si interdiffusion. These results indicate that it is promising to significantly improve the material quality and light emitting properties of n+ Ge-on-Si via MOCVD growth without high-temperature defect-reduction annealing for better monolithic light emitters on Si.

**Band Gap Tuning Across the Visible Spectrum Through Cation Sublattice Ordering**

Robert Makin1, Krystal Yock1, Steven M. Durbin1, Nancy Senabulya1, James Mathis1, Roy Clarke2, Nathaniel Feldberg3, Patrick Miska1, Christina Jones1, Logan Williams4, Zihao Dong1 and Emmanouil Kioupakis4

1CE Department W/MU, Kalamazoo, Michigan, United States; 2Applied Physics, University of Michigan, Ann Arbor, Michigan, United States; 3Institut Jean Lamour, Universite de Lorraine, Nancy, France; 4Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

When compared with their binary analogs, heterovalent ternary materials have a degree of freedom not present in the binary materials – specifically the arrangement of atoms on the cation sublattice. An ordered cation sublattice has column-II and column-IV atoms at their specified equilibrium sites. For ZnSnN2 and MgSnN2, this ordered-equilibrium structure is the orthorhombic γ-NaFeO2 lattice. At the opposite extreme of cation sublattice ordering, column-IV and column-II atoms are equally likely to occupy any cation sublattice site. This disorder increases the symmetry of the lattice; for ZnSnN2 and MgSnN2, it shifts the lattice from an orthorhombic structure towards a wurtzite structure. As we show here, it also has a profound affect on the band gap, allowing it to continuously vary over almost 1 eV.

A common method for quantifying the random distribution of atoms on lattice sites is through the long-range order parameter, \( S \). The order parameter of a
material is often determined by calculating the ratio of the integrated area of a superlattice peak, which is a reflection whose structure factor is dependent upon S, to the integrated area of a fundamental peak, which is a reflection whose structure factor is independent of S. There are additional methods as well, such as Raman spectroscopy and reflection high energy electron diffraction (RHEED). We have used all three of these methods to extract the order parameter from both ZnSnN$_2$ and MgSnN$_2$ thin films, and the results agreed to within two decimal places among all three techniques. For ZnSnN$_2$, the S values, averaged using the results from the three different techniques, range from 0.26 to 0.97. For preliminary MgSnN$_2$ films, the S values, averaged using the results from the three different techniques, range from 0.67 to 0.96.

Following the method of Wei and Zunger, who employed an Ising model approach to derive a quadratic relationship between the band gap and ordering in alloy, we find that for ZnSnN$_2$ and MgSnN$_2$, $E_{gS} = E_{gS=0} + S^2[E_{gS=1} - E_{gS=0}]$ where $E_{gS=0}$ is the band gap of the wurtzite structure, $E_{gS=1}$ is the band gap of the orthorhombic structure, and $E_{gS}$ is the band gap of a partially ordered lattice. Consequently, a plot of the band gap as a function of S should yield a linear relationship, with a slope equal to $E_{gS}(a)$ the difference in the band gap of each of the two phases). From a linear fit to the data, we find the band gap ranges between 1.12 eV to 1.98 eV for ZnSnN$_2$, and between 1.87 eV and 3.43 eV for MgSnN$_2$. Thus, the range spanned by the cation sublattice ordering tunable optical band gaps of ZnSnN$_2$ and MgSnN$_2$, approximately 1.12 eV to 3.43 eV, positions these materials as earth-abundant eco-friendly alternatives to GaN alloys capable of spanning the spectrum from the near IR to the UV, without the need for alloying.

Polarization Control of Strain-Induced Single-Photon Emitters in Atomically Thin Semiconductor Kwang-yong Jeon$^1$, Jae-Pil So$^2$, Soon-Jae Lee$^2$, Jung Min Lee$^3$ and Hong-Gyu Park$^2$; $^1$Department of Nano Science and Technology, Gachon University, Gyeonggi-do, Korea (the Republic of), $^2$Department of Physics, Korea University, Seoul, Korea (the Republic of).

Quantum emitters in two-dimensional materials have attracted much interest in quantum technologies such as quantum cryptography, computation and metrology. Recently, deterministic creations of the quantum emitter array in two-dimensional transition metal dichalcogenides (TMDCs) by strain engineering has been reported. However, in order to realize the scalable quantum photonic devices, it is necessary to control not only its position but also its polarization. Here, we control the polarization and position of the strain-induced quantum emitters using nanogap arrays fabricated by E-beam lithography and dry etching process on the SiN/SiO$_2$ wafer. Tungsten diselenide (WSe$_2$) monolayer is transferred on the fabricate nanogap arrays. Strain perturbations in WSe$_2$ monolayer can create localized excitons induced by artificial potential energy which can be tuned by nanostructures. Confocal PL mapping shows that the localized emitters are distinct from the neutral exciton which is present uniformly across the WSe$_2$ monolayer with ~10 times higher photon counts. The single-photon nature of emitter is confirmed by Hanbury-Brown and Twiss (HBT) setup. Polarization-resolved photoluminescence (PL) microscopy shows the strain-induced emitter emits the linearly polarized light. The polarization of the emitter is perpendicular or parallel to the nanowires depending on the width of nanogap. We also demonstrate the waveguide coupled on-chip single photon emitter in WSe$_2$. Our results will pave the way for the hybrid integration of passive photonic circuit with single-photon emitters in two-dimensional semiconductors for next generation quantum technology applications.

EP04.10.24
Optoelectronic Design of Thin-Film Infrared Sensitive Photodiodes Based on Lead-Sulfide Quantum Dots Epinitheas Georgitzikis$^{1,2}$, Pawel E. Malinowski$^3$, Vladimir Pejovic$^1$, Jorick Maes$^4$, Zeger Hens$^4$, Paul Heremans$^1$, 2 and David Cheyns$^1$; $^1$imec, Leuven, Belgium; $^2$Department of Electrical Engineering (ESAT), Catholic University of Leuven, Leuven, Belgium; $^3$Budapest University of Technology and Economics, Budapest, Hungary; $^4$Department of Physics, Korea University, Seoul, Korea (the Republic of).

Lead sulfide (PbS) based colloidal quantum dots (QDs) are very attractive materials for the realization of novel optoelectronic devices, combining low cost synthesis and processing, deposition over large area and on any substrate with a tunable band gap that enables selective detection in wavelengths ranging from the visible light to the short-wave-infrared (SWIR). Great effort has been made in the last years to incorporate PbS QDs in thin-film photovoltaic devices (TFPV), leading to improved efficiencies through better ligand passivation schemes of the QD surface. Even though these devices report high external quantum efficiencies (EQE) they lack the required characteristics that would make them suitable for imaging applications, namely a low dark current and high speed. In this work we demonstrate how a combined electronic and optical design PbS QDs can enable high performance infrared sensitive photodiodes.

In the electronic domain, we study devices of QD layers sandwiched between two transparent, thickness tunable transport layers as an n-p junction photodiode. We demonstrate how the proper selection of hole (HTL) and electron (ETL) transport layers through band alignment engineering can decrease the dark current of the device substantially. We argue that a major contribution to dark current in these devices derives from dangling bonds at the surface of the QDs. Time-resolved photoluminescence (TRPL) is used to characterize the recombination processes in the QD films under different ligand termination and to study the relation between the trap states and the dark current of the devices. Taking these data as a feedback we fabricated optimized devices with dark currents below 1 uA/cm$^2$ at 1450 nm and below 10 nA/cm$^2$ at 950 nm.

In the optical domain, we optimize our devices to achieve high EQE at the wavelength of our choice by properly manipulating the optical cavity inside the layers. Using variable angle ellipsometry and reflection/transmission measurements we build an optical model for PbS QD based thin-films. We show that different ligands result in different packing of the QDs, having a crucial effect on the IR light absorption coefficient. Furthermore, we tune the transport layer thickness to optimize the intrinsic cavity effect of the device structure, boosting the absorption of our stack from 40% to above 80% at the wavelength of interest even with very thin QD layers between 100 – 200 nm. Through this path we demonstrate photodiodes with low dark current and high EQE of 30% and 50% at the wavelengths of 1450 nm and 950 nm, achieving specific detectivity of 10$^{12}$ Jones.

Quantum Dots (QD) for optoelectronic devices have received much attention over the past decade due to their large-area solution processability as well as
Resonant Optical Studies of GaAs/AlGaAs Multiple Quantum Well Based Bragg Structures at Excited States

Nikesh Maharjan1, Vladimir Chaldyshev2 and Mim Nakarmi1; 1Physics, Brooklyn College and The Graduate Center of the City University of New York, Brooklyn, New York, United States; 2Ioffe Institute, St Petersburg, Russian Federation.

Resonant Bragg Structure (RBS) based on GaAs/AlGaAs multiple quantum wells (MQWs) was designed aiming to coincide the Bragg resonance with the exciton energy of the second quantum state in the GaAs quantum well to achieve double-resonance condition. The RBS samples with 60 periods of GaAs/AlGaAs quantum wells/barriers were grown on semi-insulating GaAs substrates by molecular beam epitaxy. We employed optical reflectance (OR) and electro-reflectance (ER) spectroscopies to study resonant optical properties of the RBS samples. At low temperature optical reflectance measurements, we observed enhanced Bragg reflection intensity when exciton energy coincides with the Bragg energy peak. In the electro-reflectance spectra, we also observed an enhanced and broad ER features related to excitons at the excited states under the double-resonance conditions manifesting a strong light-matter interaction. Bragg peak can significantly be tuned by changing the angle of incidence of the light. Exciton energies can be tuned by changing the temperature and external electric field. The exciton energies are very sensitive to the thickness of the quantum wells. There was noticeable change in exciton energy in the samples in the different regions from the same wafer. We performed the numerical calculations to estimate the possible exciton states. By tuning these variables, we performed OR and ER measurements to study the resonant optical behaviors at the excited energy states. By tuning the Bragg peak for double resonance in the RBS samples of different thicknesses, we observed the electro-reflectance features related to the transitions of \((x(2\text{-}hh}_2), x(2\text{-}hh}_1), x(2\text{-}hh}_3)\) and \((x(1\text{-}hh}_1), x(2\text{-}hh}_3)\) and \((x(1\text{-}hh}_3)\) which are prohibited at zero electric field, were allowed due to the increased overlap of the electron and hole wave functions caused by the electric field, built-in electric field or a DC bias applied. Details about our findings on the resonant optical properties of GaAs/AlGaAs MQW based RBS along with its implications will be presented.

光线性価格を制御するための光学的特性の開発

Dongling Geng, Elena Cabello-Olmo, Gabriel Lozano and Hernán Míguez; Spanish Research Council, Seville, Spain.

Herein we show that nanoporphosphor integration in an optical cavity allows unprecedented control over both the chromaticity and the directionality of the emitted light, without modifying the chemical composition of the emitters or compromising their efficiency. GdVO4:Dy3+/Eu3+ nanoparticles of controlled size and shape are synthesized using a solvothermal method with which highly transparent nanoporphosphor thin films are prepared. Key to the achievement herein reported is the careful analysis of the structural and optical properties of thin nanoporphoshor layers with the processing temperature in order to achieve efficient photoluminescence while preserving the transparency of the films. An optical cavity was photoluminescence produced by embedding one layer of the nanoporphosphors in the middle of a one-dimensional photonic crystal (1DPC) made by ultraviolet (UV) transparent ZrO2 and SiO2 layers. Strict control over the structural parameters yielded a photonic cavity mode that couples to the target emission peak of the nanoporphosphors, which results in an enhancement or suppression of the spontaneous emission of Dy3+ or Eu3+ ions compared with their corresponding reference. As a result the chromaticity and the directionality of nanoporphosphors can be tuned with high precision due to the interplay between photonic resonances and the natural emission of the rare-earth cations. Our approach opens a route towards the development of nanoscale photonics based solid-state lighting and displays.

III-As Growth on C-Plane Sapphire by MBE

Samir K. Saha, Rahul Kumar, Andrian Kuchuk, Timothy Morgan, Pijush K. Ghosh, M-Zamani Alavijeh, Shui-Qing Yu and Gregory J. Salamo; University of Arkansas, Fayetteville, Arkansas, United States.

The III-V growth on Al2O3(0001) can create the opportunity to realize monolithic integrated combining high-performance III-V semiconductor light sources, modulators and detectors, low waveguide and passive devices, and CMOS and RF silicon circuits on a sapphire platform. The potential integration of microwave photonics (MWP) functionality on a photonic chip can dramatically increase speed, bandwidth, processing capability and dynamic range. Here we study the initial nucleation mechanism and interface between III-As grown on an Al2O3 (0001) substrate, very dissimilar materials (lattice parameters, crystal structure, thermal expansion). Previous studies for arsenides on sapphire have focused on thick layered growth as opposed to investigating the initial nucleation. In our research, molecular beam epitaxy (MBE) is used to grow ternary (InGaAs) and binary (GaAs, AlAs, and InAs) arsenide materials on well define step and terrace surface of the substrate. At the initial stage of the growth, we observed the 3D growth mode for the InGaAs, GaAs, and InAs from 1ML to 50 nm. For the 50 nm GaAs the faceted crystal structure is observed and from rocking curve measurements of X-ray diffraction (XRD) only one out-of-plane orientation [111] has been detected. Rocking curve of 50 nm GaAs shows small linewidth (242 arcsec) indicating the high quality of the grown crystals. Asymmetric (113) phi-scan shows a weak correlation with the sapphire substrate. The In incorporation is very low for the very small amount of InGaAs deposition on the sapphire substrate and the amount of In incorporation increased with increasing the thickness of
InGaAs. Twin formation is a major challenge for obtaining a single crystalline material and these twin crystals are rotated by 60° to the original phase. We have suppressed the twin formation and improved the GaAs crystal quality by introducing a thin layer of AlAs between GaAs and sapphire as well as the in-plane orientation relationship between GaAs and sapphire has improved. Further in-situ annealing has been found to decrease the twin volume and reduced to less than 2% of the total grown material.

Investigation of Strain and Stoichiometry of Epitaxial Titanium Nitride on Sapphire

Hadley A. Smith1, 2, Said Elhamri2, Kurt Eyink1, Zachary J. Biegler1, 3, Rachel L. Adams1, 4, Tyson C. Back1, Augustine Urbas1, Brandon M. Howe1 and Amber N. Reed1; 1Materials and Manufacturing Directorate, Air Force Research Laboratory, Dayton, Ohio, United States; 2Department of Physics, University of Dayton, Dayton, Ohio, United States; 3Department of Electro-optics and Photonics, University of Dayton, Dayton, Ohio, United States; 4Department of Mechanical Engineering, University of Dayton, Dayton, Ohio, United States.

The metallic, robust and high-melting point qualities of titanium nitride (TiN) make it an interesting and viable material for plasmonics and electrodics. Previously, we analyzed how substrate temperature affects the microstructure and optical properties of TiN films grown with controllably unbalanced reactive magnetron sputtering, with substrate temperatures varying from 280°C to 760°C. The TiN films were analyzed with X-ray photoelectron spectroscopy, which revealed no compositional difference between samples. Additionally, Rutherford backscattering spectrometry on the 550°C film showed that it was stoichiometric. These results indicate that strain is the most prominent component contributing to changes in TiN microstructure, as oppose to stoichiometry changes. To further investigate any present strain, the films were analyzed with high resolution X-ray diffraction (XRD) by completing 2theta-omega scans around the (111) TiN orientation (symmetric) as well as the (113) orientation (asymmetric). Rocking curve scans were also completed around the (111) TiN peak. With the assumption that any strain in the sample would be rhombohedral, the 2theta values from each orientation were compared, and the best estimate for the strained lattice constant and bond angles were extracted. Lattice constants increased with increasing substrate temperature until 490°C. At this substrate temperature, the lattice constants plateaued around 4.245Å, and the deviation from a 90° bond angle remained at a minimum. This trend correlated with plasmonic qualities of the films, with the more relaxed films grown above 490°C yielding greater plasmonic quality. Additionally, two smaller peaks were found symmetrically placed around the film peak in the XRD rocking curve scans for the TiN grown with 550°C, suggesting some planes in the film are unfavourably tilted. The film grown with 550°C had the least amount of background counts, indicating the least amount of point defects in this film. We previously found that TiN grown with 550°C resulted in optimized optical properties for plasmonic materials; this contributes to the previous conclusion that microstructure correlates with optical properties in TiN. The results of this work emphasize the importance of specific deposition conditions—in this case, substrate temperature—to minimize strain and defects for achieving optimal plasmonic properties for TiN thin films.

Modeling of Type-II InAs/InSb Superlattice Bandstructure and Absorption Spectra Using Time Dependent Density Functional Theory

David G. Gonzalez Alcantara, J Velez and R Palai; Department of Physics, University of Puerto Rico, San Juan, Puerto Rico, United States.

Focal plane arrays (PFAs) based on type II superlattice (T2SL) operating in mid-wave infrared (MWIR- 3-5 mm) and long-wave infrared (LWIR 8-12 mm) are of great importance for many advanced surveillance and imaging systems for a variety of civil and military applications. These detectors have better accuracy and sensitivity with low false alarms even in complicated backgrounds and are promising alternatives to the technologically developed HgCdTe in MWIR and LWIR detection. When the focal plane contains hundreds or thousands of semiconductor elements a single spot of incident energy can stimulate more than one element. The unwanted electrical and optical crosstalk is the most important factor that hinder the performance. It has been found that III-V semiconductor (InAs, InSb, and InSb) strained layer superlattice (SLS) are very promising in terms of reducing the crosstalk, because of the intriguing broken gap alignment and interesting fundamental physics (Bose-Einstein condensation of excitons and the quantum spin Hall effect).

In the present work, the band structure of (InAs)\textsubscript{n}/(InSb)\textsubscript{m}, type-II superlattices is calculated within the density functional theory (DFT) framework using Perdew-Burke-Ernzerhof (PBE) approximation for the exchange-correlation functional using the Quantum Espresso (QE) package. For the calculation of spectroscopic properties of the material (absorption spectra), time dependent density functional theory (TDDFT) package in the QE distribution is used. We investigate the bandstructure of (InAs)\textsubscript{n}/(InSb)\textsubscript{m}, T2SLs with different layer thickness. Understanding and controlling the bandstructure of InAs/InSb T2SL will facilitate to achieve any desired bandgap for infrared detection and the negative bandgap will open a new avenue for the new physics phenomena.

Charge and Thermal Modeling of a Semiconductor-Based Optical Refrigerator

Shubin Zhang1, Yurii V. Morozov2, Boldizsár Janko1 and Masaru Kunito1; 1Physics, University of Notre Dame, Notre Dame, Indiana, United States; 2Chemistry, University of Notre Dame, Notre Dame, Indiana, United States.

Despite multiple attempts to achieve optical refrigeration in very high (99.5%) external quantum efficiency (EQE) GaAs, no cooling has been observed to date. In this study, we investigate optical refrigeration in GaAs by numerically solving the transient drift-diffusion equation coupled to Poisson’s equation. Obtained charge carrier distributions, together with the heat diffusion equation, allow us to observe the spatial and temporal evolution of cooling/heating within GaAs. Our results indicate that maximum cooling occurs at a laser intensity different from that which maximizes its EQE. A 6-fold difference in cooling power exists. We ultimately find that samples suspended in vacuum using a 100 µm SiO\textsubscript{2} fiber cool to 83 K. These results emphasize the critical importance of choosing an appropriate laser excitation intensity to achieve optical refrigeration along with minimizing the conductive heat load on the refrigerator. Beyond this, results of the study are applicable towards analyzing the optical response of other optoelectronic systems where accurate charge and/or heat diffusion modeling is critical.

SiO\textsubscript{2} and TiO\textsubscript{2} Sol-Gel Blends with Tunable Optical and Electronic Properties

Stephanie Arouh, Roland Himmelhuber and Robert A. Norwood; University of Arizona, Tucson, Arizona, United States.

Metallic oxide thin films are used for applications ranging from anti-reflective coatings to microelectronics. Sol-gels are useful for creating these films due to the ability to create high quality films without expensive and complex deposition equipment.

In this work, sol-gel blends are created using a combination of previously developed high index (n~2.4) TiO\textsubscript{2}-based sol-gel made directly from the metal chloride and a low index (n~1.5) SiO\textsubscript{2} based sol-gel synthesized by the standard alkoxide route. Blends are prepared with different ratios of these sol-gels and spun onto glass or ITO-on-glass substrates. The thicknesses, refractive indices, and dielectric constants of the resulting films are measured using...
Results show that including more SiO₂ based sol-gel in the initial mixture enables thicker films ranging from 1-10 μm, while resulting in lower refractive indices and lower dielectric constants. Refractive indices measured were 1.5 and 1.75, and dielectric constants up to 8 were observed at 100 kHz. This is consistent with the expected results due to SiO₂ having a lower refractive index and dielectric constant over the range of wavelengths and frequencies explored. The ability to fine tune the properties is explored, with the trade-off between processability and dielectric properties being the primary focus.

In the future, these sol-gel blends can be used within photonic circuitry, or within either stand-alone or integrated capacitors devices.

**EP04.10.33**

**Linear and Non-Linear Optical Properties of a Single Dopant in a Strained Holey SiO₂/Si Nanotube**

Mohamed El-Yadri⁴, Noreddine Aghoutane¹, El Aouami², Elmustapha Feddi², Mostafa Sadoqi¹, F. Dujardin¹, C. A. Duque⁴ and Gen Long¹; Saint John’s University, Jamaica, New York, United States; ²Group of Optoelectronic of Semiconductors and Nanomaterials, ENSET-Mohammed V University, Rabat, Morocco; ³LCP-A2MC, Institut de Chimie, Physique et Matériaux, Université de Lorraine, Metz, France; ⁴Grupo de Materia Condensada-UdeA, Instituto de Física, Facultad de Ciencias Exactas y Naturales, Universidad de Antioquia, Medellin, Colombia.

In this study, we have investigated the influence of the geometrical confinement and impurity position on the optical properties (linear and third order nonlinear) associated with the 1s-1p intersubband transition of a single dopant in a SiO₂/Si cylindrical core/shell nanotube. Our calculations are performed in the framework of the effective mass and parabolic band approximations and the energies are obtained by using a variational method. Our results show that linear and nonlinear parts of the absorption coefficient and the refractive index associated to the intersubband 1s-1p transition undergoes important changes. There are different interesting results to point out such as the shift of the absorption coefficients and refractive index to high values of photon energy. Another significant result is that the donor position considerably affects theoretical properties and their corresponding magnitudes.

**EP04.10.34**

**Design of Broadband Infrared Selective Emitter for IR Camouflage Through Multiple-Size Structure**

Junesoo Lim, Namkyu Lee, Injoong Chang and Hyung Hee Cho; School of Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of).

Detection techniques using waves are used in many areas such as ultrasound wave, radar, and infrared wave detection. However, these detection technologies also have a side effect that the ally’s operational activities that emit radiation by body temperature are exposed to the enemy. Therefore, it is required to develop anti-detection techniques for protecting our assets. To diminish the detection possibility, many researches about anti-detection for radar and ultrasound wave have been progressed. In case of the Infrared wave, there is difficulty to realize camouflage, because Infrared emission passively depends on the surface temperature of the body. For Infrared detection, Infrared detectors mostly detect wavelengths outside the band of 5 ~ 8 microns, because the absorption by atmospheric air are the largest in the 5 ~ 8 microns band. Therefore, if the emission characteristics can be manipulated that energy is emitted through in 5 ~ 8 micron band to a maximum and out a range of 5 ~ 8 micron to a minimum, the infrared camouflage can be realized. Recently, metamaterials have been cultivated as means to control emission characteristics. By modifying the structure’s size of selective emitters, we can control specific wavelengths to emit. In this study, we design the broadband infrared emitter which emits in 5 ~ 8 microns band through the multiple-size structure for reducing the thermal instability caused by the narrow bandwidth which can cause the out of control emission.

Firstly, to determine the diameter of cylinders, a numerical method was used by using Finite element method. Commercial code (COMSOL 5.2a) was used to simulate the physical phenomenon of MDM structure. For the validation, a single-diameter structure was fabricated by micro-nano fabrication process and compared with numerical results. After the emission characteristics of single-diameter structure are analyzed, we could derive two diameters of the cylinder for having the MDM structure emit in the band of 5 ~ 8 microns. In addition, we simulated the derived structure. As a result, the multiple-diameter structure shows the dual peaks within the in the band of 5 ~ 8 microns. Additionally, we compared the total radiated energy between the selective emitter and broadband emitters for evaluating the radiation performance. Total radiated energy is increased by 33% for comparing the single-diameter structure and multiple-diameter structure and is 120% and 130% more for two layers of MDM and three layers of MDM. In conclusion, through on this study, we derived a structure that emits broadband in 5 to 8 bands to camouflage from infrared detectors. In order to realize the broadband, the absorption peaks could be widened to the left and right through the multi-diameter structure and stacked method and this study will help to understand the effect of the metamaterial structural characteristics on the radiation performance and to understand the application of metamaterials to real life.

**EP04.10.35**

**Corrugated Metal-Electrode Fabry-Perot Cavity for Organic Solar Cells—Near-Perfect Optical Absorption by the Coupling of FP and Propagation Modes**

Sungjun In and Namkyoo Park; Photonic Systems Laboratory, Department of Electrical and Computer Engineering, Seoul National University, Seoul, Korea (the Republic of).

The application of nano-photonic structures for organic solar cells (OSCs) has been quite popular and successful, leading to increased optical absorption and better spectral overlap to solar irradiances. With the introduction of plasmonic cavity structures [1-3], textured light trapping structures [4-5], or multi-plasmonic effects [6-8], signiﬁcant improvements in the power conversion efﬁciency (PCE) have also been reported, now exceeding 11%. Nonetheless, with the limitations of given material properties of OSCs such as low optical absorption and narrow absorption band, together with the high-Q narrow band plasmonic effects, the PCE of single-junction OSCs has been stagnant over the past few years, at the barrier of 12% [9-10].

In this work, we demonstrate an ultra-thin inverted OSC structure which provides near-perfect optical absorption over the entire absorption band of commonly used organic active material. By introducing a smooth spatial corrugation to the vertical plasmonic cavity which encloses the active layer, we successfully derive a strong multi-peak in-plane plasmonic propagation modes, in addition to the signiﬁcant broadening of the Fabry-Perot cavity modes in the UTMF-electrode OSC. As a result, we achieve highly uniform (> 85%) and ultra-low Q (330~775 nm) broadband absorption in the ultra-thin active layer, which directly translates to the record-high PCE approaching ~13%. With the newly introduced concept of long-period spatial corrugation for the UTMF based OSC, we expect further applications of the same concept for solar cells of different materials and structures, targeting for even broader responses and higher PCE. The signiﬁcance of spectral engineering in the PCE of ultrathin OSC will be discussed, together with the detailed study on electrical carrier transport dynamics in the device.

Surface-enhanced Raman scattering (SERS) is a convenient and highly sensitive method for even single molecular level detection. SERS has been extensive use in the field of chemical, material, environmental, and medical sciences. SERS sensitivity is an important role in sensor field because high sensitivity means recognizing target molecule as early as possible. In order to improving SERS sensitivity, advanced and complex metal nano structures have been used to produce a huge electric field in hot spot. Although the metal nano structures have shown high performance, the high cost and poor spatial uniformity are critical drawbacks. In this work, we propose an inexpensive, reliable, and ultrasensitive SERS platform based on M13 bacteriophages (M13 phase) and a simple metal nano structure. The employed simple metal nano structure is a sandwich structure between single silver nanowire and gold film. When the nanowire is well dispersed on the film, the individual hot-spot can be well specified through optical microscope. Therefore, we can believe that each different position of SERS hot-spot shows same properties. Diameter of the silver nanowire is around 300 nm and length is around 30 um. Absorption and localized surface plasmon resonance spectra were measured to understand basic plasmonic properties of the structure. Three-dimensional finite difference time domain simulations (3D FDTD) was also calculated. The most important reason for using the structure is that the shape of its hot-spot is long as like M13 bacteriophage. Because the structure and M13 phase are similar in shape, they can be aligned well. M13 bacteriophage is a promising functional material due to its interchangeability and functionalized peptides on its surface. Genetic manipulated M13 phase can have selective adhesive strength with a target material. When the M13 phase placed in the hot-spot of the structure, the SERS platform can have selectivity for the target material. To verify this, SERS measurement were performed using the structure with and without the M13 phase. Target molecular, 20 microliters of paraquat (PQ), was dropped on the structure and dried. the droplet size is around 0.5 cm x 0.5 cm. Without the M13 phase, the structure shows the limit of detection over picomole range for PQ. When we introduced the M13 phase that was genetically engineered for selective binding of PQ, the structure shows the limit of detection around femt mole range for PQ. M13 phase-based SERS platform exhibited a dramatic improvement of sensitivity compare to the structure without the M13 phase.

Engineering Erbium-Doped Oxide Thin Layers for Integrated Optics

Yttria-Stabilized Zirconia (YSZ) is known to be a thermal and chemical stable functional oxide with a refractive index of about 2.12, which allows good light confinement of the optical mode. Moreover, it has a large energy bandgap avoiding two photon absorption (TPA) in near and mid-IR and its transparency covers the wavelength range from visible to mid-IR. Additionally, Kerr effect has been recently demonstrated. While these optical properties are very appealing for various applications including on-chip optical communications and sensing, YSZ has remained almost unexplored in photonics [1,2]. In this regard, we recently demonstrated YSZ waveguides with propagation losses as low as 2 dB/cm at a wavelength of 1380 nm [3]. Based on the promising results obtained in such passive photonic structures, we have recently looked into the development of active systems based on YSZ thin films. For that, we have introduced optically active rare-earth (RE) dopants into the matrix to investigate the correlation between the luminescence properties and the microstructure of thin films grown under different conditions.

In this work, we report on the optical and structural properties of Er-doped YSZ thin films showing strong emission at 1.53 and 1.536 μm under a continuous-wave pump laser excitation at about 980 nm. Yttrium-to-erbium substitution is performed in the Yttria-Stabilized Zirconia (YSZ) crystal. The observed outstanding luminescence will be analyzed and discussed. Remarkably, the Er-doped YSZ system provides a nearly perfect allocation of Er ions in the host matrix caused by a similar atomic radius between Y and Er, enabling an efficient optical activation of such dopants. These results pave the way towards the implementation of new rare-earth-doped functional oxides into hybrid photonic platforms in a customized and versatile manner, adding new functionalities including light amplifiers that may be instrumental for nanophotonic applications.

Resonant Cavity Enhanced Quantum Well Solar Cells

Resonant cavity enhanced quantum well solar cells (QWSCs) provide significant energy conversion efficiency improvement over standard QWSCs. Recent research in this area has focused on improving the performance of QWSCs through the use of resonant cavity structures. These structures can enhance the light harvesting efficiency of QWSCs by confining the light within the active region of the cell. The use of resonant cavity structures in QWSCs is particularly effective for short-wavelength light, where the bandgap energy of the QWSCs is typically lower than the energy of short-wavelength light. This allows for efficient absorption of the light within the active region of the cell, leading to improved energy conversion efficiency. The use of resonant cavity structures in QWSCs has been shown to improve the energy conversion efficiency of QWSCs by up to 40%. This improvement is achieved through the use of high-Q resonant cavity structures that confine the light within the active region of the cell, leading to increased light absorption and improved energy conversion efficiency. The use of resonant cavity structures in QWSCs is a promising technology for improving the performance of QWSCs and provides a potential solution for the energy conversion efficiency limitation of QWSCs.
Photovoltaic devices can provide a mobile source of electrical power for a variety of applications in both space and terrestrial environments. Many of these mobile power applications can directly benefit from enhancements in the efficiency of the photovoltaic devices. Space-based PV systems can also utilize thin-film technologies that improve radiation hardness, operating temperature range, efficiency, and specific power. To improve the radiation tolerance of multijunction III-V solar cells, we describe a device design which integrates reflector structures and quantum well absorbers into existing space power cell technology.

Prior work has demonstrated that InGaAs wells can be added to a GaAs cell while still maintaining a high open circuit voltage ($V_{oc} \sim 1.05 \text{V}$). Carrier collection efficiency in the wells can then be significantly increased with integrated photon management techniques. In particular, simulations indicate that adding a bottom reflector and a partial top reflector to generate resonant cavity effects can enable thin InGaAs quantum wells to extend infrared absorption and leverage optical cavity effects to increase the path length of near band edge photons. Device structures incorporating these elements we call a resonant cavity enhanced quantum well multijunction solar cell (RCE-QW MJSC). Simulations suggest enhanced absorption via resonant optical cavity effects can enable the GaAs middle subcell to be thinned to less than 1 μm without sacrificing short circuit current density.

We present photonic structures having different heights and color intensities through a flow coating method on a single substrate. Flow coating is one of the solution coatings that use coffee-ring effect. Coffee-ring effect is a non-volatile solute remaining on the surface after evaporation. This pattern originates from the capillary flow that is induced by the different evaporate rate between the edge and center of the droplet. Flow-coater confines the position of droplet with blade on specific position and deposits the solute along the shore. There are various methods of depositing thin films on solid substrates and are of substantial importance in numerous field such as microelectronics, optics and sensors. Flow coating has several important features that are different from other similar methods to fabricate photonic structures. First, lithography or nanocasting need complex steps to achieve photonic structure but flow coating do not need a develop process. Second, deep coating need a long time until liquid evaporate and form a thick film. However flow coating overcome such problems and has more advantages. Especially, flow coating can control the overall thickness easily, it changes spontaneously along the speed of blade. Particles deposit on the substrate forming close packed and well-ordered structure. Photonic structure can be made in that way. And photonic structure is three dimensional periodic structures that influence on incident light lay. When the periodicity of the photonic crystal is about half the light wave, photonic surface diffracts certain range of wave length. It has been found in nature, like avian feathers and wings of butterfly. They exhibit vivid color that reflect depends on their one structure. Two different nano size (195±5 nm and 300±5 nm) of silica Particles are prepared through the stober method. And different particles reflect different wave length showing blue or red colors when is being film structure. Ethanol is good medium to disperse silica and for flow coating. Solution evaporate fast inducing strong capillary follow, it make film quickly. The speed of deposition determines the thickness of film form 0.37±0.1 μm to 2.93±0.3 μm and shows different height of reflection peaks. Therefore, two different colored with different intensity can be made in a one substrate with one step of patterning process.

Exploring Circular Dichroism at Nanoscale by Atomic Force Microscopy Negar Otrooshi, Abraham Vazquez-Guardado, Debashis Chanda and Laurene Tetard; Department of Physics, University of Central Florida, Orlando, Florida, United States.

Studying light-matter interactions at the molecular level is critical to accelerate our understanding of life sciences. Nanoscale infrared spectroscopy, combining Atomic Force Microscopy (AFM) with IR spectroscopy, has made it possible to explore the vibrational modes excited in the sample. Using AFM subwavelength spatial resolution in IR spectroscopy can now be reached. Previous work shows that it is possible to design plasmonic substrate to locally enhance the electromagnetic field used to excite the molecules for higher sensitivity.

Here we use a cavity coupled plasmonic substrate to polarize and enhance the field used to excite the molecular vibration, detected by AFM. Our study focusses in studying the effect of chirality of biomolecules on the nanoscale resolved measurements captured with the AFM. We show that it is possible to generate a stronger confined electromagnetic field in the range of 1500-1800 cm$^{-1}$ by exploiting the cavity-coupled achiral plasmonic structure. We compare the response of the sample to both linearly and circular polarized incoming IR pulsed laser. For circular polarization, we acquire signals resulting from left handed and right - handed circular polarizations before subtracting them to reach information on the chirality. Molecules laying in the confined field at the plasmonic structures show stronger circular dichroism signal. The results suggest that using the “hot spots” of the cavity coupled plasmonic structures are significant and offer great potential for characterizing the chirality of single molecule. By using this approach, we expect to help distinguish chirality of biomolecules at nanoscale.

From Order and Disorder in 1D Photonic Crystals Towards Micro-Glitter Distributed Bragg Reflectors Mirela Malekovic, Esteban Bermúdez-Ureña, Bodo Wilts and Ulrich Steiner; Adolphe Merkle Institute, Fribourg, Switzerland.

Most vivid colours in nature originate from the interference of light with nanostructured materials. In many cases, the nanostructure is not perfect and introducing disorder results in additional optical effects that might change the reflection properties. Our current research is broadly focused on two questions: (i) how are optical properties influenced by disorder? and (ii) can we replicate natural photonic structures with a controlled degree of disorder? For this, we systematically investigate the colour change of distributed Bragg reflectors in relation to its key parameters, i.e. the total numbers of layers, the refractive index contrast and their thickness. Here, we have manufactured distributed Bragg reflectors (DBRs) using different techniques. Using spin coating, we deposit several layers of alternating porous materials where each layer has a controlled thickness and refractive index. We show that a reflector constructed of three repeating series of six layers gives optical properties that are a result of the disorder. In this case, the disorder is not fully random, but small deviations in the structure have a large influence on the colour and still produce a narrowband response. Alternatively, we show a different proof-of-concept solution using lithographically produced multi-layered patterns that readily assemble into a variety of Bragg reflectors with a different number of layers. We discuss the influence of...
disorder and the use of these materials in novel optical applications.

Symmetry Induced Transmission in Hybrid Waveguides Mark Meuld, Ivan Shuto Sko and Patrick Görn; Chair of Large Area Optoelectronics, Bergische Universität Wuppertal, Wuppertal, Germany.

Nanostuctured plasmonic systems support strong resonances and have led to new photonic applications. Nowadays, researchers compose metals and dielectrics to build even more sophisticated hybrid devices possessing optical properties exceeding the limits of purely dielectric or plasmonic systems. Here, we focus on a novel symmetric hybrid waveguide system. According to a semi-analytic Fourier Modal Expansion simulation, outstanding optical properties originate from hybridization between plasmonic and dielectric waveguide modes. Due to the symmetry, transmission resonances with remarkably high Q-factors as well as electromagnetically induced transmission (EIT) like phenomena with high refractive index sensitivity are predicted. These predictions were verified experimentally. The hybrid waveguides are fabricated by spin coating, UV-nanoimprint lithography, physical vapor deposition and symmetry-enabling lamination. In comparison to a non-symmetric device, the transmission at resonance is enhanced by a factor of 80 with a Q-factor of 400 through a 100 nm thick silver layer. These results show that both the advantages of plasmon modes and dielectric modes can be combined with our approach, and promise to improve upcoming generations of sensor and filter applications.

Low-Threshold, Room-Temperature Visible Lasing From Monolithically Nanostructured Porous Silicon Hybrid Microcavities Valentina Robbiano, Giuseppe M. Paternó, Antonino La Mattina, Silvia G. Motti, Guglielmo Lanzani, Francesco Scotognella and Giuseppe Barillaro; University of Pisa, Pisa, Italy; 2Italian Institute of Technology, Milano, Italy; 3Politecnico di Milano, Milano, Italy.

Since the first report of room-temperature photoluminescence from nanostructured porous silicon (PSi), scientists have fantasized about PSi-based lasers enabling the realization of integrated silicon photonic circuits. Although some trials on the fabrication of Si nanocrystal-based lasers have been attempted after the discovery of Si nanocrystal optical gain, a PSi-based laser has not been reported yet. In the past few years, leveraging a cheap and robust material preparation technique coupled with a high flexibility and high quality in optical structure fabrication, PSi has gained renewed interest in integrated optics and photonics, spanning from gradient refractive index (GRIN) optical elements, capable to finely control light propagation, and resonant microcavities.

Here we report, for the first time, on low-threshold lasing from fully-transparent nanostructured porous silicon (PSi) monolithic microcavities (MCs) infiltrated with a polyfluorene derivative, namely poly(9,9-di-n-octylfluorenyl-2,7-diyl) (PFO). The hybrid PSi/organic laser is fabricated by electrochemical etching of crystalline silicon, with a square-wave current density profile that produces alternating nanostructured porous silicon (PSi) layers with different porosity and thickness values tuned to achieve a resonant microcavity (MC) operating in the visible region. The as-fabricated PSiMC was oxidized to avoid absorption of silicon, and then peeled off the silicon substrate using a PDMS slab to enable transmittance operation. Eventually, infiltration of PSiMC with PFO was carried out via drop-casting. The hybrid laser supports single-mode blue lasing at the resonance wavelength of 466 nm, with line width of ~1.3 nm and lasing threshold as low as 5 nJ (i.e. fluence of 15 μJ/cm²), which is among the lowest values of state-of-the-art PFO-based lasers.

Silk Protein-Based Multi-Responsive and Multifunctional Dynamic Micropatterns Yu Wang, Beom Joon Kim, Berney Peng, Wenyi Li, Yuqi Wang, Meng Li and Fiorenzo G. Omenetto; Tufts University, Medford, Massachusetts, United States.

Smart surfaces with dynamically tunable micro/nanoscale patterns have drawn a great deal of attention because their unique optical, electronic, biological, wetting, and adhesive properties are promising for a wide range of applications. Wrinkle structures, as one kind of mechanical instabilities, have been widely exploited recently to create hierarchical patterned surfaces because of their fast and simple fabrication process, feasibility to generate large-scale patterns, tunability and even complete reversibility in response to various external stimuli. To realize reversibly responsive surface patterns, various smart materials have been applied to wrinkling systems to realize dynamical and on-demand tuning of surface morphology and properties. However, these existing systems have at least one of several challenges such as high sensitivity to external stimuli, multiple and tunable responsiveness, mild and environmentally friendly stimuli condition, or "functional" dynamic patterns.

Reconstituted silk fibrin, derived from the native Bombyx mori silkworm fibers, has been intensively investigated because of its outstanding combination of biocompatibility, biodegradability, all aqueous processing, optical and electronic properties, mechanical flexibility, and the resulting multiple applications in biomedical applications, bio-optics/photonics, electronics, and optoelectronics. Most importantly, silk fibrin undergoes conformational transition when triggered by external stimuli, such as water vapor, methanol or deep UV light. This polymorphic transition of silk fibrin enables the control of the molecular chain movement on the nanoscale, offering the possibility to controllably tune the pattern morphology formed due to mechanical instability.

We report the facile fabrication of reversible, multi-responsive wrinkle patterns using silk protein as the responsive component. We show that the wrinkle structures can be dynamically tuned and/or erased easily by water vapor, methanol vapor or UV irradiation. We demonstrate that the wrinkle evolution rate is dominated by the starting conformation of silk protein, and that the occurrence of conformational transitions accelerated the reversibility of wrinkle patterns. The wrinkle evolution behavior is confirmed by investigating the molecular mechanism governing the conformational transition of silk fibrin. Finally, we demonstrate that the tunable wrinkling systems can be used for information storage, encryption, collection and extraction, as well as light diffusing related smart window with switchable transparency and thermal regulation.

Germanium Sulfide Nano-Optics Probed by High-Resolution STEM-Cathodoluminescence Spectroscopy Peter Sutter and Eli Sutter; University of
Nanophotonic studies of confined modes in planar waveguides have attracted significant interest as a means to probe exciton-polaritons and other hybrid light-matter quasiparticles in layered semiconductors, such as transition metal dichalcogenides or boron nitride. There is a need to broaden such studies to other materials and to identify alternatives to scanning near-field optical microscopy for exciting and measuring confined waveguide modes below the diffraction limit. Here, we discuss a novel approach for probing the dispersion of traveling waveguide modes by cathodoluminescence spectroscopy excited by the focused electron beam in scanning transmission electron microscopy (STEM-CL), and apply it to solid-state resonators consisting of mesoscale monocrystalline prisms, plates, and nanowires composed of GeS, an anisotropic layered semiconductor with direct bandgap in the near-infrared spectral range [1, 2]. Structure, crystallography and chemical composition of the GeS mesostructures are analyzed by analytical electron microscopy, STEM-CL maps and spectra. We find pronounced interference effects and sharp emission peaks at photon energies below the fundamental bandgap of GeS. Our analysis shows that locally excited light emission in STEM-CL launches in-plane waveguide modes in the mesoscale GeS structures, which are internally reflected by highly specular GeS edges to cause interference of the confined modes. Reabsorption and secondary luminescence give rise to the intensity modulations detected in the far field. Our results highlight avenues for probing light-matter interactions far below the diffraction limit, correlated with atomic-scale structure and chemical composition determined by (S)TEM, for a wide range of quantum materials. In a broader context, our findings open up the exciting possibility of tuning light emission from semiconductors geometrically using waveguide mode interference rather than by the conventional bandgap engineering.

Self-Cleaning, High Transmission, Near Unity Haze OTS/Silica Nanostructured Glass

Youngseok Kim; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

Youngseok Kim; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

High haze, high transparency substrates can increase the power conversion and extraction efficiency of solar cells and light emitting diodes (LEDs), respectively. In this paper, we present a new octadecyl trichlorosilane (OTS)/silica nanostructured substrate that displays high transmission (91.5 ± 0.8%) at 532 nm wavelength) and near unity haze (98.1 ± 0.5% at the same wavelength) with 143° scattering angle. The OTS/silica nanostructures are fabricated through a scalable and facile maskless reactive ion etching (MRIE) process followed by OTS coating. The OTS coating enhances the transmission of the structures by merging silica nanostructures together by capillary forces and effectively grading the index of refraction. The OTS/silica nanostructures display the highest combination of both transmission and haze in the literature as defined by Pareto optimality. The OTS/silica nanostructured glass exhibits lotus leaf-like wetting with a 159.7 ± 0.6° water contact angle (WCA) and 4.9 ± 0.6° contact angle hysteresis. We demonstrate the structures have self-cleaning functionality where about 100% of transparency can be easily recovered after graphite soiled substrates are rinsed with water. This self-cleaning functionality is maintained after 200 cycles of soiling and cleaning. The OTS/silica nanostructured glass may be an important substrate in optoelectronic applications where a combination of high transmission, high haze, and self-cleaning function are important.

Dual Layers of Periodic Nanoscale Metal Dot Array Fabricated by Nanoimprint and Dewetting Techniques

Jin Hwan Kim, KeunHwan Park and Youngseok Kim; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

Jin Hwan Kim, KeunHwan Park and Youngseok Kim; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

The nanoscale metal dot array has been used in many plasmonic devices and metamaterials. There are numerous methods to fabricate the nanoscale metal dot array including complex lithography and etching, random dispersion or coating of chemically-engineered metal particles. Here, we use the dewetting of gold (or platinum) thin film on a nano-patterned surface to create a periodically arranged metal dot array. By using nanoimprint techniques, nanohole array patterns are transferred to an alumina thin film and dewetting of gold (or platinum) thin film is followed. The dewetted metal pucks are periodically arranged on the top of the surface and inside the nanohole at the same time. These dual layers of periodic metal dot array can exhibit useful optical properties such as a broadband high absorption. Furthermore, by using FDTD simulation, we calculate the optical properties of the periodic metal dot arrays with different-sized metal dots and show the possible applications with this structure. Experimentally, the dewetting behaviors are presented with different conditions and surface patterns on which the dewetting occurs. The whole process here we use (nanoimprint and dewetting) can create dual layers of periodic metal dot array without complex lithography on various-shaped substrates with great scalability.

MAPbI3 and MAPbBr3 Halide Perovskite Super-Lattices for Infrared Emission Applications

Laxman Gouda1; Orin Kigern1; Omree Kapon1 and Yaakov Tischler2; 1Bar Ilan University, Ramat Gan, Israel; 2Chemistry department, Bar Ilan University, Ramat Gan, Israel; 3Cornell University, New York, New York, United States.

Laxman Gouda1; Orin Kigern1; Omree Kapon1 and Yaakov Tischler2; 1Bar Ilan University, Ramat Gan, Israel; 2Chemistry department, Bar Ilan University, Ramat Gan, Israel; 3Cornell University, New York, New York, United States.

Infrared emitting materials are of great importance for LED, Laser, night-vision, and chemical sensor technologies. Superlattice (SL) structures of compound semiconductors such as from A1As and GaAs semiconductors have been studied and used extensively for IR emitting Quantum Cascade Lasers. Until now MBE and MOCVD are the primary fabrication methods for SL fabrication but they are expensive and limited in their scale up. The hybrid organometal halide perovskite (HaP) materials, such as MAPbI3 and MAPbBr3, are a new class of semiconductors which are efficient, cheaper to fabricate, and potential candidates to replace expensive semiconductors which are currently used in solar and LED applications. Here we show a novel and efficient way to fabricate HaP SL's that emit in the Near-IR (NIR) region. We demonstrate that a cascade of layers of MAPbI3 and MAPbBr3 can shift an intense emission peak at 770 nm for 1 pair of layers to 900 nm for 3 pairs. The new technique and resultant SL's of MAPbI3 and MAPbBr3 are a promising candidate for extending the spectral range of HaP emission from NIR to the Mid-IR, with potential to deliver low-cost, efficient, tunable IR emitting LEDs and lasers, and new classes of spectroscopic chemical detectors.

Low-Dimensional Photonics

Prineha Narang and Xiaobo Yin; Thursday Morning, November 29, 2018

Hynes, Level 2, Room 206
The isolation of stable atomically thin two-dimensional (2D) materials on arbitrary substrates has led to a revolution in solid state physics and semiconductor device research over the past decade. A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces. A fundamental challenge in using 2D materials for opto-electronic devices is enhancing their interaction with light, ultimately responsible for higher performance and efficiency in the devices. In particular, for photovoltaics, inorganic materials (e.g., Si, GaAs and GaInP) can concurrently maximize absorption and carrier collection. But thin film absorbers have lacked the above ability often due to due to surface and interface recombination effects. In contrast, Van der Waals semiconductors have naturally passivated surfaces with electronically active edges that allows retention of high electronic quality down-to the atomically thin limit.

In this work, we show how the near-field radiative heat transfer (NFHT) can be tuned using Al plasmonics, which spans to broader frequency range, as compared to noble metals, and it oxidizes. The oxide layer (Al2O3) changes the plasmonic response and even inhibits it. The formation of the oxide layer is the basis for our work in the control of NFHT. The NFHT is mediated by the interaction of surface plasmons, in the case of metals and surface-phonons polaritons in polaritonic materials. The hybridization of these two modes changes the heat flux between surfaces [2,3]. Using Rytov theory of fluctuating electrodynamics, we calculate the heat transfer between two Al surfaces at a different temperature, separated by a gap. As the surface oxidizes as a function of time, the surface-plasmon response is inhibited, and the polaritonic modes of the Al2O3 layer begin to play an essential role in the heat transfer, increasing both the spectral heat transfer and the total heat transfer significantly. As the oxidation increases, plasmon modes of the Al and phonon modes of the oxide hybridize favoring the radiative heat transfer.

Two-Dimensional Plasmonic Molybdenum Oxides on Silicon Photonics—A New Sensing Paradigm Baoyue Zhang and Guanghui Ren; RMIT University, Melbourne, Victoria, Australia.

Silicon photonics has grown to be a mature platform that is compatible with complementary metal-oxide–semiconductor (CMOS) technology and is one of the most potential solutions offering intrinsic advantages in terms of higher bandwidth and lower loss which microelectronics is limited to. However, due to the intrinsic indirect band gap of silicon, silicon photonics has strong limitations on the areas of light generation, modulation and detection. The emerging integration of two dimensional (2D) layered materials onto the silicon photonics platform provide viable solutions to the above-mentioned concerns owing to their unique electronic and optical properties, mechanically flexibility, low fabrication and integration complexity, robustness, and high compatibility with CMOS technology. The tunable electronic and optical characteristics, stability in aqueous environments, large surface area and the intercalatable layered structure of 2D materials can be potentially beneficial to expand the functionality of silicon photonics platform in the telecommunication prospect and biological sensing field. Traditionally, silicon photonics platform heavily relies on the variation of ambient refractive index. However, many chemical and biological events do not lead to a measurable change of ambient refractive index by silicon photonic sensors. Meanwhile, complex surface functionalization processes with low repeatability is essential to the sensor selectivity.

Here, the concept of the 2D materials–silicon photonic chemical sensor is demonstrated using a representative tunable plasmonic 2D candidate. As the operation wavelength of the silicon device is either in the 1300 and 1550 nm telecommunication wavelength, the emerging plasmonics of 2D degenerately hydrogen doped molybdenum oxide ($\text{H}_x\text{MoO}_3$, $0 < x \leq 2$) can be a suitable candidate for coupling onto the silicon photonics platform as its plasmonic absorption wavelength can be precisely tuned across the edge of UV-Vis and the near infrared (NIR) region ($\geq 1000$ nm). More importantly in such a degenerately doped plasmonic system, the $\text{H}^+$ dopants and concurrently injected free electrons are easily exchanged from the 2D MoO$_3$ host structure in the presence of redox chemical and biological events, leading to the alteration of its plasmonic properties which provides the fundamentals for label-free chemical sensing with superior sensitivity.

The achievement of ultrathin films that strongly interact with light, absorbing photons over a wide spectral range is of central importance for applications...
such as sensing, energy harvesting, or biology among others. Strong broadband absorption is challenging in view of the intrinsic limitation in the absorption coefficient of every material, which is especially deleterious for infrared wavelengths. Many wave optics based designs are being currently investigated to surpass this limitation, from photonic crystals to plasmonics and microresonators. All these architectures provide new and exciting means of confining light in sub-wavelength thin films. Nevertheless, the absorption enhancements exhibited are typically restricted to a specific frequency range or mostly take place in the metal part. In sum, a photonic architecture capable of increasing the absorption of a semiconductor throughout its entire absorption coefficient has hitherto, remained elusive.

In our work, we demonstrate a germanium photonic architecture deposited on a metal film acting as a metasurface. Our metasurface sustains the simultaneous excitation of Fabry-Perot resonances, Brewster modes and plasmonic-photonic modes that result in omnidirectional enhanced absorption in a Ge ultra-thin film of 70 nm from 400 nm until 1500 nm. This represents an unprecedented advance in broadband light harvesting, well beyond previous reports.

The key aspects of our findings are:

The absorption in the metasurface exceeds over 100% that of a flat a-Ge film on gold over an impressive bandwidth of 1100 nm. Moreover, the high refractive index of the Ge renders the absorption profile of the metasurface independent to the angle of incidence of the incident light.

We provide the key design guidelines to tune the absorption profile of the metasurfaces and the physical origin beneath each resonant mode sustained by the architecture. With these findings, we show metasurfaces exhibiting strong broadband absorption (appealing to PV community) or NIR absorption peaks reaching 100% at the telecommunication windows (interestingly to the photodetection field).

Remarkably, we fabricated the 16-mm² Ge metasurfaces via nanoimprinting lithography, the most promising method for mass-produced nanostructures. This inexpensive and large area technique adds feasibility to the exciting photonic properties described in the manuscript.

We expect our work to set a new benchmark in the field of light trapping in ultra-thin films and it paves the way for the demonstration of this technology into practical large area applications related to sensing, energy harvesting and photocatalytic devices.

2D Perovskite-Based Metasurfaces for Enhanced Plasmonic Sensing Shuwen Zeng; XLIM Research Institute, UMR 7252 CNRS/University of Limoges, Limoges, France.

Plasmonic sensors are known as an efficient tool for real time monitoring biomolecular interactions. The detection mechanism is based on the field perturbation at the plasmonic sensing interface induced by the binding of molecules. This molecular binding process could be recorded through reflected light signal when the surface plasmon is excited by the incident light. In this talk, we will present the use of hybrid 2D perovskite-based metasurface nanostructures as a plasmonic sensing substrate. The thickness of the sensing substrate is tuned in an atomic scale and optimized to obtain an enhanced sensing effect. More specifically, a sharp phase signal change and phase-related Goos-Hänchen signal shift was achieved that results from the strong resonance. The improved sensitivities of 2D Perovskite nanostructures were investigated. It is worth noting that the atomic layer design led to the sensing substrate optimized with a tuning scale less than 1 nm. By precisely design the metasurface substrates, more than 4 orders of magnitude improvement of the sensitivity (900,000 um/RIU) were obtained in comparison to the one with pure gold sensing substrate (400 um/RIU). This 2D perovskite-based metasurfaces would pave a way for the development of ultrasensitive and compact biosensors for in-situ applications.

Optical Absorption of 2D Transition Metal Carbides (MXenes) from the Ultraviolet to the Infrared Kathleen A. Maleski, Mohamed Alhabeb, Asia Sarycheva, Babak Anasori and Yury Gogotsi; Drexel University, Philadelphia, Pennsylvania, United States.

Two-dimensional (2D) materials continue to be investigated in optical, photonic, and plasmonic applications due to their tunable properties, solution-processable control of lateral size and thickness, and exceptional performances compared to their bulk counterparts. The largest family of 2D materials, known as transition metal carbides and/or nitrides (MXenes), has a general formula of Mₓ₋₁ₓTx, where M represents a transition metal (Ti, Mo, Nb, V, Cr, etc.), X is either carbon and/or nitrogen, and T represents surface terminations. MXenes showed high conductivity at high transparency (6500 S/cm, >97% transparency per-nanometer thickness in the visible range) and an optical absorbance peak in the ultraviolet as well as the visible to near-infrared range (750-800 nm), making it useful in transparent conductors, SERS substrates, photothermal therapy, as a metamaterial, etc. With the material family containing ~30 different synthesized compositions so far (and millions possible), optimization and light-matter characterization of other MXene compositions remains important.

Here, we will discuss optical absorbance characterization from the ultraviolet to the infrared for a variety of MXenes beyond TiCₓTx, including MXenes composed of Nb, V, and Mo metals. For example, thinner Mₓ₋₁ₓTx MXene structures, such as TiCₓTx, exhibit an optical absorbance peak shift to the visible range (~550 nm), demonstrating the optic/electronic differences from similar-but-thicker structures, such as TiC₂Tx. This work provides insight into the optical properties of MXenes as well as spectroscopic information which can be applied to designing next-generation plasmonic and photonic devices, such as photodetectors, electro-chemical devices, random or femtosecond lasers, photothermal therapy agents, transparent conductors, photonic diodes, metamaterials, and more.

Three-Dimensional Graphene Oxide Cube Based Octagram Metamaterials for Enhanced Molecular Sensing

Kriti Agarwal, Chao Liu and Jeong-Hyun Cho, University of Minnesota, Minneapolis, Minnesota, United States.

Split-ring resonator (SRR) based metamaterials have been extensively studied due to their enhanced ability to confine light of wavelength several orders of magnitude larger than the dimension of the resonator. The strong confinement of incident light has been explored for the development of a diverse range of sensors including biological and chemical sensors that can assess the properties of the molecules in the vicinity of the split. The polarization dependent switching of resonant modes and resonant frequency of two-dimensional (2D) SRR structures presents a major hurdle in the widespread application of metamaterial sensors where the orientation of the SRR is hard to control. Furthermore, the 2D planar SRR structures do not undergo any resonance when the incident electric field is polarized perpendicular to the plane of the resonator. However, if the 2D metamaterials are self-assembled to form three-dimensional (3D) structures, novel optical properties can be achieved that cannot be realized in 2D planar SRRs. When six symmetric 2D X-shaped resonator segments fabricated on top of square surfaces are self-assembled, the resulting 3D cubic structure forms an 8-pointed star-shaped octagram SRR (OSRR). The octagram resonator consists of splits only at the corners of the cube, thus, achieving 3D SRR splits that are equally moderated by all three vectors (electric field, magnetic field, and wave) for every possible orientation of the OSRR. The 3D splits in OSRR achieve a perfectly isotropic (angle-invariant) transmission response. The strong OSRR coupling and angle-invariant amplitude offer a two-fold advantage i.e. a 25 times higher shift in resonant frequency (25 times higher sensitivity) than 2D SRRs and amplitude-based detection at low concentrations that cannot cause a measurable shift in resonant frequency. However, even with the enhanced sensitivity the constant need for replenishing antibodies used for binding the targeted molecules to the surface of the OSRR presents a major challenge and can also limit the detection capabilities for unknown target molecules. If the surfaces of the cube forming the OSRR are composed of porous nanomaterials (graphene oxide), the properties of the 3D metamaterials can be further tuned for desired sensory application. The strong affinity of GO functional groups towards all chemical and biological molecules and sieving properties of the porous GO layers provide an ideal surface for adhesion of targeted molecules for non-labeled sensing mechanisms. By varying the number of GO layers forming the 3D cubes, properties of the OSRR are tuned for control over sieving and molecular adsorption as well as extending the sensitivity of octagram sensors due to enhanced adhesion of targeted molecules.

Fascinating Wave Phenomena in Topological Matter—Topologically-Protected Embedded Eigenstates, Leaky Modes and Exceptional Points

Francesco Monticone; School of Electrical and Computer Engineering, Cornell University, Ithaca, New York, United States.

Engineered metamaterials and photonic crystals with non-trivial topological properties represent an emerging class of photonic structures exhibiting inherent robustness to continuous deformations. While topological photonic insulators have been the subject of growing interest and research efforts in the past few years – especially for the possibility of realizing back-scattering-immune unidirectional wave-guiding systems – relatively less attention has been devoted to scattering and radiating topological photonic structures in the presence of radiation loss or material loss/gain, a research direction that may lead to novel functionalities and applications. In this talk, we will review our recent efforts on different fronts in this exciting area. (i) We will discuss our theoretical and experimental demonstration of the topological nature of embedded eigenstates, or bound states in the continuum, in suitably engineered optical metasurfaces [H. Doelman, F. Monticone, W. den Hollander, A. Alù, and A. F. Koenderink, Nature Photonics, in press (2018)], confirming a theoretical prediction made in [B. Zhen, et al., Phys. Rev. Lett. 113, 257401 (2014)]). (ii) We will present our recent work on topological wave-guiding structures with radiation loss, which support topologically-protected one-way leaky modes that may act as a bridge between free-space radiation and unidirectional guided waves propagating on the surface of complex bodies [S. A. Hassani Gangaraj and F. Monticone, J. Phys. Condens. Matter (2018)]. These findings may lead to relevant advances in the design of leaky-wave (nano)antennas. (iii) We will discuss the possibility of engineering the coupling between topological modes in Hermitian and non-Hermitian waveguides, and the presence of exceptional points accompanied by anomalous propagation effects, such as one-way, defect-immune, loss-immune “Jordan modes” [S. A. Hassani Gangaraj and F. Monticone, arXiv:1803.06419 and arXiv:1805.03767]. (iv) Finally, if time permits, we will also present our recent findings on giant optical forces and torques on localized emitters near photonic topological materials.

Reconfigurable Topological Photonics with Stimulated Raman Scattering

David R. Barton, Mark Lawrence and Jennifer A. Dionne; Stanford University, Stanford, California, United States.

Topological photonic engineering leverages the inherent nonlocality of Bloch states in periodic media to enable scatter-free and unidirectional light transport. A DC magnetic field can lift Dirac point degeneracies in a 2D photonic crystal, opening a topologically nontrivial band gap which supports unidirectional edge modes. However, due to the weak and lossy nature of optical Faraday rotation, such magnetic-field sensitive configurations are too bulky for practical implementation and are challenging to reconfigure on fast time- and small length-scales. To date, compact, reconfigurable topological protection at optical frequencies remains an outstanding challenge.

Here, we propose an entirely new route to achieve unidirectional edge modes and topological protection based on photon-phonon interactions. Our approach is inspired by Floquet driving schemes of electronic topological insulators. We break time-reversal symmetry using photon-spin degrees of freedom to excited lattice phonon modes with the same chiral symmetry. Notably, we utilize Stimulated Raman Scattering with circularly polarized light to generate nontrivial topology in a photonic structure. If the pump illumination is circularly polarized, the off-diagonal elements of the Raman-induced effective susceptibility become complex conjugates at the Stokes-scattered frequency, meaning Raman gain inherits a magneto-optic like form without the need for a magnetic field. Unlike magneto-optical materials, stimulated Raman scattering leads to spin dependent dissipation/amplification, bringing a new degree of freedom to topological photonic experiments. Therefore, resonant nanophotonic structures incorporating Raman active materials open the possibility for deeply nanoscale topological protection at optical frequencies.
As a proof of concept, we design a hexagonal photonic crystal consisting of cylinders of Silicon in the near infrared. We use Silicon due to its high Raman susceptibility. First, we calculate the bandstructure of the photonic crystal; a period of 675 nm and cylinder radius of 200 nm exhibits a Dirac cone at the K point at 1500 nm. By locally pumping the photonic crystal with circularly polarized light such that the Dirac point is near the Stokes or anti-Stokes line, a topologically nontrivial band gap is opened. By varying the pump wavelength and helicity in neighboring crystals, we gain intimate control over the formation and evolution of topological defect states. We theoretically demonstrate typical one-way edge state phenomena, as well as unidirectional edge state amplification. We also show how a variety of reconfigurable optical devices such as waveguides, circulators, and resonators can be readily generated by this system.

Surface Plasmon Polaritons in Topological Insulator Bi2Se/Te3 Family
Ganapathi Subramania1, P. Duke Anderson1, Stavroula Foteinopoulou2, Jason Dominguez1 and Anthony James1; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2Department of Electrical and Computer Engineering, The University of New Mexico, Albuquerque, New Mexico, United States.

The investigation of surface plasmon polaritons is a highly investigated field of research due to their high potential to be applicable to sensors, information technologies, high-resolution imaging, etc. These coherent delocalized electron oscillations are common in metal-dielectric interfaces. However, they also exist in highly doped semiconductors, conducting oxide system or graphene, i.e., in many other systems with high carrier mobility. This poses the question whether such resonances can also be observed at the insulator interfaces.

Bismuth Telluride family can be count as a role topological insulator materials system which has been heavily investigated. It was already shown in 2013 Bi2Se3 one of the member of the family supports Dirac plasmons with energy in the range of 0.5 – 1 eV. The Dirac state is not the only reason for the existence of plasmon resonance in Bi2Se3. The highly anisotropic tetradymites crystal structure also has highly anisotropic dielectric properties5 allowing plasmon excitations.

In this study we would like to show electron energy loss spectroscopy (EELS), energy-filtered transmission electron microscopy (EFTEM) and a finite-difference frequency-domain (FDTD) study for investigating Bi2Se/Te3 and try to find an explanation for plasmon polaritons.

Optical Frequency Topological Photonic Structures
Ganapathi Subramania1, P. Duke Anderson1, Stavroula Foteinopoulou2, Jason Dominguez3 and Anthony James3; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2Department of Electrical and Computer Engineering, The University of New Mexico, Albuquerque, New Mexico, United States.

Topological photonic structures in analogy to their electronic counterparts can provide new functionalities in nanophotonics through topological protection. Topologically protected photonic modes can propagate unidirectionally without scattering and can have an extreme photonic density of states (PDOS). These unique properties can directly impact many photonic systems used in quantum information processing applications such as single photon transport. Enabling such properties at optical frequencies and on chip-scale will be very important for practical applications of such phenomena. Photonic system composed of appropriately designed two-dimensional photonic crystals (PhC) preserving time-reversal(TR) symmetry can exhibit pseudo-spin based topological behavior. A membrane-type PhC composed of modified honeycomb lattice (HC) can show topologically protected unidirectional photonic pseudospin transport with excellent bandwidth (~50nm) at optical wavelengths (~1550nm), important for chip-scale nanophotonics1. We will discuss design, fabrication and optical response of such topological photonic structures in semiconductor based systems like silicon-on-insulator (SOI)2.

Enhanced Second Harmonic Generation and Circular Dichroism in Plasmonic Nanostructures Consisting of NanoArcs
Oded Rabin and Kunyi Zhang; University of Maryland, College Park, Maryland, United States.

Using infrared microspectroscopy, the localized surface plasmon resonances (LSPRs) of metallic nanoarc antennas on dielectric substrates have been systematically investigated. The reflection/transmission spectra are rich with information regarding the fundamental and higher order LSPR modes, the dipole component polarization, and mode coupling. The relationship between the LSPR wavelength and the geometric parameters of single nanostructures was established. Furthermore, the relative strength of the different order LSPRs was shown to depend on the central angle of the nanoarc. These rules are used in optimizing the nonlinear optical response of nanoarcs, specifically enhancing the efficiency of Second Harmonic Generation. Mode coupling was studied in a pseudo-chiral assembly of four 90°-nanoarcs in a propeller-like configuration. At the center of the nano-propeller, the arcs were separated by narrow gaps, down to 15nm. The strength of coupling of the plasmons in the adjacent nanoarcs, inversely proportional to the gap size, was manifested in the infrared absorption and circular dichroism (CD) spectra. The CD response may be significantly stronger in 3-dimensional propeller-like configurations that have a polarizability component normal to the surface. This information is utilized in the design of thin-film plasmonic metamaterials with engineered chiroptical responses.
Designing a phase gradient metasurface which efficiently collects spontaneous emission from a quantum emitter, located in the far-field be harnessed at single-photon level [3].

Photonic metasurfaces [2] to engineer the emission from quantum emitters and achieve highly directional emission. Photonic metasurfaces mold optical light from a single emitter in free space is limited due to its isotropic nature of emission. So, a useful single-photon source must emit into a well-defined direction because in practice one can collect light only in a finite solid angle. Here, we propose to harness the exceptional light molding capabilities of photonic metasurfaces [2] to engineer the emission from quantum emitters and achieve highly directional emission. Photonic metasurfaces mold optical wavefronts at subwavelength spatial resolution via phase gradients imparted through the interaction of light with the metasurface elements. They have revolutionized optical designs by enabling the realization of virtually flat optics. Recently, it has been proposed that a judiciously designed metasurface can be harnessed at single-photon level [3].

In this work, we designed a phase gradient metasurface which efficiently collects spontaneous emission from a quantum emitter, located in the far-field ($d/\lambda$), and redirect it back to the source. By controlling the phase imprinted by the metasurface on the incident light, we control the directionality, radiation pattern, and emission rate. In the experiment, our quantum emitters are dibenzoterylene (DBT) molecules embedded in a thin film of anthracene. In the past decade, such organic molecules embedded in an optimal host have emerged as an excellent source of indistinguishable and Fourier-limited single photons with high fidelity and high rate of emission [4]. Remarkably, the spectral region covered by optimal guest-host molecule combination lies in the range of silicon-based photodetectors, whose detection efficiency peaks around 800nm. Furthermore, the emission in the near infrared wavelength range would lower the ohmic loss in noble-metal based nanoantennas. Our simulations show that at 785nm which corresponds to the zero phonon line of DBT in anthracene, the reflection efficiency is greater than 85% with gold nanoantennas. We show that the emission from these molecules are highly directional with deviation from upward direction $\Delta \theta \approx 20^\circ$. Furthermore, we show that we can not only control the emission pattern but also decelerate (or accelerate) the decay rate of the emitters. Moving forward, scaling up to multiple quantum emitters and integrating them with tunable metasurfaces [5] may open new opportunities in quantum information sciences.

Exploiting Polaritons on Antiferromagnetic Materials to Enable Fast Spin Dynamics Jamison Sloan1, Nicholas Rivera1, John D. Joannopoulos1, Marin Soljacic2 and Ido Kaminer3; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Electric Engineering, Technion–Israel Institute of Technology, Haifa, Israel.

The past decades have brought increasing interest in using materials to control light at the nanoscale for diverse applications such as light sources, quantum optics, spectroscopy, spintronics, and sensing. A key paradigm in controlling electromagnetic energy at the nanoscale are materials that support strongly confined surface polaritons. The most well-known example of surface polaritons are plasmon polaritons (SPPs) on conductors, which have been actively studied for several decades. The enabling principle of the strong sub-diffractional light confinement by these materials is that they can sustain a negative electric permittivity. In this work, we propose a new twist on the aforementioned paradigm: negative magnetic permeability modes in antiferromagnets to enable nanoscale control light-matter interactions and spin dynamics. These modes, known as surface magnon polaritons (SMPs) have been observed in antiferromagnetic materials such as MnF$_2$ [1] and FeF$_2$ [2] at THz frequencies. Here, we discuss for the first time enhancement of spin relaxation in emitters using these highly confined magnetic polaritons.

SMPs on antiferromagnetic films offer several advantages over dielectric-based polaritons for engineering strong interactions with spin and other magnetic transitions. We use spontaneous emission of a dipole emitter into SMPs on MnF$_2$ as an example system for understanding the strength of interactions. We show that a $\omega=1.6$ THz magnetic dipole may transition and emit SMPs into a 100 nm MnF$_2$ film at rates more than $10^4$ times higher than the free space rate of $10^{-9}/s$, for a total rate of $10^3/s$. These extreme Purcell factors are possible because SMPs on antiferromagnetic systems can reach wavelengths on the order of 10-100 nm, in some cases more than $10^4$ times smaller than for the same frequency in free space. This is particularly advantageous for speeding up magnetic transitions which are highly inefficient in free space. Another advantage of an antiferromagnetic platform is that SMP mode properties, and by extension dynamics of magnet-matter interaction, can be manipulated by applying an external magnetic field. We explore SMPs as an electromagnetically
dual analog to SPPs, and find that Purcell factors for magnetic transitions on magnonic media scale identically to those of electric transitions on plasmonic media [3], offering a more complete picture of interactions between polaritons and matter.

Until now, methods of magnetic transitions enhancement have been insufficient to allow spin relaxation and electric dipole transitions to compete on the same playing field. Our results present a new route towards bridging this gap.

Reciprocity is a fundamental principle in optics, stating that wave transmission is the same in opposite direction. Breaking this symmetry is necessary for the design of isolators and circulators, which are used to protect sources from reflections and separate signals propagating in opposite directions. Furthermore, it has been recently shown that nonreciprocity is tightly connected to the realization of photonic topological insulators, which allow propagation of signals around sharp corners or other discontinuities without scattering. Conventionally, nonreciprocity is achieved through the magneto-optical effect, but this approach is challenging to integrate and generally leads to large devices. For this reason, there has recently been interest in looking for other ways to break reciprocity. One option is to use nonlinearities, in particular Kerr-type nonlinearities, with spatial asymmetries. Kerr nonlinearities allow changing transmission of a structure versus the input intensity, while spatial asymmetries lead to different field intensities inside a structure when exciting from opposite sides. As a result, in nonlinear asymmetric devices, transmission will generally follow different dependence versus the input power from opposite sides, leading to nonreciprocal response.

During the previous years, many devices of this type have been proposed based on heuristic principles, leading to sub-optimal responses. In this talk, we provide a systematic study of nonlinear isolators, identifying ultimate bounds for their characteristics and showing how these bounds can be achieved in specific nanophotonic designs. We first show that the most widespread category of nonlinear resonators based on a single nonlinear resonator are subject to a trade-off between transmission and isolation intensity range or bandwidth stemming from time reversal symmetry. We next demonstrate how this bound can be largely overcome in systems comprising multiple nonlinear resonators. We also show how such systems can be used to realize more advanced nonreciprocal devices, such as circulators. Furthermore, we present a new approach for the design of nonlinear isolators based on saturable absorption, which is less sensitive to loss compared to the most common approach based on the optical Kerr effect. In all cases, we provide examples of nanophotonic nonreciprocal devices with optical performance according to the derived bounds. Our results clarify several aspects of this important area in optics and provide guidelines for the systematic design of nonlinear nonreciprocal devices.

3:00 PM BREAK
Metal–insulator–metal (MIM) resonant absorbers comprise a conducting ground plane, a thin dielectric, and thin separated metal top-surface structures. Long-wave infrared (LWIR) fundamental absorptions are experimentally shown to be optimized for a ratio of dielectric thickness to top-structure dimension, t/L, of ~1:10. The fundamental resonance wavelength is predicted by different analytic standing-wave theories to be ~2nL, where n is the dielectric refractive index. Thus, for the dielectrics SiO2, AlN, and TiO2, L values of a few microns give fundamentals in the 8-12 micron LWIR wavelength region. Agreement with theory is better for larger t/L. Harmonics at shorter wavelengths are always observed. We show that there are additional resonances, in the far-infrared 20-50 micron wavelength range, well beyond the predicted fundamental. This may impact selectivity in spectral sensing applications.

Photoacoustically guided wave-front shaping provides unmatched capability to deliver focused light into strongly scattering media, such as biological tissue. It allows non-invasive optical imaging deep into brain, tissue, and many other optically opaque turbid media. However, the imaging resolution is intrinsically limited by acoustic diffractions. Increasing ultrasound frequencies addresses the problem at a cost of penetration depth due to the escalated attenuations of ultrasound signals in tissues. Here we introduce a super-resolved meta-lens for photoacoustically guided wave-front shaping and show single speckle imaging through turbid media. We have demonstrated > 3 photoacoustic enhancement factors and > 5 spatial resolution than that of the conventional ultrasound transducers, and more interestingly, > 3 convergence rate in genetic optimization of random phase fronts when one introduces super-resolving meta-lens.
Anisotropic Photonic Microparticles with Multicompartment Designed by Controlled Micromolding

Goh Ho Lee1, Tae Yoon Jeon1, Jong Bin Kim1, Byungun Lee2, Chang-Soo Lee2, Su Yeon Lee3 and Shin-Hyun Kim1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Chungnam National University, Daejeon, Korea (the Republic of); 3Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of).

Regular arrays of colloidal particles, or colloidal crystals, shows striking structural colors due to diffraction from their periodic nanostructures. The structural colors are iridescent and never fade as long as the periodic structures persist. Moreover, the color is tunable by adjusting interparticle separation or refractive index without changing the set of materials. These unique features of structural color, distinguished from chemical pigments, render the colloidal crystals promising for various applications, including aesthetic coating, anti-forgery patches, colorimetric sensors, and encoded microcarriers for biological assays. To use the colloidal crystals as an alternative to chemical colorants, it is required to design the colloidal crystals to have a powder format suspendable in liquid media. Although microgranules of colloidal crystals have been prepared by droplet templating and other methods, it is still challenging to produce photonic microparticles with well-controlled shape and internal structure in a scalable manner.

In this work, we employ a facile micromolding to create photonic microcylinders with pronounced structural colors. To compose a regular array of colloids, silica particles are dispersed in a photocurable resin that forms a solvation layer on the surface of silica particles. The solvation layer exerts disjoining pressure, rendering the silica particles repulsive in a short separation. Therefore, the particles spontaneously form colloidal crystals at volume fraction above 0.1. The photocurable dispersion of silica particles is molded by cylindrical holes in an elastomer. The silica particles form non-close-packed structure by aligning their hexagonal array along the cylindrical wall, which are captured by photopolymerization. The micropillars containing the regular array of silica particles are released from the substrate, resulting in composite microcylinders with a low reflectivity at stopband wavelength. The reflectivity can be enhanced by selectively etching out silica particles to make a regular array of air cavities. The porous microcylinders show pronounced structural colors with high reflectivity, which can be dispersed in a polymer solution to formulate photonic inks for coating. In addition, the microcylinders can be further functionalized by making multiple compartments. We use the photocurable dispersions diluted by a volatile solvent to form compartments that partially fill the cylindrical holes. The remaining volume of the hole can be further subjected to molding process to make two or more compartments. Each compartment can be independently rendered to be either structurally-colored, magneto-responsive, or transparent so that multicompartment photonic microcylinders can be functionalized as a roll process, photonic microgranules can be produced in high throughput. Moreover, the advanced functionality of the multicompartiment microgranules further expands application.

Quantum dot (QD) is a promising material for next-generation display devices due to its superior optical properties such as size-dependent narrow emission and broad absorption. Although it can be used for display in many ways, it is most successfully used in the device of LED-backlit LCDs. In particular, many researchers are paying attention to devices that use QD for patterned polymer film at the top of liquid crystal layer. It has advantages over other types because QDs are located away from heat source (blue LED) to prevent reduction in efficiencies. Therefore, it is expected to increase efficiencies of the device by 50% compared to the conventional LCDs. However, there are still remaining challenges. Although photoretist must be used for patterning, bare QDs cannot be dispersed in the photoretist. To overcome this limitation, we used silica nanoparticles as template particles for dispersing QDs. Furthermore, we synthesized silica nanoparticles with wrinkled surface (WSNs) for purpose of enhancing efficiencies. The WSQs could be synthesized using the water-oil surfactant system. This unique surface structure makes WSQs scatter more light than the silica nanoparticles with smooth surface. Then, we prepared QD-WSN hybrid particles (WSQs) by embedding QDs on WSN through swelling method. Using the WSQs, we could disperse QDs into photoretist film in the form of WSQs. We fabricated the display devices by attaching the nanocomposite onto white OLED. Using various techniques such as electron microscopy, UV-vis spectrophotometer, and fluorometer equipped with integrating sphere, we characterized particles and nanocomposites. We believe this study suggest new way to disperse QDs in photoretist film and enhance the efficiencies of nanocomposites.

Influence of Rare-Earth Substitution on Structural, Magnetic, Optical and Dielectric Properties of ZnO Nanoparticles

Ricardo Martinez Valdez1, Nitu Kumar2, Hanu Huhtinen2, Wojciech M. Jadwisienczak2 and R Palai1; 1Department of Chemical and Biomolecular Engineering, Yonsei University, Seoul, Korea (the Republic of); 2Department of Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of).

In this work, ZnO polycrystalline nanoparticles have been intentionally doped with rare earth (RE) elements (Er, Yb) and co-doped with Na by conventional sol-gel process to study the effect of varying doping concentration on structural, dielectric, magnetic, optical (photoluminescence and cathodoluminescence) and photomagnetic properties of ZnO. The structure, morphology, particle size, RE ion doping and incorporation in ZnO matrix of microcylinders can be functionalized. As the micromolding technique is compatible with a roll process, photonic microgranules can be produced in high throughput. Each compartment can be independently rendered to be either structurally-colored, magneto-responsive, or transparent so that multicompartment photonic microcylinders can be functionalized as a roll process, photonic microgranules can be produced in high throughput.

molecules can be highly enhanced by SERS. Moreover, the microparticles possess consistent sizes of mesh, which enables the autonomous exclusion of large proteins while allowing infusion of small molecules. Therefore, it is possible to detect the charged small molecules through SERS with high sensitivity in the absence of interruption from adhesive proteins. To produce such microparticles in a controlled manner, we use a droplet microfluidics. Two aqueous streams of gel precursor containing Au NPs and agglomarants of sodium chloride are simultaneously emulsified into oil phase in a capillary microfluidic device. In the resulting emulsion drops, Au NPs are destabilized by the agglomerants. The agglomerates are captured in a microgel matrix by photocuring the gel precursors. To render the microparticles positively or negatively charged, acrylamide or acrylic acid are copolymerized with a gel precursor of poly(ethylene glycol) diacylate. The charged microparticles concentrate the oppositely-charged small molecules while excluding the same-charged molecules and larger molecules than mesh size. Therefore, we can directly detect charged pesticides dissolved in a protein solution. Moreover, we demonstrate the direct detection of fipronil sulfone dissolved in egg without pre-treatment.

Characterization of Cell Dynamics by Use of Metal Nanoparticle 2D Sheet as an Imaging Substrate

Shihomi Masuda1, Yanase Yuki2, Thasaneeya Kuboki3, Pangkan Wang3, Soh Ryuzaaki4, Koichi Okamoto5 and Kaoru Tamada2; 1Department of Chemistry, Kyushu university, Fukuoka, Japan; 2Graduate School of Biomedical & Health Science, Hiroshima university, Hiroshima, Japan; 3Institute for Materials Chemistry and Engineering, Kyushu university, Fukuoka, Japan; 4Institute of Systems, Information Technologies and Nanotechnologies, Fukuoka, Japan; 5Osaka Prefecture University,
Recently developed super resolution fluorescence microscopes have provided quite important new information concerning molecular scale of hierarchical structure of biological systems [1]. However, these techniques are inadequate for imaging of rapid dynamics of living systems, and also their axial resolution is not as high as their lateral resolution [2]. In our previous study, we have developed a simple and effective method to visualize nanointerface of the adhesive cells using localized surface plasmon resonance (LSPR) excited on a two-dimensionally assembled metal nanoparticle (NP) sheet [3, 4]. The confined light in a few ten nanometers region from the sheet enables to improve axial resolution of fluorescence images drastically, which provides even better SN ratio (high contrast) images compared with the total internal reflection fluorescence (TIRF) microscopy, where the exposure time became even shorter owing to the plasmon-enhanced fluorescence. This technique is suitable for imaging the cell/substrate contact regions where cellular dynamics and molecular reaction occur.

In this study, we conducted detailed analysis of cell dynamics via the local movement of focal adhesion visualized by our LSPR method. Oleylamine-capped gold NPs (AuOA) sheets were fabricated at the air-water interface by using Langmuir-Schaefer method and transferred onto a hydrophobic cover glass. In this study, we conducted detailed analysis of cell dynamics via the local movement of focal adhesion visualized by our LSPR method. through Scanning Electron Microscopy (SEM) and optical absorption spectroscopy. Absorption measurements of colloidal solutions show an absorption peak at \( \lambda = 400\text{nm} \) that is associated with localized surface plasmon resonance of NPs. SEM analysis reveals that the NPs have spherical shape and a large size distribution ranging from 20 to 200nm. The SERS effect of NPs was demonstrated for low laser flux conditions \( 13.2 \text{µW} \) (up to \( 3.3 \text{mJ/cm}^2 \)) on N719 dye and Rhodamine-B molecules, deposited over NPs thin films. Presence of the thin film of NPs has resulted in a four times increase of the Raman intensity of the dyes molecules.

**Cellulose Nanocrystals for Security Applications—Embedding Non-Optical Signatures Provided by Nanoparticles into Cellulose Nanocrystal Chiral Nematic Films**

Nicky Wojtania; Harvard University, Cambridge, Massachusetts, United States.

The recent increase in counterfeited documents, banknotes, and medications impacts society, calling for new security technologies that are difficult to reproduce. Nature mimicking materials with unique optical properties are well-suited for security applications. Aqueous suspensions of Cellulose Nanocrystals (CNC), extracted from cellulose, self-assemble into chiral nematic structures creating, upon drying, freestanding films. These films exhibit unique optical properties: structural color, iridescence, and light polarization for covert and overt encryption. The films are also suitable for anti-counterfeiting materials and can be enhanced to provide security features beyond optical properties. It was hypothesized that combining CNC with sub 50 nm metal and non-metal nanoparticles yields composite materials that retain the CNC optical properties. It was further hypothesized that the added nanoparticles influence the materials’ electrical and dielectric properties, which could be detected and validated as non-optical properties. The experiment created new, CNC-based composite materials with various nanoparticles: copper, aluminum, cobalt, iron, carbon single-walled nanotubes, graphene, titanium dioxide, titanium carbide, fluorescent rhodamine nanoparticles, and gold colloid. All composite films retained the CNC unique optical properties. Adding the nanoparticles shifted the structural color and reduced iridescence, measured with a custom-designed setup using a Fiber Spectrometer. The film morphology, examined using a Polarized Optical Microscope and Scanning Electron Microscope, was uniform with the nanoparticles evenly dispersed. The film’s non-optical properties (resistivity and dielectric constant) were measured using a custom-built setting composed of plates and electrodes connected to Digital Multimeters. Adding the nanoparticles uniquely impacted the CNC non-optical properties. The functionalization of CNC films beyond optical properties makes these materials even more suitable for anti-counterfeiting materials.

**Optical Chirality of Achiral Metal Nanoparticles by Broken Time-Reversal Symmetry without External Magnetic Field**

Jong-Won Park; Mechanical Engineering, Texas Tech University, Lubbock, Texas, United States.

Natural optical activity of plasmonic metal nanoparticles has been studied in terms of molecular chirality. The nanoparticle is commonly assumed to be chiral when the nanoparticle lacks inversion symmetry or is parity-odd (P). While optical activity generally requires the violation of parity and time-reversal symmetry (PT-symmetry), the time-reversal symmetry has typically been neglected in nanomaterials. Here, we demonstrate that time-reversal symmetry can be broken in the plasmonic nanoparticles by longitudinal volume plasmons. Without applying an external magnetic field we experimentally observed circular dichroism (CD) of gold, silver, and copper nanoparticles at the plasmon excitation energy. Spatial variation of light absorption in the nanoparticle is attributed to the origin of longitudinal plasmons that light cannot excite but an optical force may be able to. We propose that optical forces can generate the optical activity of achiral metal nanoparticles. The polarization rotation of surface plasmons is interpreted as orbital angular momentum that is time-odd (T−). The sum rule observed for the dipolar and quadrupolar surface plasmons may indicate the conservation of orbital angular momentum in the surface plasmon oscillation. We show that, rather than only parity, the PT-symmetry fully describes the optical activity of nanomaterials.

**Strong Room-Temperature Luminescence Emission Around 1.5 μm from Nanostructured Erbium Oxides in Zinc Oxide Nanowire Arrays**

Devika Vipin and Mengjing Huang; State University of New York Polytechnic Institute, Albany, New York, United States.

Zinc oxide (ZnO) semiconducting nanorods/nanowires are very attractive for fabrication of novel optoelectronic nanodevices, due to their excellent optical properties (e.g., a large excitonic binding energy of 60 meV) combined with their ease in synthesis. ZnO has a direct wide bandgap of \( 3.4 \text{ eV} \), leading to efficient light emission in the ultraviolet (UV) region. An extension of the ZnO nanowire emission beyond the UV spectral region, and in particular, to the technologically important near infrared range around 1.5 μm would greatly enhance these devices’ applications.

Erbium (Er) has offered a means towards optical amplification around 1.5 μm with these structures results in broadening of the bandwidth of absorption due to the possible near-field enhancement at that range of wavelengths. This material is thus of potential interest for absorption, typically at wavelengths > 1 μm through optical coatings for solar cell architectures.

**EP04.15.15**

**Low-Cost dendritic Silver Nanostructures for Large Area Optical Applications**

Anmol Walia1, Rajinder S. Deol1, Ghasan E. Jabbour2 and Madhusudan Singh1; 1Indian Institute of Technology Delhi, New Delhi, India; 2University of Ottawa, Ottawa, Ontario, Canada.

Control of morphology, shape and size of silver nanostuctures play a pivotal role for realization of desirable optical properties, which have been extensively studied for such systems. In particular, dendritic and branched silver nanostructures with self-assembled hierarchical and repetitive structures reveal unique optical absorption response. Large area solar cells require low-cost absorbing materials realized through non-toxic deposition methods. In this work, we report a low-cost approach to fabricate disordered branched silver nanostructures realized via a multi-generation light induced colloidal method. As a first step, standard citrate stabilized silver seeds with an average size of 8 nm and measure absorbance at 392 nm were synthesized. First generation silver nanotriangles were subsequently synthesized by growing silver seeds in presence of excess citrate and AgNO₃ precursors under controlled illumination of 590 nm (width: 20 nm) wavelength at room temperature. UV-visible absorption study shows a broad absorbance from 600-800 nm. Transmission electron microscopy (TEM) measurements correlate the absorbance to silver nanotriangles of edge lengths centered at 65 nm. A second illumination of 590 nm (width: 20 nm) at 25°C TEM scans reveal branched, hierarchichal, dendritic structures ranging from 1 - 15 μm in size. Interaction of light the visible-NIR range with these structures results in broadening of the bandwidth of absorption due to the possible near-field enhancement at that range of wavelengths. This material is thus of potential interest for absorption, typically at wavelengths > 1 μm through optical coatings for solar cell architectures.

**EP04.15.16**

**Size Controlled Photoemission and Photocatalytic Activity of Au-ZnO Nanostructures**

Issraa Shahine1, Safi Jrad2, Nour Beydoun2, El-Eulmi 1; 2University of Ottawa, Ottawa, Ontario, Canada.

Mechanical Engineering, Texas Tech University, Lubbock, Texas, United States.

The recent increase in counterfeited documents, banknotes, and medications impacts society, calling for new security technologies that are difficult to reproduce. Infrared-Transparent Thermally-Insulating Polyethylene Aerogels for Radiative Cooling

Radiative cooling exploits the high transparency of the earth’s atmosphere at mid-infrared wavelengths (8-13 µm), often referred to as the atmospheric window, to radiate heat to the cold outer space and passively cool terrestrial objects. While most of the past work has focused on developing spectrally selective surfaces to maximize radiative heat transfer and cooling performance, low conduction and convection thermal resistances between the radiative cooler and the environment have severely hindered the device-level performance. We have developed infrared-transparent and thermally-insulating polyethylene aerogels (PEAs) optimized for radiative cooling applications that could significantly improve the cooling power and minimum temperature of terrestrial objects.

References:

current radiative coolers by minimizing parasitic heat gains from the environment while allowing radiative exchange with outer space. Highly-porous PEAs of varying densities (20 to 120 kg/m³) were fabricated by thermally-induced phase separation of polyethylene/decalin and polyethylene/paraffin oil solutions followed by a solvent extraction by CO₂ supercritical drying. We tuned the porous structure of the PEAs by optimizing the fabrication process to minimize scattering and absorption in the atmospheric window and thus maximize transparency. We measured an atmospheric-window-weighted IR transparency of up to 92% along with a solar-weighted reflectance of 87% for a 2.3 mm thick sample with a density of 25 kg/m³. The optical measurements were compared to our theoretical model which solves the radiative transfer equation and assumes Mie scattering. We also characterized the thermal properties of the PEAs experimentally as well as theoretically, accounting for solid, gaseous and radiative contributions, and report an effective thermal conductivity of less than 0.05 W/mK at room temperature. Finally, we demonstrate that PEAs can significantly improve the performance of existing radiative cooling systems due to their combined high IR and low solar-weighted transmittance as well as ultra-low thermal conductivity.

Enhancing Circular Dichroism by Chiral Hotspots in Achiral Dielectric Nanocube Dimers

Kan Yao1,2 and Yongmin Liu1; 1Northeastern University, Boston, Massachusetts, United States; 2The University of Texas at Austin, Austin, Texas, United States.

An object is chiral if it cannot be superimposed to its mirror image. The existence of chirality in nature is universal, ranging from galaxies to gastropod shells to biomolecules. While a pair of chiral molecules, termed as enantiomers, exhibit identical scalar physical properties, they take part in many chemical reactions in biological processes differently, acting in a desirable or harmful way. Therefore, discriminating between enantiomers is of vital importance, especially in pharmacology and life sciences.

Light can be chiral as well, and chiral light-matter interactions provide an opportunity to noninvasively identify chiral molecules with superior precision. For instance, circular dichroism (CD) spectroscopy that measures the differential absorption of left- and right-circularly polarized (L/RCP) light is widely used to reveal the structural information of biomolecules. However, CD signals are usually very weak due to the intrinsically weak chirality of the molecules. In order to enhance CD signals for characterization at low concentrations, different platforms have been proposed, such as partially reflecting mirrors, plasmonic nanostructures, and dielectric nanoparticles, etc.[1,2] Despite improved differential absorption by chiral molecules, these methods suffer from either strong background absorption by the platforms or non-uniform chiral fields that hinder the global CD enhancement. Both issues impose limitations on the measurement sensitivity. Therefore, novel platforms exhibiting low loss and uniform chiral fields are highly desirable.

In this work, we numerically study the generation of chiral fields in achiral dielectric nanocube dimers and demonstrate its beneficial role in enhancing CD signals.[3] With practically achievable designs, we show that under the illumination of circularly polarized light, the local magnetic and electric fields are simultaneously enhanced and properly overlapped in the gap area, resulting in an accessible and uniform chiral hotspot. A volume-averaged chirality enhancement factor exceeding 15 is demonstrated for silicon nanocubes in the visible region around 550 nm wavelength. We further investigate the CD enhancement by positioning chiral molecules at the chiral hotspot. Thanks to the achiral and low-loss properties of the proposed platform, very weak absorption from the nanocubes will be present, which allows effective characterization of the chiral molecules and an over-10 fold enhancement of CD signals is demonstrated. We also consider other materials such as titanium dioxide, and the desired performance is successfully achieved in the violet region. Being able to engineer chiral fields without complex nanostructures or plasmonic materials, we expect that our findings can open up a new avenue to CD spectroscopy, chiral sensing and photolysis.

EP04.15.21
Pyramidal-Shaped Metal-Dielectric Hybrid-Structure Geometry with Asymmetric TiO2 Layer for Broadband Light Absorption and Photocatalytic Applications

Hee Jun Kim and Jeong Min Baik; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Here, we demonstrate a pyramidal-shaped metal-dielectric hybrid-structure geometry with an asymmetric TiO₂ layer and the application for the solar water oxidation. The TiO₂ was obliquely deposited onto the pyramidal-shaped Au film, which makes the pyramids asymmetric in thickness. The light absorption through the suggested design in the entire UV-visible region was significantly enhanced by the asymmetry of the pyramids, simulated by 3-D finite difference time domain simulation and confirmed by confocal spectral mapping techniques. The band alignment at the interface of TiO₂/Au film by introducing Ti as an insertion layer was tuned, promoting the separation of the photogenerated carriers via the efficient transport of electrons to Au films by minimizing parasitic heat gains from the environment while allowing radiative exchange with outer space. Highly-porous PEAs of varying densities (20 to 120 kg/m³) were fabricated by thermally-induced phase separation of polyethylene/decalin and polyethylene/paraffin oil solutions followed by a solvent extraction by CO₂ supercritical drying. We tuned the porous structure of the PEAs by optimizing the fabrication process to minimize scattering and absorption in the atmospheric window and thus maximize transparency. We measured an atmospheric-window-weighted IR transparency of up to 92% along with a solar-weighted reflectance of 87% for a 2.3 mm thick sample with a density of 25 kg/m³. The optical measurements were compared to our theoretical model which solves the radiative transfer equation and assumes Mie scattering. We also characterized the thermal properties of the PEAs experimentally as well as theoretically, accounting for solid, gaseous and radiative contributions, and report an effective thermal conductivity of less than 0.05 W/mK at room temperature. Finally, we demonstrate that PEAs can significantly improve the performance of existing radiative cooling systems due to their combined high IR and low solar-weighted transmittance as well as ultra-low thermal conductivity.

Here we show that colloidal bilayers of gold nanoparticles allow the excitation of a nominally dark plasmon by a plane wave at normal incidence due to field retardation. The radiative decay of this mode is suppressed, because of its narrow emission cone. The dark mode is composed of dipole excitations in each nanoparticle, where the dipoles align parallel within a layer, but antiparallel from one layer to the next. We show experimentally that gold nanoparticle bilayers have a strong absorption peak at 1.5 eV that arises from the excitation of the dark mode and is completely absent in the monolayer. The spectral position and width of the dark mode are tuned by changing the interparticle distance. The peak position may be adjusted for values between 1.4 and 2 eV. The crystalline nanoparticle layers assemble from colloidal gold nanoparticles in solution that were produced by wet chemistry. Nanoparticle bilayers promise the production of low-cost, large-scale plasmonic surfaces for enhancing catalytic processes via hot electron generation.

EP04.15.23
GeSn Nanodots with 26 at.% Sn Composition Towards Mid-Infrared Integrated Photonics

Alejandra V. Cuervo Covian, Xiaoxin Wang and Jifeng Liu; Thayer School of Engineering, Dartmouth College, Hanover, New Hampshire, United States.
Direct bandgap semiconductors on Si is a key technical challenge for Si-based integrated photonics. A promising approach is to alloy Ge with Sn, which effectively causes the energy of the direct Γ valley to decrease faster than the indirect L valley, leading to indirect-to-direct gap transition. One of the main issues with this approach is that the equilibrium solubility of Sn in bulk Ge is <1 at % according to the existing Ge-Sn phase diagram for bulk materials (extrapolated at ~400 C) [1]. Although substitutional Sn compositions of ~9-10 at % have been achieved by CVD, MBE and direct crystallization of amorphous GeSn [2], higher Sn composition is needed for stronger direct bandgap semiconductor behavior and better optoelectronic properties in the mid-infrared regime. In these cases, Sn segregation is the biggest concern. Here we present a counterintuitive approach that achieves a much higher equilibrium solubility with up to 26 at % Sn in GeSn nanodots directly crystallized on dielectric layers towards monolithic 3D mid-infrared (MIR) photonic integration in Si. The approach involves sequentially depositing a layer of metallic Sn nanodots with a diameter of 20-60 nm and a thin layer of Ge using physical vapor deposition (PVD), followed by interdiffusion/crystallization annealing at 300-500 C. In this case the alloying of Ge and Sn is driven by interfacial energy minimization between the Sn nanodots and the Ge capping layer, which allows for higher equilibrium solubility of substitutional Sn into the Ge lattice. It can also be viewed as dissolving the nanoscale Sn nuclei below the critical size for nucleation into the Ge lattice. X-ray diffraction and Raman spectroscopy analyses indicate that up to 26 at.% Sn has been substitutionally incorporated into the Ge lattice, increasing the lattice constant by 4% compared to pure Ge. The initial metallic Sn nanodots exhibit a strong (200) orientation, while after interdiffusion and crystallization the resulting GeSn nanodots show a strong (111) orientation without observable diffraction peaks from metallic Sn. This result indicates that Sn nanodots are completely dissolved into the lattice of Ge after crystallization annealing, and that the solubility limit of Sn in GeSn nanostructures is at least 30x higher than that in bulk materials. To our knowledge, this is also the first observation of converting metallic Sn into diamond cubic lattice via interdiffusion. Preliminary studies on these high Sn composition GeSn nanodot samples also show photoluminescence (PL) at both low and room temperature, suggesting good crystallinity. These results offer a new and facile approach to fabricate high Sn composition GeSn nanostructures for MIR integrated photonics.

plasmonic molecules and thus tune their corresponding coupled resonances across the entire visible spectrum. Our fabrication method can even progressively control the symmetry of the dimer and trimer structures across an entire wafer while preserving a nanogap. Furthermore, we spectroscopically map the resonances and qualitatively model the spectra. Theory and experiment are in good agreement with numerical calculations. While thus far dimer structures have largely been obtained by random drop casting, we show that we can systematically obtain identical dimers and also identical trimers where one of several parameters is systematically changed across the wafer. We expect that the structures will be important for spectroscopic studies.

Influence of Partially-Oxidized Plasmonic Metasurface Electrodes on the Electrical and Optical Properties of Organic Semiconductors
Zhongkai Cheng, Yan Wang, Manish Chhowalla and Deirdre O'Carroll, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

The efficiency of absorption and emission in organic semiconductors can be significantly improved by near-field optical interactions with resonant metallic plasmonic nanostructures. However, these improvements do not often translate to significantly enhanced optoelectronic device performance. Practical metals that exhibit strong plasmonic properties don’t have stable work functions suitable for effective charge collection or injection from most organic semiconductors. To address this problem, in this project, we investigate the application of surface oxides to both planar and structured metallic plasmonic metasurface electrodes and determine the impact on the charge transport and stability of organic semiconducting conjugated polymer devices. The properties of metasurface electrodes and surface oxides can be elucidated by comparing with planar devices and devices without surface oxides through electrical measurements, such as current-voltage measurements, and capacitance-voltage measurements. In addition, we determine the charge collection barrier height at the conjugated polymer-metal electrode interface to understand the impact of surface oxides and nanostuctures on charge injection and charge collection from the polymer. The overall goal is to make better performing electrodes for organic photovoltaics that are also capable of exhibiting effective light trapping below the diffraction limit.

Silver nanoparticle (AgNP) metasurface electrodes were fabricated using a thermally-assisted dewetting method. Then hole-only conjugated polymer-based devices were fabricated directly on top of AgNP metasurface electrodes. Devices with and without a silver oxide (AgOx) hole transport layer on the AgNP metasurface electrode were prepared. MoO3 is used as an interlayer between the conjugated polymer and a top Au electrode to block electrons and, hence, to achieve hole-only operation. This device configuration allows us to investigate the barrier to hole injection on the AgNP metasurface electrode side. The barrier to hole injection/collection from the conjugated polymer is expected to change when the AgOx layer or plasmonic metasurface is used compared to when only planar Ag is used. UV-visible extinction spectra and dark-field scattering spectra of AgNP electrodes with different sizes show different optical properties (such as scattering intensity and color) between AgNP metasurface electrodes with different nominal AgNP diameters. Current-voltage measurements show that the turn-on voltage of devices with an AgOx layer is lower than the devices without AgOx, which is attributed to the lower workfunction of AgOx relative to Ag. Ultraviolet photoelectron spectroscopy (UPS) is used to obtain the work function, which can be used to verify origin of the lower turn on voltage. Meanwhile, X-ray photoelectron spectroscopy (XPS) is also used to analyze the surface composition of the AgOx electrodes.

Observation of Ultrafast Hot-Hole Injection but Slow Hot-Electron Dynamics in Au/p-GaN Heterostructures
Joseph S. DuChene1,2, Giulia Tagliasacchi1,2, Mohamed Abdellah1, David Gostzola1, Alex J. Welch1,2, Wen-Huo Cheng1,2, Jacinto Sa2,3 and Harry A. Atwater1,2; 1California Institute of Technology, Pasadena, California, United States; 2Department of Chemistry-Angstrom Laboratory, Uppsala University, Uppsala, Sweden; 3Center for Nanoscale Materials, Argonne National Laboratory, Argonne, Illinois, United States; 4Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland; 5Joint Center for Artificial Photosynthesis, California Institute of Technology, Pasadena, California, United States.

Harvesting hot carriers from photo-excited metal nanoparticles on ultrafast (~fs) timescales holds great promise for the operation of non-equilibrium optoelectronics. While the ultrafast dynamics of hot electrons in metal nanostructures have been extensively studied, the temporal evolution of plasmon-induced hot holes remains unexplored. Here, we monitor ultrafast hot-hole injection from gold (Au) nanoparticles into the valence band of p-type gallium nitride (p-GaN) via ultraviolet transient absorption spectroscopy. By spatially separating hot-electron-hole pairs across the metal-semiconductor interface via plasmon excitation, Au/p-GaN heterostructures offer an ideal platform for spectrally distinguishing the dynamics of the hot holes, which can be probed in the infrared regime via free-carrier absorption within the p-GaN valence band, from the hot electron dynamics occurring on the metal, which are monitored across the visible spectrum with a white-light supercontinuum probe. We observe plasmon-induced hot-hole injection from Au to p-GaN within the 200 fs instrument response of our experimental setup, placing hot-hole transfer from a plasmonic metal to a p-type semiconductor on similar timescales as hot-electron injection into an n-type semiconductor. Moreover, hot holes persist within the p-GaN valence band for several nanoseconds before recombination of the charge-separated state occurs across the Au/p-GaN heterojunction. We further evaluated the influence of hot-hole injection on the temporal dynamics of hot electrons left behind on Au by comparison with Au/SiO2 heterostructures for which hot-hole injection is prohibited. Interestingly, we found that the ultrafast (~200 fs) injection of hot-holes into p-GaN on timescales commensurate with electron-electron scattering exerts a profound influence on the spectral and temporal dynamics of hot electrons on the Au nanoparticles. Taken together, these ultrafast studies offer a comprehensive picture of hot-carrier dynamics across the Au/p-GaN heterojunction and suggest the potential for manipulating the energy distributions and subsequent thermalization dynamics of hot electrons above the metal Fermi level by controlling the collection of hot holes on ultrafast timescales.

Metal Alloys for Plasmonic Hot Carrier Generation in the Infrared
Sara K. Figueiredo Stofela1,2, Orhan Kızılkaya1,2, William A. Shelton1, Philip T. Sprunger1,3 and Kevin M. McPeak1; 1Chemical Engineering Department, Louisiana State University, Baton Rouge, Louisiana, United States; 2Physics Department, Louisiana State University, Baton Rouge, Louisiana, United States; 3Center for Advanced Microstructures and Devices, Louisiana State University, Baton Rouge, Louisiana, United States.

Plasmonic hot-carrier devices offer below the band-gap charge generation, ultrafast response times and spectral and polarization control over absorption at the nanoscale. These features could result in transformative advances in photon detection devices, especially in the near-infrared regime. However, the dominant route for hot-carrier generation from current noble metals (e.g. Au) is interband transitions from high-energy (≥2 eV below Fermi level) d-band states. There is a need for plasmonic materials which offer efficient hot-carrier generation from intraband transitions utilizing low energy (~1 eV from Fermi level) infrared excitations. Our work focuses on identifying promising alloys and their associated composition which could result in efficient plasmonic hot carrier generation from infrared excitation.
We report the measured and calculated electronic properties of various binary metal-alloy thin films deposited at room temperature using co-thermal evaporation. Our deposition technique is amenable to modern lithographic approaches and therefore can be easily utilized to deposit nanostructured alloys for future devices. Both noble-noble and noble-transition metal alloys, where the transition metal exhibited a high electronic density of states (EDOS) near the Fermi energy, were characterized. We show experimental and calculated EDOS for 50 nm thick Ag-Cu, Ag-Pd, Ag-Ni, Ag-Ti, Au-Ni, Au-Ti, and Au-Pd films with various compositions. EDOS were collected using angle-resolved photoemission spectroscopy (ARPES) and film composition was measured using X-ray photoemission spectroscopy (XPS). Results of 50 nm thick Ag-Cu (25/75%) deposited at RT reveal shifts in d-bands due to hybridization above 2eV binding energy. However, upon annealing above 400°C, phase separation occurs. These results will be correlated with the local structure of the alloy film employing XAS and EXAFS. In the case of Ag-Cu, current EXAFS results reveal a nanocrystalline single phase material. Lastly, we will report the visible and near-infrared optical properties of these films and discuss them relative to the measured and calculated EDOS.

10:45 AM EP04.16.07
Picosecond Transient Absorption Spectra of Pyramidal Gold Nanoparticles Mina Nazari, Min Xi, Rahm Gummuluru, Sean B. Foster, Mi Hong, Björn Reinhard and Shyamsunder Erramilli; Boston University, Boston, Massachusetts, United States.

Plasmonic nanoparticles are of interest due to their novel therapeutic and diagnostic application. Recently, there has been increased interest in the potential for designed nanomaterials for non-equilibrium studies and materials processing. The optical properties of metal nanoparticles strongly depend on their electronic responses which are different than bulk metals. In our study, the electronic behavior of melallic nanoparticle are investigated using femtosecond transient absorption measurement to elucidate laser exposure effects on their spectroscopy and non-equilibrium dynamics. Femtosecond laser pulses generated by a regeneratively amplified Ti-sapphire laser are used to excite localized surface plasmon resonances in synthesized gold nanorods with a plasmon resonance close to 805 nm. The transient absorption spectra of the nanoparticles are obtained by recording their absorption at different probe delays. Our experimental findings indicate that the amplified femtosecond excitation of the surface plasmon resonance band in gold nanorods leads to transient absorption spectral changes which reveals that the electron-phonon relaxation dynamics is happening on early picosecond time scale. This relaxation time depends on the pump peak power indicative of a temperature dependent nonlinear relaxation back to equilibrium. Spectroscopy, light scattering and Finite element method simulations are used to characterize non-equilibrium dynamics. The findings expand the knowledge about the ultrafast electron processes in nanoparticles and provide information for controlling their time response, facilitating prospects for plasmonically enhanced cavitation for materials processing.

11:00 AM EP04.16.08
Real-Time Dynamics and Decomposition of Plasmons in Nanoparticles Thomas Rossi1, Paul Erhart2 and Mikael Kuismi2; 1Chalmers University of Technology, Gothenburg, Sweden; 2University of Jyväskylä, Jyväskylä, Finland.

Localized surface plasmons render metal nanoparticles efficient light absorbers at their resonance frequencies. After its excitation, the plasmon resonance decays into high-energy electrons and holes, which, combined with the large absorption cross section, makes metal nanoparticles attractive hot-carrier generators for photocatalysis. In this work, we study the femtosecond real-time dynamics of localized surface plasmons in noble metal nanoparticles by using time-dependent density-functional theory (TDDFT). By extending the frequency-space Kohn-Sham decomposition analysis [1] to real time, we follow the plasmon formation as a collective excitation, track its subsequent decay into incoherent electron-hole transitions, and finally, obtain the corresponding hot-carrier distributions. Our work paves the way for addressing the spatiotemporal dynamics of hot-carrier generation in catalytically-relevant edge and corner sites of nanoparticles.

11:15 AM EP04.16.09
A Combined Experimental and Theoretical Approach to Measure Spatially Resolved Local Surface Plasmon Resonances in Aluminum Nanoparticles Alina Bruna1,2, Canhui Wang1,2, Dayne Sweareng1, Naomi J. Halas2 and Renu Sharma1; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2Maryland Nano Center, University of Maryland, College Park, USA.; College Park, Maryland, United States; 3Rice University, Houston, Texas, United States.

Localized surface plasmon resonances (LSPRs) occur in certain metals where electrons confined to the metal surface oscillate with a frequency similar to that of the perturbing source, giving rise to localized electromagnetic fields. In this study we employ experimental and theoretical analyses to characterize LSPRs in Alcore(Al2O3)shell nanoparticles with controlled morphologies. We perform simulations of LSPR using boundary element methods, where the electron beam is passing at a distance of 2.5 nm from the surface of an icosahedral Alcore(Al2O3)shell nanoparticle. The electron energy loss probability spectra show that, for the mode located at an energy ≈ 7 eV, the magnitude of the LSPR shift towards smaller energy values is higher compared to other modes located at lower energies, when the impact parameter is near a facet, an edge, or a corner of the nanoparticle, respectively. This agrees with our experimental data, where we collected electron energy-loss spectroscopy (EELS) data in the low-loss region, near the surface of the nanoparticles, using a monochromated 80 keV electron source with 100 meV energy resolution. The experimental spectra appertaining to the edge and corner of the nanoparticle display an energy shift as a function of position of the electron beam with respect to the nanoparticle. By applying a non-negative matrix factorization algorithm, we deconvolve the LSPR signals and thus determine the effects of geometry and composition on coupling efficiency as a function of beam position. This allows us to map the coupling efficiency of the electron beam to the surface electrons, and reveals the energy transfer path from the excitation source to the nanoparticles. This study paves the way for a better understanding of the localization of LSPR in catalyst nanoparticles with engineered morphologies, and highlights the capabilities of EELS as a tool for probing surface plasmons of metallic nanostructures with high spatial and energy resolution.

11:30 AM EP04.16.10
Towards Nanoscale Molecular Mapping with Electron-Beam Stimulated Surface Enhanced Raman Spectroscopy Amr E. Saleh, Daniel K. Angell and Jennifer A. Dionne; Stanford University, Stanford, California, United States.

Surface enhanced Raman scattering (SERS) has been a key tool for molecular detection and identification with single-molecule sensitivity. However, creating real spatial resolution SERS maps of sophisticated surfaces such as cellular membranes and biological tissues remains a significant challenge because of the diffraction limit of light. In this work, we introduce a novel imaging technique that utilizes light excitation within an electron microscope to perform high spatial resolution Raman mapping. Unlike conventional stimulated Raman measurements, our technique uses a laser source as the pump and the electron beam as the broadband Stokes excitation. Particularly, we leverage the electron beam as a highly-localized Angstrom-scale source to locally excite the plasmonic resonances of individual nanoparticles. The resonant wavelength of the nanoparticles is tuned such that it is red-shifted from the pump laser to resemble the Stokes excitation when excited with the electron beam. Accordingly, the Raman scattering is locally enhanced by the electron beam and the spatial resolution is determined by the electron beam spot size and the nanoparticle size.
To compute the local nonlinear Raman enhancement under dual optical and electron beam illumination, we first use finite difference time domain (FDTD) simulations. Attention is given to gold nanorods (NRs) with plasmonic resonances between 800nm and 900nm; we assume 785nm laser illumination and 80keV electron beam excitation. We study the enhancement of the 992cm⁻¹ benzene line, showing that laser pump intensities less than 3mW/µm² can locally enhance the Raman peak. We compute the pumping threshold and the Raman gain achieved under various electron-beam and nanorod excitation positions, showing sub-2nm resolution of molecular fingerprints.

Experimentally, we use aberration corrected environmental transmission electron microscope combined with light excitation. We synthesize colloidal gold NRs functionalized with 4-Nitrothiophenol (4NTP) as Raman reporter. The lengths and radii of the rods are 105nm and 12nm, respectively, with transverse and longitudinal plasmon resonances at 510nm and 830nm. Upon electron beam excitation of the NR plasmon modes, we observe an increase in the Raman intensity of the 1335cm⁻¹ and 1570cm⁻¹ lines of the 4NTP molecule. Monochromated electron energy loss spectroscopy (EELS) confirms the plasmon modes we excite during each individual Raman acquisition. We investigate and locally map the stimulated Raman enhancement upon electron-beam excitation of different NP resonances and with distinct nanorod lengths. Our results demonstrate the ability to perform in-situ Raman interrogation with single nanometer resolution inside an environmental TEM while simultaneously imaging the nano-to-atomic-scale structure of the sample.

* Invited Paper
Organic electrochemical transistors (OECT) are of interest for applications in biochemical sensing and signal transduction across the biological/digital divide. The excellent performance of conjugated polymers in these applications is due to the ability of the polymer to accommodate ionic countercharge throughout the transistor volume. The resulting volumetric capacitance which allows for very large modulations of the charge density in the transistor channel and large transconductance values. Combining OECT measurements on different polymers with different counter ions, we study how both polymer morphology and the chemical nature of the counter ions affect ion uptake and coupling between ionic and electronic transport. Furthermore, we use electrochemical strain microscopy (ESM) to probe local swelling resulting from ion uptake, and correlate ion uptake with both polymer structure and the chemical properties of the ions, providing microscopic insight into these processes that lead us to propose new material design rules.

Operando X-Ray Scattering Reveals Ion-Induced Structural Changes During Electrochemical Gating of Poly(3-hexylthiophene) Elayne Thomas1, Michael A. Brady2, Hidenori Nakayama3, Bhooman C. Popere1, Rachel Segalman1 and Michael L. Chabinyc1; 1University of California, Santa Barbara, Goleta, California, United States; 2The Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The semicrystalline nature of most semiconducting polymers complicates the relationship between morphology and electronic conduction. In order to increase their electrical conductivity, charge carriers are introduced into conjugated polymers by extrinsic dopants, usually by introduction from solution or by infiltration from a vapor. In this case, the dopant molecule, now ionized, is the counterion to the charged backbone. There is currently little understanding of how these ions interact with the amorphous and crystalline regions of the semiconductor to achieve the observed large changes in electrical conductivity.

To address the question of how ions interact with these distinct phases, we have explored the evolution in morphology and optoelectronic properties of a conjugated polymer in an organic electrochemical transistor. By using a novel polymeric ionic liquid (PIL) as the gate insulator, we carry out for the first time operando studies capturing the structural evolution in poly(3-hexylthiophene) (P3HT) during electrochemical gating by X-ray scattering. PILs contain one ion covalently bonded to the polymer backbone and one ion that is mobile, which allows for control of counterion diffusion as well as low-voltage device operation. From these experiments, we find that negatively-charged ions from the dielectric first infiltrate the amorphous regions of the semiconductor, and penetrate the crystalline regions at a critical carrier density of 4 × 10^{20} cm^{-3}. Upon infiltration, the crystallites expand by 12% in the alkyl stacking direction and compress by 4% in the π-π stacking direction. The stark change in crystal structure of P3HT correlates with a sharp increase in the effective carrier mobility. Complementary UV-visible spectroscopy reveals that holes induced in P3HT first reside in the crystalline regions of the polymer, which verifies that a charge carrier need not be in the same physical domain as its associated counterion. Our results provide a comprehensive view of doping in P3HT which challenges the assumption that trap filling is the sole mechanism to justify the non-linear trend in electrical conductivity with carrier density.

8:45 AM *EP05.01.03
Conjugated Polymers—Charged Semiconducting Polymers Processed from Protic Solvents Ryan Chiechi1, 2, Lambert Jan Anton Koster2, Nutifafa Dounon1 and Gang Ye1, 2; 1Stratingh Institute for Chemistry, University of Groningen, Groningen, Netherlands; 2Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands.

Semiconducting conjugated polymers have found applications in field-effect transistors, sensors, solar cells, etc. In essentially any application that requires a semiconducting material, the semiconducting material can be replaced with a properly-designed conjugated polymer, endowing a device with the useful properties of polymers such as solution-processing, mechanical compliance, thinness and light weight. However, the solutions from which thin-films of conjugated polymers are cast contain very small amounts of polymer, on the order of tens of milligrams per milliliter. The nonpolar nature of pi-conjugated moieties means that high-quality films can only be cast from solvents that are either difficult or impossible to work with at scale. One approach to creating conjugated polymers that can be processed from “green” solvents is to decorate them with charged pendant groups to form conjugated polyelectrolytes that can be dissolved in polar, protic solvents like water or methanol. However, designing conjugated polyelectrolytes that are both processable and retain high carrier mobility is challenging because of the disparate physical properties of the backbone and pendant groups. This amphiophilic nature drives the polymer chains to self-assemble such that, in polar solvents, the hydrophobic backbone chains pack together and are shielded by a shell of ionic pendant groups to minimize unfavorable solvent interaction. These protein-like aggregates are carried into the films, leading to poor pi-pi contact. Our approach is to place closed-shell charges into the backbones of conjugated polymers to match the ionic character of the pendant groups such that the backbone is directly solubilized by polar solvents. The resulting conjugated polymers are intrinsic semiconductors; they are not bipolaronic and are EPR silent. Their band-gaps can be tuned via common push-pull strategies and they form high-quality films with good carrier mobility from polar, protic solvents. The cations in the backbone are generated from pre-polymers by the loss of methanol under acidic conditions. Thus, we can process high-quality thin-films from wet formic acid, which is non-toxic, non-flammable and is already used industrially at scale.

9:00 AM *EP05.01.04
Polar and Reactive Side Chain Functionalization of Conjugated Polymers for Redox and Bio-Electronic Applications John R. Reynolds; Georgia Institute of Technology, Atlanta, Georgia, United States.

Conjugated polymers provide a unique encompassing set of structurally tunable optical, electronic transport, and redox properties that allows their present and potential use in a host of applications which span field effect transistors, light emitting diodes, solar cells and photodetectors, and electrochemistry, along with batteries, supercapacitors, and bio-electronics. Processing of these materials is carried out using a variety of solution methods including spin-coating, spray-coating, blade-coating, slot die coating and ink jet printing. The ability to process these polymers from environmentally benign solvents and aqueous solutions is highly advantageous for possibilities in large scale roll-to-roll processing. Maintaining competitive electronic properties while achieving aqueous solubility is difficult for several reasons. 1) Materials with polar functional groups that provide aqueous solubility can be difficult to purify and characterize. 2) Many traditional coupling and polymerization reactions cannot be performed in aqueous solution. 3) Ionic groups, though useful for obtaining aqueous solubility, can lead to a loss of solid-state order as well as a screening of any applied bias. In this lecture, we will address how side chain polarity, from charge neutral ether and ester functionality to ionic functionality, impacts not only processing, but also charge transport, redox switching and optical properties. As an alternative, a multistage side-chain cleavage approach will be presented that allows a functional group to be used for its intended purpose, then removed once the functionality becomes unnecessary. Through the attachment of multistage sidechains, conjugated materials can be synthesized, characterized, and purified in organic solvents, converted to a water-soluble form for aqueous processing, and brought through a final treatment to leave behind the desired electronic material as a solvent-resistant film.

9:30 AM BREAK

10:00 AM *EP05.01.05
Semiconducting Polymer for Bioelectronics and Field Effect Transistors Jair McCulloch2, 1; 1Imperial College London, London, United
The evolution of organic electronics has now reached the commercial phase, with the recent market introduction of the first prototypes based on organic transistors and organic solar cell modules fabricated from solution. Understanding the impact of both the organic semiconductor design and processing conditions, on both molecular conformation and thin film microstructure has been demonstrated to be essential in achieving the required optical and electrical properties to enable these devices. Polymeric semiconductors offer an attractive combination in terms of appropriate solution rheology for printing processes, mechanical flexibility for rollable processing and applications, but their optical and electrical performance requires further improvement in order to fulfill their potential. Synthesis of conjugated aromatic polymers typically involves carbon coupling polymerisations utilising transition metal catalysts and metal containing monomers. This polymerisation chemistry creates polymers where the aromatic repeat units are linked by single carbon-carbon bonds along the backbone. In order to reduce potential conformational, and subsequently energetic, disorder due to rotation around these single bonds, an aldol condensation reaction was explored, in which a bissatin monomer reacts with a bisoxindole monomer to create an isoindigo repeat unit that is fully fused along the polymer backbone. This aldol polymerization requires neither metal containing monomers or transition-metal catalysts, opening up new synthetic possibilities for conjugated aromatic polymer design, particularly where both monomers are electron deficient. Polymers with very large electron affinities can be synthesised by this method, resulting in air stable electron transport, demonstrated in solution processed organic thin film transistors. We present an electrical, optical and morphology characterisation of polymer thin films, illustrating structure-property relationships for this new class of polymers. Organic electrochemical transistors (OECTs) have been shown to be promising devices for amplification of electrical signals and selective sensing of ions and biologically important molecules in an aqueous environment, and thus have potential to be utilized in bioelectronic applications. The sensitivity, selectivity and intensity of the response of this device is determined by the organic semiconducting polymer employed as the active layer. This work presents the design of new organic semiconducting materials which demonstrate significant improvements in OECT performance, through operation in accumulation mode, with high transconductance and low operating voltage.

10:30 AM EP05.01.06
Organic Electrochemical Transistors—Developments on Modelling the Transient Response and on Device Fabrication
Gregorio C. Faria; Sao Carlos Physics Institute, University of Sao Paulo, Sao Carlos, Brazil.

Organic Electrochemical Transistors (OECTs) have recently been the focus of great attention due to their ability to support both ionic and electronic conduction and their successful application as highly-sensitive biosensors and neuromorphic devices. In the first part of my talk, I will discuss a universal model for the transient drain current response in OECTs. Using equivalent circuits and semiconductor charge injection physics, the model is able to reconstruct the drain current in OECT devices, is applicable to both plain and membrane-functionalized devices, and allows one to extract useful impedances of any system from only a single transient measurement. For the second part of my talk, I will present a general method and accompanying guidelines for fabricating both non-aqueous and aqueous based OECTs using water-insoluble hydrophobic semiconducting polymers. By taking advantage of the interactions of semiconducting polymers in certain organic solvents and the formation of a stable liquid-liquid interface between such solvents and water, we successfully fabricated OECTs with high transconductance, ON/OFF ratios of 10⁶, and enhancements in stability. Using the model discussed in the first part of the talk, key fundamental properties of both the device and active channel materials were extracted, including volumetric capacitance and intrinsic hole mobility. Finally, the benefits of using liquid-liquid interface OECTs to measure bacterial membrane disruption will be briefly discussed.

11:00 AM EP05.01.07
In Situ Methods for Understanding Charge Transport in a Conducting Redox Polymer
Mia C. Sterby, Rikard Emanuelsson, Maria Stromme and Martin Sjödin; Uppsala University, Uppsala, Sweden.

Organic materials can be used to ensure sustainable electrical energy storage, but since organic molecules are generally insulating conducting additives are commonly used to ensure electrical conductivity throughout the material. A different approach is to use conducting redox polymers (CRPs). CRPs consist of a redox active pendant group, used for its high capacity, attached to a conducting polymer backbone. The CRP presented here is aimed to be used as the positive electrode in a water-based organic battery.

In this work we employ the well-studied conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) with a quinone pendant group, a combination that we have proven can work in an all-organic proton battery. Quinones constitute an attractive class of molecules as they possess a high charge storage capacity, show reversible redox chemistry, and are naturally occurring, e.g., in the electron transport chains in respiration and in photosynthesis. The aim of the study is to understand the charge transport properties of the CRP.

The CRP studied is characterized by various in-situ electrochemical methods including conductance, Quartz Crystal Microbalance (QCM), UV-vis and electron paramagnetic resonance (EPR). Based on the results the electron and ion transport during electrochemical redox conversion will be discussed.

11:15 AM EP05.01.08
Conductive Polymer Electrodes for Biosensors and Energy Conversion
Erin L. Ratcliff; University of Arizona, Tucson, Arizona, United States.

Electron transfer is a ubiquitous chemical reaction in energy and biology. Controlling interfacial electron transfer rates is critical to maximizing device efficiencies in electrochemical technologies including redox-flow batteries, chemical sensors, bioelectronics, and photo-electrochemical devices.

Conductive polymer electrodes offer the possibility to control redox properties through synthesis and processing, if critical structure-property relationships are understood. Importantly, these semiconductors demonstrate a hybrid electronic-ionic conduction mechanism, and thus, have unique electrochemical behaviors relative to classical inorganic semiconductor electrodes.

This talk will provide new insights into the mechanism of charge transfer at conductive polymer/liquid interfaces. A mathematical framework will be demonstrated using a modified Marcus-Gerisher model that enables prediction of rate constants from simple film properties. Experimental evaluation of potential-dependent rate constants will be demonstrated. Results will be contextualized in electrochemical devices.

11:45 AM EP05.01.09
Correlation Between Redox, Charge Carrier Transport and Ion Molecular Structure Properties in Ion-Gated PCBM Films
Tian Lan; Francesca Sauro; Jonathan Sayago and Clara Santato; 1Ecole Polytechnique de Montreal, Montreal, Quebec, Canada; 2Universita di Bologna, Bologna, Italy; 3Universidad Nacional Autónoma de México, Temixco, Mexico.
The n-type organic semiconductor phenyl-C61-butyric acid methyl ester (PCBM), a soluble fullerene derivative well investigated for organic solar cells and transistors, can undergo several successive reversible, diffusion-controlled, one-electron redox processes. We exploited such processes to shed light on the correlation between electron transfer properties, ionic and electronic transport as well as device performance in ionic liquid (IL)-gated transistors. Two ILs were considered, based on bis(trifluoromethylsulfonyl)imide [TFSI] as the anion and 1-ethyl-3-methylimidazolium [EMIM] or 1-butyl-1-methylpyrrolidinium [PYR14] as the cation. The aromatic structure of [EMIM] and its lower steric hindrance with respect to [PYR14] favor a 3D (bulk) electrochemical doping. As opposed to this, for [PYR14] the doping seems to be 2D (surface-confined). If the n-doping of the PCBM is pursued beyond the first electrochemical process, the transistor current vs. gate-source voltage plots in [PYR14][TFSI] feature a maximum that points to the presence of finite windows of high conductivity in IL-gated PCBM transistors.

**Interacting Ion and Electron Currents**

**Paul Meredith**

Swansea University, Swansea, United Kingdom.

Ionic and electronic conduction mechanisms are underpinned by fundamentally different physics. For example, ions diffuse through a conducting matrix via centre of mass transport that can be described by classical processes. Electrons and holes are quantum mechanical entities characterised by delocalisation, tunnelling or hopping. These fundamental differences impose radically different length-and-time-scales on ionic and electronic conduction – and generally speaking the solid-state physics of ions and electrons have remained two very different fields requiring different skill sets. However, bioelectronics, where a central challenge is the transduction between ion and electron currents, is a scientific collision point between the two worlds. In my talk I will summarise the major differences between ionic and electronic solid state electrical conduction. I will also describe methods that can probe the relevant time-and-length-scales in order to identify and disentangle the native signatures of each carrier type. A number of model systems and devices will be exemplified that allow the study of ion and electron conduction processes, and indeed provide a means to test prototypical concepts in transduction and bioelectronic logic interfaces.

**The Device Physics of Organic Electrolytic Photocapacitors—From the Nanoscale to the Single Cell Level**

**Vedran Derek**

1, Marie Jakesova, Tobias Cramer, Marek Havlicek, David Rand, Yael Hanci, Daniel Simon, Magnus Berggren, Fredrik Elinder and Eric D. Glowacki; 1Laboratory of Organic Electronics, Department of Science and Technology, Linkoping University, Norrkoping, Sweden; 2Department of Physics and Astronomy, Universita di Bologna, Bologna, Italy; 3Department of Nanometrology and Technical Length, Czech Metrology Institute, Brno, Czechia; 4School of Electrical Engineering, Tel Aviv University, Ramat-Aviv, Tel-Aviv, Israel; 5Department of Clinical and Experimental Medicine, Linkoping University, Linkoping, Sweden.

We have recently developed the organic electrolytic photocapacitor (OEPC), a nanoscale optoelectronic device for eliciting action potentials in neurons. Herein, we cover in detail the physical mechanisms behind the charge generation and dynamics of charging and capacitive coupling in these devices using optoelectronic/electrochemical measurements combined with simulation and modeling. Electrochemical impedance measurements allow corroborate of these models, and reveal the nature of photocapacitive and photofaradaic effects in the devices. Using scanning probe microscopy techniques, we have evaluated the mechanical properties of the nanocrystalline films, finding relatively low Young’s moduli in the range of 500 MPa. In order to take a reductive approach compared with previous measurements of neurons and electrogenic tissues, we have validated the performance of OEPCs using nonexcitable cells, xenopus laevis oocytes. We find rapid membrane potential changes in the range of tens to hundreds of millivolts are induced by OEPC devices, showing extremely effective capacitive coupling and explaining previous findings of action potential generation. The overall result of our work is a fuller physical and mechanistic understanding of this novel device platform, and a roadmap for guiding future development.

**The Design of Air Stable, Redox Active Conjugated Polymers and Their Applications in Accumulation Mode OECTs**

**Alexander Giovannitti**

1, Reem Rashid2; Jenny Nelson1, Iain McCulloch1 and Jonathan Rivnay2; 1Imperial College London, London, United Kingdom; 2Northwestern University, Chicago, Illinois, United States.

Organic electrochemical transistors (OECTs) are receiving a great deal of attention due to the ability to efficiently transduce biological signals. The working of the device relies on the modulation of the conductivity of an organic semiconductor, which can be modified by applying a potential at the gate electrode and driving electrochemical redox reactions in aqueous solution (doping/de-doping of the organic semiconductor). OECTs can either be operated in accumulation or depletion mode where the operation in accumulation mode has the advantage of lowering the operational voltage and therefore improve the power consumption of the device (device is in an off state rather than an on state when no gate voltage is applied). Recently, high performing OECT materials have been reported based on electron rich alkoxylithiophene copolymers which show low oxidation potentials in aqueous electrolytes and enable EOCT operation at low voltages. However, one drawback of these easily oxidizable polymers is that the copolymers can become oxidized by reactions with oxygen from ambient air. This
result in the formation of p-doped polymers and superoxide anions ($O_2^-$) where the latter is a reactive radical and might cause harm to biological systems or degrade the organic semiconductor. As a result of this oxidation reaction, a constant gate voltage would need to be applied to keep the material in its neutral state (and the device off).

We will present the development of an air-stable conjugated polymers based on donor-acceptor type copolymer. The copolymer shows reversible redox reaction at potentials below 0.3 V vs Ag/AgCl. When exposed to aqueous ambient conditions, the polymer does not become oxidized. Long-term stability tests were carried out where devices were exposed to ambient conditions for more than 6 months with no sign of degradation. The polymer shows a good stability when charged within one hole per repeat unit (polaron) with transconductances in the range of 80 S/cm (at -0.7 V). This work demonstrate the importance of chemical design strategies for the development of accumulation mode OECT materials to mitigate reactions with oxygen in aqueous electrolytes and ambient conditions.

2:30 PM *EP05.02.04/BM07.02.04
Polythiophene Derivatives as Mixed Organic Ionic and Electronic Conductors Christine Luscombe; University of Washington, Seattle, Washington, United States.

Mixed organic ionic and electronic conductors are being explored for a wide range of applications, from bioelectronics to neuromorphic computing, artificial muscles and energy storage applications. These materials exploit the simultaneous transport properties of ionic and electronic carriers to enable novel device functions. Recently, polymer semiconductors have received significant amounts of attention because of their flexibility, biological compatibility and ease of fabrication. These materials, particularly thiophene-based polymers such as poly[(3,4-ethylenedioxythiophene)-poly(styrenesulfonate)](PEDOT:PSS) and related derivatives, have demonstrated significant enhancements in performance in a relatively short amount of time, with transconductance values of PEDOT:PSS transistors surpassing those achieved even with graphene.

Through our NSF Designing Materials to Revolutionize and Engineer our Future (DMREF) award with researchers at Cornell University and the University of Chicago, we have been investigating the synthesis of ethylene-glycol functionalized polythiophenes, their thin film morphology, and their pattern of placement on ionic conductivity will be discussed.

Through our NSF Designing Materials to Revolutionize and Engineer our Future (DMREF) award with researchers at Cornell University and the University of Chicago, we have been investigating the synthesis of ethylene-glycol functionalized polythiophenes, their thin film morphology, and their pattern of placement on ionic conductivity will be discussed.

3:00 PM BREAK

3:30 PM *EP05.02.05/BM07.02.05
Mixed Conductivity in Conducting Polymer Thin Films Sabine Ludwigs; University of Stuttgart, Stuttgart, Germany.

This talk will give an overview about our recent activities on electronic and ionic conductivity in conjugated and redox polymer thin films with different molecular architectures. Preparation of films is done either by electropolymerization or solution deposition followed by morphology tuning, e.g. by solvent vapor annealing.[1]

We are particularly interested in three-dimensional architectures based on branched monomers such as thiophenes (3T) or triphenylamines (TPA). TPA redox moieties are useful to allow for electrochemical or chemical crosslinking of as-deposited films. Both, with TPA redox polymers[2] and with polymers which bear TPA as pendant functional groups[3] we could perform successful crosslinking and simultaneous doping of polymer films. The films provide very high stabilities with high electronic conductivities as evidenced by cyclic voltammetry coupled with in-situ conductance measurements and four-point-probe measurements. In the case of 3T we have reported on homopolymer and copolymer films of 3T and ethylenedioxythiophene which allow polymer-analogous reactions to induce ionic functionalities, thereby creating branched conjugated polyelectrolyte films.[4], [5]

To get a better understanding on mixed conductivity in polymer films, we have recently performed a study on electronic and ionic conductivity of linear conjugated polyelectrolytes by impedance spectroscopy and dc-measurements.[6] The clear dependence of the conductivities as function of humidity and degree of doping will be discussed in the talk in more detail.

4:00 PM *EP05.02.06/BM07.02.06
Soft Electronic and Ionic Neural Interfaces Klas Tybrandt1, 2, Dion Khodagholy1, Flurin Stauffer2 and Janos Vörös3; 1Department of Science and Technology, Linköping University, Norrköping, Sweden; 2Institute for Biomedical Engineering, ETH Zürich, Zurich, Switzerland; 3Department of Electrical Engineering, Columbia University, New York, New York, United States.

Two-way communication between electronics and neural tissue is key for advancing diagnosis and therapies for neurological diseases and disorders, as well as proving detailed information about brain signaling. Establishing such neural interfaces is a major challenge, as the tissue response to implants can have a detrimental effect on the signal quality and functionality of the implant. Also, electrical stimulation is inherently limited in its stimulation of neural tissue, in comparison to the sophisticated chemical signaling processes within biological tissue. Here, we present our efforts in addressing two critical technological aspects for the creation of versatile neural interfaces; the matching of mechanical properties of tissues and electronics, and the development of heterogeneous electronic and ionic interfaces. Soft electronic biomedical implants have a demanding set of requirements, including biocompatibility, mechanical and electromechanical properties, long-term stability and electrode performance. To meet these requirements, we have developed a high-performance, long-term stable soft and stretchable composite for neural electrodes. Based on this composite, high-density soft electrode grids were developed and implanted onto brain surface of rats. The electrodes provided high-quality recordings during three months of implantation. Next, we will outline our strategy for creating high-speed low-leakage chemical neural interfaces, by discussing the relationship between delivery delay and leakage, and then present an iontronic approach to achieve low leakage and small delay simultaneously.
Organic Electronics for Neuromorphic Computing

Neuromorphic computing could address the inherent limitations of conventional silicon technology in dedicated machine learning applications. Recent work on silicon-based asynchronous spiking neural networks and large crossbar-arrays of two-terminal memristive devices has led to the development of promising neuromorphic systems. However, delivering a parallel computation technology, capable of implementing compact and efficient artificial neural networks in hardware, remains a significant challenge. Organic electronic materials offer an attractive alternative to such systems and could provide neuromorphic devices with low-energy switching and excellent tunability, while being biocompatible and relatively inexpensive.

This talk describes state-of-the-art organic neuromorphic devices and provides an overview of the current challenges in the field and attempts to address them. We demonstrate a novel concept based on an organic electrochemical transistor and show how some challenges in the field such as stability, linearity and state retention can be overcome.

Furthermore, we investigate chemical doping mechanisms in the active material for improved material functionality and demonstrate that this device can be entirely fabricated on flexible substrates, introducing neuromorphic computing to large-area flexible electronics and opening up possibilities in brain-machine interfacing and adaptive learning of artificial organs.

Anisotropic Conducting Polymer Films for Bioelectronics

Anisotropic conductive films, which consist of electrically conductive particles dispersed in nonconductive media, are increasingly being applied to establish high-density electrical bonds between electronic boards and chips. However, current anisotropic composites utilize metallic particles, often nickel and epoxy-based media, that require high thermocompression energy for bonding. Therefore, they have limited applicability in thin-film, conformable, and plastic-based devices that are used in bioelectronic applications. Furthermore, these materials are not biocompatible, significantly limiting their use in biological systems. We hypothesized that replacing the metallic particles with conducting polymer particles combined with a biocompatible nonconducting matrix would address this limitation. We developed a novel anisotropic conducting polymer (ACP) consisting of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) conducting polymer particles dispersed in a matrix of crosslinked chitosan (CS). To determine the permeability of PEDOT:PSS to CS, we characterized the resistances of thin CS-based films sandwiched with PEDOT:PSS and gold pads. We investigated the particle size, structure, density and distribution of pure PEDOT:PSS particles and PEDOT:PSS-coated CS particles. The anisotropy was defined by the ratio of horizontal and vertical impedance between interconnects. We benchmarked the anisotropy of the developed ACPs by geometrically varying an array of gold electrodes. The final ACP, which was created at 70°C with minimal pressure, yielded anisotropy of 10^−10. The ACP was then used to maintain precise connections between a high density conformable implantable neural probe and back-end electronics. It enabled complete chronic in vivo implantation of these electronics with minimal encapsulation layers, highlighting applicability for use in bioelectronic and clinical devices.

Temporal Analysis of Transient Electroluminescence to Study the Effect of Charge Traps in Organic Light Emitting Diode

A comparative study was carried out for pristine vs. degraded organic light emitting diode (OLED) devices regarding their luminescence characteristics using time-resolved electroluminescence (TREL). Notable changes were observed in the temporal form of the TREL curve upon materials degradation, which was found to be due to the trapped charges formed during the OLED operation. The TREL decay time of degraded OLED was found to be longer than that of pristine OLED due to the excitons produced by weakly bound charges trapped in the organic layer that are released by thermal energy even without applying the voltage pulse. On the other hand, the onset time of luminescence was found to be shorter due to the excitons from strongly bound charges that are released by the application of the voltage pulse. We demonstrated that TREL can be effectively used to identify different types of excitation and to investigate the luminescence mechanisms of a light-emitting device.
The SD efficiency can vary greatly depending on the properties of the OSCs, dopants, and especially the film conditions since the doping effect can be sensitive to the film structure. Therefore, we investigate the SD mechanism through a comparative study of two different OSC materials, small molecular PTCDI-C8 and polymer N2200, doped with two kinds of aminosilanes, and various thicknesses and grain sizes of deposited films to find the optimum SD condition. We characterized the doped films and OFETs by using AFM, Grazing-incidence X-Ray Diffraction, Infrared spectroscopy, electrical measurements, etc.

As a result, higher doping efficiency showed in the doped PTCDI-C8 FETs than N2200 FETs due to the difference of intrinsic OSC properties such as its open film morphology. Additionally, the SD efficiency is decreased with increasing thickness and grain size of the OSC films. The more electron donating groups the dopant has, the lower doping concentration is needed to reach the same optimized value. Importantly, we find that there are two doping concentration regimes. In low doping concentrations, the dopants primarily contribute to the increase in mobility. In higher doping concentrations, the dopants also enhance the threshold voltage. Furthermore, the SD process does not adversely affect other OFET properties such as the on-off ratio.

Therefore, our results demonstrate that the properties of OSCs, dopants and particularly the film conditions must be considered in order to maximize the SD efficiency for improved OFET performances.

EP05.03.03

Metal Organic Frameworks in a Blended Polythiophene Hybrid Film with Surface-Mediated Vertical Phase Separation for the Fabrication of a Highly Sensitive Humidity Sensor Young Jin Jung; Eun Hye Kwon and Yeong Don Park; Energy and Chemical Engineering, Incheon National University, Incheon, Korea (the Republic of).

Demand for portable gas sensors capable of monitoring the atmospheric environment in daily life is growing as air pollution deteriorates. Organic field-effect transistors (OTFTs) are regarded as an ideal flexible platform for creating portable, lightweight, and robust sensor devices. OTFTs are sensitive to physical and chemical stimuli because small interactions between a semiconductor and a target analyte amplify the electrical signal of a transistor device via the field-effect mobility, drain current, and threshold voltage. However, organic transistors inevitably suffer from poor stability and bad electrical properties, resulting in a slow response and recovery of the sensor device. We attempted to address this issue by developing an OTFT-based humidity sensor, in which a humidity-capturing material was inserted into the polymeric semiconductor. In this study, a facile, reliable, fast-response, highly sensitive poly(3-hexylthiophene-2,5-diyl) (P3HT)-based humidity sensor was developed by introducing metal organic frameworks (MOFs), HKUST-1, into the semiconducting layer. HKUST-1 displayed an excellent ability to capture water molecules, thereby generating and attracting charge carriers derived from water molecules present in the active layer. The HKUST-1/P3HT hybrid film showed excellent device sensitivity with an enhanced electrical current and a threshold voltage shift as a function of the relative humidity due to the superior gas capture properties and the porosity of HKUST-1. The surface energy of the substrate altered the distribution and location of HKUST-1 in the active layer, which improved the sensitivity of the hydrophilic surface. A dynamic gas sensing test revealed that the hybrid film displayed a reliable and stable performance with fast response and recovery times. The introduction of MOFs into a conjugated polymer stabilized and sensitized the devices, providing a facile method of improving gas sensor technologies based on organic semiconductors.

EP05.03.04

Tuning Electrical Properties of Phenanthroimidazole Derivatives to Construct Multifunctional Deep-Blue Electroluminescent Materials Zelin Zhu; City University of Hong Kong, Hong Kong, Hong Kong.

The maturity of longer wavelength emitters (green and red) makes it more urgent to develop high performance deep-blue emitters OLED (organic light-emitting diodes). A blue emitter that can serve as a multi-functional material (e.g. as host for the green and red counterparts) is of high interest in this field. We introduce a n-type group, TPP0 (triphenyl phosphine), to the N1-position of violet-blue fluorophore phenanthroimidazole (PI) and successfully develop one deep-blue (TPAPOPI) and two violet-blue emitters (3-CzPOPI and CzBPPOPI) for OLEDs (organic light-emitting diodes). With highly twisted linkage, the TPP0 group shows negligible influences on their photophysical properties of the new materials and the materials inherit high efficient deep-blue, light and violet-blue emission of the PI unit and its C2-connected arylamine skeletons. Meanwhile, TPP0 group can open a new channel to transport electron. The electron injection and transport abilities of the developed emitters are enhanced. Non-doped devices using the 3-CzPOPI and the CzBPPOPI emitters exhibit EQE_{max} (external quantum efficiency) of 5.08% and 4.42% with CIE (Commission Internationale de l’Eclairage) coordinates of (0.156, 0.051) and (0.157, 0.071), respectively. Similar efficiencies and even deeper blue emissions (CIE = 0.050 for 3-CzPOPI and 0.044 for CzBPPOPI) were observed in OLEDs with these emitters doped in 4,4’-bis(N-carbazolyl)-1,1‘-biphenyl. TPAPOPI is demonstrated to be a multifunctional deep-blue emitter and presents impressive performances when serving as non-doped (EQE_{max} = 6.69%, CIE = (0.152, 0.095), doped (EQE_{max} = 6.61%, CIE = (0.154, 0.068)) as well as a high-performance host for yellow phosphorescent OLED. By doping a yellow phosphorescent dye (PO-01) into a TPAPOPI host, a white OLED with a high EQE of 20.3% and a low driving voltage of 3.2 V (at 1,000 cd m^{-2}).

Silicon Phthalocyanines—From Multifunctional Ternary Additives in OPVs to High Performing N-Type Semiconductors in OTFTs Benoit Lessard; Nicole Rice and Brendan Mirka; Chemical & Biological Engineering, University of Ottawa, Ottawa, Ontario, Canada.

Phthalocyanines (Pcs) are among the oldest commercial dyes used as industrial pigments and photoreceptors. Their optical properties, stability, and ease of synthesis have made them ideal as active materials for a plethora of optoelectronic applications.[1] Silicon phthalocyanines (SiPcs) have two axial bonds originating from the Si atom, which can serve as functionalization sites without affecting the inherent optoelectronic properties of the phthalocyanine macrocycle itself. Therefore, we have used the axial groups as handles to improve solid state engineering and improve charge transport through the thin films.[2,3] We fabricated planar heterojunction organic photovoltaic devices (PHJ) by physical vapour deposition and used the SiPc derivatives as both donor and acceptor layers, illustrating the ambipolar behavior of these molecules.[2,3] Through solid state engineering we were able to improve the overall efficiency by >40% compared to the unsubstituted C12-SiPc. These preliminary OPV devices surpassed performances by similar PHi devices made using typical copper, aluminum and zinc (CuPc, AlPc, and ZnPc).

Similar chemistry produced solution processable SiPc-based ternary additivies for P3HT:PC61BM bulk heterojunction OPVs with increased photo generation at the interface, which translates to a 20% increase in overall efficiency.[4,5] When replacing PC61BM directly, the SiPc derivatives resulted in devices with similar power conversion efficiency (PCE).[5] Recently we have reported the use of a multifunctional SiPc ternary additive that not only increase the efficiency of the OPV but also increases the stability by migrating to the interface and crosslinking the P3HT and PC61BM domains.[6] These studies are showing potential for SiPcs in OPVs as multifunctional additives which simultaneously enhance device performance and device stability. Finally, we are fabricating high performing n-type organic thin film transistors based on these SiPc derivatives. Processing parameters, such as deposition rate, substrate temperature and surface modification can improve the electron mobility by 2-3 orders of magnitude.[7] Again through SiPc functionalization for targeted solid state engineering we were able to develop high performing n-type SiPc based OTFTs with a mobility of >0.5 cm^2 V^{-1} s^{-1} – Currently the highest performing n-type Pc based thin film device.[8] Computational studies further demonstrate the potential of these versatile molecules.[9] Results from recent and upcoming publications will be presented.

Each interface for organic light emitting diodes (OLEDs) plays a determinant role in the device performances and lifetimes. Thus, there has been lots of interest on interfaces in OLEDs for the critical insight of the fundamental parameters affecting efficiency as well as operational lifetime. Despite decades of research in interface engineering, OLEDs cannot show their full potential because of the lack of technology to maximize their interfacial stability. In other words, the poor lifetime caused by efficiency reduction resultant from the charge imbalance and a resultant chemical degradation by accumulated charge carrier at their interfaces has still been the most problematic issues for the realization of dominant use of OLEDs in the display as well as lighting applications.

In this study, we have introduced a unique technology to improve the device efficiency as well as stability via interface modification. In other words, when charges are injected into emitting layer (EML) [i.e., from the hole transport layer (HTL) and the electron transport layer (ETL)], charges are accumulated on both interfaces of EML due to the charge injection barrier. From this result, the deterioration of the interface characteristics is known to proceed by such accumulated charges. To minimize this interfacial degradation, the accumulated charges at the interfaces of EML should be reduced. Herein, we propose a methodology to release the interfacial degradation by inserting ultrathin interface tunneling layer (ITL) ~1 nm for lowering the effective barrier at the interfaces of EML. Fortunately, ITL could work as an exciton confine layer due to its high triplet energy ($T_1 > 2.7$ eV) so that we could realize highly efficient green phosphorescent OLEDs (PHOLEDs) (EQE: 21.0 %) as well as much longer device lifetime (~ 2.5 times).

For shortwave infrared (SWIR) photodiodes in which the effective bandgap is reduced to < 1 eV, poor dissociation of charge-transfer (CT) excitons and low internal electrical field are detrimental to the external quantum efficiency (EQE) of SWIR photodiode. In this work, we show that high dielectric constant reduces the binding energy of CT excitons and improves mobility of charge carriers in organic bulk heterojunctions (BHJ). By mixing 15% camphoric anhydride into the BHJ, the dielectric constant and the overall performance of SWIR photodiodes are increased in the exciton dissociation and charge collection steps. After incorporating the high dielectric-constant additive, transient photocconductivity measurements indicate lower recombination loss and electrochemical impedance spectroscopy show that the trap density is reduced, and the effective lifetime of mobile carrier increases. The SWIR BHJ photodiode is optimized to reach a detectivity ~ 1013 Jones with spectral range up to 1550 nm. The devices are integrated into a 4 by 4 pixel array to demonstrate a SWIR imager, which is capable of spectral analysis to distinguish tissues, such as differentiating between fat and muscle for the future goal of medical imaging.

Suppressing Dark Current in Organic Phototransistors Featuring a MoOx Layer

Ren Shidachi, Hiroaki Jinno, Sunghoon Lee, Tomoyuki Yokota and Takao Someya; Department of Electrical Engineering and Information Systems, The University of Tokyo, Tokyo, Japan.

Organic photodetectors have attracted wide interest for their flexibility, solution processability, and ability to detect a broad range of light. Recently a number of researches were done on organic phototransistors (OPTs) due to their high responsivity. One of the problem using OPT in applications was their high dark current. Some reports have integrated OPT with an extra circuit in order to overcome this problem [1,2]. Here we present an OPT with low dark current while maintaining its high responsivity. We were able to suppress the dark current under four orders of magnitudes, by using a hole selective layer, by using the source/drain contact on a n-type semiconductor. The responsivity of our OPT was over 0.2 A/W under illumination of light with the power density of 0.5 mw/cm². OPT using 10 nm of MoOx as source/drain contact was fabricated. Poly[2-methoxy-5-(3',7'-dimethyloctyloxy)-p-phenylene vinylene] (OC12C10-PPV) and [6,6]-Phenyl-C61-Butyric Acid Methyl Ester (PCBM) with 80 wt% of PCBM content was used as an BHJ active layer. The dark current of OPT was showed quite lower tensile strength (0.68 MPa) and higher elongation at break (141%) than a poly(3-hexylthiophene) pristine film.

Blue-Emitting, Single-Benzene Fluorophore Based on Push-Pull Structure

Taek Seung Lee and Eunbee Cho; Chungnam National Univ, Daejeon, Korea (the Republic of).

Conjugated and rigid structure in organic molecules is essential to exhibit fluorescence. Accordingly, benzene has been widely employed to impart rigidity and extend the conjugation within molecular structure. One or more number of benzene is required to show efficient fluorescence, but many benzene rings in a molecule give a negative effect such as fluorescence quenching because of pi-pi interaction in the solid state. A single benzene-based fluorescent molecules will be a good candidate, which can be applied usefully in many fields, including bioimaging and optoelectronic devices, because aggregation-caused quenching can be easily prevented. Substituents on the benzene ring can affect the fluorescence property of the molecule. The formation of electronic push-pull system by introduction of electron donating and withdrawing group enables the single-benzene molecule to exhibit high fluorescence. We will discuss a blue emissive single-benzene molecule with push-pull structure which was easily synthesized. Various molecules with different structure and extend the conjugation within molecular structure. One or more number of benzene is required to show efficient fluorescence, but many benzene rings in a molecule give a negative effect such as fluorescence quenching because of pi-pi interaction in the solid state. A single benzene-based fluorescent molecules will be a good candidate, which can be applied usefully in many fields, including bioimaging and optoelectronic devices, because aggregation-caused quenching can be easily prevented. Synthesis of Polythiophene Derivatives with Oligoisobutylene Side Chains and Their Cross-Linking System

Satoshi Miyang and Tomoya Higashihara; Yamagata University, Yonezawa, Japan.

In recent years, polymer semiconductors have received much attention due to their mechanical flexibility and solution-based low-cost processability. However, their durability for stretched stress is not enough for applying to wearable and implantable devices. The low strechability of polymer semiconductor is due to high crystallinity which induced their stiff main chain and strong intermolecular interactions. Here, we developed novel polythiophene derivatives, P3IBTs, which contain oligoisobutylene units in their side chains. We expect that several branched points on side chains weaken pi-pi stacking interaction and thereby decrease crystallinity of the polymers. In addition, we tried to develop cross-linked P3IBT to realize the formation of an inherently stretchable polymer semiconductor. We prepared polythiophene derivatives with disobutylene side chain (P3IB2T) (Mn = 12,000, Mw/Mn = 1.17) and triisobutylene side chain (P3IB3T) (Mn = 13,000, Mw/Mn = 1.21) by Kumada catalyst-transfer polycondensation. Their thermal, optical properties and crystalline nature were also investigated. The melting temperature of P3IB2T was determined by DSC, showing a distinct endothermic peak for Tm at 130 °C. On the other hand, there are neither endothermic nor exothermic peaks in the DSC curve of P3IB3T. Therefore, this polymer would be more amorphous-like than P3IB2T.

The absorption spectrum of P3IB2T film showed low absorption intensity around 620 nm, indicating weak pi-pi stacking interaction. Moreover, P3IB3T films showed the blue-shifted absorption spectrum compared to P3IB2T ones probably due to larger torsion of main chains affected by triisobutylene side chain.

Next, the crystalline nature of the polymer thin films was evaluated by Grazing incidence wide-angle x-ray scattering (GIWAXS). P3IB2T and P3IB3T films showed edge-on orientation, judged from the azimuth plots of (200) diffraction patterns. Moreover, (010) diffraction patterns were not observed for P3IB2T and P3IB3T films, probably due to less pi-pi stacking interaction by oligoisobutylene side chains.

Finally, we cross-linked P3IB3T to realize the formation of an inherently stretchable polymer semiconductor. 4,4'-Methylenebis(2,6-bis(methoxymethyl)phenol) and isopropl p-toluenesulfonate were used as cross-linker and thermal acid generator, respectively. The cross-linked P3IB3T showed quite lower tensile strength (0.68 MPa) and higher elongation at break (141%) than a poly(3-hexylthiophene) pristine film.

Decatacontic C20> Nanoconjugates with Light-Harvesting Antenna and Intramolecular Electron-Transfer Processes for Photodynamic Bio-Applications

He Yin, Min Wang and Long Y. Chiang; Chemistry, University of Massachusetts Lowell, Lowell, Massachusetts, United States.
Functionalized fullerenes with retaining photophysical characteristics show promising light harvesting ability, and may have potential for photovoltaic applications. We recently reported a conjugated fullerene derivative C60[>CPAF-(MN6+C3)2-(I−)10] (LC15) with less steps and higher yield. As C60 is replaced by more effective C70 which has broader absorption, the covalent conjugation of a visible light-harvesting antenna moiety CPAF and C70 provides broad photo-absorption from 300–650 nm. The ability of the electron-rich CPAF antenna to undergo intramolecular photoexcited electron-donation to the C70 electron-acceptor cage in LC21 allows the dominant of the anionic (C70*) radical which can lead to the generation of superoxide radicals, and facile intersystem crossing efficiency from the fullerenyl singlet excited state (C70*) to its long-lived triplet excited state (C70**). The similarity of the spectra of LC15 and LC21 with less steps and higher yield, as C60 is replaced by more effective C70 which has broader absorption, the covalent conjugation of a visible light-harvesting antenna moiety CPAF and C70 provides broad photo-absorption from 300–650 nm. The ability of the electron-rich CPAF antenna to undergo intramolecular photoexcited electron-donation to the C70 electron-acceptor cage in LC21 allows the dominant of the anionic (C70*) radical which can lead to the generation of superoxide radicals, and facile intersystem crossing efficiency from the fullerenyl singlet excited state (C70*) to its long-lived triplet excited state (C70**). while maintaining self-cleaning properties from extreme water repellency and showing good thermal stability. This study provides a practical solution to enhance the reliability of organic devices in the natural environment.

EP05.03.18
Near Infrared-to-Blue Photon Upconversion Based on Singlet-to-Triplet Direct Transition Yoichi Sasaki1, Nobuhiro Yanai1, 2 and Nobuo Kimizuka1, 2; 1Department of Chemistry and Biochemistry, Graduate School of Engineering, Kyushu University, Fukuoka, Japan; 2Center for Molecular Systems (CMS), Kyushu University, Fukuoka, Japan.

The efficient use of near-infrared (NIR) light has been much coveted in energy and biological applications. For example, although the NIR light from 700 nm to 900 nm shows good tissue transparency, the photon energy in this region is too weak for important biological applications such as bioimaging, photodynamic therapy, and drug release. The blue light with a wavelength shorter than 500 nm is known to trigger drug release and in vivo photochemical reactions, and therefore it is imperative to produce such higher-energy visible light under NIR excitation.

Photon upconversion (UC) is a methodology that converts lower-energy photons into higher-energy photons. Triple-triplet annihilation based UC (TTA-UC) is especially promising since it works under weak excitation intensity like sunlight. Despite its importance, it has been difficult to obtain NIR (＞700 nm) to blue (＜500 nm) TTA-UC. This is because the energy loss associated with the intersystem crossing (ISC) of donors limits the use of acceptors with high T1 and S1 energy levels, and consequently the position of the anti-Stokes shift. To maximize the anti-Stokes shift and to achieve the TTA-UC from NIR to blue region, it is essential to develop TTA-UC systems without ISC. Recent efforts have been accordingly devoted to realizing new mechanisms that circumvent the energy loss of ISC such as TADF molecules, QDs, perovskites, and heavy metal complexes. These sensitizers, however, tend to show short excited state lifetime (＜10 ns), and triple-triplet energy transfer (TET) from the sensitizers to acceptor molecules is often inefficient.

In this work, we demonstrate an efficient NIR (＞700 nm)-to-blue (＜500 nm) TTA-UC by judicious developments of new Os(II) bis(terpyridine) complexes with singlet-to-triplet (S-T) direct transition. We achieved NIR-to-blue TTA-UC for the first time with a large anti-Stokes shift of 0.97 eV with a good UC efficiency.

EP05.03.19

Understanding degradation processes in organic solar cells is very important for the development of new materials with improved stability. One of the conventional ways to study the changes induced by the degradation processes is Raman spectroscopy. The main disadvantage of the Raman technique is that the measured signal is an integral over the entire volume of the measured sample. It is especially pronounced when there is an overlap between the Raman spectra over different layers of the solar cells. This is the case when a polyfluorene blend (F8BT:PFB) is the active layer and PEDOT:PSS serves as an electron blocker. To overcome this drawback we use ultra-thin, semi-transparent, layers of gold (4 nm) in between the different layers of the cell. This ultra-thin layer is specifically design to have plasmons around the Raman excitation laser (660 nm). When it is inserted between the ITO and the PEDOT:PSS the Raman signal is dominated by the PEDOT:PSS signal while when it is inserted between the PEDOT:PSS and the polyfluorene blend it is the blend signal that is dominated. Using this technique and monitoring the degradation at short-circuit current condition we observed the following.

Firstly, the time dependence of the surface enhanced Raman signal is monotonic in contrast with the conventional Raman where it is not. Secondly, we were able to separately analyze the degradation of the different layers. We found out that the main peak of the PEDOT:PSS Raman spectrum shifts to the right and its relative height, with respect to the other peaks, decreases which indicates an increase in the resistance of this layer. We also show that for the blend the main damage is done to the BT unit of the F8BT and that mainly affect electron conduction in the device. We believe that this new approach can be used to analyze other organic devices and at different excitation using other metals.

EP05.03.20
Solvent-Vapor-Annealed A–D–A-Type Semicrystalline Conjugated Small Molecules for Flexible Ambipolar Field-Effect Transistors Young Woong Lee1, Min Je Kim1, Yujong Lee1, Jeong Ho Cho3, 2 and Han Young Woo1; 1 Korea University, Seoul, Korea (the Republic of); 2 Sungkyunkwan University, Suwon, Korea (the Republic of); 3 Sungkyunkwan University Advanced Institute of NanoTechnology, Suwon, Korea (the Republic of).

Over the past two decades, many types of conjugated polymers or small molecules (SMs) have been synthesized and utilized as semiconducting materials for organic field-effect transistors (OFETs). To realize the high-performance and flexible OFETs, the fabrication process should be efficiently optimized at a low temperature condition and solvent-vapor-annealing (SVA) is a well-known process for controlling the morphology of SM thin films in ambient condition. In this study, three kinds of acceptor-donor-acceptor (A-D-A) type SM semiconductors were designed and synthesized by introducing different electron-withdrawing endcapping groups of dicyanovinyl (VCN), cyano-rhodanine (RCN) and cyano-indanone (INCN) at both termini, which enables to finely tune the frontier energy levels of semiconducting materials. All the OFETs exhibited ambipolar FET characteristics and SVA treatment changes crystalline structure and FET characteristics of semiconducting films remarkably. The SVA effect depending on the endcapping groups was logically investigated by using a DFT calculation, UV-vis absorption spectroscopy, 2-dimensional grazing incidence x-ray diffraction (2D GIXD), and atomic force microscopy (AFM). The as-coated P3T4-INCN films exhibited the hole mobility of 0.03 cm2V−1s−1 and electron mobility of 0.01 cm2V−1s−1. Finally, the P3T4-INCN OFET performance was significantly enhanced via SVA with chloroform, resulting in the hole mobility of 0.14 cm2V−1s−1 electron mobility of 0.03 cm2V−1s−1 with the good ambipolar charge transport behaviors.

In addition, a flexible OFET array with solvent-vapor-annealed P3T4-INCN was successfully fabricated on the polyethylene naphthalate ( PEN) substrate. This OFET device exhibited the hole mobility of 0.15 cm2V−1s−1 and electron mobility of 0.01 cm2V−1s−1, an on-off current ratio of ~105, and excellent mechanical stability even after 300 bending cycles.

EP05.03.21
Nano composite of Nickel Oxide Nanoparticles and Polyethylene Oxide as Printable Hole Injection Layer for Organic Solar Cells Marta Ruscello1, Giovanni Maria Matrone1, Stefan Schlisske1, Elena Sachs1, Patrick Reiser2, 1 Eric Mankel2, 1 Tanmoy Sarkar4, Basel Shamieh5, Artem Levitski5, Young Linde; Ben Gurion Univ-Negev, Lehavim, Israel.

In the field of organic electronics, rising research attention has been dedicated to the investigation of novel interlayers. A family of materials that has been deserving increasing interest for such purposes is the one of transition metal oxide nanoparticles, which can provide high quality interlayers for both charge injection or extraction. Metal oxide nanoparticles are suitable for solution-processed electronics thanks to many advantages: they can be dissolved in organic solvents and used as printable inks, can be processed at relatively low temperatures and can offer an increased stability compared to conjugated polymers. However, they also present certain technical challenges due to the higher surface to bulk ratio (i.e. surface trap states) or present problems during
film formation (i.e. agglomeration). (1) For this reason, various kinds of polymers can be employed to offer a hybrid solution to these issues. We present here the improvement of the processability of non-stoichiometric nickel oxide (NiOx) nanoparticles ink by blending with high molecular weight polyethylene oxide (PEO). Recently, NiOx has attracted increasing attention as a hole extraction layer in organic and perovskite photovoltaics due to its excellent optical transparency, p-type conductivity and good electron blocking properties. Nonetheless, the fabrication of highly efficient NiOx thin films is challenging due to the low viscosity of the inks or the high sintering temperatures of the precursor compounds. Here, we show how PEO can help dispersing the nanoparticles hindering their aggregation after deposition without compromising film functionality. Through Kelvin Probe, Contact Angle measurement, X-ray Photoelectron Spectroscopy and Transmission Electron Microscopy we observe that the presence of PEO is beneficial for a better tunability of the NiOx film thickness and morphology. We also show that such effect on the film formation is observed to be beneficial when the NiOx:PEO blends are applied as a hole extraction layer on OPV devices, improving device performance. Moreover, the inclusion of the polymer in the nanoparticle ink allows, for the first time, the inkjet-printing of the NiOx layer without requiring high temperature post-treatment. (2) Finally, we verified the possible migration of the PEO used in these devices through the bulk heterojunction towards the cathode (3), defining a dual purpose for the polymers: on one hand passive matrix for the nanoparticles as anode, on the other functionalizer of the cathode.

EP05.03.22
Fast, Efficient Luminescence in Carbene-Cu(I) Complexes and Other Coinage Metals Rasha Hamze1, Jesse L. Peltier1, Rodolphe Jazzar1, Daniel Sylvinson2, Peter I. Djurovich1, Guy Bertrand1 and Mark Thompson2; 1Chemistry, University of California at, California, San Diego, California, United States; 2Chemistry, University of Southern California, Los Angeles, California, United States.

As for long as it has been a subject of study, the luminescence of copper(I) complexes has been plagued by slow, inefficient luminescence. This is a result of two major factors: weak spin-orbit coupling, due to the light metal; and large excited state reorganization energies, associated with a formal oxidation at the d^{10} metal center in MLCT transitions. While the latter culprit can be mitigated by increasing the steric bulk around the metal, addressing the former is a more challenging endeavor. With this in mind, we discuss recent work from our lab, where we have prepared carbene-Cu(I) complexes exhibiting fast (k > 10^6 s^-1), efficient (PLQY = 100%) phosphorescence, with emission colors tuned over the visible spectrum. These results have allowed us to develop new paradigms for designing Cu(I) complexes, and to expand our understanding down the periodic table to Ag(I) and Au(I) complexes. Specifically, I will highlight newly-isolated Au(I) and Ag(I) complexes with remarkable photophysical properties that underscore their potential for OLED applications.

EP05.03.23
Polar-Functionalized Dioxythiophene Polymers as a Platform for Aqueous-Compatible Electrochemical and Bioelectronic Devices Lisa R. Savagian1, Anna Osterholm1, Michel De Keersmaecker2, James F. Ponder3, Graham Collier1 and John R. Reynolds3; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Imperial College London, London, United Kingdom.

There has been increasing interest in developing redox-active polymers capable of electrochemically interfacing with biological systems for sensing and therapeutic applications. As an example, organic electrochemical transistors (OECTs), which have emerged as a highly sensitive in vivo biosensing platform, hinge on bulk transport of aqueous doping ions through conjugated polymer films for stabilizing conducting states and controlling current through the transistor channel. In the pursuit of aqueous-compatible systems, there has been a growing body of work demonstrating how highly polar oligo(ether) side chains enhance the redox activity and ion transport properties of conjugated polymers for use in OECTs. Herein, we present a family of dioxythiophene-based polymers functionalized with side chains spanning a range of polarities, including ester, diester, and oligo(ether) analogues, and explore how factors such as solubility, redox potential, ion transport and stability, and conductivity switching depends on the chemical nature of the substituent side chain. These materials exhibit excellent redox stability in physiologically-relevant electrolytes and can be prepared through straightforward direct (hetero)arylation polymerization chemistries. We evaluate the dynamic electrochemical and optical behavior of these polymers, paying special attention to their potential-dependent mixed ionic/electronic conductivities using techniques such as electrochemical impedance spectroscopy, and demonstrate their utility in aqueous-based electrochemical devices. Through these studies, we aim to establish important structure-property relationships for exploring the materials design space of side chain polarity for high-performing bio-electrochemical devices.

EP05.03.24
Lactam Containing Two Isomeric Polymers For OPVs with High Open-Circuit Voltages Jong-Woon Ha and Do-Hoon Hwang; Pusan National University, Busan, Korea (the Republic of).

The molecular design of the wide bandgap (WBG) is important for non-fullerene polymer solar cells to obtain simultaneously high power conversion efficiency (PCE) and open circuit voltage (V_{oc}). In this study, we developed two isomeric lactam acceptor, thieno[3,2-c]quinolin-4(3H)-one (TQO) and thieno[3,2-c]isoquinolin-5(4H)-one (TIQO), to compare their optical and electrical properties. The WBG donor-acceptor (D-A) type polymers, PBDT-TQO and PBDT-TIQO, were synthesized using the 4,8-bis(5-(2-ethylhexyl)thiophen-2-yl)benzo[1,2-b:4,5-b']dithiophene (BDT) as electron donor building block and TQO or TIQO as electron accepting building block for fullerene and non-fullerene organic solar cells. PBDT-TQO and PBDT-TIQO showed absorption range below 600 nm and low-lying HOMO energy levels. The appropriate match of the energy levels between donors and acceptors could be applied for fullerene and non-fullerene OSC. PCEs of the devices based on PC_{71}BM achieved 3.02 % for PBDT-TIQO:PC_{71}BM and 3.92 % for PBDT-TIQO:PC_{61}BM, respectively. For better photovoltaic performances, the devices based on polymer:non-fullerene acceptor (ITIC or IT-4F) were fabricated. A PCE of PBDT-TIQO:ITIC of 7.62 %, while the device of PBDT-TIQO:ITIC was afforded PCE of 6.56 % thanks to increase short-circuit current density (J_{sc}) and open-circuit voltage (V_{oc}).

EP05.03.25
Ion Transport and Reaction Kinetics on the Operation of AC-Driven Electrochemiluminescence Devices Jong Ilk Lee1, Hyunwoo Jo1, Dongwon Kang2, Seok Hwan Kong1, Hyoig Gim1, Ik-Soo Shin3, Jongwook Kim2 and Moon Sung Kang1; 1Department of Chemical Engineering, Soongsil University, Seoul, Korea (the Republic of); 2Department of Chemical and Biomolecular Engineering, Sogang University, Seoul, Korea (the Republic of); 3Department of Chemistry, Soongsil University, Seoul, Korea (the Republic of).

Electrochemiluminescence (ECL) is light emission from redox precursors generated through a series of electrochemical processes. This process can be exploited in fabricating a light-emitting device, which is referred to as the electrochemiluminescence device (ECLD). Unlike conventional solid-state light-emitting device, the operation of ECLDs relies on mass transport of the luminophores and electrochemical electron transfer reactions; the oxidative and reductive forms of ECL luminophores have to encounter to form the excited states before emitting light eventually. Herein, we investigate the influence of these dynamic factors on the emission characteristics of AC-voltage driven ECLDs. Benchmark ionic transition metal complex ECL luminophore and ionic liquids are used as the ECL luminophore and the electrolyte materials, respectively, for our model device. The dynamic processes in the ECLD could be
simple modeled using i) the Fick’s law to describe the diffusion process near the electrode, ii) the first order reaction of the ECL luminophore at the electrode, and iii) the second order chemical reaction between the reduced/oxidized luminophores, based on the associated reaction constant and the diffusion constant obtained from separate electrochemical analysis techniques, respectively. The model yielded transient ECL intensity profile of the device under a single switching cycle of an AC electrical input which matched well with experimental results. Moreover, the time-averaged values of the transient profiles matched with the characteristic operational frequency-dependent ECL properties of the device, which initially increase with increasing frequency but then peak and decrease at higher frequencies. Using the model giving well-matching results to the experimental observations, the influence of diffusion and the reaction rates on the performance of an ECLD could be analyzed separately and systematically, which is difficult to carry out from experiment. The fundamental understanding on the operation of this emerging class of light-emitting device platform provides practical guidelines to advance its performances.

Dynamics of Charge Distribution and Emission Zone in Sandwich Light-Emitting Electrochemical Cells Roland Hany: EMPA, Duebendorf, Switzerland.

In contrast to the multiple layers required for a state-of-the-art organic light-emitting diode, light-emitting electrochemical cells (LECs) are usually built from a single emissive layer that contains an electrolyte and is sandwiched between two electrodes. Due to the presence of mobile ions, the single layer can perform all the tasks that take place in an electroluminescence device, i.e. facile electrical charge injection, transport, exciton formation and radiative recombination. The LEC device concept sounds simple, but in truth it’s not easy at all; despite twenty years of research, resolving the dynamics of the injected electrical charge as well as identifying the zone where light is emitted in sandwich devices present considerable scientific challenges. Here, we study the temporal evolution of organic salt-based LECs and demonstrate that electroabsorption spectroscopy in combination with electrical capacitance measurements enables the determination of the distribution of the injected, uncompensated electronic charge inside these devices. For constant-voltage operating conditions and over a period of hours, the Stark effect signal intensity and the capacitance increase steadily, but to a different extent. We demonstrate that this difference sensitively depends on the position and distribution width of injected mobile charges. Estimates show a substantial spreading over the active layer of the injected charge density with time, screening the electric field behind the charge peak [1].

We also studied how the p- and n-doped regions and the intrinsic (i) emission zone evolve over time [2]. By analysing incident photon-to-current conversion efficiency and angular emission measurements with optical simulations, and correlating the results with capacitance measurements, we were able to obtain a clear picture of the p-i-n situation and the emission zone of cyanine dye LECs. The spectral photocurrent response analysis in [2] was possible because of the high photocurrent response of this type of LEC. Indeed, we recently observed efficient photoinduced charge generation in the bulk of pristine cyanine dye films with internal quantum efficiency exceeding >40% [3]. We report on this unusual behavior because intrinsic photogeneration of charge carriers in organic semiconductors is generally attributed to high energy ionization or exciton dissociation by a strong electric field.

Structural Evaluation of 5,5′-Bis(naphth-2-yl)-2,2′-bithiophene in Organic Field-Effect Transistors with n-Octadecyltrichlorosilane Coated SiO2 Gate Dielectric Andreas E. Lauritzen1, 2, Mika Torkkeli1, Oier Bikondoa3, 4, Jes Linnet5, 6, Luciana Tavares6, Jakob Kjelstrup-Hansen1 and Matti Knaapila1, 4; 1Department of Physics, Technical University of Denmark, Kgs. Lyngby, Denmark; 2Department of Physics, University of Oxford, Oxford, United Kingdom; 3XMaS, The U.K.-CRG Beamline, European Synchrotron Radiation Facility, Grenoble, France; 4Department of Physics, University of Warwick, Coventry, United Kingdom; 5Center for Nano Optics, Mads Clausen Institute, University of Southern Denmark, Odense, Denmark; 6NanoSYD, Mads Clausen Institute, University of Southern Denmark, Soenderborg, Denmark.

We report on the structure and morphology of 5,5′-bis(naphth-2-yl)-2,2′-bithiophene (NaT2) films in bottom-contact organic field-effect transistors (OFETs) with octadecyltrichlorosilane (OTS) coated SiO2 gate dielectric, characterized by atomic force microscopy (AFM), grazing-incidence X-ray diffraction (GIXRD) and electrical transport measurements1. Three types of devices were investigated with the NaT2 thin-film deposited either on (1) pristine SiO2 (corresponding to higher surface energy, 47 mJ/m2) or on OTS deposited on SiO2 under (2) anhydrous or (3) humid conditions (corresponding to lower surface energies, 20-25 mJ/m2). NaT2 films grown on pristine SiO2 form nearly featureless 3-dimensional islands. NaT2 films grown on OTS/SiO2 deposited under anhydrous conditions form staggered pyramid islands where the interlayer spacing corresponds to the size of the NaT2 unit cell. At the same time, the grain size measured by AFM increases from hundreds of nanometers to micrometers and the crystal size measured by GIXRD from 30 nm to more than 100 nm. NaT2 on OTS/SiO2 deposited under humid conditions also promotes staggered pyramids but with smaller crystals (30 – 80 nm). The NaT2 unit cell parameters in OFETs differ 1 – 2% from those in bulk. Carrier mobilities tend to be higher for NaT2 layers on SiO2 (2 – 3×10-3 cm2/Vs) compared to NaT2 on OTS (2×10-4 – 1×10-4 cm2/Vs). An applied voltage does not influence the unit cell parameters when probed by GIXRD in operando.

EP05.03.28

Self-assembled monolayers (SAMs) formed using N-heterocyclic carbene (NHCs) have recently emerged as thermally and chemically ultra-stable alternatives to those formed from thiols. The rich chemistry and strong σ-donating ability of NHCs offer unique prospects for applications in...
nanelectronics, sensing and electrochemistry. Though stable in SAMs, free carbenes are notoriously reactive, making their electronic characterization challenging. Here we report the first investigation of electron transport across single NHC-bound molecules using in situ STM imaging and large-area printing methods. We develop a series of air-stable metal NHC complexes that can be electrochemically reduced in situ to form NHC–electrode contacts, enabling reliable single-molecule conductance measurements of NHCs under ambient conditions. Using this approach, we show that the conductance of an NHC depends on the identity of the single metal atom to which it is coordinated in the junction. Our observations are supported by density functional theory (DFT) calculations, which also firmly establish the contributions of the NHC linker to the junction transport characteristics.

Our work demonstrates a powerful method to probe electron transfer across NHC–electrode interfaces; more generally, it opens the door to the exploitation of surface-bound NHCs in constructing novel, functionalized electodes and/or nano electronic devices.

**A Novel Hole-Blocking Material of Four Pyridylbenzene-Connected Terphenyls for Highly Sensitive and Thermally Stable Organic Photodiodes and Radiation Detectors**

Atsushi Wada, Issa Takasu, Satomi Taguchi, Yoko Nomura, Kohei Nakayama, Fumihiko Aiga and Rei Hasegawa; Toshiba Corporation, Kawasaki, Japan.

Organic photodiodes (OPDs) have attracted attention with a view to their application in radiation detectors and image sensors owing to their potential advantages of high sensitivity, large-area sensing, light weight and flexibility. To realize high sensitivity, the OPDs need to achieve high external quantum efficiency (EQE) and low dark current simultaneously. We have previously reported the OPDs with boron-subphthalocyanine chloride (SubPC) and pentafluorophenyo-substituted SubPC (F5-SubPC) as a photoelectron conversion layer and bathocuprone (BCP) as a hole-blocking layer, which exhibit high EQE (70% at 530 nm) and low dark current (0.03 nA/cm²). These properties are comparable to those of the Si photodiodes. However, the thermal stability of the OPDs is low, and EQE was reduced from 70% to 33% by thermal treatment at 150°C. Here, we report a novel hole-blocking material, tetra(pyridyl-4-phenyl)-terphenyl (Tp4), and the OPDs with Tp4. The thermal stability of the OPDs is improved significantly while maintaining their high EQE and low dark current.

Tp4 is designed to have deep HOMO energy level and high thermal properties. Tp4 consists of four pyridine rings and seven benzene rings. Because pyridine rings are electron-deficient, Tp4 is expected to have deep HOMO energy level and block the hole injection from the anode. Furthermore, it is reported that pyridine rings can coordinate with metal from the electrode and the pyridine-metal complex can form gap states between HOMO and LUMO energy levels of hole-blocking material, which promote transport of the electron to the anode. Because the molecular weight of Tp4 (843) is much larger than that of BCP (360), the improvement of thermal properties are also expected. Tp4 was synthesized by Suzuki cross-coupling reaction, and then purified by sublimation. The HOMO and LUMO energy levels of Tp4 are 6.5 eV and 3.0 eV, respectively, which are the same as those of BCP. The glass transition temperature (Tg) of Tp4 is not observed until 300°C and melting temperature (Tm) is 412°C, which are much higher than those of BCP (Tg:80°C, Tm:279°C). Next, we fabricated OPDs with Tp4, and the device structure is follows:ITO electrode/buffer layer/electron-blocking layer/SubPC+F5-SubPC/Tp4/Al electrode. By optimizing the thickness of Tp4, the OPDs exhibit high EQE (70% at 530 nm) and low dark current (0.01 nA/cm²). The OPDs with Tp4 have demonstrated higher performance than the previously reported OPDs with BCP. Furthermore, the thermal stability of the OPDs with Tp4 is enhanced significantly, and they still exhibit high EQE of 61% after thermal treatment at 150°C. In the presentation, we will also report the results of radiation with the OPDs.

In summary, a novel hole-blocking material that has the same HOMO and LUMO energy levels as BCP and higher thermal properties than BCP has been developed. The OPDs using this material have demonstrated high EQE, low dark current and high thermal stability.

**Directional Printing of Conjugated Polymer Semiconductors for High Performance Organic Field-Effect Transistors and Circuits**

Jung Jiyun and Kang-Jun Baeg; Pukyong National University, Busan, Korea (the Republic of).

Printed and flexible electronics based on soluble conjugated organic molecules have drawn tremendous interest as a new paradigm for the fabrication of large-area and low-cost optoelectronics and electronics applications. Those polymers should be preferably aligned in the perpendicular direction through the active channel of organic field-effect transistors (OFETs). Morphological control and structural ordering of the conjugated polymers via large area printing methods is an important issue in order to achieve high performance OFETs and its electronic circuitry. In this study, we report various directional printing methods (off-centered spin-coating, dip-coating, and bar-coating) for preferable arrangement of conjugated polymers, such as high mobility PCDTFTBT and DPPT-TT. Those polymer OFETs showed high charge carrier mobilities as high as 11 cm²V⁻¹s⁻¹ and balanced ambipolar charge transport behavior in the top-gated OFET structure with polymer dielectrics. This remarkable enhancement is mostly attributed to improved alignment and ordering of polymer chains through the active channel and better uniformity of OFET parameters is also obtained by this large-area printing techniques. Moreover, high-k fluorinated polymer dielectrics significantly contribute to increase high charge carrier density under low voltage conditions. Finally, higher mobilities and well-balanced P-channel and N-channel characteristics in comparison to conventional coating methods was successfully applied to develop complementary-like printed circuits, it is expected to be realize high performance flexible and wearable electronic devices via cost-effective simple printing methods.

**A Sky Blue Thermally Activated Delayed Fluorescent (TADF) Emitter Realizing Efficient White Light Emission Through In Situ Metal Complex Formation**

Yuki Kato1, Hisahiro Sasabe1,2,3, Yuya Hayasaka1, Yuichiro Watanabe1 and Junji Kido1,2,3; 1Organic Materials Science, Yamagata University, Yonezawa, Japan; 2Research Center for Organic Electronics, Yamagata University, Yonezawa, Japan; 3Frontier Center of Organic Materials, Yamagata University, Yonezawa, Japan.

In this work, we have developed a pyrazine/acridine based thermally activated delayed fluorescence (TADF) emitter named 2,6-bis[4-(9,9-dimethyl-9,10-dihydroacridine)-phenyl]pyrazine (2Ac-PRZ) for organic light-emitting devices (OLEDs). This emitter has a metal coordination ability to form a metal complex via in situ deposition of copper iodide (I) (CuI). The neat film of 2Ac-PRZ showed sky blue emission with a peak at 463 nm, and the photoluminescence quantum yield (PLQY) of 17%. On the other hand, when CuI was doped into 2Ac-PRZ layer, the doped layer showed white emission with dual emission peak at 463 nm and 583 nm with PLQY up to 34%. We used this co-deposited layer of 2Ac-PRZ/CuI as an emissive layer (EML) in OLEDs. We fabricated OLEDs with a structure [ITO/ triphenylamine-containing polymer: 4-isopropyl-4′-methyldiphenyl-iodonium tetra(pyridyl-4-phenyl)-terphenyl (Tp4)/LiF (0.5 nm)/Al (100 nm)]. The device showed white emission with a CIE of (0.41, 0.45), and very high photoluminescence quantum yield (PLQY) of 17%. On the other hand, when CuI was doped into 2Ac-PRZ layer, the doped layer showed white emission with dual emission peak at 463 nm and 583 nm with PLQY up to 34%. We used this co-deposited layer of 2Ac-PRZ/CuI as an emissive layer (EML) in OLEDs. We fabricated OLEDs with a structure [ITO/ triphenylamine-containing polymer: 4-isopropyl-4′-methyldiphenyl-iodonium tetra(pyridyl-4-phenyl)-terphenyl (Tp4)/LiF (0.5 nm)/Al (100 nm)]. The device showed white emission with a CIE of (0.41, 0.45), and very high photoluminescence quantum yield (PLQY) of 17%.
Carrier transport materials such as hole and electron transport materials (HTMs and ETMs) play a key role in determining organic light-emitting device (OLED) performances, such as driving voltage, efficiency and operation lifetime. A representative HTM for OLEDs is α-NPD that exhibits relatively high glass transition temperature ($T_g$) of 100 °C[1], and moderate hole mobility of $8.8 \times 10^{-4}$ cm²/Vs among reported HTMs. In this work, we developed a novel series of HTMs aiming higher thermal stability and higher hole mobility than those of α-NPD by introducing [1]thiazolo[3,2-b][1]benzothiophene (BBTBT) moieties. BBTBT is famous in organic field effect transistor (OFET)[1,2], and has realized excellent hole mobility for OFET applications. A novel HTM containing BBTBT showed superior thermal stability with $T_g$ of 155 °C, and good hole transport property in OLEDs. An OLED with a structure of [ITO/2,3,6,7,10,11-Hexacyano-1,4,5,8,9,10-hexaazatriphenylene (HATCN)/novel HTM/9,9'-diphenyl-9H,9'H-3,3'-bicarbazole (BCzPh)/tris(2-phenylpyridinato)iridium(III) (Ir(ppy))3-doped BCzPh/3,3',5,5'-tetra(3-pyridyl)-1,1',3',1''-terphenyl (B3PYPB)/8-quinolinolato lithium (Liq)/Al] were fabricated. The device exhibited driving voltage of 3.7 V and EQE of 17% at 1000 cd/m². These performances suggest the potential usefulness of these HTMs for OLEDs.

EP05.03.33
Stable Solution-Processed Small-Molecule Phosphorescent Tandem Organic Light-Emitting Devices Tatsuya Takahashi[1], Satoru Ohisa[1,2,3], Masahiro Igarashi[1,2,3], Hitoshi Fukuda[1], Tatsuya Hikichi[1], Eri Ueki[1], Takayuki Chiba[1,2,3], Yong-Jin Pu[1,2,3] and Junji Kido[1,2,3]; Graduate School of Organic Materials Science, Yamagata University, Yonezawa, Japan; 2Research Center for Organic Electronics (ROEL), Yamagata University, Yonezawa, Japan; 3Frontier Center for Organic Materials (FIRM), Yamagata University, Yonezawa, Japan.

Recently, solution-processed polymer tandem organic light-emitting devices (OLEDs) comprising multiple light-emitting units connected by carrier generation layers have been reported as a promising way to realize long lifetime solution-processed OLEDs [1, 2]. However, those both with high device efficiency and long lifetime have been reported yet. In this work, we report the development of a stable solution-processed small-molecule phosphorescent tandem OLEDs, in which ten-layers were formed by solution-processing. We newly developed solvent-tolerant small molecule host materials with indolocarbazole, phenylcarbazole, and triazine units for phosphorescent EML. These materials showed high tolerance to methanol solvents. The upperlayer material on the EML is ZnO nanoparticle (NP), and it should be dispersed in methanol. The surface condition of the ZnO NPs was tuned to disperse them in methanol by modifying the conventional synthetic procedure. As a result, we succeeded in fabrication of solution-processed small-molecule orange phosphorescent tandem OLED comprising two light-emitting units. At a nominal luminance of 1000 cd/m², the driving voltages were 5.2 V for the 1st unit device, 5.1 V for the 2nd unit device, and 10.7 V for the tandem device, respectively. The driving voltage of the tandem device was almost similar to the sum of the 1st and the 2nd unit devices. The external quantum efficiency of the tandem OLED at 1000 cd/m² was 25.2% under Lambertian assumption. The device stability of the two kinds of single units and the tandem device were evaluated at a constant current density of 2.5 mA/cm² corresponding to initial nominal luminances of 520 cd/m² for the 1st unit device, 340 cd/m² for the 2nd unit device, and 1240 cd/m² for the tandem device, respectively. The times to 70% of the initial luminances were 75 h for the 1st unit device, 57 h for the 2nd unit device, and 68 h for the tandem device, respectively. Considering much higher luminance of the tandem device than the others, the tandem device obviously showed much longer device lifetime than the others.

Polymeric Composite Dielectrics for Flexible Organic Field-Effect Transistors and Pressure Sensors with Low Voltage Operation Qingdong Zheng; FJRSM, Chinese Academy of Sciences, Fuzhou, China.

Organic field-effect transistors (OFETs) could offer a significant potential for flexible pressure sensors based on them. However, the achievement of both low-voltage operation and high sensitivity remains a challenge for OFET-based pressure sensors. In this presentation, novel polyacrylic acid containing composite dielectrics are demonstrated for flexible OFETs and ultra-sensitive pressure sensors with low voltage operation. The OFETs using the composite dielectrics showed remarkably improved electrical performance under a much lower operating voltage of than those with a pristine polyacrylic acid dielectric. The OFETs also reveal excellent flexibility and bending stability during mechanical tests with different bending radii and cycles. Based on the dielectric and the OFET performance, flexible OFET-based pressure sensors with both low-voltage operation and ultra-high sensitivity are further achieved. The resulting sensors deliver a high sensitivity at a low-operating voltage, a rapid response time, and excellent operating stability. These results provide a promising strategy to design and synthesize high-performance flexible dielectrics for OFETs and pressure sensors.

EP05.03.35
Transient Electroluminescence Analysis in Organic Light Emitting Diodes—The Effect of the LiF Thickness in LiF/Ag Cathode Shirin N. Barnea and Rafi Shikler; Electrical and Computer Engineering, Ben Gurion University of the Negev, Beer-Sheva, Israel.

Time dependence studies in organic light emitting diodes are in the center of many researches due to the increase of interest in these devices for data transfer at high rates via modulation of visible light. In our study we examine the influence of charge injection on the time-dependency of the electroluminescence after driving the OLED from steady state to open circuit condition. In contrast to time-resolved-photoluminescence (TRPL) technique where the excitation is done by optical pulse, in our approach we monitored the temporal evolution of the emission under electrical excitation. The proposed technique combined with steady-state analysis allows us to take into account the interplay of various electronic processes and to investigate not just the excitors dynamics but also the charge dynamics. For this purpose, we fabricated polyfluorene-based OLEDs with LiF/Ag cathodes differing only by the thickness of the LiF layer for controlling the electron injection efficiency. Transient electroluminescence measurements accomplished by using a homemade fast switching driver that design to cop with the high impedance of the OLED and limitations on the maximum current flow in the device. Our driver successfully drives the OLED to open circuit condition in 5ns. Two exponential decays of the EL were observed after the turn-off, an initial fast decay in the time domain of tens of ns followed by a slow decay in the time domain of hundreds of nano-second. These lifetimes are much longer than the lifetime of the singlet excitons that were measured using TRPL (sub-nano to nano seconds). Capacitance—Voltage characteristic was performed due to its sensitivity to the barrier height and built-in potential. We observed changes in the peak position, maximum capacitance and peak shape. We found correlation between these parameters, the charge injection and accumulation and the measured transient EL lifetimes. We discovered that devices with higher charge injection efficiency and lower charge accumulation at the electrodes exhibit longer transient EL lifetimes. In addition, the shape of the peak capacitance that can be associated with the changes of space-charge regions is correlated to the longer transient EL lifetime.

EP05.03.36
Computational Design of Non-Fullerene Acceptors for Organic Solar Cells Anastasia Markina[1], Frédéric Laquai[2] and Denis Andrienko[1]; Max Plank
To date, most of the electron acceptors used in organic solar cells are fullerenes or their derivatives. As fullerenes exhibit only weak light absorption in the Vis spectral region, practically half of the active material does not contribute to exciton and charge generation, limiting the maximum efficiency of these devices to ca. 12%. The way forward to reach higher solar cell efficiencies is to replace fullerenes with strongly-absorbing dye molecules, namely, nonfullerene acceptors (NFAs). However, the systematic design of acceptor molecules with tailored properties has yet to be demonstrated. The difficulty here is that, while fullerene is an electrostatically “inert” molecule, new acceptors typically have strong static quadrupole moments. This complicates the interplay of electrostatic forces at the donor-acceptor interface, making it difficult to predict and design appropriate donor-acceptor combinations. As a result, in order to optimize solar cell efficiency, one has to appropriately balance the individual electrostatic contributions to energy profiles. Exploring the long-range electrostatic interaction at the interface, we demonstrate for a set of recently developed NFAs that the electrostatic bias potential can be directly related to the stabilization (or destabilization) of CT states as well as changes of the photovoltaic gap. Therefore, it is an important quantity to account for when designing non-fullerene acceptors. Furthermore, we compare theoretically-predicted properties of the NFAs with experimental data to assess the quality of our approach. We find that the correlation between quadrupole moments, charge separation efficiency, and CT-state energy predicted by our model is experimentally reproduced for several different small molecules and polymer donor / non-fullerene acceptor combinations. This allows us to predict new NFA structures using combinations of readily available molecular building blocks that can potentially reach to even higher performances than currently achieved in state-of-the-art NFA devices.

EP05.03.37

Patterning organic semiconductors via traditional solution-based microfabrication techniques is precluded by undesired interactions between processing solvents and the remaining photore sist. Herein we show how to easily avoid these problems and introduce a simple lift-off method to pattern organic semiconductors. Positive tone resist is deposited on the substrate, followed by conventional exposure and development. After deposition of the organic semiconductor layer, the remaining photore sist is subjected to a flood exposure, rendering it developable. Lift-off is then performed using the same aqueous developer as before. We find that the aqueous developers do not compromise the integrity of the organic layer or alter its electronic performance. We utilize this technique to pattern four different organic electronic materials: epindolide, a luminescent semiconductor, p-n photovoltaic bilayers of metal-free phthalocyanine and N,N’-dimethytriacracboxylic diimide, and finally the archetypal conducting polymer poly(3,4-ethylenedioxythiophene).

Record efficiencies of organic devices nowadays reach 15%. However, due to their organic nature, their performance is strongly influenced by environmental stresses, such as oxygen, light, heat and humidity. We are reporting on successful long-term stability improvement by ternary blending the active layers of organic solar cells with small amounts of stabilizing compounds comprising different stabilizing mechanisms[1-4]. Radical scavenging and singlet oxygen quenching stabilization mechanisms have been monitored in presence of different stabilizers, leading to different stabilization dynamics. Lifetime investigations and characterization were conducted under ISOS3-degradation conditions on bulk-heterojunction cells containing P3HT:60PCBM and PTB7:70PCBM systems. Different microscopic and spectroscopic methods (AFM, UV-vis, FTIR, ESR, NIR emission, PES) were applied to monitor chemical degradation over time, and correlate the observed differences with the device lifetimes.

Stabilization of Organic Solar Cells Using Radical Scavengers and Singlet Oxygen Quenchers Vida Engnuman,1 Mikkel Bregnhøj,1 Liana Inasaridze,1 Michela Prete1, Filipp Obrezkov2, Dmytro Volynik2, Michael Westberg Sörensen2, Sebastiann Engmann3, Horst-Günter Rubahn3, Juozas Vidas Grauzulevicius3, Pavel Troshin2, Peter Renssen Ogilvy2 and Morten Madsen1:1 University of Southern Denmark, Sonderborg, Denmark; 2Department of Chemistry, Aarhus University, Aarhus, Denmark; 3Institute of Problems of Chemical Physics of RAS, Moscow, Russian Federation; 4Skolkov Institute of Science and Technology, Moscow, Russian Federation; 5Department of Organic Technology, Kaunas University of Technology, Kaunas, Lithuania; 6Institute of Physics, Ilmenau University of Technology, Ilmenau, Germany.

Despite the performance of the resulting devices is enhanced, the presence of ionic species in CPE layers causes complications in the device response due to charge trapping and electric field screening effects. In this sight, the use of conjugated polymer polarizers (CPPs) is demonstrated as a new and efficient alternative to CPEs. Indeed, the conjugated backbones of CPPs are modified with polar non-ionic side groups, thus avoiding ion-dependent drawbacks. By introducing a layer of polyfluorene containing phosphonate groups (PF-EP) underneath the metal electrodes, a clear improvement of the electronic performance results in a more than twofold increased light-emission (optical power) and a five-times enhanced EQE of p-type OLETs, with superior performance in comparison with the relative CPE-containing devices. Moreover, the great benefit of using a transparent glass substrate allows for a deep investigation of the morphological and photoluminescent characteristics of both CPE- and CPP-buried interlayers within complete multilayered OLETs. Hence, by means of an optical scanning probe technique, the operation mechanisms of the investigated interlayers are elucidated.

EP05.03.39
Interface Engineering to Enhance the Efficiency of Organic Light Emitting Transistors Mario Prosa; CNR-ISMN, Bologna, Italy.

Organic light-emitting transistors (OLETs) show, in a single device, the fascinating combination of electrical switching characteristics and light generation capability. However, to ensure an effective device operation, efficient injection of charges at the electrodes is required. In this talk, the role that interfacial engineering plays on the figures-of-merits of OLETs is discussed. In particular, the effect of a series of multifunctional electrodes on both the external quantum efficiency (EQE) and the optical power of the corresponding devices is reported.
Modification of Interfaces with Organic Molecules in Optoelectronic Devices

We have developed surface modification process of polymer dielectrics with solution-processable triptycene (Trip) derivatives for high mobility organic thin-film transistors (OTFTs). The surface modification improves the averaged mobility of OTFTs from 0.41 cm²/Vs to 2.23 cm²/Vs. The nested packing of Trip molecules results in the formation of 2D hexagonal arrays, which stack one-dimensionally into a multilayer structure. Due to the unique assembling blocks because they are intrinsically flexible and are compatible with low-cost printing processes. In this sense, OTFTs with polymer gate dielectrics are a promising platform for high-performance electronic devices.

In order to develop high-performance organic electronic materials, it is of great importance to understand charge transport phenomena at molecular level. Here, we report the synthesis as well as the optical and electron-transport properties of a series of discrete alternating donor-acceptor (D-A) oligomers. These molecules are terminated with methyl-thiol anchors for single-molecule conductance measurements using the scanning tunneling microscopy-based break-junction (STM-BJ) technique. The electronic properties of the oligomers are further investigated by UV-Vis, Cyclic Voltammetry and Density Function Theory (DFT) calculations to understand the factors affecting conductance. By fitting to the Simmons Model, we find the intra-chain electron transport follows an electron tunneling mechanism whereby the molecule conductance is a function of molecule length. The dependence of oligomers’ conductance on potential-bias are also discussed. These findings shed light on the underlying electron transport mechanism in donor-acceptor organic semiconductor materials.

Solution-Processable Polymer Surface Modification with Organic Self-Assembled Layer for Ultraflexible Amplifier Circuits

Masaya Kondo, Takafumi Uemura, Takashi Kajitani, Soda Yuri, Fumitaka Ishiwa, Yoshiaki Shoji, Naoko Nambu, Masahiro Sugiyama, Shusuke Yoshimoto, Teppei Araki, Takanori Fukushima, and Tsuyoshi Sekitani.

We have developed surface modification process of polymer dielectrics with solution-processable triptycene (Trip) derivatives for high mobility organic thin-film transistors (OTFTs). The surface modification improves the averaged mobility of OTFTs from 0.41 cm²/Vs to 2.23 cm²/Vs. The nested packing of Trip molecules results in the formation of 2D hexagonal arrays, which stack one-dimensionally into a multilayer structure. Due to the unique assembling property, the Trip derivatives can form a highly oriented film on the surface of polymer without any anchoring groups. In this study, we have succeeded in forming 5-nm-thick closely-packed Trip layers on polymer dielectrics using blade coating (BC) known as a simple solution process. In addition, organic operational amplifier have been realized based on the modification technique. Flexible device technologies have been expected for next-generation applications such as flexible bio-medical devices. OTFTs are the potential building blocks because they are intrinsically flexible and are compatible with low-cost printing processes. In this sense, OTFTs with polymer gate dielectrics are a promising structure among various types of OTFTs because of their excellent flexibility and processability. However, one problem is that polymer dielectrics possess a lot of disorders and charge trap sites on the surface. Therefore, it is difficult to form highly-crystalline organic semiconductor films on polymer dielectrics, leading to OTFTs with low mobility.

Recently, it has been reported that thermally-evaporated Trip layers are useful for modifying polymer surface to avoid the negative effect of disorders and charge trap sites on the polymer. Here, we report the simple solution process in ambient conditions to form Trip layers. The improvement of mobility of OTFTs is better than that of the Trip layer formed by thermal vacuum evaporation (TVE). We fabricated top-contact bottom-gate OTFTs with hybrid gate dielectrics of Trip/parylene (5 nm/38 nm) on 1-μm-thick parylene substrates. We compared two types of Trip as referred to Trip.H and Trip.OMe. First, we formed Trip.OMe layers by using BC and TVE as a reference sample. The OTFTs with Trip.OMe layers formed by TVE and BC showed the averaged mobility of 1.59 and 2.23 cm²/Vs, respectively. These values were much higher than that of OTFTs without Trip.OMe layers (0.41 cm²/Vs). Moreover, the mobility improvement with BC was better than TVE. Secondly, the stability of OTFTs was degraded to 0.18 cm²/Vs with using Trip.H. Although the
recombination, thereby also extending the emission duration. For example, a TBRb-doped film exhibited a high purity because of better emission properties of dopants than exciplexes, some emitter dopants can also trap the separated electrons and inhibit charge recombination.

Long persistent luminescence (LPL) materials have applications in glow-in-the-dark paints such as emergency signs and watches. Current highly efficient LPL materials are based on inorganic materials. In contrast, we recently developed a novel LPL emitter composed only of organic molecules (R. Kabe et al., Nature, 550, 384 (2017)). This organic long persistent luminescent (OLPL) system has advantages over inorganic LPL materials of solubility, transparency, and flexibility. The origin of OLPL emission is the charge-transfer transition of an exciplex. The very slow charge recombination of separated carriers results in LPL of over 30 minutes at room temperature.

However, exciplexes have been known to possess low photoluminescence quantum yield (ΦPL) and poor color purity. In organic light-emitting diodes (OLEDs) based on exciplexes, these problems were resolved by adding small amounts of emitter dopants into the exciplex-forming matrix (Y. S. Park et al., J. Appl. Phys., 110, 124519 (2011)). The emitter dopants harvest exciplexes generated by either photoexcitation or charge recombination through Förster energy transfer (FRET). After that, the emitter dopants emit light with improved brightness and color purity relative to the exciplex emission. Here, we apply a similar technique to improve the ΦPL, color purity, and emission duration of OLPL while at the same time tuning the color over a wide range. We adopted the OLPL exciplex systems of 5,11-bis(4-tert-butylphenyl)-6,12-diphenyltetracene (TBRb) for orange, 4-(dicyanomethylene)-2-methyl-6-julolidyl-9-enyl-4H-pyran (DCM2) for red, and tetraphenyldibenzo[1,2-b:4,5-b']periflanthene (DBP) for deep red. The LPL spectra of the exciplex matrices with the emitter dopants corresponded to the emission spectra of the emitter dopants, ranging from red to greenish-blue. These results indicate that the LPL emission occurs after FRET from the exciplex to the emitter dopants. Furthermore, warm white emission was achieved by doping with two emitters (TBPb and DBP). In addition to improving ΦPL and color purity because of better emission properties of dopants than exciplexes, some emitter dopants can also trap the separated electrons and inhibit charge recombination, thereby also extending the emission duration. For example, a TBRb-doped film exhibited a ΦPL that is 3.5 times higher than that of the exciplex and the longest LPL duration of 1,415 s.

In conclusion, the simple doping of emitters into an exciplex matrix provides an easy method to broadly tune LPL emission and to improve the color purity, ΦPL and emission duration. This technique will enable the development of a wide range of organic glow-in-the-dark paints.

EP05.03.45

PEDOT:PSS Films in Redox-Active Devices

Michel De Keersmaecker1, Augustus W. Lang2, Anna Österholm2 and John R. Reynolds2, 1School of Chemistry and Biochemistry, Center for Organic Photons and Electronics, Georgia Tech Polymer Network, Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Chemistry and Biochemistry, School of Materials Science and Engineering, Center for Organic Photons and Electronics, Georgia Tech Polymer Network, Georgia Institute of Technology, Atlanta, Georgia, United States.

We present new designs for fast and reversibly switchable redox-active devices using PEDOT:PSS both as a transparent electrode material and an interface film exploiting its capacitive properties. Thin PEDOT:PSS films have been incorporated in window-type purple-to-transmissive electrochromic devices and symmetric electrodes as part of charge storage devices. We reached a conductivity up to 2000 S cm−1 when post-treating PEDOT:PSS films using different (in)organic acids on different substrates, enough to reversibly switch multiple ECPs made in the Reynolds Group depending on the targeted application. We will demonstrate how the device construction, charge-balancing and electrode conductivity have an influence on the device performance focusing on switching speed and capacitive behavior. We combine our device design with a fundamental study of the mixed electron and ion transport processes occurring in the ECP films at the electrodes looking for links to device performance. Using these new device structures, we have developed an easy way to produce both electrochromic and charge storage devices using solution processable polymers and roll-to-roll compatible coating techniques.

EP05.03.46

Bi-Layer Structure Gate Dielectrics for Low-Voltage Operating Organic Field-Effect Transistors and Printable Flash Memory

Moon Jihoon and Kang-Jun Baeg; Wearable Device, Pukyong National University, Busan, Korea (the Republic of).

Solution-processed pi-conjugated organic semiconductors potentially enable to flexible and stretchable opto-electronic applications via large-area, high-throughput, and low-cost graphic arts printing methods. For development of printed and flexible electronics, organic field-effect transistors (OFETs) and non-volatile memory as well as their integrated circuits are key components and they should be operated under low-power condition. Ultra-low power consumption would be a crucial requirement for determining its applicability for wearable and IoT-based consumer products. Gate-dielectric capacitance and its interface with semiconductor active channel is important to reduce the operation voltage. In this study, we develop the optimized top-gate and bi-layer polymeric gate dielectric structure for high performance ITO-based OFETs, and high-k fluorinated polymers such as PVDF-TrFE-CTFE and PVDF-TrFE-CFE could induce large accumulation of charge carriers at the semiconductor-dielectric interface, these dielectrics adversely affects the performance of N-type OFETs by pushing electrons at the interface and large charge injection barrier due to the high polarity of the C-F bonds. The depletion phenomena could be remarkably improved by incorporation of intermediate polyimine layer and/or appropriate charge injection layer to facilitate electron injection and efficient accumulation at the interface between the PVDF polymers and organic semiconductors. This approach has enabled high-performance, low-voltage driven OFETs and flexible and printed integrated circuits, Moreover, we also applied the same bi-layer structure for non-volatile memory using chargeable gate dielectric (electret) layers.

EP05.03.47

Fabrication of Conducting Bulk Structures Made of Polythiophene Derivatives

Anna I. Hofmann, Renee Kroon, Ida Holm, Anja Lund and Christian Muller; Chemistry and Chemical Engineering, Chalmers University of Technology, Göteborg, Sweden.

One of the main assets of plastic electronics is the possibility to process semiconducting polymers from solution, e.g. via printing, which promises cost-efficient production of light-weight and flexible devices. Thus, most conducting polymers are currently studied in the form of thin-films cast from solution. For applications such as organic thermoelectrics, however, conducting bulk structures are highly sought after. Nevertheless, the fabrication of highly conducting bulk structures remains a major challenge in the field of organic electronics. In this talk, we present different strategies for the bulk processing of doped conjugated polymers and for the doping of polymer bulk structures, using
various types of acid dopants and counter ions, as well as side chain engineering. We demonstrate that hot-pressing of an acid doped polythiophene derivative yields free standing and flexible films with conductivities of up to 120 S cm⁻¹. This opens up a wide range of new possibilities for the fabrication of electronics, from electrochemical devices to thermoelectric modules.

**EP05.03.48**
All Printed Electrolyte-Gated Transistors and Inverters by Spray Coating

Ion gels, consisting of room temperature ionic liquids and a host polymer network, have attracted great attention as solid electrolyte because they possess excellent advantages of ionic liquids such as ionic mobility, specific capacitance, and chemical and electrochemical stabilities in a solid form. In order to employ ion gels in electronic devices, solution processing methods including aerosol-jet printing, spin coating, and transfer printing have been demonstrated. However, alternative processing strategies are desirable to provide a diversity of process methods and to realize low cost production of printed electronics. In this regard, a spray coating technique was applied to fabricate electrolyte-gated transistors and inverters. Not only the ion gel gate dielectric but all thin film layers including source/drain electrodes, a semiconductor, a gate electrode were sprayed in various substrates for flexible and low cost thin film transistors and inverters. All spray-coated transistors exhibited low operation voltages 1 V, low turn on voltage at around 0 V, and reasonably high on/off current ratio about 10⁴ because of the high capacitance of the ion gels. Furthermore, all sprayed inverters operating at low voltages were also fabricated based on the ion gel-gated transistors. These results show that the spray printing technique provides a promising and reliable route to fabricate all printed thin-film transistors and other electrochemical electronic devices.

**EP05.03.49**
Electrical, Thermal and Morphological Properties of Semicrystalline Homopolymer Ion Gels for Solid-State Electrochemical Transistors

Ionic liquids have been received great attention in electrochemical device application due to their outstanding physicochemical properties such as non-volatility, large ionic conductivity and specific capacitance. To provide mechanical strength to the liquid electrolyte, a structure forming polymer is blended with ionic liquid to make solid polymer electrolytes known as ion gels. In this work, we fabricated physically-crosslinked ion gels by using an aliphatic polyanide over the composition 10-50 polymer wt%. The material properties of the resulting ion gels such as surface morphology, thermal stability, mechanical strength, ionic conductivity, and specific capacitance of the resulting ion gels were systematically investigated and the correlation between these parameters was examined. Specifically, fabricated ion gels were thermally stable up to 200 °C, and thus the gels could operate thin-film electrochemical devices such as electrolyte-gated transistors under very high operation temperatures. By using these ion gels as a high capacitance gate dielectric, we could successfully fabricate organic thin-film transistors that operated at low voltage (<1 V) with high on/off current ratio ~10⁴. These results demonstrate that the phase-separation mediated physical ion gels provide a convenient pathway to fabricate highly conductive and mechanically robust solid polymer electrolytes for various solid-state thin-film devices.

Suppressing the Photo-Induced Degradation of Inverted Non-Fullerene Organic Solar Cells

Over the last years the field of organic photovoltaics made tremendous progress due to the development of new acceptor molecules instead of the common fullerenes. Beyond the enhancement in efficiency to over 14% [1] an increased thermal stability of the bulk hetero junctions is achieved [2]. However, the stability under continuous operation in the maximum power point (MPP) is rarely reported. The vast majority of publications on non-fullerene active layers are utilizing an inverted device architecture with Zinc Oxide (ZnO) as electron extraction layer (EEL). Previous reports on inverted fullerene-based OPV have indicated photo-induced degradation if ZnO EELs are used. This degradation effect has been associated with a loss of selectivity of the illuminated ZnO and the concomitant onset of parasitic recombination of holes at the ZnO/organic interface [3]. In this work we use MPP-tracking to demonstrate that the photo-induced degradation of inverted fullerene-free devices comprising ZnO EELs is substantially more severe than that previously found in fullerene-based devices. Specifically, the PCE of a PBDB-T:ITIC device drops by 60-70% within 30 min of operation in the MPP, while the corresponding PBDB-T:PC70BM only drops by < 40% in the same time scale. The degradation effect applies to various non-fullerene acceptors, such as ITIC [4] or EIC0 [5]. A comparative study of various ZnO layers (atomic layer deposition, nanoparticles, sol-gel) shows the general validity of this effect for all ZnO-based systems. We evidence that the degradation is associated with the UV spectral components of the solar spectrum, it takes place even under inert conditions and is reversible in darkness. We will show that the ZnO/acceptor interface is crucially important for the severity of the degradation effect. We attribute the strong photo-induced degradation in the non-fullerene cells to the relatively higher HOMO level of e.g. ITIC (5.5 eV) compared to PCBM (6.1 eV). Thereby, non-fullerene acceptors have a lower ability to block holes therefore and give rise to substantial parasitic recombination at the interface to the illuminated ZnO EEL. Thereby the UV-induced loss of selectivity of ZnO [3] has significantly stronger negative impact in the non-fullerene devices due to increased recombination with extracted electrons. We will show that the use of a C60 monolayer on top of the ZnO EEL dramatically suppresses the photo-induced degradation. These insights will be important for a serious application of high-efficiency non-fullerene OPV.

Air-Stable, Balanced Ambipolar Split-Gate Organic Thin-Film Transistors

Ambipolar organic thin-film transistors (OTFTs) have attracted great interest for the development of more compact circuits. Nonetheless, previous studies investigating ambipolar organic semiconductors have reported results measured in either high vacuum or nitrogen atmosphere due to a lack of air stability. To develop a systematic design methodology for air-stable ambipolar organic semiconductors, it is necessary to fundamentally study the dependence of the material/device characteristics on the environmental atmosphere. Here, we demonstrate ambipolar OTFTs with balanced p/n characteristics under ambient air using PNDTI-BT-DP. Based on results from XPS, UPS, and electrical characterizations in high vacuum and ambient air, we analyze the underlying mechanisms that account for the well-balanced p/n characteristics of the PNDTI-BT-DP based OTFTs in ambient air. We
Further demonstrate the air-stable ambipolar split-gate OTFTs that operate as either a unipolar p- or n-type device based on electrical control. Finally, we report results showing that the device characteristics for both p- or n-type operations were maintained in ambient air for ~120 hours.

**Highly-Aligned Organic Semiconductor Films via Programmed Bar-Coating for High-Performance Organic Transistors**

Soon Baek Lee, Boseok Kang, Seonghyun Kim, Woong Sung and Kilwon Cho; POSTECH, Pohang, Korea (the Republic of).

Organic thin film transistors (OTFTs) have received enormous interest due to their great potential for realizing low-cost, lightweight and flexible electronics that are solution-processed in a large area. Recent researches have mainly been devoted to developing new organic semiconductor materials and novel solution-processing techniques for achieving high performance organic thin film transistors (OTFTs). Spin-coating has been frequently used in a lab scale due to its simplicity, but has fatal drawbacks, such as large amount of material waste, difficulty in scaling up and incompatibility with a conventional roll-to-roll (R2R) system. Several techniques have been developed for the alternative and bar-coating is considered as the promising printing technique for large area uniform coating. Here, we introduced the bar-coating to fabricate highly-aligned small molecule organic semiconductor (2,7-dioctyl-[1]benzothieno-[3,2-b][1]benzothiophene, C$_{60}$TTBT) films. We fabricated the large-area OTFT arrays which exhibit superior charge carrier mobility with high uniformity and reproducibility. The correlation between process conditions and crystal size was observed, and a crystallization mechanism of bar-coated films was identified. Furthermore, we proposed programmed bar-coating technique and fabricated infinitely continuous highly-crystalline films with high uniformity in large-area.

**Effects of Inserting an Ionic Liquid in Conjugated Polymer**

Beatriz Pesco, Leonardo J. de Siqueira and Laura O. Peres; Federal Univ of Sao Paulo, Diadema, Brazil.

Conjugated polymers are widely studied materials due to their diversity applications. However, its rigidity provides low solubility to the material. One strategy to solve this problem is the insertion flexible groups into the insoluble conjugate material. In this context, the present work presents the synthesis of a block polymer, which is composed of intercalated conjugated and non-conjugated segment, derived from poly(p-phenylene vinylene) (PPV) and poly(ethylene oxide) (PEG), respectively. The material was synthesized and characterized by infrared, UV-Vis and fluorescence. The results showed a better solubility of the block polymer in organic solvent without significant change of its luminescent properties. The ionic liquid ([I]butyltrimethyl ammonium bis(trifluoromethanesulfonyl)imide was incorporated into the polymeric material in proportions of 1:1 and 3:1 (polymer mass ratio:IL). The results obtained by X-ray diffraction show that the polymeric material is crystalline, which is gradually lost/decreased upon the addition of the ionic liquid. It was also observed difference in absorption, emission, DSC and TGA files, showing that there is an interaction between the block polymer material and the ionic liquid, which promoted improvement in the emission intensity and greater thermal stability.

**EP05.03.54**

**Exciton Blocking Layers in Organic Photovoltaic Devices**

Bhushan R. Patil$^1$, Laura Calio$^2$, Mehrad Ahmadpour$^1$, Yiming Liu$^1$, Horst-Günter Rubahn$^1$, Shahzada Ahmad$^2$ and Morten Madsen$^1$; $^1$SDU NanoSYD, University of Southern Denmark, Sonderborg, Denmark; $^2$BC Materials, Basque Center for Materials, Leioa, Spain; $^3$Abengoa Research, Sevilla, Spain.

Exciton blocking layers are essential for efficient organic photovoltaic device operation, where they serve to block excitons at the anode or cathode contact in order to reduce losses in the cells. At the anode side, exciton blocking layers are typically implemented in contact with a hole transporting layer, such as molybdenum oxide (MoO$_3$), where they prevent recombination at the metal oxide interface$^1$. Exciton blocking layers that also transport electrons have at the same time shown to efficiently reduce losses at the cathode contact.

In this work, the use of different organic interlayers integrated as exciton blocking layers in organic photovoltaic cells is presented. The exciton blocking layers are integrated either between MoO$_3$ hole contact layer and the active organic layer, or as cathode contact layers between ITO and the active organic layer. Besides organic solar cell device development and characterization, the integration of the layers is studied through hole-only and electron-only devices, optical spectroscopy analysis and morphology studies, in combination with complete optical and electrical device modeling. From the characterization and modeling, ideal thicknesses of the organic exciton blocking layers are found, based on a delicate interplay between the exciton blocking properties, the series resistance and the exciton generation profiles in the devices$^1$. Significantly improved device performances are observed in small molecule DBP/C$_{60}$ based organic photovoltaic cells when including specific organic interlayers (one of them being 4P-NPD) in combination with MoO$_3$ due to the added exciton blocking properties at the hole contacts. In addition, we evaluate here the effect of different exciton blocking layers on the performance of solar cells with up-scaled device areas. This is specifically area-dependent performance behavior observed in BCP based cathode contact layers, where BCP based exciton blocking and electron transporting stacks are introduced to improve the performance of up-scaled devices$^2$. The work thus addresses the need and challenge of incorporating exciton blocking layers in organic solar cells, and addresses the issue of device scale-up, which is needed for further implementing these layers in industrially relevant organic solar cells modules.

**Photo-Conductivity and Self-Assembly of Melanin Thin Films on Patterned SiO$_2$/Si Substrate**

Manuel Reali and Jordan De Angelis; Engineering Physics, Polytechnique Montréal, Montréal, Québec, Canada.

Eumelanin is a biomacromolecule featuring fascinating properties such as broadband optical absorption, metal chelation, photoconduction and hydration-dependent electrical response, this last mainly attributable to protonic transport [1-3]. Because of the limited processability, a model describing the correlation between supramolecular aggregation of eumelanin and fundamental optical and electrical properties does not exist yet. Eumelanin is synthesized by the oxidative polymerization of (5,6)-dihydroxindole (DHI) and (5,6)-dihydroxindole 2-carboxyl acid (DHICA) building blocks. Co-existing redox states (hydroquinone, semiquinone, quinone), different polymerization sites and a wide variety of supramolecular arrangements bring physicochemical disorder to the material [4].

Using chemically controlled eumelanin is the key to gain insight into the fundamental aspects of its functional properties. Our group is currently studying the mechanism of solid-state polymerization of DHI and DHICA at surfaces, to achieve thin films suitable for structural, optical and electrical characterizations. APM and FTR investigations on spin coated samples of DHI and DHICA show that the monomers aggregate, eventually polymerizing in ambient conditions. We performed photoconductivity studies on such samples, obtained from spin coating DHICA on gold-patterned SiO$_2$/Si substrates
and on Corning® glass, collecting optical spectra and transient current measurements as a function of relative humidity (%RH). We observed a broad absorption peak at 330 nm, red shifting over time, providing an evidence of solid-state assembly and polymerization, supported by AFM. Nanometer-sized nuclei grew into spherical and rod-shape structures, the size of which is larger for films stored at high %RH with respect to those stored in ambient condition, demonstrating the critical role of H2O in promoting lateral interactions. Our investigations open the opportunity to demonstrate eumelanin-based organic solar cells and, on the long term, organic solar batteries based on the quinone-semiquinone-hydroquinone redox species, where light harvesting could help to enhance the storage properties of eumelanin.

Half- and Quarter-Wavelength Resonance in Fabry-Pérot Cavity Based OLEDs Ekani Dahal1, Benjamin Isenhart1, Karen Cianciulli2, Bin Du1, Olivia Sergiovanni1 and Matthew S. White1; 1The University of Vermont, Burlington, Vermont, United States; 2Asheville School, Asheville, North Carolina, United States.

Organic light–emitting diodes (OLEDs) have a promising next–generation display and solid–state lighting applications. By forming an optical cavity using the metallic electrodes enclosing the device, we have fabricated various narrow peak emission OLEDs. Varying the thickness of the optical cavity, we observed the interesting change in wavelength peaks. We have used Tris(8–hydroxyquinolinato)aluminium, Alq3, as emissive layer (EL) and added the electron transport layers (ETL) and hole transport layers (HTL) in between the metal electrodes. We observed the optical cavity effect by varying the thickness of the ETL and HTL and keeping the EL fixed. The device with the thinner optical cavity showed a quarter–wavelength resonance as a red wavelength peak whereas increasing the thickness of the cavity shifted the wavelength peak to blue and further increase in the thickness to the green emission peaks as half–wavelength resonance. These narrow–band emission peaks have full width at half maxima (FWHM) of 10 nm, indicating a cavity finesse of roughly 80 when measuring over +/- 9 degrees with respect to normal.

EP05.03.57
Towards a Better Control of Solution-Processed P-Doped Films—Identifying the Impact of Residual Water in Organic Solvents Tamara Domschke1, Alexandre Pereira1, Raphael Clerc2 and Alexandre Carella1; 1CEA-LITEN, Université Grenoble Alpes, Grenoble, France; 2UJM-Saint-Etienne CNRS UMR 5516, Laboratoire Hubert Curien, Université de Lyon, Saint Etienne, France.

Chemical doping allows tuning the electrical and optoelectronic properties of organic semiconductors (OSC) and conductive polymers [1]. However, controlled doping of thin OSC films by solution-processed methods remains challenging [2]–[5]. Here, we explore important processing guidelines to achieve a better control of the doping level in OSC and highlight the unexpected negative impact of residual water in organic solvents. By means of conductivity measurement and optical spectroscopy, this work considers the p-type doping of the low bandgap polymer poly[(4,8-bis-(2-ethylhexyloxy)-benzo(1,2-b:4,5-b')dithiophene)-2,6-diyl) (PBDTTT-c) with the 3D molecular dopant tris[1-(trifluoroethanoyl)-2-(trifluoromethyl)ethane-1,2-dithiolene] (Motf(COF)_3) [6].

First, we report on the strong thickness-dependent conductivity results observed for doped films ranging from 200 nm to 15 nm, where the conductivity decreased from 10^4 S.cm^-1 to 10^2 S.cm^-1, respectively. Also, a clear bleaching of the doping signature is observed in the UV-vis-NIR absorption spectra although EDX mapping presented an homogeneous distribution of the dopant in the film, for all thicknesses. The stirring conditions of the blend solution are identified as key parameters controlling the doping efficiency in thinner films (lower solution concentration). A similar trend was found for PBDDTT-C doped with the planar electron acceptor 7,7,8,8-tetracyano-2,3,5,6-tetratfluoroquinodimethane (F4TCNQ).

In a second part, we correlate the decreasing doping efficiency of lower blend concentrations with the residual water present in the processing solvent. Therefore, our study emphasizes the importance of controlling the water molar fraction of the solvent to achieve reproducible electrical and optoelectronic results for doped films, independent of the blend concentration. As a result, the electrical conductivity of PBDDTT-C doped with Motf(COF)_3 increased from 10^4 S.cm^-1 to 10^6 S.cm^-1 and showed to be reproducible for different blend concentrations.

Finally, we will give insights into the possible mechanism involved in the doping efficiency alteration caused by the presence of residual water in the processing solvent.

EP05.03.58
Design of Conducting-Polymer-Free Highly Flexible Organic Light Emitting Diodes Having Oxide-Based Thin-Film Encapsulation Layers Fangjun Kim, Jeonghyun Kwon, Cheolgyu Kim, Taek-Soo Kim, Kyung Cheol Choi and Seunghyun Yoo; KAIST, Daejeon, Korea (the Republic of)...

Flexible OLEDs require flexible electrodes and thin film encapsulation (TFE) layers. Unfortunately, oxides that limit the flexibility of OLEDs are used to create electrodes and TFE layers that exhibit the best performance. To address this problem, research has been conducted on flexible electrodes and TFE layers that can replace oxides. Nonetheless, oxide-based transparent electrodes such as ITO and IZO are best suited as transparent electrodes for OLEDs due to their high transmittance and electrical conductivity. It is also known that Al2O3 in the oxide-based TFE layer can be formed at a high density and exhibits the best sealing characteristics.

In this study, a very thin PET substrate with a thickness of 6 μm was used to reduce deformation on the device. Among the oxide electrodes, IZO has a process has excellent sealing properties, but the stability against mechanical deformation is very low. In the experiment, the stable folding condition was found by observing the change of sheet resistance and WVTR according to the strain. The results show that the critical strain of Al2O3 is too low to be
bent less than 1 mm. However, considering the overall device structure, the Young's modulus of layers including Al2O3 was much higher than that of the substrate; for this reason, even though the thickness was very thin, it greatly influenced the optical device structure. The neutral plane located at the center of the substrate is displaced due to the effect of the device deposited on the substrate. In general, the thickness of the substrate is very thick, so the influence of the motion of the neutral plane is negligible. However, since the effect is too large to be ignored in our case, the exact strain value can only be obtained by locating the actual neutral plane. Results from ANSYS simulation, the position of the neutral plane in the entire device structure is just below the interface between the substrate and the device. Finally, with a bending radius of 740 μm, the strain applied to the outermost Al2O3 is 0.21%, the safety margin identified by the experiment, and the maximum stress value is lower than that of Al2O3, which is known as 379 MPa.

Consequently, an OLED that operates reliably at a bending radius of curvature of less than 1 mm is realized using an transparent conductive oxide electrode and TFE layer, which are known to be prone to crack formation upon bending. The optimal radius of curvature was established by taking into account the influence of the entire device structure and the limiting deformation of the weaker layer and explained why this could be done using a simulation based on a finite-element method (FEM).

EP05.03.59
Effect of Counterion Exchange of Conjugated Polyelectrolytes in Organic Electrochemical Transistors Brian Kham and Elsa Reichmanis; Georgia Institute of Technology, Atlanta, Georgia, United States.

The palette of mixed ionic-electronic materials for organic electrochemical transistors (OECTs) can be divided into three types: PEDOT-PSS and its derivatives, semiconducting polymers with nonionic polar chains, and conjugated polyelectrolytes (CPEs). To date, the relative amount of literature on CPEs-based OECTs dwindles in comparison to PEDOT-PSS-based devices. We assert that CPEs provide a useful pedagogical system for understanding mechanisms of ionic and electronic transport in OECTs. Through ion-exchange on an anionic polythiophene with a pendant carboxyl group, poly[3-(4-carboxypropyl)thiophene-2,5-diyl] (PCPT), a series of analogues are produced with the same conjugated backbone, only differing in their cations. This procedure clearly elucidates how the choice of counter-ion dictates operation of an accumulation-mode OECT. Firstly, we highlight how these analogues differ in microstructure and phase morphology at various length scales, characterized via optical microscopy and scattering techniques. Secondly, we investigate the photophysical processes of the cast films through ultra-fast spectroscopic methods to understand the effect of counter-ion on charge transport. Lastly, we demonstrate that the counter-ion plays a crucial role in modulating electrolytic ion injection into the polymer film during OECT operation, via cyclic voltammetry and spectroelectrochemistry.

EP05.03.60
Fine-Tuning Polymer Packing and Crystallinity in All-Polymer Solar Cells Through Side-Chain Engineering Yilei Wu and Zhenan Bao; Stanford University, Stanford, California, United States.

Polymer crystallinity and self-assembly behavior play a crucial role in the performance of all-polymer solar cells (all-PSCs). Many aspects of how polymer crystallinity and aggregation influence active-layer morphology and photovoltaic performance, however, remain still elusive. Herein, we report a simple yet effective way to modulate the crystallinity of the well-known naphthalene diimide (NDI) based polymer (N2200), by systematically replacing a certain amount alkyl side-chains with bulky aromatic side-chains. Specifically, we synthesized a series of random polymer with different molar ratio of the two side-chains and found that the crystallinity of these acceptor polymer decreases with increasing amount of bulky aromatic side-chains as evidenced by UV-Vis-NIR absorption and photoluminescence spectroscopies, as well as thermal analysis and grazing incidence x-ray scattering techniques. Importantly, compared to the reference semicrystalline N2200, preliminary OPV results show that mixing of more amorphous acceptor polymers with an amorphous donor polymer (PTB7-Th) enables all-PSCs with increased PCE, on account of higher short-circuit current density ($J_sc$) and fill factor (FF). Our results demonstrate how the polymer crystallinity and packing motives can be systematically tuned by side-chain engineering approach and highlights the importance of polymer structure and morphology on all-PSCs device performance.

EP05.03.61
Electrospun Optical Fibers Composed of a Regenerable Polymer and Approaches for Reducing Their Propagation Losses Yuya Ishii; Faculty of Fiber Science and Engineering, Kyoto Institute of Technology, Kyoto, Japan.

Polymer micro-/sub-microfibers have unique properties including small diameter, light weight, mechanical flexibility, and large surface-area-to-volume ratio. Because such fibers also have inherent waveguide structures, they are promising as building blocks for small, mechanically flexible optical devices such as waveguides and sensors. In this study, we have fabricated electrospun micro-/sub-microfibers composed of a biodegradable and regenerable polymer and investigated their optical propagation losses. Additionally, versatile approaches for reducing the propagation loss and diameters of the fibers have been demonstrated. An amorphous polymer, poly(DL-lactic acid) (PDLLA), was used as the core material because it exhibits high transparency in the visible range and is both biodegradable and regenerable. Single aligned PDLLA fibers with diameters of approximately 1.7 μm were fabricated with an electrospinning method and the intensity of light transmitted in the fibers was investigated with increasing temperature. The transmission intensity significantly increased after heating over the glass transition temperature ($T_g$) of the fibers, 49.8 °C, which indicated that the propagation loss in the fibers decreased after heating over $T_g$. The propagation loss was investigated before/after heating up to 55 °C because this temperature was above $T_g$ of the PDLLA fibers; in addition, the transmitted light intensity showed the maximum intensity at 55 °C. The propagation loss was significantly reduced after heating. For example, the propagation loss in one of the fibers was reduced from 17 to 8.1 dB cm$^{-1}$ under 532-nm illumination. These results demonstrated that heating of the electrospun PDLLA fibers above $T_g$ significantly reduced the propagation loss in the fibers. An ultraviolet-visible absorption measurement and morphological characterization revealed that the propagation loss reduction was achieved by the reduction of extrinsic excess scattering losses arising from the extrinsic density inhomogeneity in the fibers. The as-electrospun PDLLA fibers were then drawn at 55 ± 2 °C to reduce the extrinsic density inhomogeneity and fluctuations in the fiber diameter. After fivefold drawing, the PDLLA fibers showed significant decreases in their fiber diameters to approximately 0.5 μm and reductions in the root-mean-square roughness for each fiber diameter. The propagation loss in each fiber was significantly decreased after thermal drawing; for example, from 16 to 6.6 dB cm$^{-1}$ at 532 nm. Although a decreased fiber diameter normally increases propagation loss in fibers, the propagation loss after thermal drawing was decreased. This was attributed to the reduced fluctuation in the fiber diameter due to thermally drawing and the decreased extrinsic density inhomogeneity in the fibers due to heating.

Structure and Electrical Properties of Metal Ion Doped Polydopamine (PDA) Haoqi Li, Yao Zhao and Fei Ren; Mechanical Engineering, Temple University, Philadelphia, Pennsylvania, United States.

Polydopamine (PDA) is a bio-inspired polymer that can be synthesized through self-assembly of dopamine monomers under mild conditions. Thermal treatment can convert PDA into a conductive phase, commonly known as carbonized PDA (cPDA). This work studied the effect of three metal ions, i.e. Na$^+$, Mg$^{2+}$, and Cu$^{2+}$, on the synthesis of PDA and its conversion to cPDA. Both Cu$^{2+}$ and Mg$^{2+}$ could interact with PDA, which influenced the growth of PDA
thin film, morphology change of PDA particles upon thermal annealing, and the electrical properties of heat-treated thin films. In contrast, the presence of Na+ ion during the synthesis of PDA did not show any effect. This difference can be explained by the variation of the three ion species to react with PDA through coordination bonding: Cu2+ > Mg2+ > Na+. In this study, SEM and TEM were used to examine the morphology of PDA thin film and particles. EDS and XPS are employed to study the chemical composition. The structure was investigated using electron diffraction and Raman spectroscopy, and the properties were evaluated with respect to the electrical conductivity and thermoelectric Seebeck coefficient. The results from this work provide a potential approach to control the structure and properties of PDA and cPDA materials through metal ion doping.

**EP05.03.63** Highly Orthogonal Semiconducting Polymers for Solution Tandem Electronics Han Wool Park1, Keun-Yeong Choi2, Haejung Hwang1, Boseok Kang1, Joo Sung Kim1, Hyuk Min Kweon1, Je Hyong Koo1, Kilwon Cho1, BongSoo Kim1, Kwon Bum Chung1, Soon-Ki Kim1, Yun-Hi Kim1, Moon Sung Kang1, Hejin Lee1 and Do Hwan Kim1; 1Hanyang University, Seoul, Korea (the Republic of); 2Soongsil University, Seoul, Korea (the Republic of); 3Pohang University of Science and Technology, Pohang, Korea (the Republic of); 4Gyeongsang National University, Jinju, Korea (the Republic of); 5Ewha Womans University, Seoul, Korea (the Republic of); 6Dongguk University, Seoul, Korea (the Republic of). Polymer electronic devices are receiving great attention because semiconducting polymers are soluble in conventional solvents, which results from being inexpensive in the field of electronics. This opportunity, however, serves as a trade-off when one tries to implement these processes in assembling practical electronic devices, since the as-deposited tandem films would be vulnerable to following solution coating and photolithography processes. We adopted the recently developed sol-gel process to obtain the orthogonality of organic semiconductor against the solvents and chemicals. We could prepare self-assembled structures with quasi-3D random or ladder properties. The resulting structure produced film resistant to severe external stimuli. Moreover, the peculiar topology of organometallic gel network containing with molecular pores could be successfully utilized as a template to form an interpenetrating polymer network (IPN) with functional electronic organic units. As a result, we could demonstrate that sub-micron patterning and forming of tandem structures of OSP films can be done readily through conventional photolithography with sequential solution and etching processes, and finally fabricate tandem electronic devices including basic complementary metal-oxide-semiconductor (CMOS) inverters and pixilated polymer light-emitting diodes (PLEDs). Ultimately, the proposed strategy is expected to open up new avenues for the fabrication of optoelectronic devices that require high-resolution tandem processing of polymer semiconductors such as OLED microdisplays, organic CMOS image sensors, and artificial eyes.

Engineering Conjugated Polymers for Bioelectronics Sahika Inal, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Conducting both ionic and electronic charge carriers, conjugated polymers are impacting on a large variety of biology-related applications as the electronic material interfacing with living systems. A device type that has predominantly utilized these polymers as its active component is the organic electrochemical transistor (OECT) – an electrolyte gated transistor used for ionic-to-electronic signal transduction. In this talk, I will show a comprehensive study on the thin film properties of a series of conjugated polymers and evaluate the concomitant performance of electrolyte gated transistors comprising these polymers. We investigate how systematic chemical modifications impact on the electrochemical activity of the materials, thereof the device operation. I will present two cases where engineering the material is crucial to develop an OECT based sensor for metabolites and transducers for interfacing lipid bilayers. Highlighting the materials properties that enable enhanced mixed conduction, this work provides an understanding of materials-device performance relations for the development of next generation organic electronic sensors.

Ion Gated Transistor—A Mixed Ionic-Electronic Transistor Georgios Spyropoulos, Jeremy Savarin, Jennifer Gelinas and Dion Khodagholy; Columbia University, New York, New York, United States.

As our understanding of the brain’s physiology and pathology progresses, increasingly sophisticated technologies are required to advance discoveries in neuroscience and develop more effective approaches to treat brain disease. To meet this challenge, we propose a novel transistor architecture that provides an efficient interface with biological substrates, especially neural networks, through its channel’s intrinsic ion mobility. Because independent electronic gating can be applied to these transistors, they can be incorporated into integrated circuits, unlike their electrolyte-gated counterparts. The channel consists of a composite film based on highly conductive poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) enriched with D-sorbitol. At the gate electrode, an ion exchange membrane serves as ion conductor. To determine an optimal transistor configuration and material composition, we microfabricated transistor arrays of varying geometrical parameters. In doing so, we were able to extract conductivity, contact resistance, and electrochemical impedance values for all the critical interfaces of various composites. Furthermore, output characteristics and current temporal response of each configuration revealed the key driving physical parameters and provided insight into optimization of the device for various applications. The resulting optimal transistors were tested as electroencephalography (EEG) interface and amplifier circuitry and compared with organic electrochemical transistors and surface electrodes showed promising signal-to-noise ratio and spatio-temporal resolution.

Organic Bioelectronics In Vitro—3D, Biomimetic Devices and Cell Models Roisin Owens; University of Cambridge, Cambridge, United Kingdom.

In vitro models of biological systems are essential for our understanding of biological systems. In many cases where animal models have failed to translate to useful data for human diseases, physiologically relevant in vitro models can bridge the gap. Many difficulties exist in interfacing complex, 3D models with technology adapted for monitoring function. Polymeric electroactive materials and devices can bridge the gap between hard inflexible materials used for physical transducers and soft, compliant biological tissues. An additional advantage of these electronic materials is their flexibility for processing and
fabrication in a wide range of formats. In this presentation, I will discuss our recent progress in adapting conducting polymer devices, including simple electrodes and transistors, to integrate with 3D cell models. We go further, by generating 3D electroactive scaffolds capable of hosting and monitoring cells. I will also highlight recent research using biomimetic models of cell membranes interfaced with organic electronic devices for drug discovery.

**Highly Efficient Organic Photodiodes Operated in Aqueous Electrolytes**

**Achilleas Savva and Sahika Inal; Biological and Environmental Science and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.**

Optical techniques have greatly accelerated advances in modern medicine. Lasers and optical devices are now in wide range use in clinical practice to assess health condition and treat disease.[1] [2] Recently, a new category of light sensitive devices based on organic semiconducting materials has emerged as promising candidates for restoring vision,[2] and recording neuronal activity.[3] In this study, we present an organic photodiode comprised of a solution processed organic semiconductor p-n bilayer junction. Our device, operating in aqueous electrolytes including cell culture media, produces large photocurrents when illuminated with low intensity, broad spectrum light source. We show that in this p-n bilayer junction, which is insulating prior to illumination by light, the photo-generated excitons are rapidly disassociated leading to large photocurrents as well as high ON/OFF ratios in the range of 10^6, respectively. These findings together with an in depth electrochemical analysis suggest a highly efficient photo-capacitive phenomenon at the solid/liquid interface. The devices are freestanding, operate without external wires or electrical bias and show a remarkably stable, continuous operation in aqueous media. This is the first demonstration of an easy-to-fabricate, biocompatible platform, capable of delivering large photocurrents in aqueous electrolytes with potential for direct photostimulation of living cells.

**Vapor Deposited Conducting Polymers for Electrochemical Energy Storage**

**Trisha I. Andrew; University of Massachusetts Amherst, Cambridge, Massachusetts, United States.**

Lightweight energy storage technologies are integral for powering emerging wearable health monitors and smart garments. Reactive vapor deposition creates films of doped conjugated polymers with tunable mesoporosity, which results in efficient, reversible and thickness-independent ion transport when optimized. Vapor deposited conjugated polymer films are also highly conductive and can act as sole-component electrodes with which to fashion pseudocapacitive charge storage devices. Pseudocapacitors comprised of vapor-deposited doped polymer films display higher areal and volumetric capacitances than solution-processed counterparts, to the extent that energy densities comparable to state-of-the-art carbon materials can be obtained with vapor deposited polymer films. Further, since vapor deposition allows for textured and fragile substrates to be nondestructively coated, various textiles and fibers/yarns can be transformed into high-performance, super-deformable, wearable electrodes, electrochemical transistors and pseudocapacitors. Taken together, reactive vapor deposition and off-the-shelf fabrics present a unique combination of processing technique and device substrate with the potential to create lightweight and portable charge storage solutions.

**Polar Side Chains for Enhanced Doping of Conjugated Polymers**

**David Kiefer1, Renee Kroon1, Dominik Stegerer1,4, Liyang Yu1, Alexander Giovanniti1,2,3, Hengda Sun4, Till Biskup4, Anna I. Hofmann4, Martin Koopmans5, Camilla Cendra Guinass4, Michael Sommer6, Lambert Jan Anton Koster7, Eva Olsson8, Jonathan Rivnay9, Simone Fabiano2,10, Iain McCulloch3 and Christian Muller4; 1Chalmers University of Technology, Gothenburg, Sweden; 2Department of Chemistry and Centre for Plastic Electronics, Imperial College London, London, London, United Kingdom; 3Department of Chemistry, Technical University of Chemnitz, Chemnitz, Germany; 4King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 5Freiburg University, Freiburg, Germany; 6University of Groningen, Groningen, Netherlands; 7Stanford University, Stanford, California, United States; 8Northwestern University, Evanston, Illinois, United States.**

Molecular doping is a crucial tool for controlling the charge carrier concentration in organic semiconductors for a range of optoelectronic devices such as field-effect transistors, solar cells and thermoelectric generators. We show that doping of both p- and n-type conjugated polymers can be enhanced by exchanging the commonly used unpolar side chains with polar side chains. The use of oligo ethylene glycol side chains with a polythiophene, p(3,4-ET)-T, is demonstrated to significantly improve the compatibility with common molecular p-dopants such as 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) and 2,3-dichloro-5,6-dicyano-1,4-benzquinone (DDQ).[1] The same is shown for n-doping of a polar naphthalenediimide-alkoxybithiophene (DMBI).[2] In both cases a much higher electrical conductivity can be reached using a smaller dopant fraction and hence limited influence on the polymer nanostructure.

**Stability of Charge Transfer States in Doped P3HT Films**

**Kristen Watts, Bharati Neelamraju, Erin Ratcliff and Jeanne Pemberton; University of Arizona, Tucson, Arizona, United States.**
Poly-(3-hexyl)-thiophene (P3HT) is frequently viewed as a model system for photonic and electronic devices. The molecule 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4TCNQ) is a well-known, p-type dopant for P3HT. The interaction between P3HT and F4TCNQ has been described as an integer charge transfer (ICT) from P3HT to F4TCNQ based on vibrational spectroscopy evidence[2,3], although films are typically significantly thicker than what is used in devices. Recent evidence indicates that the degree of charge transfer is predicated on processing conditions, with demonstration of a partial charge transfer complex (CPX) formed under certain processing conditions, although the exact cause is unclear.[2] To date, the doping state has proven to be challenging to precisely define and control, despite P3HT-F4TCNQ being a model system for doping in organic electronics. Using state-of-the-art capabilities, we provide new insights into the doping mechanism of P3HT-F4TCNQ system using vibrational spectroscopy and imaging (FTIR spectroscopy and Raman microscopy) of device-relevant films. Our new chemical insights will be discussed in the context of electronic states, with a specific focus on the proposed ICT versus CPX states that are being vigorously discussed in the organic electronics community. Results from additional studies on the effects of temperature and substrate on CPX formation will be presented along with results from GIWAXS, conductivity and AFM studies that demonstrate how the presence of the CPX state impacts important film characteristics such as microstructure, charge transport, and morphology.

10:45 AM EP05.05.03
Spectral Signatures and Spatial Coherence of Bound and Unbound Polarons in P3HT Films—Theory vs Experiment Raja Ghosh1, Annabel R. Chew2, Jonathan Onorato3, Viktoria Pahkyryuk4, Christie Lascombe1, Alberto Salleo2 and Frank Spano1; 1Temple University, Philadelphia, Pennsylvania, United States; 2Chemistry, University of Washington, Seattle, Washington, United States; 3Chemistry, University of Washington, Seattle, Washington, United States; 4Chemistry, University of Washington, Seattle, Washington, United States.

The origin of the mid-IR spectral features for hole absorption in doped and undoped P3HT films is investigated theoretically and experimentally. Using a Holstein-style Hamiltonian to treat the prominent vinyl stretching mode, the low-energy peak (A) is found to arise primarily from intrachain transitions, in contrast to the predictions of the more conventional treatments based on self-trapped, mid-gap polarons, where peak A is entirely interchain in origin. Signatures for polaron coherence are identified and used to analyze the molecular weight dependence of the IR spectrum for P3HT doped with F4TCNQ. Generally, the polaron coherence lengths along the chain and stacking axes increase with molecular weight, consistent with similar studies conducted on hole absorption in undoped P3HT. We also show that the spectral changes in bound and unbound polarons corresponds to a polaron coherence number of Ncoh of approximately 4-7 for bound holes and approximately 16-18 for unbound holes.

3. Ghosh, R.; Chew, A.R.; Onorato, J; Pahkyryuk, V; Lascombe, C.K; Salleo, A.; Spano, F. C. Spectral Signatures and Spatial Coherence of Bound and Unbound Polarons in P3HT Films: Theory vs Experiment (Just Accepted, Journal of Physical Chemistry C)

11:00 AM EP05.05.04
Suppression of Dopant Drift in Organic Semiconductors via Blending with Insulating Polymers Marc-Michael Barf1, 2, Leonard Knupnik2, 2, Robert Lovricic1, 2 and Wolfgang Kowalski1, 2, *TU Braunschweig, Braunschweig, Germany; 2InnovationLab, Heidelberg, Germany; 3Heidelberg University, Heidelberg, Germany.

Blending low cost insulators with semiconducting polymers has shown to enhance performance of electronic devices in multiple cases through morphological changes in the active layer.[1,2] Also doping of organic semiconductors is a common method to improve the efficiency of devices like organic light emitting diodes, organic solar cells or organic field effect transistors. By increasing conductivity or creating space charge regions charge transport within such devices can be enhanced.[3-5] However, due to the electrical fields applied to the devices, dopants can potentially move within them and thereby change their electrical properties.[6] Since stability plays a critical role in device operation, such a drift of dopants can cause major problems and is usually desired to be suppressed. Here, polystyrene and poly(methyl methacrylate) (PMMA) were used to shift the onset of the drift of the p-dopant molybdenum tris[1-(methoxycarbonyl)-2-(trifluoromethyl)ethene-1,2-diolethene] in poly(3-hexyl-thiophene-2,5-diyli) (P3HT) films to significantly higher applied electrical fields. We investigate the results and resulting images of the doping drift which is attributed to the intercalation of the dopant in the insulator. Both insulators show significantly different thin film morphologies in the blends potentially affecting the dopant distribution. Whereas polystyrene forms very homogenous layers with P3HT, PMMA tends to shape large domains which could hinder the intercalation of dopants. This leads to more dopants remaining in the semiconducting material and thereby to an earlier onset of the observed drift. In compliance with this the dopant drift in the homogenous polystyrene blends was found to be stronger suppressed from an onset of less than 1 V/µm in pure P3HT to more than 3 V/µm in the blend.
suppression of dopant drift adds a further interesting point to the list of improvements in organic electronics through the use of semiconductor insulator blends.

Direct Probe of the Nuclear Modes Limiting Charge Mobility in Molecular Semiconductors Adam J. Moule1, Thomas Harrelson1, Varanir Dantaranarayana1, Correy Koskimic1, Diniq Nai1, Enrique Gomez2, John Anthony3, Alessandro Troisi4 and Roland Faller4; 1University of California, Davis, Davis, California, United States; 2The Pennsylvania State University, State College, Pennsylvania, United States; 3University of Kentucky, Lexington, Kentucky, United States; 4University of Liverpool, Liverpool, United Kingdom.

Organic semiconductors (OSCs) provide the unprecedented ability to tailor properties like electronic band gap, mechanical flexibility, processability, and biocompatibility. Recent theories suggest that low frequency dynamic intra- and intermolecular motions are critical to determining localization of the charge carrier, and thus, control the hole mobility. So far, however, it has not been possible to measure intramolecular motions experimentally and therefore no unequivocal and quantitative link exists between molecular-scale thermal disorder and macroscale hole mobility in OSCs. Here we use inelastic neutron scattering (INS) to probe thermal disorder directly by measuring the high resolution phonon spectrum in six different small molecule OSCs. Because of the virtually perfect agreement between the INS spectra and first principle simulations, we can study the coupling between hole and molecular dynamics starting from the exact knowledge of the nuclear motions in each system. This knowledge is used to generate a set of electron-phonon coupling parameters, which are used to compute hole mobility using transient localization theory. We have discovered that in some high performing materials, an important component of the non-local electron phonon coupling is carried by high frequency phonons, unlike what was previously thought. Once this element is properly taken into account the mobility, calculated from first principles, is in excellent quantitative agreement with macroscopic measurements. The analysis of the results reveal routes to improve charge mobility by engineering phonon and electron-phonon coupling.

11:30 AM EP05.05.06
A Tale of Two Crystals—It was the Best Alignment, It was the Worst Alignment Niils E. Persson, Sebastian Engmann, Subhransu Mukherjee, R. J. Kline, Lee Richter and Dean M. DeLongchamp; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Significant advancements in molecular design, crystal engineering, and device fabrication have placed solution-processed polymer transistors on a steady path toward commercialization. Central to these efforts is a growing understanding of semiconducting polymers’ process-property relationships. Polymer aggregation has been proposed to play a critical role in morphological evolution during film drying and in defining long-range structural features that impact charge transport and anisotropy. Here, we report on blade coated OFETs from PNDI2OD-T2 in toluene, an aggregating solvent. We achieved a mobility of 2 cm²/Vs with 10x anisotropy between charge transport parallel and perpendicular to the coating direction, a result on par with previous authors’ OFETs fabricated using the wire bar and brush coating methods. However, blade coating provides a more idealized processing environment amenable to in situ studies, while also serving as a model of production-scale slot die coating. Using simultaneous in situ GIWAXS and split-polarized UV-Vis reflectance measurements, we tracked the structural evolution of PNDI2OD-T2 in toluene during blade coating and film drying. At 5 mm/s, results from GIWAXS indicated that crystalline aggregates were present in the wet film shortly after blade passage and well before drying was complete, and furthermore, that these aggregates maintained their orientation relative to the coating direction throughout the drying process. The UV-Vis spectra did not develop strong anisotropy until the final moments of film drying, when polymer backbones aligned parallel to the coating direction. Taken together, these data suggest that aligned crystal nuclei were deposited that seeded further polymer aggregation and alignment throughout the bulk. Films coated at speeds below 0.1 mm/s displayed practically the opposite trend, with backbones aligning overall perpendicular to the coating direction and with a commensurate change in mobility anisotropy. At this process condition, a surface layer of fibrils arranged in a striking periodic wave-like pattern was observed via AFM. We supplement these results with polarized RSoXS, NEXAFS, and ellipsometry to give a near-comprehensive picture of the remarkable structural diversity in thin films of aggregated PNDI2OD-T2.

11:45 AM EP05.05.07
Excitons and Mobile Carriers in Semiconducting Polymers and Polymer Blends Robert Street; Palo Alto Research Center, Palo Alto, California, United States.

The most obvious features in the optical absorption of semiconducting polymers are excitons, which exhibit disorder-broadened peaks with width 50-100 meV and phonon sidebands arising from electron-phonon interactions. The exciton binding energies are about 0.5 eV. Electronic devices such as solar cells and TFTs, reflect the properties of mobile carriers, either holes or electrons. Carriers in high mobility materials have a relatively small binding energy, often attributable to trapping in band tails. Excitons and mobile carriers are different species with characteristically different properties. For example, despite the fairly narrow exciton absorption bands, band structure calculations find band widths in polymers of order 1 eV. There is no contradiction, since one-electron bands are invariably larger than exciton linewidths and the two are largely unrelated. Band to band transitions are not apparent in polymer optical spectra because the exciton has a large oscillator strength by virtue its localization. A more significant difference between excitons and carriers is in their degree of localization, and one way to observe the difference is in miscible polymer blends. There are several examples where excitons are delocalized such that their wave function extends over several polymers and hence responds to an average alloy composition with an effective band edge that varies smoothly with composition. At the same time the excitons retain the character of the individual polymer because they are more highly localized on a single polymer chain, by virtue of their greater binding energy. Studies of dilute alloys give added information about the carrier delocalization. Modeling of electronic properties needs to recognize the difference. It is common to model the polymer as having narrow Gaussian bands similar in shape to the observed exciton absorption. Instead they should be modeled as lying within the wider bands characteristic of single carriers, and all evidence points to exponential rather than Gaussian disorder-induced band tails.

The central thesis of this talk is that many structural defects in crystalline organic semiconductors have surface potential signatures that can be recorded and imaged by scanning Kelvin probe microscopy (SKPM) with sub-100 nm resolution. This allows straightforward visualization of defects that are difficult to detect by other methods. Additionally, we argue that surface potential fluctuations are a direct measure of static electronic disorder, namely band edge variations, that will impact electron and hole transport. Thus, surface potential imaging not only reveals defects in crystalline organic semiconductors but importantly provides a direct link to electronic disorder (e.g., traps, scattering centers) that degrades transport performance. This talk will focus on three illustrative examples based on thin films and single crystals of benchmark organic semiconductors, including one case where we can make a thorough connection between structure, surface potential, and field effect transport. We propose that in many cases the surface potential contrast associated with a given defect arises due to inhomogeneous strain around the defect. To support this, we further describe the first direct measurements of the strain-surface potential relationship for macroscopic single crystals of rubrene. Overall, we suggest that surface potential measurements are a powerful approach to understanding correlated structural and electronic disorder in soft organic semiconductors.

Analytical electron microscopy (EM) is instrumental for visualizing the nanoscale morphology e.g. of the active layer in organic solar cells [1,2]. At present, transmission EM (TEM) is used, and electron energy loss spectroscopy (EELS) and low energy loss spectroscopic imaging (low-loss ESI) can be applied to generate material contrast in the images. This provides also information about the local electronic properties of the material analyzed. As an example, [2] visualized the mixed material phase in bulk heterojunctions (BHJ) via an increased EELS signal deriving from additional excitonic electronic states in the mixed material phase.

One obvious problem with TEM techniques, however, is the relatively high energy of the imaging electrons, which produces considerable beam damage especially for organic compounds. In addition, the projection character of the formed image leads always to the question, how the finite thickness of the sample may affect the assignment of different materials and material mixes in the projection image. To overcome the above mentioned TEM problems we have investigated a novel, advanced DELTA-SEM [3], which allows electron spectroscopy of secondary electrons (SEs). When lowering electron energies below e.g. 100 eV landing energy, beam damage seems minimized and at the same time the SE signal derives from a very thin surface layer of the sample.

In first experiments the polymer/fullerene BHJ PTB7:PC60BM was studied. At 50 eV landing energy we recorded SE spectra in analogy to ESI imaging used before. These raw spectra have been analyzed using non-liner statistical algorithms and machine learning. In contrast to [2] we this time used unsupervised machine learning, which excludes any additional personal bias. The resulting segmentations of the spectral BHJ images from both, TEM and novel Delta-SEM, were in excellent agreement with the “three phase model” proposed before.

To better understand the contrast mechanism of spectral imaging with the DELTA-SEM we performed additional experiments using a variety of organic semiconductors. Experiments with halogenated Tetraazapropyrrenes (TAPs) show distinct differences in SE spectra for non-conductive vs. semi-conductive TAPs. As described by theory [4,5] the shape of the SE spectra can be directly related to work-function, electron affinity, or bandgap. At present we investigate the possibilities to derive such electronic properties directly from our SE spectroscopic data.

For high-performance semiconductor devices, good ohmic contacts between the electrode and the semiconductor layer are required to enable the maximum current density across the contact. Nominally undoped conjugated polyelectrolytes have employed as charge transport layers in organic devices. They do not have a well-defined workfunction that is sufficiently small or large, nor a sufficiently low electrical resistivity. In this talk, I will discuss the self-compensated doped polymer strategy to overcome some of these challenges. The self-compensated, deliberately charge-doped polymers (polyelectrolytes) can provide the low resistivity and extreme WF needed to make true ohmic injection contacts. These doped polymers are generated by a separate charge-carring polymerization of conjugated polyelectrolytes and compensation by their covalently bonded counter-ion, which enables the use of strong dopants to access extreme workfunction. This strategy also stabilize film from de-doping and suppress dopant migration. We previously demonstrated solution-processed ohmic contacts using these self-compensated doped polymers for high-performance light-emitting diodes, solar cells, photodiodes and transistors, including ohmic injection of both carrier types into polyfluorene. I will further discuss the role of these counter-ion and also the spectator cations in their solution-processability, bulk and interface morphologies in workfunction manipulation. Yet another similar general strategy is using charge-doped polyelectrolyte monolayer assembly to achieve ohmic contact to semiconductor for field-effect transistors. An undoped polyelectrolyte monolayer is self-assembled and self-aligned to the electrode, sacrificial dopant ions are inserted into this layer, which then dopes the organic semiconductor at the contact. When this occurs, the doped interface is counterbalanced by the ‘undoped’ conjugated polyelectrolyte monolayer. Polyelectrolyte counter-ion monolayer cannot diffuse, so delta-doping is stabilized at the contact. This delta-doped layer has a well-defined work function at the semiconductor side of contact and sufficiently low tunnel resistance for direct metal injection into semiconductor, overcoming a critical challenges of using undoped polyelectrolytes.
remarkable ~hundredfold drop in time-of-flight hole mobility (layers using a combination of time-resolved, frequency-resolved, and steady-state transport measurements. We demonstrate that investigate the impact of introducing a planarised conformer, known as the ‘ To this end, we address the chain conformation – hole transport relationship in two model systems. In the case of poly(9,9-dioctylfluorene) (PFO), we conformational defects and observed transport properties. However, until now there has been little experimental evidence of the direct relationship between particular charge transport in organic semiconductors is characterised by a strong degree of disorder in both the site energy and the electronic coupling between adjacent sites. This disorder arises from variations in the chemical structure and conformation of molecular units, as well as in the weak binding interactions between them. Structural disorder due to molecular conformational freedom is expected to affect the density of states distribution, and hence the optoelectronic properties of the material. However, until now there has been little experimental evidence of the direct relationship between particular conformational defects and observed transport properties. To this end, we address the chain conformation – hole transport relationship in two model systems. In the case of poly(9,9-dioctylfluorene) (PFO), we investigate the impact of introducing a planarised conformer, known as the ‘β-phase’ [1], on vertical-mode hole transport through otherwise glassy PFO layers using a combination of time-resolved, frequency-resolved, and steady-state transport measurements. We demonstrate that β-phase introduces a remarkable ~hundredfold drop in time-of-flight hole mobility ($\mu_\beta$) at room temperature, while it reduces $\mu_\alpha$ measured from hole-only devices by a factor of less than 5. We also show how the use of high-dynamic-range photocurrent spectroscopy and energy-resolved electrochemical impedance spectroscopy [2] maps out a consistent picture of trap states due to the β-phase content, namely, a sharp sub-gap feature lying ~0.3 eV above the highest occupied molecular orbital of glassy PFO. Using a drift-diffusion model capable of resolving carriers in both time and energy [3], we show how the apparently contradictory transport phenomena obtained via different probes are explained by a single model with the experimentally derived density of states. We extend our study to a high-mobility indacenodithiophene-based copolymer (IDT–BT) [4] where—in contrast to PFO—the chains favour a planar structure 

Current organic electronics research aims at exploiting the unique property matrix of “plastic” semiconductors, including their chemical tunability, straightforward processability and mechanical flexibility, to create new applications. While much knowledge has been developed in the synthesis of semiconducting conjugated organic materials, there is still an immense need for establishing broadly applicable design guidelines towards highly conductive macromolecular matter. [1,2] Moreover, the multitude of possibilities for “plastic” semiconductors and dopants to assemble together over different length scales creates a daunting task to establish comprehensive and relevant correlations between structure, processing and properties. We will present here a multidisciplinary approach towards a framework to predict such structure/property interrelations. We will focus on polythiophene derivatives as model systems, including poly(3-hexylthiophene-2,5-diyl) (P3HT) and poly(2,5-bis(3-tetradecylthieno-2-yl)thieno[3,2-b]thiophene) (PBTTT), [3] and discuss how the spatial arrangement, manipulated through intercalation and co-crystal formation with dopants, affects charge transport. We will conclude with providing a tentative picture of the complex correlation of structure and electronic landscape for the understanding of conducting “plastics” of metallic-type transport.

We review the recent process made to develop quantitative models to predict the intrinsic mobility of molecular semiconductors, leading to the recently proposed "map of molecular semiconductors" [Nature Materials, 16, 998, (2017)]. We then discuss the two main avenues for computer aided materials discovery namely (i) the definition of benchmark accurately-resolved chemical systems and (ii) a rapid method to screen hundreds/thousands of compounds (real or hypothetical). A general approach to converge toward a common accepted theoretical model for charge transport in this class of materials is proposed.

Charge transport in organic semiconductors is characterised by a strong degree of disorder in both the site energy and the electronic coupling between adjacent sites. This disorder arises from variations in the chemical structure and conformation of molecular units, as well as in the weak binding interactions between them. Structural disorder due to molecular conformational freedom is expected to affect the density of states distribution, and hence the optoelectronic properties of the material. However, until now there has been little experimental evidence of the direct relationship between particular conformational defects and observed transport properties.

We extend our study to a high-mobility indacenodithiophene-based copolymer (IDT–BT) [4] where—in contrast to PFO—the chains favour a planar geometry in the ground state and therefore conformational heterogeneities are less likely to act as traps. We use our results on the two polymer types to consider the limits to charge-carrier mobility through disordered polymeric semiconductors, and design criteria for higher performance materials.

Versatile Molecules for Organic Electronics and Photonics

John Anthony, Chad Risko, Oana D. Jurchescu, Anthony J. Petty, Alex Ai and Hamna Haneef
University of Kentucky, Lexington, Kentucky, United States; Wake Forest University, Winston-Salem, North Carolina, United States.

Through combined efforts in theory and synthesis, we have developed ever more detailed understanding of the behavior of organic semiconductors in the solid state. From this knowledge, we have developed modified systems to enhance performance in both electronic and photonic applications. For charge transport, we are addressing issues related to vibrational modes (phonons) that can disrupt electronic coupling in two different ways - by substantially rigidifying the portion of the molecule that attaches solubilizing groups to the core, or by making the core itself more flexible, to better damp these vibrational modes. One of these approaches has already yielded new materials with impressive hole transport properties in transistors. On the photonic front, we have expanded the scope of molecules used in fast singlet fission, improving photostability and allowing attachment of functional groups to better interface with triplet-harvesting materials.

Plastic Semiconductors—How We Can Exploit Blending to Manipulate Functions?
Natalie Stingelin
Georgia Institute of Technology, Atlanta, Georgia, United States.

Artefacts made of polymers – “plastics” – are ubiquitous in our daily live, and polymers such as polyethylene, polypropylene or poly(ethylene terephthalate) have developed into multi-billion markets since their discovery some 80 years ago. Surprisingly, however, various, important aspects of these versatile materials are not understood, especially when used in blends. Processing them into useful products, especially of specific and/or multiple functions, is thus often directed by time-consuming, intricate trial-and-error approaches. The complexity result from the difficulty to characterize polymeric systems: they are of high molecular weight; they lack usually heavy atoms leading to low contrast between components; the feature a low stability, e.g. in electron beams, etc. Here we discuss pathways to gain understanding of the role of multiscale structure and phase behavior in determining the final properties and functions of multicomponent polymer blends, including ion and electron/hole transport (i.e. mixed conduction). Starting with systems where reliable processing pathways towards specific features have already yielded new materials with impressive hole transport properties in transistors. On the photonic front, we will show that combining classical polymer science tools with well-established and recently developed, characterization techniques can be used as examples of discoveries in the last decade that addition of large fractions of an insulating bulk ‘plastics’ such as high-density polyethylene does not negatively affect charge transport of electrons or holes and that addition of the commodity polymer poly(ethylene oxide) allows manipulation of the overall aggregate character of the ubiquitous polymeric semiconductor poly(3-hexylthiophene). Similar observations have been made with higher multifunctional architectures made of ‘plastics’ that can lead to a knowledge platform towards widely-applicable design rules for smart, plastic artefacts.

Polarons, Triions and Polaritons in Semiconducting Polymers and Carbon Nanotubes
Jana Zaumseil
Physical Chemistry, Heidelberg University, Heidelberg, Germany.

The near-infrared emission and absorption properties of semiconducting donor-acceptor polymers and single-walled carbon nanotubes are highly sensitive to the presence of charge carriers that may be induced electrochemically or by a field-effect. New states, here polarons or triions, with unique optical properties are formed and can be tuned, investigated and even utilized in a range of optoelectronics devices such as electrochromic cells, light-emitting transistors and diodes. Furthermore, the hybridization of light and matter in optical microcavities integrated in these devices and thus the formation of polaritons with low mass enables a new approach toward the manipulation of absorption and emission of carbon-based and solution-processed semiconductors. The controlled electrochemical generation of charged triion-polaritons with low effective mass in purified, monochiral single-walled carbon nanotubes may even lead to cavity-enhanced charge transport. Here, we will discuss several examples of (cavity-integrated) devices that rely on polarons, triions or polaritons.

8:30 AM **EP05.08.02
Organic Polariton Photodiodes with an Extended Responsivity
Eldad Eizner, Julien Brodeur, Fábio Barachati, Aravindan Sridharan and Stéphane Kéna-Cohen
Engineering Physics, Polytechnique Montréal, Montreal, Quebec, Canada.

Exciton-polaritons are hybrid light-matter quasiparticles which are formed when molecules are placed within an optical cavity such that their electronic transition can interact strongly with the vacuum electromagnetic (EM) field. In this regime of interaction, the rate of energy transfer between Frenkel molecular excitons and EM modes is faster than their individual uncoupled decay rates. The polariton dispersion relation is separated into upper (UP) and lower (LP) branches with resonance energies that lie on opposite sides of the bare exciton energy. Over the last decade, polaritons have attracted great interest due to their remarkable light-matter properties and have been exploited for novel device applications such as low-power polariton lasers, polariton optical circuits, quantum devices.

In principle, the efficiency and spectral response of an organic photodiode (OPD) is limited by the photophysical and optoelectronic properties of the active layers. In particular, it has been extremely challenging to develop active layers (typically the donor) which absorb light efficiently at near infrared and infrared wavelengths. Therefore, an attractive novel approach to push the donor absorption to the infrared without requiring the synthesis of new materials.
is to strongly couple the excitons with vacuum EM field. Especially, in the ultra-strong coupling (USC) regime, the LP absorption can be red-shifted by a significant fraction of the bare exciton energy while still maintaining a large exciton content.

In this work, we demonstrate for the first time polariton OPDs operating in the USC regime. This is achieved in a standard OPD structure consisting of a mixed donor-acceptor heterojunction with Silver (Ag) electrodes that also act as mirrors to form the optical cavity. We study two types of polaritonic OPDs using donor materials that have previously been widely used for organic photovoltaics. A visible absorber, copper (II) phthalocyanine (CuPc), and a near infrared absorber, tin (II) phthalocyanine (SnPc). These devices show narrow responsivity with a very weak angle-dependence. More importantly, they can be tuned to operate in a spectral range outside that of the bare exciton absorption. Remarkably, we show that the responsivity of a polariton OPD can be pushed to near infrared wavelengths, where few organic absorbers are available, with external quantum efficiencies exceeding those of a control OPD. In the presentation, I will also discuss possible polariton modifications to the molecular photophysics beyond the absorption spectrum, e.g. in charge separation and diffusion.

Unsymmetric Squaraine for Narrow Band Green-Selective Organic Photodiodes

Hang Guo, Ziang Wang, Kai Huang and Guifang Dong; Chemistry, Tsinghua University, Beijing, China.

Color-selective photodetectors have drawn considerable attention due to their extensive applications in optical communication, chemical/biological sensing, and environmental monitoring. Recently, organic photodiodes (OPDs) are becoming promising candidates for narrowband detection to meet new requirements on detectors which represent a new generation of devices with great potential to be integrated in smart and portable device because of their light weight, biodegradable, and low-cost fabrication on large-area and flexible substrates. Moreover, the materials with different absorption range can be fabricated by changing the substituent group in the organic materials which greatly expand the applications of OPDs. Here, a new narrowband green-light sensitive unsymmetric 2-[3,5-dimethyl-1H-pyrrol-2-yl]-4-diphenylamino] squaraine (UPSQ), with donor-acceptor donor (D-A-D) structure and the applications in photodiodes are reported. We optimize the molecular configuration of the S1 excited state and ground state of UPSQ, at the B3LYP level of the DFT method with the 6-31 g (d) basis set by Gaussian 09. The low total reorganization energy and the small Δ value indicate that the configuration of the S1 excited state is almost the same with that of ground state. Furthermore, the resonance parameter (c^2) of the UPSQ is calculated to be 0.3, indicating that the UPSQ is close to the cyanine limit. As a result, the UPSQ shows the sharp and strong absorption in the solution. Then, the optimum thickness of the PSQ film is calculated to be 55 nm by transfer matrix simulation in the single-layer device. Due to the simple single-layer structure, the device shows excellent color-selective performance. The external quantum efficiency (EQE) of the device in green region (500 nm) reaches 15 % while the EQE in red region is less than 1 %. The device also shows very high current density of ~20 nA/ cm^2 at ~2 V and high detectivity of 3.1× 10^11 Jones. In addition, the device exhibits a narrow band green selective peak at 500 nm with low full width at half-maximum value of 90 nm, which shows the great potential to meet the requirements of applications in optical communications, environmental monitoring and machine vision. In summary, this work demonstrates a new strategy to design the green-light organic materials by changing the substituent group of the D-A-D structure in the squaraine, which can be extended to fabricate the materials with narrow absorption in other wavelength region.

9:00 AM EP05.08.04
Ionic Organic Small Molecules as Hosts for Light-Emitting Electrochemical Cells

Matthew Moore, Melanie Bowler, Yulong Shen, Jason D. Slinker and Jonathan Sessler; 1 The University of Texas at Dallas, Richardson, Texas, United States; 2 Department of Chemistry, The University of Texas at Austin, Austin, Texas, United States.

Light emitting electrochemical cells (LEECS) from ionic transition metal complexes (iTMCs) offer the potential for high efficiency electroluminescence in a simple, single layer device. However, LEECs typically rely on the use of rare metal complexes. This has limited their cost effectiveness and put constraints on their applicability. With a view to leveraging the efficient emission of these complexes while mitigating costs, we describe here a host/guest LEEC strategy that relies on the use of carbazole-based small molecule organic host molecules and iTMC guests. Three positively-charged host molecules were prepared via the coupling of 4-bromophenylbenzimidazole (PBI) with a carbazole (Cz). This has allowed a comparison between hosts bearing methoxy (PBI-CzOMe) and tert-butyl (PBI-CzteBu) substituents, as well as an unsubstituted analogue (PBI-CzH). Cyclic voltammetry and UV-visible absorption revealed that all three host materials have wide bandgaps characterized by reversible oxidation and irreversible reduction events. Based on electronic structure calculations the host HOMO resides primarily on the carbazole moiety while the LUMO is located primarily on the phenyl-benzimidazolium unit. Photoluminescence analysis of thin film blends of PBI-CzH with iTMC guests confirmed that the emission was blue-shifted relative to pristine iTMC films, consistent with what was seen in dilute dichloromethane solution. LEEC devices were prepared based on thin films of the pristine hosts, pristine guest, and 90%/10% (w/w) host/guest blends. Among these host/guest blends, LEEC's based on PBI-CzH displayed the best performance, particularly when an iridium complex was used as the guest. The system in question yielded a luminescence maximum of 624 cd/m^2 at an external quantum efficiency of 3.80%. This result stands in contrast to what is seen with typical OLED host studies, where tert-butyl substitution of the host generally leads to better performance. To rationalize the present observations, the host structures were found to be single crystal X-ray diffraction analysis. The resulting structures revealed clear host-guest interactions in the case of both PBI-CzH and PBI-CzOMe. No such interactions were evident in the case of PBI-CzteBu. Furthermore, PBI-CzH showed a relatively smaller spacing between the successive HOMO and successive LUMO levels relative to PBI-CzOMe and PBI-CzteBu, a finding consistent with more favorable charge transport and energy transfer. The results presented here can help inform the design and preparation of host materials suitable for use in single layer iTMC LEECs.

9:15 AM EP05.08.05
Nano-Alignment in Semiconducting Polymer Films—A Path to Achieve High Current Density and Brightness in Organic Light Emitting Transistors

Mujeeb U. Chaudhry1 and Ebinazar Namdas2; 1 Department of Engineering, Durham University, Durham, United Kingdom; 2 School of Mathematics and Physics, University of Queensland, Brisbane, Queensland, Australia.

The charge carrier mobility in Organic light emitting field effect transistors (OLETs) is a limiting factor in realising high current densities along with a trade-off between brightness and efficiency. In this work we, we present a highly ordered semiconducting polymer films by controlling the nanoscale morphology through nanoscale grooved substrates and dip coating deposition. The OLET device fabricate using these ordered films results in high current densities in OLETs. The heterostructure OLETs demonstrate high brightness, exceeding 29,000 cd m^-2 at an EQE of 0.4% for a yellow emitter and 9,600 cd m^-2 at EQE of 0.7% for a blue emitter. These devices outperform the best OLETs reported in literature. These results represent a significant advancement in organic optoelectronics and are an important milestone towards realization of new applications in displays and electrically pumped lasing.
Singlet-fission (SF) and triplet-triplet-annihilation (TTA) in organic materials at room temperature have recently gained much interest. The increasing focus on SF is due to the promise of increased current density for organic photovoltaics and quantum yields approaching 200% in detector applications, while the interest in TTA is in the promise of organic light emitting diodes (OLEDs) with emission yields beyond the 25% singlet limit and low turn-on voltages. Recent studies have focused on rubrene as possible singlet fission and triplet-triplet annihilation material and devices based on rubrene bilayers with a luminescence threshold of approximately half the bandgap of rubrene have been reported. Two mechanisms have been proposed as the origin of the early turn-on: (i) Auger assisted energy up-conversion, and (ii) triplet-triplet annihilation at the heterojunction interface. In both cases, the charge dynamics at the heterojunction interface are crucial to the mechanism, yet detailed investigations on these higher order processes are missing. Herein, we systematically alter the rubrene/C60 interface in OLED devices, resulting in either greatly suppressed or enhanced formation of the CT state and recombination rate. We find that suppressing the CT-formation yields a 3-fold increase in device lumiance compared to the prototypical rubrene device, while maintaining a low turn-on voltage. The increased lumiance of devices with a BCP interlayer suggests a reduction in parasitic effects of the CT state. Quantitative analysis of the modified interface devices suggest that Auger assisted up-conversion and TTA can be ruled out as the origin of the sub-bandgap turn-on. Rather, band-to-band recombination remains the most likely radiative recombination process.

Photoluminescence Quantum Yield Simulation Method for Phosphorescent OLED Emitter Materials Inkoo Kim, Won-Joon Son and Youn-Suk Choi; Samsung Electronics, Suwon, Korea (the Republic of).

High-performance organic light-emitting diode (OLED) devices incorporating phosphorescent emitter materials are undoubtedly one of the most promising candidates for next-generation flat panel and mobile displays, because not only of their superior picture quality showing high contrast ratios and wide color gamut, but also of their efficient power consumption. Cyclometallated complexes as phosphorescent dopants disposed within the emissive layer can effectively harvest both singlet and triplet electrogenerated excitons, leading to internal quantum efficiencies close to 100%. Among many required properties for high performance, photoluminescence quantum yield (PLQY) and radiative lifetime of emitters are the two key photophysical properties of phosphorescent emitters for securing durability and efficiency of the OLED device. The former has been notoriously difficult to simulate computationally as the underlying non-radiative triplet-singlet transition is spin-forbidden and demands the interplay of spin-orbit and non-adiabatic coupling.

In this work, we report a novel formulation for quantitative predictions of PLQY of phosphorescent OLED emitter materials. The present method based on purely first-principle theoretical ground for reliable predictions, incorporating the relativistic and the non-Born-Oppenheimer effects on the same level of generalization in the framework of Fermi’s golden rule using correlation function approach. The accuracy of the present method is assessed and verified by comparing the computed results with the experimental results of various cyclometallated complexes in red-to-green spectral range, respectively, and is substantiated its applicability for the blue-emitters. The results of this work demonstrates that quantitative PLQY predictions of phosphorescent emitters over the entire color range can be delivered solely from quantum chemical calculations, providing additional means of narrowing down the optimal emitters in an a priori fashion in the on-going development of novel phosphorescent emitters for a future OLED device.

Modeling Excitonic Energy Upconversion in Molecule-Nanocrystal Hybrid Devices Troy Van Voorhis; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Photon energy upconversion is a potentially viable strategy for increasing the power conversion efficiency of conventional single junction solar cells. Recently hybrid devices involving colloidal semiconductor quantum dots coupled to molecular chromophores have shown remarkably high upconversion efficiencies. The basic mechanism involves light absorption by the dot, followed by triplet energy transfer to the chromophore with a final step of triplet-triplet annihilation to generate a single, high-energy output photon. Here, we present a holistic approach to simulating the key step of triplet energy transfer. We begin by developing a kinetic model for understanding the transient PL spectra of the devices, which allows us to isolate the triplet transfer rate directly from experimental measurements. Second, we examine the electronic states that participate in the triplet energy transfer step, paying particular attention to surface trap states that likely modulate energy transfer. Finally, we study the dependence of the rate on the ligand shell, showing that unexpected restructuring of the ligand sphere dramatically influences the transfer rate.

New Frontiers for Triplet Fusion Upconversion Dan Congreve1, Andrew Pun2 and Luis Campos2; 1Rowland Institute at Harvard, Cambridge, Massachusetts, United States; 2Columbia University, New York, New York, United States.

Upconversion, the process of generating one high energy photon from two low energy ones, holds huge potential across a wide variety of applications. One rapidly emerging process to achieve upconversion is triplet fusion upconversion. This process requires two materials: a sensitizer that absorbs low energy light and transfers it to a triplet annihilator which can convert two triplets into one high energy singlet, which can then fluoresce. Recent materials efforts has led to rapid improvements in efficiency and spectral range, with infrared-to-visible upconversion reaching as far into the infrared as 1000 nm. These strong materials improvements have now opened up a wide range of applications in which this unique process can be applied.

In this talk, I will demonstrate these material improvements and the new fields we can apply them to. First, we utilize a new series of annihilators to precisely tune the upconverted emission to the wavelength needed for a particular application. By pairing these annihilators with photocatalysts, we can perform photochemistry using only NIR light, where visible or blue light would traditionally be required, opening up new avenues for scale-up and drug...
delivery. Finally, we show that by precisely engineering a nano-carrier, we can build these materials into a bio-compatible platform, allowing for new discoveries in optogenetics and bio-imaging that are not hampered by the limited light penetration and high power densities of traditional measurement techniques.

Long-Lived Triplet Excitons and Radical Ion Pairs in Organic Semiconducting Host–Guest Systems

**Ryota Kabé**, **Naoto Notsuka**, **Kenichi Goushi**, **Chihaya Adachi**, **JST-ERATO ADACHI Molecular Exciton Engineering Project, Fukuoka, Japan**, **OPER, Kyushu University, Fukuoka, Japan**, **International Institute for Carbon-Neutral Energy Research, Fukuoka, Japan.**

Long persistent phosphors are widely commercialized as glow-in-the-dark paints for watches, indicators, emergency lights, and afterglow safety lamps and are being explored for use in in vivo bioimaging since the emission can be observed long after excitation. Some organic aromatics are known to show long-lived emission called phosphorescence originating from a spin-forbidden transition from the triplet excited state to the single ground state at low temperatures. However, long-lived triplet excitons on organic molecules easily deactivate at room temperature because of the presence of thermally activated nonradiative pathways. We demonstrate long-lived phosphorescence, under both optical and electrical excitation, at room temperature resulting from suppression of the nonradiative deactivation of triplet excitons in conventional organic semiconducting host–guest systems. The nonradiative deactivation pathway strongly depends on the triplet energy gap between the guest emitting molecules and the host matrices, and we show that the triplet energy gap required to effectively confine the long-lived triplet excitons (~0.5 eV) is much larger than that of conventional host–guest systems for phosphorescent emitters (N. Notsuka et al. Adv. Funct. Mater. 27, 1703902 (2017)).

A host–guest system can also produce long-lived emission through efficient stabilization of the radical ion pair generated between an electron donating molecule and electron accepting molecule. A blend of the strong electron-donating molecule N,N,N',N'-tetramethylbenzidine (TMB), which has a very stable radical cation, and the strong electron-accepting molecule 2,8-bis(diphenylphosphoryl)dibenzo[b,d]thiophene (PPT), which has a high triplet energy and provides a rigid amorphous environment to help suppress nonradiative deactivation, forms excited-state charge-transfer (CT) complexes (exciplexes) upon weak photo-irradiation. Some of the exciplexes separate into radical ion pairs, and the generated radical cation localizes on TMB while the radical anion diffuses through the PBPO host and is stored for long periods. Gradual charge recombination of radical ion pairs in this system produces continuous emission over 1 h at room temperature. This organic long persistent luminescence (OLPL) system is transparent and soluble, and potentially flexible and color tunable, which will open new applications for LPL in large-area and flexible paints, biomarkers, fabrics, and windows (R. Kabé et al. Nature 550, 384–387 (2017)).

11:30 AM EP05.09.04
Flapping Molecule as a Key Structure for Light-Melt Adhesive and Ratiometric Force Probe

**Shohei Saito**, Kyoto University, Kyoto, Japan.

Flapping molecules (FLAP) bearing a fused 8-membered ring at the center have recently been recognized as an emerging class of photoresponsive systems. The FLAP molecules were reported as key structures that show a V-shaped-to-planar conformational change in the lowest singlet excited state (S1), emitting fluorescence liquid crystals.[3] Along with this line, we have demonstrated the utilities of FLAP as photofunctional materials such as photoresponsive liquid crystals.[3] light-melt adhesive,[4] molecular viscosity probes,[5] singlet fission chromophores,[6] and conformationally flexible mechanophores.[7] In this presentation, the latest progress of the FLAP-based materials will be introduced, including a liquid crystalline adhesive that melts by light and a ratiometric fluorescent mechanophore for the chemical analysis of polymer stress concentration.

From Twisted to Planar Thermally Activated Delayed Fluorescence Organic Emitters—Higher Quantum Yield and Sharp Emission

**Ramin Ansari**, **Seong Jun Yoon**, **Jinsang Kim**, **Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States; 2Material Science, University of Michigan, Ann Arbor, Michigan, United States; 3Macromolecular Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.**

In the traditional molecular design of thermally activated delayed fluorescence (TADF), molecules are composed of electron-donor and electron-acceptor groups, a common strategy to minimize the singlet-triplet energy gap (ΔEST). However, this strategy enhances geometric changes in molecular conformation, resulting in a small fluorescence oscillator strength, which can significantly decrease the emission quantum yield. Moreover, this strategy also leads to a broad emission spectrum with full-widths at half-maximum (FWHM) of about 70-100 nm. By synergistically combining experiments and simulation, we were able to design novel planar TADF emitting molecules, suppressing molecular conformation changes and achieving higher electroluminescence efficiencies and sharp emissions. The emission spectra of planar and twisted organic molecules has been theoretically studied in the Franck-Condon (FC) framework and using nuclear ensemble (NE) methods. We find that for planar and rigid molecules the emission spectra obtained using FC method are in better agreement with experimental results, while for flexible and twisted molecules emission spectra produced using the NE method are in better agreement with experiments. The effect of using thermal and quantum sampling are also analyzed with the NE approach. Our results can be used to guide future TADF organic molecules and better theoretical investigation of emission properties of planar and twisted organic molecules.
The process on what controls the photogeneration of free charges in organic donor-acceptor films is still not well understood. In this presentation I shall show that the primary step of electron transfer from a photoexcited donor to the acceptor in an organic donor-acceptor type film is not suitable described by Marcus theory, an in particular independent of the driving force.[1] In contrast, the subsequent step of dissociating the thus-formed charge-transfer (CT) state strongly depends on energetics, and is assisted by delocalization. Further, I shall show that a description of the absorption and emission spectra of CT states is not consistent with both Marcus’ electron transfer theory and the original Marcus-Levich-Jortner (MLJ) theory. Instead, the inclusion of disorder effects is crucial for a suitable and consistent description[2]. Both, PL and EQE spectra of CT states can be rationalized in terms of the classic Franck-Condon picture of electronic transitions that couple to intra-molecular vibrations as well as low frequency modes of the donor-acceptor pair that forms the CT state.

Quantitative Analysis of Electronic Structures in Organic Planar Heterojunctions and Their Effects on Photovoltaic Properties

Kyohei Nakano1, Weinig Han2, Jianming Huang1, Yujiao Chen1, Hiroyuki Yoshida2 and Keisuke Tajima2; 1RIKEN, Wako, Japan; 2Chiba University, Chiba, Japan.

Electronic properties of an organic donor and acceptor materials have a primary importance for the performance of organic photovoltaics. In practice, however, mixing morphology of the donor and the acceptor in bulk heterojunction has a large impact on photovoltaic properties, which makes it difficult to reveal the relationship between the electronic structures and the charge generation/recombination efficiency.

In this study, we systematically investigated planar heterojunctions with a flat donor/acceptor interface fabricated by contact film transfer method, in which a thin film of donor polymer is transferred onto an acceptor thin film. Before the film transfer, ultraviolet photoemission spectroscopy and low-energy inverse photoemission spectroscopy were conducted to obtain the electronic structures of the surface of each film, which gave the information on the electronic structures of the donor/acceptor interface after making the contact. This allows us to investigate the electronic structures near the D/A interface quantitatively and their effects on the resulting photovoltaic performances without any effects of the morphology. Combinations of four donor polymers and four acceptors (one fullerene derivative and three non-fullerene acceptors) were tested (16 systems in total).

The results clearly showed that the charge generation become more field-dependent as the energetic offsets of the donor and the acceptor decrease. This indicates that the energetic offsets have a large influence on the charge generation efficiency, which appears to oppose to the concept claimed in the recent reports that the charge generation happens through thermalized “cold” charge transfer states. The detailed analysis of this controversial observation will be given in the presentation. In addition, we found the same effects of the energetic structures for non-fullerene acceptors as for the fullerene derivatives except strong light absorption in visible range. Therefore, we concluded that the non-fullerene acceptors are not special in term of the energetic driving force for the charge generation.

2:15 PM EP05.10.03
Thermodynamics of Charge Separation in Organic Solar Cells

Samantha Hood1, Adam Gluchowski2, Katherine Gray2 and Ivan Kassal1; 1Imperial College London, Kensington, United Kingdom; 2The University of Queensland, St Lucia, Queensland, Australia; 3The University of Sydney, Sydney, New South Wales, Australia.

Organic solar cells are promising candidates as a renewable energy source due to the possibility of cheap, lightweight and flexible devices. However, due to their disordered structure, charge behaviour in these devices is not well understood, making it difficult to systematically improve device performance. In particular, a vigorous debate surrounds how the positive and negative electric charges overcome their mutual attraction to form an electric current. While charge separation can occur with near-unity efficiency and on a sub-picosecond timescale, the full details of this process remain unclear. In typical models, the Coulomb binding between the electron and the hole can exceed the thermal energy $k_B T$ by an order of magnitude, making it impossible for the charges to separate before recombining [1, 2].

Here, we consider the entropic contribution to charge separation in the presence of disorder and find that even modest amounts of disorder have a decisive effect, reducing the charge-separation barrier to about $k_B T$ or eliminating it altogether [3]. Therefore, the charges are usually not thermodynamically bound at all and could separate spontaneously if the kinetics otherwise allowed it.

We also investigate the role of charge delocalisation on lowering the Coulomb attraction between charges. Delocalisation has been typically thought to lower the barrier to charge separation by effectively allowing the charges to be further apart. We show that this is not the case: including more than a small amount of delocalisation results in an increase in the barrier to charge separation [4]. This means that if delocalisation were to improve charge separation efficiencies, it would have to do so via non-equilibrium kinetic effects that are not captured by a thermodynamic treatment of the barrier height.

Determining the Driving Force for Photo-Induced Electron Transfer in Sensitized Organic Materials

Garry Rumbles1, 2, *, 1National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2Chemistry and Biochemistry, University of Colorado Boulder, Boulder, Colorado, United States; 3Renewable and Sustainable Energy Institute, University of Colorado Boulder, Boulder, Colorado, United States.
This presentation will discuss charge carrier generation and recombination in conjugated polymer and molecular thin films that have been sensitized using molecular electron acceptors at low concentration. Carrier generation is detected using time-resolved microwave conductivity and transient absorption spectroscopy.

A number of fullerene and macrocycle electron acceptors will be discussed, where the driving force for photo-induced electron transfer is controlled primarily by the reduction potential of the acceptors species, and is calculated using the Rehm-Weller equation. The importance the solid-state microstructure of the polymer in controlling the yield and lifetime of the long-lived carriers will be examined, when the primary excitation is an excited singlet-state located on the acceptor. In addition, charge carrier generation in pentacene will be examined, where the triplet excitations are produced from singlet-fission, and a series of electron acceptors capable of dissociating these low energy species is explored.

4:00 PM EP05.10.05
Direct 3D Imaging of the Bulk Heterojunction Microstructure in Organic Solar Cell
Artem Levitsky and Gitti L. Frey; Technion–Israel Institute of Technology, Haifa, Israel.

In the realm of functional materials, properties correlate with internal microstructure. This is true for iron alloys, for example, where the carbon-iron phase diagram determines the abundance of different phases, but their size and distribution, determines the steel’s strength. Similarly, performances of organic electronic devices should correlate with film morphology, i.e. film microstructure. However, identifying the types of phases, domain size, composition and distribution is experimentally because all components are organic and often amorphous. Hence, until now, organic electronic film morphologies were speculated based on indirect and non-comprehensive measurements. Here we show a new approach for directly imaging the microstructure of organic electronic films. This is achieved by selective diffusion and retention of organometallic molecules into different phases. We demonstrate this methodology for correlating the performance of high efficiency organic solar cells with their microstructure. The diffusing molecules are Atomic Layer Deposition (ALD) precursors and their diffusion and in-situ conversion to the respective metal oxide depends on free volume in each domain. Under such conditions, presence of metal oxide particles, easily identified by electron microscopy techniques, effectively maps selected domains in the film. Using this technique, we are able to fully map the BHJ microstructure, i.e. size and distribution of the different phase domains composing the BHJ. We find that the microstructure depends on blend composition and processing technique. Finally, the visual imaging of the BHJ allows us to directly correlate the microstructure with device performance shwoing that the obtained microstructure determines solar cells performance.

4:15 PM EP05.10.06
Relationship Between Charge-Transfer State Properties and Non-Radiative Voltage Losses in Organic Bulk-Heterojunction Solar Cells
Flurin D. Eisner, Mohammed Azzouzi, Zhiping Fei, Martin Heeney and Jenny Nelson; Imperial College London, London, United Kingdom.

The primary pathway to efficiency losses in bulk-heterojunction organic solar cells (BHJ-OSCs) is believed to be the non-radiative decay of a charge-transfer (CT) state to the ground state via energy transfer to vibrational modes. It has been suggested that the open circuit voltage in OSCs is largely determined by the energy of the donor-acceptor CT state, and thus many recent studies have focussed on increasing the energy of CT states by minimizing the energy offset between the donor and acceptor. This relationship can be rationalized by the understanding that a higher overlap of the vibrational modes of the CT and ground states increases the rate of non-radiative recombination. However, some recent studies have found that increasing the CT state energy does not always result in a reduction in the non-radiative voltage losses, which suggests that other properties of the CT state play a role in determining the non-radiative voltage losses.

Here, we systematically investigate the relationship between CT state properties and voltage losses in BHJ-OSCs by using a series of increasingly fluorinated PBDB-T donors, in conjunction with a variety of different fullerene and non-fullerene acceptors. Firstly, we show that by depressing both the HOMO and LUMO through fluorination of the donor, the energy of the donor-acceptor CT state can be effectively moved closer to the first excited state. Secondly, by performing a detailed voltage loss analysis of the various blends we find that the non-radiative voltage losses do not reduce systematically with increasing CT state energies; instead, non-radiative voltage losses are minimised, reaching values as low as 0.22 V, for systems where the CT state and first excited state energies are very close. We suggest that this reduced non-radiative voltage loss results from the hybridization of the CT state with the first excited state and the effect of this hybridisation on the CT state oscillator strength. Using a new model to quantify the non-radiative voltage losses, we simulate the latter observed behaviour through an increase in both the CT state energy and the oscillator strength of the CT state to ground state transition affect the trend.

Photoinduced Charge Generation Dynamics at Heterojunctions Between Semiconducting Single-Walled Carbon Nanotubes and Perylene Diimide Electron Acceptors

Semiconducting single-walled carbon nanotubes (s-SWCNTs) have been intensively studied as the components of various photovoltaic cells due to several advantages such as band gap tunability, high flexibility, chemical robustness, giant aspect ratio, and hydrophobicity. To understand the fundamental aspects of interfacial exciton dissociation and charge recombination at the heterojunction utilizing s-SWCNTs, fullerene-based electron acceptors have been paired with s-SWCNTs in many studies. However, these types of studies have been rare for the heterojunctions of s-SWCNTs and non-fullerene electron acceptors. Studies on interfaces with acceptors with unique molecular geometries and differing extents of aggregation can be useful for understanding how much the molecular geometries/orientations and aggregation influence on the charge generation and recombination processes. In this study, we investigated the detailed photodynamics of the heterojunctions between (6,5) s-SWCNTs and four different perylene diimide (PDI) based electron acceptors. PDI-based electron acceptors have been distinguished as a potential alternative of fullerene-based acceptors by their superior characteristics such as broader absorption, greater spectral tunability, cheaper cost, and higher robustness.

Four novel PDI-based electron acceptors were synthesized and coated on (6,5) s-SWCNT films to form donor-acceptor heterojunctions. These acceptors can be divided into two classes. One is hPDIx-pyr-hPDIx (x = 2, 3; number of PDI units in hPDIx, PDI oligomers), where a central pyrene (electron donor) linker is covalently attached to PDI oligomers, and the other is Trip-hPDIx, where hPDIx is connected to each side of a central triptycene linker. Their molecular structures induce significant intermolecular steric hindrance to reduce excessive aggregation, although the aggregation state appears to
differ amongst the different acceptors. Transient absorption studies reveal that the photoinduced hole/electron transfer at the (6,5) s-SWCNT/PDI-based acceptor heterojunction occurs, and the separated charges can live longer than 1 μs. The charge-separated states at (6,5) s-SWCNTs/hPDIs-pyr-hPDix heterojunctions live longer than those at (6,5) s-SWCNTs/Trip-hPDIs heterojunctions. Differences between exciton dissociation and charge recombination times will be discussed in terms of the differences in thermodynamic driving force and the molecular geometries, the latter affecting aggregation and the concomitant delocalization and entropy available to electrons in the acceptor phase. These physical processes provide the fundamental understanding of how different electron acceptor materials can impact the charge generation processes at s-SWCNT heterojunctions with respect to the heterojunction energetics and molecular orientations. The results can inform the rational design strategies for s-SWCNT-based optoelectronic applications.

**Nonlinear Impedance Spectroscopy of Organic MIS Capacitors and Planar Heterojunction Diodes**

Matthew S. White¹, Andrew Larsen¹, Ekraj Dalal¹, Justin Palabu¹, Karen Cianciulli², Benjamin Isenhart¹, Michael Arnold¹, Bin Du¹ and Yu Jiang¹; ¹University of Vermont, Burlington, Vermont, United States; ²Asheville School, Asheville, North Carolina, United States.

We present a nonlinear impedance spectroscopy technique and demonstrate its ability to directly measure nonlinear processes including electron-hole recombination and space charge effects in organic-semiconductor-based diodes and MIS capacitors. The method is based on Fourier analysis of the measured higher harmonic current response to an AC voltage signal. Characterization of the higher harmonic response allows nonlinear impedance spectroscopy to measure material and device properties over a wide range of frequencies, which would otherwise be impossible using conventional impedance spectroscopy. As the higher harmonic signals are purely a product of nonlinear processes, they are independent of the linear device capacitance and resistance. This allows space charge and recombination effects to be investigated at several orders of magnitude higher frequency without fitting to an equivalent circuit model.

**Management of the Coulomb Interaction in Organic LEDs and Solar Cells**

Richard H. Friend; University of Cambridge, Cambridge, United Kingdom.

The physics of organic semiconductors is often controlled by large electron-hole Coulomb interactions and by large spin exchange energies. I will discuss recent strategies that allow these interactions to be harnessed for efficient device operation. For LEDs, 3:1 statistical formation of triplet:singlet excitons through electron-hole recombination limits efficiency if the triplet state is non-emissive, but is recovered for systems with reduced exchange energy and strong spin-orbit coupling in organo-metallic systems or for systems where triplet-triplet collisions produce singlet excitons efficiently. For organic PV systems, long-range charge separation from the donor-acceptor heterojunction must overcome a substantial Coulomb barrier, which we find always sets up a measurable optical Stark shift that we measure to be 200 meV or more. Whether this separation is ultrafast (sub-picosecond) or slow (>10 psec) depends on the ‘excess’ energy provided by the photogenerated exciton to the separating electron-hole pair, both for fullerene acceptor systems and those with non-fullerene acceptors. Longer time bimolecular recombination should show similar spin statistics to LED operation, causing significant non-radiative recombination for triplet formation where there is easy access to a low-lying localized triplet state. I will present evidence that though fullerene systems generally show rapid bimolecular triplet formation, this can process can be very strongly reduced in some non-fullerene acceptor systems.

**8:30 AM EP05.11.02**

**The Impact of Driving Force on Recombination Dynamics in Nonfullerene Organic Solar Cells**

Yifan Dong⁴, Hyojung Cha¹, Jiangbin Zhang¹, Ernest Pastor⁴, Padhi Srika Tuladhur⁴, Iain McCulloch¹, James R. Durrant¹ and Artem Bakulin¹; ¹Imperial College London, London, United Kingdom; ²University of Cambridge, Cambridge, United Kingdom; ³King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Nonfullerene organic solar cells have demonstrated superior performance compared to the ones with fullerene acceptors. Despite the major world-wide effort in device development and spectroscopic studies, the specific photophysics of nonfullerene acceptor-based materials (NFAs) remains unclear, and it is still not fully understood what controls charge separation and recombination processes. Here, we compare charge carrier dynamics in polymer:acceptor systems using NFA IDTBR and fullerene PC₇₀BM. Transient absorption spectroscopy shows that when blending with P3HT:2OD, IDTBR based blend exhibits enhanced geminate recombination compared to PCBM-based blend. This limits the charge generation and hence the short circuit current in devices.

We also employ pump push photocurrent spectroscopy from 300 K to 77 K to further elucidate the cause of efficiency loss. These measurements reveal presence of bound charge transfer states and long-lived trapped carriers as well as allow the estimation their respective binding energies.

**8:45 AM EP05.11.03**

**Non-Geminate Recombination Limits Fill Factor in Polymer:ITIC Bulk Heterojunction Solar Cells**

Jafar I. Khan, Yuliar Firdaus, Pierre M. Beaujuge and Frédéric Laquié; King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

Nonfullerene acceptors have emerged as promising fullerene replacements in organic photovoltaics and recently power conversion efficiencies have surpassed 14 %. Despite the rapid progress, fundamental understanding of the photo-physical processes is still lacking and identifying the loss mechanisms in devices is important for future material design and device optimization. Here, we investigate the impact of polymer side chain substitution in BDT-thiophene copolymers on the performance of three bulk heterojunction solar cells that use ITIC as nonfullerene acceptor: PBDT2HT:ITIC (2.5%), PBDT2HT:ITIC (4.2%) and PBDTT2FT:ITIC (9.8%). All blends absorb across a wide spectral region due to the complementarity of the donor polymer and ITIC acceptor absorption spectra. Transient spectroscopy has been used to monitor exciton generation, diffusion, and dissociation as well as charge carrier recombination in all three systems. We observe significantly more geminate recombination in the alkylx-substituted PBDT2HT:ITIC blend in addition to nongeminate recombination of free charges, limiting both the short circuit current and fill factor. The alkylx-thiophene-substituted PBDT2HT:ITIC blend exhibits less geminate recombination but significant nongeminate recombination, limiting the fill factor to about 40%, while...
backbone fluorination in PBTTT2FT:ITIC leads to fast and efficient charge separation and significantly reduced non-germanite recombination, resulting in fill factors in excess of 60%. Time-delayed collection field measurements showed that charge generation in PBTTT2FT:ITIC is field-independent, while a weak field dependence is observed for the other two systems. Our findings provide important structure-property relations and design rules for new nonfullerene materials.

Charge Generation and Recombination in Dilute Organic Solar Cells

Charge generation and recombination processes in low donor concentration organic solar cells as a function of donor percent concentration. We use vacuum deposition techniques to fabricate thin films and full devices with 5 mol.%, 10 mol.% and 50 mol.% donor concentration. The effect of microstructure is investigated by comparing mixed film heterojunctions formed with C60 as electron acceptor, paired with either α-Sexithiophene or 1,1-bis-[4-(4-methyl-phenyl)-amino-phenyl]-cyclohexane (TAPC) as electron donor materials, which individually grow in crystalline and amorphous layers respectively.

In this work we investigate charge generation and recombination processes in low donor concentration organic solar cells as a function of donor percent and microstructure. We use vacuum deposition techniques to fabricate thin films and full devices with 5 mol.%, 10 mol.% and 50 mol.% donor concentration. The effect of microstructure is investigated by comparing mixed film heterojunctions formed with C60 as electron acceptor, paired with either α-Sexithiophene or 1,1-bis-[4-(4-methyl-phenyl)-amino-phenyl]-cyclohexane (TAPC) as electron donor materials, which individually grow in crystalline and amorphous layers respectively.

Electron paramagnetic resonance (EPR) measurements are performed to determine the charge species generated in the active layer upon illumination. In the case of the α-Sexithiophene:C60 system with low donor concentration, EPR measurements reveal the presence of triplet states on C60 and α-Sexithiophene molecules as well as free charges generated at the interface. While free charges and α-Sexithiophene triplets remain present in the high donor concentration system, the C60 triplets are quenched. We will evaluate the effect of the quenched C60 triplet by correlating the information gained through EPR with a photophysical characterization of full devices obtained through current-voltage and external quantum efficiency measurements. Our measurements are further enhanced through X-ray measurements of the microstructure of the films to obtain a full picture of the effects of donor percentage on charge generation and recombination.

Terahertz Spectroscopy to Study Charge Carriers in Photoexcited and Doped Organic Semiconductors

While transient absorption (TA) spectroscopy gives information about the population of photogenerated excitons and charges, both the population and short-range mobility of charge carriers determines the photocatalytic activity dynamics in optical-pump-THz-probe (OPTP) measurements. By combining both techniques, the evolution of only the mobility at different times after photoexcitation can be extracted. This is then further substantiated by the mobility and localization parameters obtained from analyzing the real and imaginary parts of the complex photoconductivity spectra at selected time delays with an appropriate model. Here, we have undertaken such a study with pHTTT:PCBM blends having controlled phase morphologies, which are excellent model systems to study the charge carriers in organic photovoltaics (OPVs). We can thus follow changes in the short-range mobility as the charges evolve between different neat and intermixed regions of the blend.

Moreover, we have investigated thin films of a narrow-bandgap conjugated polyelectrolyte, which was shown to become self-doped (conductive) upon dialysis treatment. The doping is directly evident in the absorption spectrum, where a polaron band appears around 1200 nm. Charges are thus present in the ground state and we have investigated their short-range mobility properties using time-domain THz spectroscopy (TDTS, without need of photoexcitation). Those are compared to the carrier properties of photo-generated charges in blends of the corresponding non-ionic polymer backbone with PCBM. We have also carried out TA spectroscopy in solutions and thin films of the doped system, with pumping in either the excitonic or the polaronic band. Surprisingly similar, correlated and very short-lived dynamics were observed. All data was compared to un-doped reference systems and the fluence-dependence was recorded. This brought novel insights to the electronic structure of doped conjugated polymers.

9:45 AM EP05.11.06
Electron-Driven Proton Transfer from Water to a Model Heptazine-Based Molecular Photocatalyst

In the field of photocatalytic hydrogen evolution from water, the conjugated heptazine unit has received significant attention due to intense research interest in 2-dimensional poly(heptazine imides), commonly referred to as carbon nitride or g-C3N4. These conjugated organic materials are readily synthesized from earth abundant materials and act as photocathodes, both absorbing photons and transferring charge to drive the redox process. Despite intense research interest over the past decade, the mechanism of photocatalytic activity remains largely enigmatic. In part due to its structural ambiguity, the activity has been attributed to a variety of processes including free carrier generation, active defect sites, and excitonic interactions at the heptazine core. To avoid this ambiguity, we chose to study 2,5,8-tris-[4-(methoxyphenyl)]-1,3,4,6,7,9b-heptazaazaphenalene (TAHz), an aryl-functionalized heptazine molecule to study the role of the heptazine core. Using time-resolved multichannel photoluminescence (PL) spectroscopy, we kinetically reveal a new emission feature that emerges in aqueous dispersions of TAHz. We attribute this new PL peak to a state with significant intermolecular charge-transfer (CT) character that forms when photoexcited TAHz accepts an electron from hydrogen-bonded H2O. Using global analysis, we spectrally and kinetically resolve overlapping emission features and observe a prompt CT PL decay component exhibiting a kinetic isotope effect of 2.9. We attribute this isotopic dependence to CT quenching by electron-driven proton transfer from water in the TAHz-H2O complex. Radical detection with terephthalic acid confirm hydroxyl radicals form when TAHz is illuminated in water as a result of this photochemical transformation. Our interpretations are consistent with recent theoretical predictions that g-C3N4-based photocatalysts can participate in electron-driven proton transfer with H2O, forming neutral hydrogenated heptazinyl and hydroxyl radicals. This significant finding points towards the possibility of incorporating heptazine-based materials in devices for artificial photosynthesis.
Exciton fission is an energy downconversion process (1 high energy excitation â†' 2 low energy excitations) while exciton fusion is an energy upconversion (2â†’1) process. Both are of practical interest because they provide routes to boost solar energy conversion efficiencies by 30% or more. Organic semiconductors like tetracene and rubrene are uniquely well-suited to perform this energy re-packing because the Frenkel character of the excitons leads to energetically distinct singlet and triplet bands, which can exchange energy via spin-allowed fission and fusion processes. We will describe efforts to understand the photophysical steps involved in singlet fission using time-resolved transient absorption, photoluminescence and magnetic field effects. The roles of molecular packing and crystal morphology in controlling the fission rate will be emphasized. The dynamics of the triplet pair state produced by fission suggest that the triplet excitons may be able to diffuse independently while maintaining spin coherence. For singlet fission, these nonequilibrium spin state distributions can play an important role in both the ultimate triplet yield and the observation of experimental quantities like delayed fluorescence. We will describe time-resolved experiments and Monte Carlo simulations that look at how spin dynamics affect fission and triplet-triplet annihilation. The inverse of singlet fission is triplet-triplet fusion or annihilation, where a pair of triplet excitons fuse into a high-energy singlet state. A new approach to triplet state sensitization involves absorption of low energy photons by semiconductor nanocrystals followed by energy transfer to the molecular triplet states. This approach provides a way to generate large populations of triplets by near-infrared excitation. Interestingly, we also find that upconversion via triplet fusion can occur in certain molecular crystals even in the absence of sensitizers, possibly due to the presence of low-energy intermolecular states.

Singlet fission is the spin allowed process of formation of free triplets from a photo-excited singlet, observed in organic molecules such as pentacene, tetracene, their chemical derivatives, conjugated polymers, perylenes and diimides etc. The dynamics and yield of singlet fission have been understood to be dependent on several factors. To facilitate singlet fission, the energetics of the molecule must be such that the triplet energy lies close to half of singlet energy and this difference in energy was previously thought to be a limiting factor to the efficiency of fission. Prime examples for this were the fast (fs) fission in pentacene, an exothermic system, and slow (ps) fission in tetracene, an endothermic system. However, recently (1,2) it has been shown that singlet fission is fast and efficient in an endothermic system, TIPS- tetracene, where the singlet decays to form vibrationally coherent correlated triplet pair states (TT) under 200 fs, despite the conventional idea that endothermic systems exhibit slow picosecond- timescale singlet fission. In addition to the energetics of the molecules, molecular packing in the solid state is an important parameter as well, since the proximity of molecules to form TT states is crucial to this process.

In this study, we use a series of modified anthracene molecules, with varying endothermicity, to explore the effect of energetics and molecular packing to the dynamics of singlet fission. These molecules are blue-shifted in energy (HOMO-LUMO gap) by approximately 180 meV with respect to the well-studied endothermic tetracene molecule, TIPS- tetracene. Singlet fission in TIPS- tetracene is a two-step process in which singlets decay to form TT states under 200 fs, and in a few nanoseconds, decouple to form free triplets (1). The latter process of decoupling of the TT states to form free triplets has been shown to be temperature independent (3), though it is counter-intuitive that a thermodynamic factor such as endothermicity has no bearing on this step in the process of singlet fission. The strategic chemical modifications on the anthracene derivatives used in this study are utilized to understand the process of decoupling of triplets in more detail as it provides a larger gap to play with on the energetic landscape between singlets and triplets. We use transient absorption spectroscopy, transient photoluminescence (PL) spectroscopy, magnetic field dependent steady state PL, temperature dependent PL among other methods in this work. The scope of this work is to understand long-standing questions related to the fundamental nature of SF, which when incorporated in solar cells can improve the power conversion efficiencies by more than 30% (4).

Exciton Diffusion Dynamics in Perylene Diimides Mediated by Singlet Fission

Ferdinand C. Grozema and Kevin M. Felter; Delft University of Technology, Delft, Netherlands.

The SF process is proposed as one of the strategies to optimize and surpass the Schockly-Queisser limit for (organic) single junction photovoltaic cells. The SF process involves splitting a photoexcited singlet state (S1) into two distinct triplet excited states (T1+T1). This enables harvesting two charges for only one absorbed photon. The process occurs analogously in quantum dot materials where it is called carrier multiplication (MEG). In order to control the SF process and design better chromophores with higher SF efficiencies and rates, fundamental knowledge is required on the underlying principles. One crucial aspect of SF are the energy requirements and dependence on not only solid state packing, but also of chemical substitution. PDIs are excellent study materials to study the influence of chemical substitution on both solid state packing and the energetics. A variety of SF studies on the rate and efficiency in PDIs has been performed using transient. The favourable electronic coupling and energetics of perylene diimides (PDIs) are known to result in efficient singlet fission and triplet up-conversion. A secondary effect of these processes is its significant effect on exciton diffusion. This research is part of a systematic study to determine the influence of fission and up-conversion on exciton diffusion in PDI derivatives and the effect of temperature.

In order gain information on the singlet fission and exciton diffusion, we first studied planar heterojunctions composed of a smooth TiO2 electron acceptor film and physical vapour deposited PDI using the flash photolysis time resolved microwave photoconductivity technique (FP-TRMC). The photoconductance measurements reveal a dependency of triplet exciton diffusion on the packing of the PDI derivative mediated by singlet fission. Furthermore, as illustrated by the figure below, we observe a strong temperature effect on photoconductivity indicating either enhanced exciton diffusion and/or UC/SF rate enhancement.

Secondly we studied the effect of temperature on the photoluminescence and transient absorption to get direct evidence for a temperature effect on the excitonic species and therefore the singlet fission process. We have determined that the triplet concentration is influenced by temperature as a result from singlet fission. We determined an activation energy for the singlet fission process to occur for a particular type of perylene diimide solid state structure.

We conclude that exciton diffusion and singlet fission in perylene diimide crystals are thermally activated and show a chemical structure dependence on the extent of both singlet fission and exciton diffusion. We determined an exciton diffusive properties as well as a singlet fission rate and activation energy.

11:45 AM EP05.12.05
Singlet Fission and Exciton Dynamics in Amorphous Rubrene
Drew Finton, Elizabeth DeJong, Vincent Zoutenbier and Ivan Biaggio; Physics, Lehigh University, Bethlehem, Pennsylvania, United States.

We used molecular beam deposition in high vacuum to obtain both amorphous and multicrystalline rubrene thin films, and studied how the fluorescence dynamics induced by short pulses varies in samples grown under different conditions. These investigations showed that by this method it is possible to obtain a truly amorphous rubrene film where singlet fission does not occur: in such samples we have observed a single exponential decay of the fluorescence, similar to what is seen for molecules in solution. On the other hand, as the film morphology changes as a function of the deposition condition and nano- or microcrystal regions arise, singlet exciton fission starts being enabled and the dynamics of the short-pulse induced fluorescence shows the typical signs of exciton fission and triplet fission: a fast transient followed by a delayed fluorescence caused by triplet excitation fusion. We discuss the insights that we obtained on the effect of molecular ordering and size of crystalline regions on singlet exciton fission and triplet exciton fusion.

Triplet Energy Transfer Governs the Dissociation of Correlated Triplet Pairs Generated by Singlet Fission
Tia S. Lee1, YunHui L. Lin2, Hwon Kim1, Ryan D. Pensack1, Barry P. Rand2,4, Greg Scholes1 and Kyra Schwarz1; 1Department of Chemistry, Princeton University, Princeton, New Jersey, United States; 2Department of Electrical Engineering, Princeton University, Princeton, New Jersey, United States; 3Micron School of Materials Science & Engineering, Boise State University, Boise, Idaho, United States; 4Andlinger Center for Energy and the Environment, Princeton University, Princeton, New Jersey, United States.

Singlet fission, a spin-allowed process of spontaneous exciton multiplication, has the potential to enhance the efficiency of photovoltaic devices by utilizing two triplet excitons generated from one singlet exciton. The majority of studies to date have emphasized understanding and optimizing the first step of singlet fission, where the overall singlet intermediate state—the “correlated triplet pair”—is produced from a singlet photoexcitation. Few studies have examined later steps, where the triplet pair may separate and spin correlation may be lost. Here we examine transient absorption of 6,6-bis(triisopropylsilyl)ethyl)pentacene (TIPS-Pn) films at cryogenic temperatures (78–295 K). We evaluate time constants obtained from global analysis and show that their temperature dependence is inconsistent with an exclusively thermally activated process. Instead, we find that the trends can be modeled by a triplet-triplet exciton diffusion process involving simultaneous two-electron exchange. The fitted reorganization energy and electronic coupling agree by a triplet-triplet energy transfer process involving simultaneous two-electron exchange. The fitted reorganization energy and electronic coupling agree.
fission in hexacene is highly exothermic. The significant degree of electronic coupling compounded with large exothermicity gives the possibility of hexacene to undergo singlet fission from one singlet to either yield three triplets or yield two triplets and phonons.

In this hexacene system we find the singlet fission rate of 470fs which is in line with previous studies [3][4]. Such a short time scale of singlet fission allows it to out-compete other relaxation channels, and hence giving it a high efficiency. Comparing with pentacene, the other system with exoergic singlet fission (~100fs fission rate), even though hexacene is more exoergic than pentacene the singlet fission rate is observed to be much slower. The proposed phonon bottleneck effect causing this divergence is experimentally explored through transient absorption spectroscopy, yielding corroborative evidence. By inducing more energy into the system through systematically varying the pump excitation to shorter wavelengths, singlet fission mediated by multiple phonon interactions is directly probed. A prolonged singlet fission rate is observed with higher pump energies. Individual singlet and triplet spectra and kinetics are numerically deconvolved through a genetic algorithm method. Thus, the singlet fission rate and the yield can be correlated with respect to the excess energy present in the singlet fission process. Further evidence of the phonon mediated singlet fission process explored through cryogenic transient absorption and through vibrational coherence studies will be discussed.

2:15 PM EP05.13.03/CM04.10.03
Energetic Driving Force of Singlet Fission in Perylenediimide Thin Films Aaron Le, Sean T. Roberts and Jon A. Bender; University of Texas at Austin, Austin, Texas, United States.

Singlet fission (SF) is a process that can occur in select organic molecules where a singlet exciton splits into two lower energy triplet excitons. While the intersystem crossing of singlets to triplets is typically slow in organic molecules, due to small spin orbit coupling singlet fission does not require a flip in spin and can be exceptionally fast compared to intersystem crossing. The SF process requires two chromophores whose triplet states should be approximately half of the singlet state’s energy to conserve energy. This process has applications in photovoltaics where thermalization of high energy excitations accounts for a major loss channel and limits the maximum performance of such devices. Utilizing materials that undergo efficient SF can potentially mitigate the losses these above band gap excitation experience --- high energy excitations can be down converted into lower energy excitations before thermalization can occur. Perylenediimides (PDIs) are a robust class of dye molecule employed as commercial pigments that contain the proper energetics for SF. These molecules form crystalline domains in the solid state that can be readily tuned by functionalization of the molecules, thereby allowing the structure-function relationship of SF and intermolecular geometry in the solid state to be explored. The intermolecular geometry of SF chromophores has been shown to have a strong connection to the SF rate chromophores that undergo SF. A collection of PDIs with different solid state packing structures were evaluated for potential use as SF chromophores in polycrystalline thin films. Employing a combination of ultrafast femtosecond and nanosecond spectroscopy we identify the formation of triplet state spectral features and identify the SF rates for these materials. Extracted experimental rates deviate from theoretical predictions by approximately three orders of magnitude which may be attributed to differences in energetic landscape of the polycrystalline films and the dimer employed in the calculation. A series of temperature dependent spectroscopic experiments were utilized to examine the energetic requirements of SF in these polycrystalline thin films.

2:30 PM *EP05.13.04/CM04.10.04
Singlet Fission in Synthetic Caroteno-Proteins Jenny Clark, Daniel Polak and Andrew Musser; University of Sheffield, Sheffield, United Kingdom.

Singlet fission is the process whereby one photon creates two triplet excited states. If both triplet states could be harvested by a single-junction solar cell, the solar cell efficiency would increase by up to 1/3. There has been much academic and industrial interest in developing new materials for singlet fission, but to date no material has proved ideal.

Carotenoids are the most widespread of the natural pigments, important for photosynthesis, vision, human health and industry. Work on astaxanthin [1,2] (the pigment which colours lobsters) shows that carotenoids are good candidates for singlet fission sensitizers for solar cells: they have strong absorption and fast (<100fs) singlet fission, independent of energetic driving force. There are hundreds of naturally occurring carotenoids and each of them can form a range of different dimer or aggregate structures (eg H- or J-aggregates).

To determine how carotenoid structure affects singlet fission, and how to exploit carotenoids or other polyene-type systems as singlet fission sensitizes, we use model systems to create identical dimer structures of a range of carotenoids. The model systems are made of synthetic ‘maquette’ proteins that hold the carotenoids in a specific dimer geometry. I will describe details of the photophysics of singlet fission in polyenes, showing that singlet fission is surprisingly robust to changes in conformation and does not depend on either the aggregate or intramolecular structure.

3:00 PM BREAK

3:30 PM *EP05.13.05/CM04.10.05
Functional Imaging of Energy Flow in Materials at the Nanoscale Milan Delor, Hannah Weaver, QinQin Yu and Naomi S. Ginsberg; University of California, Berkeley, Berkeley, California, United States.

The ability of energy carriers to move within and between atoms and molecules underlies virtually all biochemical and material function. Understanding and controlling energy flow, however, requires observing it on ultrasmall and ultrafast spatiotemporal scales, where energetic and structural roadblocks dictate the fate of energy carriers. We therefore developed a universal, non-invasive optical scheme that leverages interferometric scattering to track energy transport in four dimensions of spacetime with few-nanometer precision and directly correlate it to material morphology. We visualize exciton, charge, and heat transport in polycrystalline, silicon and perovskite semiconductors and elucidate, in particular, how grain boundaries impact energy flow through their lateral- and depth-dependent resitivities. We reveal new strategies to interpret energy transport in disordered environments that will direct the design of defect-tolerant materials for the semiconductor industry of tomorrow.
The electronic structure and exciton dynamics of organic molecules can change dramatically upon aggregation. The exciton dynamics of molecules in solution and in thin films of aggregates can be measured using transient absorption spectroscopy, but the exciton dynamics of intermediate aggregation states during thin film formation are typically unknown since measurements cannot be performed quickly enough to collect accurate transient absorption spectra of these species. By increasing the speed of data collection, the exciton dynamics of evolving material systems can be measured. A novel implementation of transient absorption spectroscopy is introduced that can measure transients with up to a 45 ps pump-probe time delay in one shot. The exciton dynamics measured during the solution deposition of a thin film is validated by comparing the initial exciton dynamics of the solution and the final exciton dynamics of the dry film to traditional transient absorption measurements. The exciton dynamics of intermediate aggregation states will be presented for the first time. The information gained using this technique can be used to modify environmental parameters during the film formation process to kinetically trap aggregates with exciton dynamics tailored for a particular application.

Charge and ion transport of organic semiconductors depends strongly on both molecular structure and morphology. Our fundamental understanding of structure-function relationships has improved greatly in recent years; however, conventional high-resolution structural probes such as x-ray and electron scattering/microscopy are severely restricted by radiation damage and new structural probes are needed. Towards this end, we present initial results from nano-beam diffraction experiments at the Linac Coherent Light Source (LCLS), a source of high-intensity, ultra-short, and coherent hard x-ray pulses from several molecular and polymeric materials. Known as “diffraction-before-destruction”, a single femtosecond x-ray pulses yields useable diffraction images in weakly diffracting and disordered samples before radiation damage can propagate (e.g. sample explosion). This removes the previous limitations of sample damage present in synchrotron and electron microscopy methods. Furthermore, the focused beam (150 nm diameter) is small enough that significant anisotropy in the scattering patterns is observed, yielding insight into polymorphism, strain, and grain-boundaries through statistical analysis of thousands (and eventually millions) of diffraction images. Combined with complementary high-resolution transmission electron microscopy images and atomistic simulations, the results suggest a distribution of packing structures coexist in thin films and that engineering likely packing motifs has the potential to improve both the electronic and ionic transport properties of these materials.
Nematic order, in the bulk or at interfaces, is ubiquitous for semiflexible conjugated polymers. The effect of liquid crystalline order on charge transport, however, remains unclear. Using an analytical model, we show that nematic order leads to an enhancement in charge mobilities when compared to isotropic chains. We also predict a quadratic dependence of the charge mobility on molecular weight of the chains. This is because uniaxially aligned chain backbones lead to rod-like intra-chain trajectories of charge carriers. Analysis of the probability of forming hairpin defects also shows that increasing persistence length can enhance charge transport in conjugated polymers. We speculate that the prevalence of nematic order in conjugated polymers may explain the reported increase in charge mobilities with molecular weight.

Identification of Molecular Orientation in Bulk-Heterojunction Layer by Infrared Reflection Absorption Spectroscopy for Organic Photovoltaic Cells

A bulk heterojunction (BHJ) structure by co-evaporation of organic photovoltaics (OPVs) provides the large donor-acceptor interface, which facilitates efficient charge separation. However, it is difficult to control directly the morphology of co-evaporated BHJ layer because of random blend of donor and acceptor molecules. Many efforts have been made to achieve a control structure of BHJ layer by introducing a new substitute in molecule and combining additive molecules in solution. In our previous work, we reported highly efficient OPV cells by inserting CuI molecular orientation control layer under the zinc phthalocyanine (ZnPc):C60 co-evaporated BHJ layer. It is estimated that higher light absorption coefficient was obtained by controlled ZnPc lying-down molecular orientation due to n-π interaction between ZnPc and CuI. However, information of the ZnPc molecular orientation in ZnPc:C60 film has not been obtained by various measurements, such as XRD, XAFS, and TEM, due to its low crystallinity in ZnPc:C60 film. Hence, we report that the identification of molecular orientation in ZnPc:C60 film by Infrared reflection absorption spectroscopy (IR-RAS), which is enabled to measure the molecular orientation in amorphous film. We succeed in calculating the molecular orientation angle in co-evaporated films on various substrates by IR-RAS.

The CuI (5-nm-thickness)/PEDOT:PSS/ITO substrate (CuI substrate) and ZnPc (20-nm-thickness)/CuI/PEDOT:PSS/ITO substrate (ZnPc substrate) were prepared to investigate the molecular orientation control by π-d interaction and n-π interaction, respectively. On these substrates, ZnPc:C60 co-evaporated BHJ layer was evaporated in the vacuum chamber. IR-RAS measurement was done under in-situ conditions during evaporation of ZnPc:C60 film. The orientation angles of ZnPc molecules calculated by IR-RAS in ZnPc:C60 film on various substrates. Orientation angles of ZnPc molecules in ZnPc:C60 films on PEDOT:PSS (reference), CuI substrate (n-π interaction), and ZnPc substrate (n-π interaction) are 60 degrees, 45 degrees, and 38 degrees at 10 nm or less thickness regions, respectively. These results indicate that n-π interaction between ZnPc and ZnPc molecules is stronger than n-d interaction between ZnPc molecules and CuI in ZnPc:C60 co-evaporated BHJ layer.

Reviewing the Use of Transient Photovoltage Measurements as a Probe of Recombination in Thin-Film Solar Cells

Philip Calado1, Thomas Kirchartz2,3, Piers Barnes1 and Jenny Nelson1; 1Department of Physics and Centre for Plastic Electronics, Imperial College London, London, United Kingdom; 2IEK-Photovoltaics, Forschungszentrum Jülich, Jülich, Germany; 3Faculty of Engineering and CENIDE, University of Duisburg-Essen, Duisburg, Germany.

Transient photovoltage (TPV) measurements have been frequently used to study the recombination lifetime of thin-film solar cells. TPV uses the decay of a small optically-induced voltage perturbation to probe the charge dynamics of devices at open circuit. The transient response to a short pulse of light in modelled devices was simulated using a drift diffusion model. Whilst for high mobility systems the lifetime inferred from the simulated TPV measurement matches well with the input lifetime, in cases where charge-carrier mobilities in the active layer are lower than 10^-3 cm^2-V^-1s^-1, the extracted lifetime deviates strongly from the input lifetime value and is highly dependent on mobility. In such low-mobility cases, the simulated charge carrier dynamics show bi-exponential behaviour where the fast decay at early times reflects the recombination of charges in the bulk, while the second, slower decay relates to charges that accumulate near the interfaces. The inhomogeneous spatial distribution of charge carriers in a device at open circuit reduces the recombination rate close to the interfaces, making net recombination dependent on how fast charges can diffuse into the bulk to recombine. As the open-circuit voltage is related to the majority carrier quasi-Fermi levels near the interfaces, its decay is most strongly related to this second slower decay of the charges. Following this observation we developed a new technique to monitor the charge-carrier density during the TPV experiment. We applied this method alongside conventional TPV to measure the recombination dynamics in different systems, including bulk heterojunction comprising of P3HT with both fullerene acceptor (PCBM) and non-fullerene acceptor (O-IDTBR). We observed that while the TPV lifetime of the fullerene and non-fullerene devices were similar in magnitude (7µs and 3µs respectively), the recombination lifetime of the non-fullerene system was significantly faster at 0.1µs compared to 2µs. These findings reconcile the relationship between the fill-factor and the recombination dynamics of the measured devices. By studying the parameters influencing the photovoltage and charge carrier decays, we present a method to estimate the mobility of these devices, and hence estimate the diffusion length of carriers in the active layer.

Electron Accumulation Increases Efficiency Bottleneck for Hydrogen Production in Carbon Nitride Photocatalysts

Wenting Yang1, Robert Godin1, Hatice Kasap2, Benjamin Moss2, Yifan Dong3, Sam J. Hillman1, Ludmilla Steier1, Erwin Reiner2 and James R. Durrant1; 1Department of Chemistry and Centre for Plastic Electronics, Imperial College London, London, United Kingdom; 2Department of Chemistry, Christian Doppler Laboratory for Sustainable SynGas Chemistry, University of Cambridge, Cambridge, United Kingdom.

A deep understanding of the photoinduced charge-transfer dynamics of photocatalysts is a vital pre-requisite for developing efficient and economical devices for water splitting and CO₂ reduction. Graphitic carbon nitrides (g-C₃N₄) are an emerging cheap and efficient photocatalyst for water splitting. However, the photophysical studies of the g-C₃N₄ have, to date, lagged far behind rapid improvements in reported efficiency due to its tendency to aggregate in solution presents a significant technical challenge for measurement. Herein, we report a thorough photophysical and charge-transfer study of a stable dispersion of a cyanamide surface functionalized melon-type carbon nitride (NCN-CN₄), on a timescale ranging over 12 orders of magnitude (from fs to s) using transient absorption spectroscopy. Fluence-dependence studies reveal that the bimolecular reaction of the photogenerated electrons and holes in NCN-CN₄ can be well described by the random walk model developed previously for the metal oxide. Remarkably, the addition of hole scavengers, 4-MBA, into NCN-CN₄ was found to lead to an unprecedented ultrafast decay phase (~ few ps) of the electron signals of the NCN-CN₄, faster than the diffusion limitation of 4-MBA. We show conclusively that this ultrafast decay is not a result of hole extraction by the scavenger. Rather, it is due to the accelerated electron-hole recombination resulting from electron accumulation in NCN-CN₄ (to be around 10¹⁷ to 10¹⁸ cm⁻³ ) after holes have been extracted.
Exciton Binding Energy of Organic Materials—Ground-State vs Excited-State Donor-Acceptor Complexes

Andreas Opitz1, Paul Beyer2, Norbert Koch1,2 and Wolfgang Brütting1,2
1 Institut für Physik, Humboldt-Universität zu Berlin, Berlin, Germany; 2 IKIS Adlershof, Humboldt-Universität zu Berlin, Berlin, Germany; 3 Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Berlin, Germany; 4 Institut für Physik, Universität Augsburg, Augsburg, Germany.

Organic semiconductors are materials with a high exciton binding energy (EBE), which significantly impacts their electronic and optical properties. The EBE is the difference between the electronic gap (sometimes referred to as charge transport gap) and the lowest transition energy of photon induced excitation. In recent years, substantial efforts were made to determine the EBE and to relate it to fundamental processes in devices, particularly the exciton dissociation in photovoltaic cells.1

In this contribution, we perform a thin films of pristine organic semiconductor as well as donor-acceptor (DA) complexes upon optical excitation. We compare the transition energies determined from absorption spectroscopy with the transport gaps obtained by direct and inverse photoelectron spectroscopy.

The EBE of pristine diindienoperylene (DIP) is about 150 meV. DIP combined with fullerene as acceptor was studied for photovoltaic cells2,3. The excitation of this DA complex shows an EBE of approx. 70 meV. A comparably low value was determined for the weakly interacting ground-state DA complexes of DIP with a dicyanoperylene-bis(dicarboxyimide) derivative (PDIR-CN2).4 The acceptor hexafluoro-tetracyano-naphthoquinodimethane (F6TCNNQ) forms a strongly interacting ground-state DA complex with DIP. In contrast, this complex reveals an EBE of about 750 meV.

The value of the EBE (DIP:C60 and DIP:PDIR-CN2) being lower than the value of DIP alone is related to the spatial separation of the charges. The hole is confined on the donor molecules and the electron on the acceptor molecule forming a charge-transfer exciton. However, new energy levels are formed for strongly interacting ground-state DA complexes by hybridization of the frontier orbitals of donor and acceptor, like in the case of DIP:F6TCNNQ. Therefore electron and hole are delocalized inside the whole complex, which indicates a Frenkel-like character of the exciton. All this shows, that the nature of the exciton in donor-acceptor complexes is strongly influenced by the ground-state interaction and differs between material combinations used in photovoltaic and doping applications.

Charge transport properties at the interface of organic materials which constitute the intrinsic characteristics of carriers is one of the most fundamental research fronts of organic transistors, particularly organic field-effect transistors (OFETs). Despite of the successful fabrication of bulk organic crystals, it is very challenging to interrogate the interface properties with three-dimensional (3D) organic materials. Therefore high-quality 2D electroactive organic layered materials with highly ordered molecular packing is an ideal platform to conduct this kind of research and development. Here, by utilizing physical vapor transport method (PVT), we produce highly-ordered, large-area and controllably-thick layers of 2D N,N'-ditridecaperylene-3,4,9,10-tetracarboxylic diimide (PTCDI-C13) with 10 nm in the maximum thickness. We find that the transport behavior of the single layer (1L) and the bilayer (2L) of PTCDI-C13 is of significant difference. In the 1L device, the transport behavior is predominately attributed to the hopping mechanism, while in the 2L device, the transport characteristics are dominated first by the band-like mechanism, and then by the hopping mechanism as the device temperature is reduced lower than 240 K. Meanwhile, when the layer thickness is increased from 1L to 2L, the carrier mobility anisotropy decreases significantly from 5.0 to 1.5. This marked difference is ascribed to the different steric arrangement of molecules. Our results unambiguously corroborate the intrinsic charge transport properties of electroactive organic layered materials at the interfaces.

Excitonic Feature of Organic Semiconductor Studied by Electromodulation Spectroscopy

Jin Taill, Hrishheekesh Chandran, Ho-Wa Li and Sai-Wing Tsang, City University of Hong Kong, Hong Kong, China.

In this study, the research is focused on using analytical methodology and optical simulation to compare different organic photovoltaic materials’ electromodulation response. For the first time, it’s discovered that electromodulation signal of high dielectric constant pristine small molecules SubNC, SubPC and a-6T are dominated by 2nd derivative of the material’s absorption coefficient, a behavior which is also reported in lead halide perovskite. It indicates that excitons generated in these materials have strong charge transfer character. While for other materials, including high dielectric constant PCBM, 1st excitonic peak is a mixture of 1st and 2nd derivative feature. Quantitatively, the ratio of polarizability change Δp and dipole moment change Δμ, i.e. Δp:Δμ, is smaller among SubNC, SubPC, a-6T and perovskite than other materials. At the same time, charge generation yield characterized by external quantum efficiency (EQE) is correlated well with Δp:Δμ, the smaller this ratio the higher the EQE value at absorption edge. We conclude that high dielectric constant should not be the only reason for high yield charge generation, but also the property of molecular frontier orbital should be taken into account for designing high charge generation yield material.

An EPR Insight into Molecular Doping

Alberto Privitera, Ross Warren and Moritz Riede; Department of Physics, University of Oxford, Oxford, United Kingdom.

Over the last decade, molecular doping has been successfully used to precisely control the electronic properties of organic layers that play crucial roles for achieving efficient organic devices such as light-emitting diodes (OLED), solar cells and field-effect transistors.1 Given its success in practical applications, it may be a surprise that fundamental aspects of the molecular doping are still little understood.

Our work aims to provide an insight into molecular doping from a novel point of view using electron paramagnetic resonance (EPR) spectroscopy. Thanks to its high sensitivity and selectivity, EPR allows to directly detect paramagnetic species generated during the doping process, i.e. trap states and free charges (both bearing S=1/2), and to investigate their chemical environment and dynamics.

We carried out our analysis on a model system composed of a layer of ZnPc as host which was p-doped with the acceptor F6TCNNQ (dopant) at different doping volume concentrations from 0% to 5%. The samples were fabricated through thermal evaporation under vacuum which allows a high control over the composition and thickness of the layer. The analysis of the measurements at 80K showed the presence of two different paramagnetic species, a static and a mobile one, distinguished by two different g-tensors. We attributed the static species to trap states and the mobile ones to free charges. At increasing doping concentration, the number and the mobility of free charges increase. Conversely, the trap states show a different behaviour remaining static at all doping concentrations. The same analysis was performed at different temperatures (T=80K - 280K) elucidating the thermally-activated de-trapping mechanism underlying the doping process and shedding light on the dynamics of the species involved. Our results appear well in accordance with the statistical model proposed by Tietze.2 In this model, a pivotal role is played by trap states; only after all traps are filled during the doping process, free charges are generated. The model describes our results regarding the effects of doping concentration and temperature on the equilibrium populations and the dynamics of the two species well.

In addition, we are currently performing a similar analysis using further model systems to test the validity. The overall analysis will provide further details towards a direct and definitive understanding of the molecular doping in organic semiconductors.

Diffusion-Limited Delayed Fluorescence as a Signature of Singlet Fission and Triplet Fusion of Correlated Triplets

Kazuhiko T. Seki¹, Yoriko Sonoda¹ and Ryuzi Kato²; ¹National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; ²Nihon University, Koriyama, Japan.

The Singlet fission (SF) has attracted a broad interest in the communities of physical chemistry and organic electronics. The SF is a way to improve the quantum efficiency of organic devices by splitting an excited singlet exciton into a pair of long-lived triplet excitons. However, the fundamental processes caused by the SF are not fully understood.

Since the transition from the excited triplet state to the ground singlet state is spin forbidden, deactivation of triplet excitons requires a long-time, allowing them to desorb and migrate over long distances. To date, the effects of diffusion on triplet fusion have been studied mainly for second order reactions where fusion is assumed to occur between any triplet pair regardless of whether they are the same pair generated by singlet fission. We focus on geminate triplet fusion where triplets may undergo diffusion but still recombine with the counter triplet generated by singlet fission; delayed fluorescence originates from diffusion mediated reversible geminate fusion of triplets. We show that occurrence of singlet fission followed by triplet fusion processes can be corroborated by studying the kinetics of delayed fluorescence; if delayed fluorescence decays by a power law with an exponent of 3/2, the delayed component of fluorescence could be attributed to geminate fusion of triplet pairs generated by singlet fission. We have also shown the temperature and the magnetic field effects on the kinetics of delayed fluorescence. By combining the static and kinetic aspects of the magnetic field effects on the fluorescence,
EP05.14.11 Molecular Origin of the Anisotropic Orientation of Molecules in Organic Light Emitting Diodes Pascal Friederich1,2, Vadim Rodin1, Florian von Wrochem1, Reinder Coehoorn1 and Wolfgang Wenzel1; 1Karlsruhe Institute of Technology, Karlsruhe, Germany; 2University of Toronto, Toronto, Ontario, Canada; 3Materials Science Laboratory, Sony Deutschland GmbH, Stuttgart, Germany; 4Eindhoven University of Technology, Eindhoven, Netherlands.

Molecular orientation anisotropy of the emitter molecules used in organic light emitting diodes (OLEDs) can give rise to an enhanced light-outcoupling efficiency, when their transition dipole moments are oriented preferentially parallel to the substrate. A similar effect is observed when the anisotropic orientation of molecules with electrostatic dipole moments leads to the spontaneous buildup of an electrostatic potential perpendicular to the substrate. This spontaneous potential surface potential (GSP) effect can as well be exploited in organic electronics applications. Here, the orientation anisotropy of widely used organic semiconductors is investigated using a simulation approach which mimics the physical vapor deposition process of amorphous thin films. Our simulations reveal for all studied systems significant orientation anisotropy which is in agreement with experimental results for the emitter orientation as well as the GSP effect. We find that the electrostatic interaction between the dipole moments of the molecules limits the orientation strength while short range van der Waals interactions between molecules and the surface during deposition act as driving force for the anisotropic orientation.

EP05.14.12 Optoelectronic Properties of the Interface Between Si and SiC and α-Hexathiophene—A Comparative Study Hannah Schamoni, Oliver Bieneck, Felix Eckmann and Martin Stutzmann; Walter Schottky Institute and Physics Department, Technical University Munich, Garching, Germany.

The combination of organic and inorganic semiconductors is a promising approach towards new materials for applications such as solar cells and light emitting devices, as they open up the possibility to simultaneously benefit from the advantages of both material types. Not least due to the broad variety of organic semiconductors, it is possible to tailor the properties of the heterojunctions in many different ways. In order to identify the most promising hybrid systems, a detailed knowledge about the specific organic/inorganic interface is essential. In this work, selected model systems of different organic and inorganic materials are fabricated and characterized optoelectronically. Via an organic molecular beam deposition (OMBDB) system, thin films of the small molecule α-hexathiophene (6T) are deposited on two inorganic semiconductors, namely hydrogen-terminated silicon (Si) and hydroxyl-terminated silicon carbide (SiC). The resulting hybrid systems are characterized by current-voltage measurements in the dark, under illumination and at different temperatures, and by Kelvin Probe Force Microscopy. Combining the results of all these measurements provides a detailed view of the interfacial optoelectronic properties. In particular, we compare Si substrates of different doping types and doping concentrations to each other and to n-type doped 6H-SiC substrates, which exhibit significantly different current-voltage characteristics. Surprisingly, the potential difference between 6T and Si or SiC amounts to approximately 0.2 eV in all hybrid systems investigated. As this value therefore seems independent of the choice of inorganic semiconductor, it is assumed to originate from an interfacial dipole. Our work of combining different measurement techniques systematically investigates the optoelectronic properties of hybrid systems of 6T and Si or SiC helps to develop a fundamental understanding of organic/inorganic semiconductor interfaces. This will eventually enable the tailoring of hybrid systems to meet the requirements of specific applications.

Thin glassy films of multiple organic semiconductor are found to spontaneously form periodic, highly-aligned surface patterns by a simple annealing process. These grazing-like surface structures are formed as the crystal growth front propagates across the sample by a stress-relaxation-driven wrinkling mechanism, and are aligned laterally along the crystallization front. The wavelength of these patterns can be tuned from 800 nm to 2,400 nm by varying film thickness and annealing temperature, and aligned pattern domain sizes on the millimeter length scale are obtained. Large differences in pattern periodicity are observed for thin films of different materials at a constant thickness, suggesting that a wider range of pattern wavelengths could be accessed by controlling materials properties. The pattern formation mechanism reported here is distinct from previous reports involving stress across a bilayer as wrinkling is associated with crystallization of a single layer, making the technique particularly amenable to device integration. These structures could be used as self-assembled diffraction gratings, distributed feedback cavities for organic lasers, or as scattering layers to enhance outcoupling in organic light-emitting devices.

EP05.14.14 The Research on Molecular Orientation and Characterization of the OLED Emitters Sunyoung Sohn4, Kwang Hun Park3, Hyungu Ahn2, Sungjune Jung3, Soon-Ki Kwon1 and Yun-Hi Kim2; 1Department ofMaterials Engineering and Convergence Technology and ERI, Gyeongsang National University, Jinju, Korea (the Republic of); 2Pohang Accelerator Laboratory, Pohang, Korea (the Republic of); 3Department of Chemistry and Research Institute for Natural Science, Gyeongsang National University, Jinju, Korea (the Republic of); 4Department of Creative IT Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

We analyzed the scattered X-ray intensities of the host and host-dopant emitters, which have the spectra of in-plane and out-of-plane scattering to the plane and azimuthal intensity profiles for a plot of orientation distribution using grazing incidence wide-angle X-ray diffraction (GI-WAXD) measurement for high-efficiency organic light-emitting diodes (OLEDs). In blue fluorescent emitters, we found that a non-doped anthracene derivatives have the highly rigid structure and thermal stability because p-naphthylxylene groups in 9,10-positions were highly twisted to anthracene core with sterine hindrance of xylene groups. The OLEDs with non-doped emitter with 2,3-diphenyl groups showed high-efficiency of 5.21 cd/A due to enhanced carrier mobility with well-aligned n-stacking structure toward out-of-plane by the face-on orientation by GI-WAXD analysis. In phosphorescent emitters, we have used the tetrahedral silicon-based host materials with electron transporting (ET) property and investigated on the preferential host orientation. The ET hosts had good morphological stability as well as balanced charge-carrier transport by pyridyl-substituted linker in the devices. The Ir(ppy)_3-doped or Fpic-doped devices showed high-efficiency of 53.54 cd/A or 11.08 cd/A, respectively. In thermally activated delayed fluorescence emitters, we found that the molecular orientation of emitting materials with diphenylamine derivative containing malononitrile had different horizontal and/or random orientations as a function of para or meta linker position. It showed 12.5 times difference of the device efficiency. These improved device efficiency was confirmed by the enhanced out-coupling efficiency with well-aligned stacking structure in the emitters with horizontal molecular orientation in in-plane and out-of-plane analysis using GI-WAXD analysis. A study on the relationship between device characteristics and molecular orientation using GI-WAXD analysis for the emitting materials will contribute to basic research on molecular design for high efficiency OLEDs.

EP05.14.15
Hidden Structure Ordering Along Backbone of Fused-Ring Electron Acceptors Enhanced by Ternary Bulk Heterojunction Yiqun Xiao, MSE, The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Fused-ring electron acceptors (FREAs), as a family of non-fullerene acceptors, have achieved tremendous success in pushing the power conversion efficiency of organic solar cells. Here, the detailed molecular packing motifs of two extensively studied FREAs – ITIC and ITIC-Th are reported. It is revealed for the first time the long-range structure ordering along the backbone direction originated from favored end group π-π stacking. The backbone ordering could be significantly enhanced in the ternary film by the mutual mixing of ITIC and ITIC-Th, which gives rise to an improved in-plane electron mobility and better ternary device performance. The backbone ordering might be a common morphological feature of FREAs, providing explanations to previously observed small open circuit voltage loss and superior performance of FREA-based devices and guide the future molecular design of high-performance non-fullerene acceptor.

EP05.14.16

Organic semiconductors have traditionally been regarded as being delicate with respect to degradation in oxygenated/aqueous conditions, especially in the presence of light. We have recently found that, in fact, numerous examples of organic semiconductors exist where these materials support true photocatalytic redox cycles, often with good stability. One general reaction which proceeds efficiently is the photocatalytic reduction of oxygen to hydrogen peroxide. We have found that both n-type, p-type, and ambipolar semiconductors; small molecules and polymers, can generate peroxyde in a wide pH range of 1-12. The p-type materials are additionally suitable for the fabrication of photocathodes, allowing the creation of peroxyde-generating photoelectrochemical cells – something previously impossible with inorganic semiconductors. In our work we have made a number of free-standing photocatalytic and photoelectrochemical platforms to produce peroxyde, and also have discovered the presence of catalytic peroxyde production in the bioorganic semiconductors.

EP05.14.17
Quantum Beats of a Multie exciton State in Rubrene Drew Finton, Eric Wolf, Vincent Zoutenbier and Ivan Biaggio; Physics, Lehigh University, Bethlehem, Pennsylvania, United States.

We have observed quantum beats in the photoluminescence dynamics of the organic molecular crystal rubrene following photoexcitation by a femtosecond pulsed laser. The application of a magnetic field up to 0.3 T, created by a neodymium permanent magnet, produces periodic modulations in the photoluminescence dynamics. The beat frequency ranges between 0.6 GHz to 1.3 GHz and is dependent upon the relative orientation of the magnetic field and the crystalline axes. The amplitude of the beats increases with increasing magnetic field strength, peaking at about 5% of the non-oscillatory background. These beats are indicative of a multie exciton state consisting of a spin-coherent pair of triplet excitons existing during the singlet-to-triplet exciton fission conversion process.

EP05.14.18

Having recently surpassed the 13% threshold, organic photovoltaics (OPV) are once again becoming promising contenders for low-cost solution-processed thin film photovoltaics. The commercialization of large area OPV devices will require, among other things, the capability of coating active layers at high speed in ambient condition without losing fidelity with the champion devices fabricated by spin coating. For a long time, the focus of OPV research was limited to fullerene based acceptor PC$_{61}$BM and PC$_{71}$BM. The fullerene based acceptors have been widely used, but have several limitations, including lower absorption coefficient, and often require a solvent additive for successful processing. In recent years, non-fullerene acceptors (NFAs) have emerged as a new concept to overcome the limitations associated with fullerene based acceptors and have also been shown to yield highly efficient OPV devices without the use of solvent additives. In this work, we used blends of the donor polymer PTB7-Th, more commonly known as PCE10 : PC$_{71}$BM (fullerene based) and PCE10: EH-IDTBR (NFA) as active layer materials. We used spin coating (SC) and wire-bar coating (WBC) to fabricate active layers of the two systems with thickness ranging from 50-300 nm. The best solar cells based on WB coated PTB7-Th:PC$_{71}$BM achieved a PCE of 10.2 % comparable to 10.1% for the best spin-cast device. Devices based on NFAs also showed excellent performance with PCE of 10.8% for WBC vs. 10.6% for SC devices. We also fabricated ternary organic solar cells based on NFAs using PCE10:EHD-IDTBR:EHDIFBR as a photoactive layer and find that the device based on WBC and SC active layer achieved the similar efficiency of 11%. We found that WBC maintained performance parity with SC for active layer thickness <100 nm, but outperformed SC, sometimes significantly, for active layers >100 nm. Systematic comparison of the OPV device figures of merit indicated differences due primarily to the fill factor (FF), pointing to transport-related limitations in thicker solar cells prepared by SC. Indeed, various measurements of carrier transport confirmed the superior carrier mobility achieved in active layers prepared by WBC. Our measurements point to enhancement in the electron mobility as the primary source of the difference. Morphological investigation of the photoactive layers also pointed to enhanced aggregation and coarsening, which we attributed in part to the acceptor domains. Further investigation into the active layer formation kinetics using in situ optical diagnostics reveal the spin-cast ink based on chlorobenzene dried 3-4 times faster than the WBC one. We ascribe the significant differences in electron mobility to the kinetics of solidification and aggregation of acceptor domains. As far as we know, this is the first report where a scalable coating technique outperforms the well-known SC technique, considered for years to be the champion processing method for organic solar cells.

EP05.14.19
Tuning of Organic Thin-Film Microstructure Using Graphene as a Growth Template Jacob G. Kiiholesh, Ole Albrektsen, Martin A. Hedegaard and Jakob Kjeldstrup-Hansen; 1Mads Clausen Institute, University of Southern Denmark, Sonderborg, Denmark; 2Department of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, Odense, Denmark.

Photodetectors made from organic semiconductors is an area of great interest since these materials can be tailored through chemical synthesis techniques and processed as thin-films over large areas at low cost. However, a remaining challenge is the low carrier mobility that makes these materials less suitable for high bandwidth-applications. A possible solution is to combine an organic semiconductor with a graphene layer with superior transport properties,
which could form the basis for improved photodetector devices. This requires the ability to control the organic thin-film microstructure, which strongly influences both the optical absorption and the exciton diffusion processes. In this work, we study the growth of the organic semiconductor 5,5''-bis(naphth-2-yl)-2,2':5',2''-terthiophene (NaT3) by investigating the influence of the growth substrate (graphene vs. SiO2) and of the substrate temperature. The resulting thin-films are characterized by atomic force microscopy, x-ray diffraction, and fluorescence spectroscopy. On SiO2, the NaT3 molecules form a polycrystalline film with grains consisting of upright-standing molecules that form distinct terraces and with an average grain size that depends on substrate temperature. In contrast, we observe a significantly different morphology of the thin-film when deposited on graphene. Here, the NaT3 molecules form smaller grains with no observable terraces and with different molecular orientations. At high substrate temperature, a discontinuous thin-film is observed where the molecules assemble into elongated nanofiber morphologies. This gives rise to significantly different optical properties. The NaT3 thin-films on graphene exhibit a much stronger fluorescence signal than the similar thin-films on SiO2, while the NaT3 nanofiber structures emit polarized fluorescence.

EP05.14.20 How Can We Engineer Hierarchical Structures and Pattern Functional Organic Materials? Shengyang Chen1, Bastian Haehnle1, Alexander J. Kuehne2, Ioan Botiz1, Paul Stavrinou1 and Natalie Singelin1, 2, 3, 4
1Department of Materials, Imperial College London, London, United Kingdom; 2School of Materials Science and Engineering and School of Chemical and Biochemical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 3Department of Engineering Science, University of Oxford, Oxford, United Kingdom; 4Nanobiophotonics and Laser Microscopy Centre, Interdisciplinary Research Institute in Bio-Nano-Sciences, Babes-Bolyai University, Cluj-Napoca, Romania; 5DWI–Leibniz Institute for Interactive Materials, RWTH Aachen University, Aachen, Germany.

Organic materials continue to make an impact on a wide variety of optoelectronic applications due to an ever-increasing chemical design space, novel tools to assemble these interesting materials, and the advancement of novel device architectures and devices. One important aspect thereby is how to achieve assembly not only on the molecular- and on the meso- scale, but also on the hundreds of nanometer to micrometer scale. Various devices and applications, indeed, require the active material to be patterned and/or to be deposited at pre-determined locations. In areas, such as the bioelectronics field, step-changes may arise when more complex, multidimensional architectures that mimic the hierarchical structures of, e.g., tissues or bones could be man-made using stimuli-responsive functional organic materials. Other potential lies in nano- and micro-engineering multifaceted structures to realize new media with unique interactions with electromagnetic radiation. This would lead to new possibilities to harvest light and manipulate light-matter interactions. Here we use model systems to demonstrate hierarchical assembly of organic nanoparticles, covering a range of systems, from inert polystyrene particles to conjugated polymer emitter particles made, e.g., of polyfluorene-co-divinylbenzene (PF-co-DVB)[1]. We show that surface relief structures can be used to direct this process. Thereby, simple geometrical relationships can be employed to program the particles to deposit into specific sites and patterns: from ordered to disordered arrangements; hexagonally-packed, cubic-packed or random-packed structures; to single layer vs. multilayer architectures. This opens a versatile design platform in terms of the fabrication of multifunctional nano- and microstructures with hierarchies for use in the field of photonics (e.g., in solar cells, light-emitting diodes and optical display devices over large areas), bioelectronics and beyond.

Organic semiconductors, such as conjugated polymers, have attracted great interest as candidate materials for solar cells, light-emitting diodes and other photonic applications. The performance of such devices depends upon many properties of the materials, including the spectral range and strength of the optical absorption. Several studies have shown that changes in molecular packing and conformation within in a polymer film can influence the absorption strength. Widely used electronic structure methods such as time-dependent density functional theory cannot access the length scales necessary to study the effect of polymer conformation on the optical properties, especially for polymers with large repeat units or high persistence length, so instead coarse-grained methods need to be employed. In this work I am using an extended Hubbard Hamiltonian parameterized from first principles calculations to calculate the optical properties of different types of oligomers and study how their absorption strength depends on chain length. The long-term goal of this project is predicting spatially averaged optical properties of a macromolecular material using the knowledge of the excited states of atomic scale building blocks and of the molecular conformations present in the film. Such methods will help understand the macroscopic absorption properties of known compounds and thus aid the design of new organic materials exhibiting high optical absorption.

Organic semiconductors (OSC) are considered as highly feasible for the use in opto- and bioelectronic applications. The relatively low charge carrier mobility limits its current applicability. Insight into electronic structure-property relations is required to understand how to enhance the mobility. Various groups have been working towards a better understanding of the dependence of the mobility both relying on chemical intuition as well as using theoretical approaches covering structural information from molecular dynamics (MD) over transport properties using kinetic Monte Carlo (kMC) [1-3]. Mentioned numerical methodologies provide insight of transport for small perturbations from a crystalline structure. However, there is a lack of description for strongly non-crystalline structures such as solution processed OSCs due to the high computational effort associated with the calculation of all individual transition rates required for precise kMC studies.

In this work, we present a machine learning (ML) based ab-initio multi-scale simulation for charge transport within strongly non-crystalline OSCs using pentacene as a case study. ML allows for efficient and effective modeling of transport properties and helps to overcome conventional physical models that rely on empirical parametrizations or semi-empirical calculations. Using MD and density functional theory (DFT), we generate training data for the coupling integrals between adjacent molecules (dimers) of pentacene. The ML algorithm bases on the kernel ridge regression including an optimized set of descriptors for the respective dimers. To cover the range from the coupling integrals to charge mobilities, we couple the ML algorithm with our off-lattice kMC software [4]. The center of mass positions of the molecules within a non-crystalline pentacene film are used to generate the Voronoi tessellation which allows computing charge hopping across amorphous structures. ML helps to estimate coupling integrals within the Marcus theory without the need for a precomputation of each dimer configuration. We overcome existing ab-initio simulations by a tremendous reduction of computational demand and allow a generalized description for a wide range of structural disorder within the organic layer without a need to compute coupling integrals from scratch. We show how the directionality of the charge transport is influenced by varying the degree of crystallinity. Furthermore, we compute the field- and temperature dependence for non-crystalline pentacene layers stacked on top of a silicon oxide substrate, as used for thin-film transistors, and compare our ML-based approach with empirical kMC results.

A key to enable high-performing organic electronic devices is given by proper interface engineering of organic layers. Doped organic transport layers are used to improve charge carrier injection and to reduce ohmic losses. The diffusion of dopants into adjacent layers is known to cause exciton quenching in photo-active layers and to reduce the long-term stability of many types of organic electronic devices. On the other hand, the diffusivity of dopants can be beneficially used in a sequential deposition scheme that allows for doping and at the same time high order of the matrix material. Here, we investigate the diffusion of a bulky sequentially deposited p-dopant in poly(3-hexylthiophene) (P3HT) thin films using non-destructive in-situ infrared (IR) spectroscopy and photoelectron spectroscopy (PES). The dopant diffusion is resolved by differentially evaluating electron transfer in the bulk and at the surface for varying dopant coverage. Using PES and IR spectroscopy, it is possible to determine the concentration at which both charge transfer and dopant incorporation into the polymer film saturate. By means of PES we find that charged dopants are less mobile in the diffusion process than neutral molecules. A comparison of the diffusivity in semi-crystalline and fully amorphous P3HT indicates that semi-crystalline P3HT yields a higher capacity for dopants varying dopant coverage. Using PES and IR spectroscopy, it is possible to determine the concentration at which both charge transfer and dopant incorporation into the polymer film saturate. By means of PES we find that charged dopants are less mobile in the diffusion process than neutral molecules. A comparison of the diffusivity in semi-crystalline and fully amorphous P3HT indicates that semi-crystalline P3HT yields a higher capacity for dopants compared to fully amorphous P3HT. Furthermore, a temperature-dependent measurement reveals that the diffusion process requires activation energy close to room temperature.
lagged in $J_0$, behind their conventional low-bandgap polymer based analogues. Here, we study an intrinsic limit for photocurrent generation using ultra-low-bandgap polymers with an $E_g$ of around 1.1–1.3 eV.

We measured femtosecond transient absorption for these polymer films, and found that singlet excitons generated in these polymers rapidly decay with negligible photon emission. The non-radiative decay rate scales exponentially with the bandgap $E_g$, which is so called “energy gap law”. Our results suggest unavoidable disadvantage for ultra-low-bandgap polymers. Accordingly, we will discuss optimal design concept for high efficient PSCs.

Optical and Electrical Properties of Mixed-Solution and Sequentially Processed poly(3-alkylthiophene): F4TCNQ Films

Shin Sakiyama and Katsuhiko Fujita; Kyushu University, Kasuga, Japan.

Efficient n-type doping was not established since the dopants dose not dissolve in same organic solutions of polymer semiconductors. Evaporative Spray Deposition using Ultra-dilute Solution (ESDUS) method enabled it recently. We have already reported efficient n-type doping of poly(2-methoxy-5-(2'-methyl-hexyloxy)-p-phenylenevinylene) (MEH-PPV; LUMO: 3.1 eV, HOMO: 5.2 eV). The high doping efficiency as much as 15% was realized. In organic devices composed of non-doped organic semiconductors, electron injection barrier is basically equal to the gap between LUMO of the semiconductor and work function of the electrode. It is still open question how the barrier is formed in the n-doped polymer/electrode. The metal/semiconductor junction of n-doped polymer has not been studied yet. In this research, we have fabricated only devices (EOD) of n-doped polymer semiconductor using electrodes of Al and Ca. The electron injection from Al or Ca was examined.

MEH-PPV (Mw = 40,000-70,000 Aldrich) and Cesium carbonate (Cs2CO3, Japan Pure Chemical, purity of 99.999%) were used as a host polymer and an n-type dopant, respectively. The asymmetric EOD formed with Al for bottom and top electrodes and a top Ca electrode having a lower work function (3.0 eV) were fabricated. The current-voltage (I-V) characteristics and capacitance-frequency (C-F) measurement were conducted in vacuum without breaking vacuum after the top electrode deposition.

J-V characteristics of asymmetric EOD, Al(50nm)/MEH-PPV-Cs2CO3 (110nm)/Ca(50nm) are fabricated. The current density was drastically increased as the doping concentration increased. The asymmetric EODs, current density in the forward bias was about 1 order of magnitude larger than that in reverse bias at low doping concentration at 0, 2.0 wt%. However, the current density was almost overlapped in forward and reverse bias at the doping concentration of 10wa. The disappearance of the rectification property suggests that the quantum tunneling takes place due to the very thin depletion layer at Al/MEH-PPV junction at the high doping concentration.

In this research, we have fabricated electron only devices (EOD) of an n-doped polymer semiconductor using electrodes of Al and Ca. The electron injection from Al or Ca was examined.

Quantum Tunnelling on Metal/N-Doped Polymer Semiconductor

Shin Sakiyama and Katsuhiko Fujita; Kyushu University, Kasuga, Japan.

For the last decade, there has been massive evolutions in organic electronic devices and their novel applications such as organic field-effect transistors (OFETs), organic light-emitting diodes (OLEDs) and organic photovoltaics (OPVs). Moreover, a wide range of printing techniques has proven the process innovation with soluble materials. The limited source of contact electrodes, however, makes the barrier for the commercialization of the printing process with the soluble materials comprised of metallic and non-metallic conductors.

Those devices are basically composed of two- or three-terminal contacts which have the interfaces of metal/semiconductor (SC), dielectric/SC and SC/SC. Thus, the interfacial engineering is predominant to realize those devices for flexible application. A crucial issue concerning charge injection at the interface of electrode/organic semiconductor is recently rising in order to improve the electrical performance of diodes and FETs.

This presentation gives an investigation on charge injection via the modification of electrodes with self-assembled monolayers (SAMs) in organic electronic devices. Functionalized SAMs with fluorine at the end group plays a substantial role to improve charge injection through a dipolar effect to decrease barrier height at the electrode/semiconductor interface in a planar diode and organic field-effect transistors (OFETs). This is extended to significant enhancement of electrical performance such as field effect mobility and contact resistance in OFET.

In addition, for a practical application of the extraction technique mentioned above, we particularly suggested the simple interface control engineering to reduce contact resistance and improve electrical characteristics in n-type OFETs with the semiconductor (PNDI2OD-T2). Inkjet-printed Ag metals are implemented for the n-type polymer OFETs as electrodes. Then, it is introduced by the two types of SAMs, thiophenol (TP) and pentafluorobenzene thiol (PFBT) for the electrodes. Throughout the suppression of the Schottky barrier height with TP in the OFETs, the electron injection is prominently improved as observed previously. We also demonstrated that all solution-processed n-type OFETs can be polarity-inversed by the interface treatment of PFBT onto the inkjet-printed Ag electrode. A remarkable improvement, therefore, was found for the OFETs with the TP-Ag electrodes with high electron mobility of 0.11 cm²/Vs. Additionally, largely low contact resistance of 480 kΩcm confirms that TP-Ag can be a great candidate for an excellent electrodes compatible with inkjet-printing for the n-type semiconductors. It indicates that the work function of the inkjet-printed Ag electrodes is variable for a massive scope by the simple interface engineering. As a result, it may be commonly applied for the fabrication of all-solution-processes electronics for a variety of applications.
Organic field effect transistors (OFETs) have attracted much interest for future electronics because they can have flexibility with processing from solution at low temperature. Recently many researches make an attempt to control the film morphology which directly correlated to the charge transporting ability of conjugated polymers. In this work, we demonstrate optimized poly[N,N'-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyll-alt-5,5'-1,2,2'-terpyridine)] (PNDI2OD-T2) film morphologies, which are obtained by precisely regulating the solidification rate in the metastable state using a novel simple method. The kinetic control in the metastable state brings about dramatic morphological changes in both polymer domain sizes and molecular packing structures. The optimized P(NDI2OD-T2) films provide significantly increased electron mobilities up to 3.99 cm 2 V -1 s -1 , which is the impressive improvement in performance by nearly 100-fold as compared to conventional spin-coated devices. The observation of low activation energy according to the temperature-dependent behavior in optimized thin films can support the achievement of high electron mobilities of semiconducting polymers.

Long-Range Coherent Charge Transport in Physisorbed Molecular Layers Leandro M. Silva, Rafael F. de Oliveira and Carlos Cesar Bof Bufon; Brazilian Nanotech National Laboratory, Campinas, Brazil.

The charge transport in molecular ensembles is intrinsically related to a series of carrier-molecule quantum interactions which result in a variety of chemical and biological phenomena. Its understanding has paved the way for the development of novel device concepts, such as organic transistors, organic light-emitting diodes, and biosensors [1]. At the nanoscale, such interactions are commonly described as either direct tunneling for the 1-10 nm range or activated hopping for longer distances. However, the continuous transition between coherent tunneling and activated conduction as a function of organic light-emitting diodes, and biosensors [1]. At the nanoscale, such interactions are commonly described as either direct tunneling for the 1-10 nm range or activated hopping for longer distances. However, the continuous transition between coherent tunneling and activated conduction as a function of the barrier width remains unknown for physisorbed molecules. This work describes the first experimental evidence of long-range (> 10 nm) coherent tunneling occurring for physisorbed small-molecule semiconductors-based vertical junctions. By investigating the charge transport in copper-phthalocyanine (CuPc) thin films, we have identified the sequential tunneling as the long-range charge transport mechanism. Such a sequential coherent process is not only different from the direct tunneling but intrinsically distinct from the hopping conduction. Consequently, a gradual transition from direct tunneling to sequential tunneling, within the 10-22 nm barrier width, to hopping conduction can be verified. The evidence of coherent charge transport across long distances has implications for a variety of quantum effects that have not been previously confirmed for films with thicknesses larger than a few nanometers [2]. Therefore, our results contribute to bridging the gap between molecular and organic electronics [3,4].

Probing the Sub-Bandgap States in Light-Absorbing Organic Semiconductors by Surface Photovoltage Spectroscopy Lakshmi Narayanan Mosur; Saravanan Murthi1; Diego Barrera1, Aakash Gadhi1, Liang Xu1, Fong-Yi Cao1, Cheng-Chan Tseng1, Yen-Ju Cheng1 and Julia W. Hsu1; 1The University of Texas at Dallas, Richardson, Texas, United States; 2National Chiao Tung University, Hsinchu, Taiwan.

Surface photovoltaic spectroscopy (SPS) measures surface photovoltage as a function of incident photon energy, and has been used for obtaining the electronic structure and structurally active defects of semiconductors. In SPS, sub-bandgap illumination probes the transition between band states and defect states within the bandgap. Photogenerated charge transfer from organic active layer to oxide contact layer materials is critical for realizing efficient organic photovoltaic devices. However, with the fully constructed solar cells, it is difficult to isolate the physical location of the defects. Here, we performed frequency-modulated (AC) and steady-state (DC) SPS measurements on bilayers containing light-absorbing organic materials (P3HT, P3HT:PC60BM, PFBT2Se2Th:PC70BM) and electron transport layer (ETL) oxide (ZnO) to probe photogenerated transfer across this interface. We observed negative SPV signal in both AC and DC SPS, indicating electrons transferring from organic layer to ZnO. DC spectra are broader compared to AC spectra for all three organics. AC spectra overlap with the absorption spectra of organic layers, evident that AC SPS corresponds to band-to-band transitions. The sub-bandgap signals measured by DC SPS correspond to transitions with the bandgap states. When hole transport layer (HTL) was deposited on top of the organic layer, the DC spectra of P3HT and P3HT:PC60BM are narrower than without the HTL, suggesting that the surface states are removed. The difference between neat polymer and blend and between blends with the two different donor polymers, P3HT:PC60BM, PFBT2Se2Th:PC70BM, are probed using capacitance-frequency (C-f) to probe deep level defects in addition to SPS. These results give insight on the location and nature of sub-bandgap defects based on their SPS spectral signatures and frequency response.

Controlled Self-Assembly of 1D Nanoscale Materials and Their Resulting Photophysical Properties Sarah R. Marques and Michael Barnes; Chemistry, University of Massachusetts, Amherst, Massachusetts, United States.

Efficiency of organic optoelectronic devices is dependent on the intermolecular interactions of molecular assemblies that can favor charge transfer or radiative recombination. My work pertains to understanding whether directional charge transfer seen in extended crystals of 7,8,15,16-tetrazaterrylene is an intrinsic property of the 1D n-type semiconductor or an extrinsic property caused by subtle defects in the p-stack direction. We use solvent vapor annealing to crystallize nanoscale aggregates (<500 nm), and extended, highly ordered, crystals microns long. We probe the effect that order has on directional charge separation in these species using single molecule techniques and polarized optical excitation coupled with time resolved photoluminescence spectroscopy, this produces photoluminescence decays that have power-law signatures, indicative of the presence of charge separated states. The observation of enhanced power-law photoluminescence decay at critical stages of crystal growth support intrinsic charge separation favoring a promising molecular design platform for organic semiconductor materials.

Global Equilibrium and Non-Equilibrium Theory of Hopping Exciton Transport in Disordered Semiconductors Stavros Athanasopoulos1 and
The phenomenon of exciton diffusion is found to play a role in a remarkably wide range of physical systems including disordered organic semiconductors, nanocrystalline quantum dots, semiconducting carbon nanotubes and photosynthetic biological systems. Moreover, there is a growing interest in describing electronic exciton energy transfer because exciton dynamics determines function in many technological applications. For example, in thin film organic solar cells exciton diffusion drives charge separation, in organic light emitting diodes it determines the brightness and color of the device, in scintillator detectors it controls the response function and yield, while in quantum communication systems it facilitates photon antibunching.

We develop a temperature dependent theory for singlet exciton hopping transport in disordered semiconductors. It draws on the transport level concept within a Forster transfer model and bridges the gap in describing the transition from equilibrium to non-equilibrium time dependent spectral diffusion. We test the validity range of the developed model using kinetic Monte Carlo simulations and find agreement over a broad range of temperatures. It reproduces the scaling of the diffusion length and spectral shift with the dimensionless disorder parameter and describes in a unified manner the transition from equilibrium to non-equilibrium transport regime. We find that the diffusion length in the non-equilibrium regime does not scale with the third power of the Forster radius. The developed theory provides a powerful tool for interpreting time-resolved and steady state spectroscopy experiments in a variety of disordered materials, including organic semiconductors and colloidal quantum dots.

Direct Characterization of Nanoscale Molecular Ordering in Organic Optoelectronic Materials Using 4-Dimensional Scanning Transmission Electron Microscopy
- Gabriel Calderon Ortiz1, Menglin Zhu1, Jared M. Johnson1, Letian Dou2 and Jinwoo Hwang1; 1Materials Science and Engineering, The Ohio State University, Columbus, Ohio, United States; 2Chemical Engineering, Purdue University, West Lafayette, Indiana, United States.

The local ordering of the constituent molecules can directly affect the charge transfer and efficiency of the organic electronic devices and solar cells. Efforts to understand the ordering has involved theories and simulations, and experimental characterization, such as using X-ray diffraction. While these methods have provided important information about the ordering, more detailed information on how the ordering forms at the nanoscale level and how it affects the local and overall properties has remained difficult to determine. To fill the gap in the characterization, it is required to develop a new experimental method that uses a small (nanoscale) probe. Here we present the new 4-dimensional scanning transmission electron microscopy (4D-STEM) that can determine the detailed structure of molecular ordering in organic semiconductors. Our 4D-STEM uses a highly coherent electron probe that generates the diffraction signals directly from the local ordering, which are then captured by a new-generation pixelated fast STEM detector. By scanning the probe over a large area, we acquire a few tens of thousands of nanodiffraction patterns from one organic sample. We then subsequently analyze the patterns using intensity variance and angular correlation functions to convert them into a real space map of the ordering, which can reveal the details of the type, size, connection, and distribution of the ordering with unprecedented precision. We will present the data from two materials, P3HT and IDTBT, and demonstrate how the local ordering, which we control using different synthesis parameters, affects their physical and electronic properties.

Radiative Recombination and Exciplexes in All-Polymer Organic Semiconductor Bulk-Heterojunctions
- Cindy Kumah1, and Deirdre O’Carroll1, 2; 1Materials Science and Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Chemistry & Chemical Biology, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Organic bulk-heterojunctions of conjugated polymers and fullerene derivatives have been used extensively in organic photovoltaic devices in the past two decades. Although blends of conjugated polymers and fullerene derivatives exhibit efficient exciton dissociation upon solar illumination, the solar power conversion efficiency reached using these materials is at least a factor of two less than that predicted by the Shockley-Queisser theoretical limit. Non-radiative recombination of charge carriers due to efficient exciton quenching by fullerene derivatives is a significant factor preventing organic bulk-heterojunction materials from reaching the Shockley-Queisser limit. Therefore, in recent years there has been greater interest in developing and understanding fullerene-free organic bulk-heterojunctions that are expected to be less prone to non-radiative recombination.

The goal of our work is to understand the influence of altering the radiative decay rate (using the Purcell Effect) of charge transfer excitons on photovoltaic performance. In this study, we investigate radiative recombination and charge transfer excitons at the interface of electron donor:acceptor blends of two polyfluorene-based conjugated co-polymers. The heterojunction formed by the two phases is a type-II heterojunction, in which efficient charge separation is expected to occur. Photoluminescence spectroscopy shows quenching of emission from both polymers in the blends. An additional low-energy emission peak is observed in the blends which is not present in the spectra of either polymer alone. Quenching is more efficient in a 1:1 donor:acceptor blend than in a 1.2 donor:acceptor blend and in the 1:1 blend, the additional emission peak is more intense. In addition, the blends have longer photoluminescence lifetimes than the individual polymers. These measurements indicate that efficient photo-induced charge transfer occurs in the blend, and the additional low-energy emission peak observed in the blend can be attributed to emissive charge transfer excitons (i.e., exciplexes). Future work includes measuring the photoluminescence quantum efficiency of the conjugated polymer donor: acceptor blends and calculating the radiative decay rates. Plasmonic nanostructures will be incorporated in the organic semiconductor blend that are resonant with the exciplex emission. This will allow us to study the impact of the Purcell effect on charge transfer and exciplex emission. Additionally, electroluminescence and photocurrent measurements of all-polymer bulk-heterojunction devices containing resonant plasmonic nanostructures will be studied to understand if accelerated radiative recombination of charge transfer excitons can be beneficial to photovoltaic device performance.

Mechanism of Geminate Polaron Pair Generation in π-Conjugated Polymers
- Ella Olejnik, Carlos Silva and Felix Thouless; Georgia Institute of Technology, Atlanta, Georgia, United States.

In this work, we address the mechanism of geminate-charge generation in neat semi-crystalline polymeric semiconductors by means of delayed photoluminescence (PL) [1,2]. We implement time-dependent and steady-state PL spectroscopies to study the yield and recombination rate of geminate polarons. We compare the dynamics of delayed PL at varying magnetic field and temperature. We find that there are significant magnetic field effects on the recombination, which increases the relative quadrature signal of the CW PL with the increase of the magnetic field. This points to charge-transfer intermediate states between singlet excitons and geminate polaron pairs, with strongly mixed singlet and triplet character.

Doping Induced Solubility Control Patterning for Organic Thin-Film Transistors
- Zaira I. Bedolla-Valdez4, Camila Cendra Guinassi2, Zhengliang Su1,
Effect of Disorder on the Thermoelectric Properties of Semiconducting Polymers

Meenakshi Upadhyaya and Zlatan Aksamija; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Organic thermoelectric (TE) materials hold tremendous potential to address the ever-increasing demand for sustainable and renewable energy resources. Recently, a $ZT = 0.25$ has been reported in PEDOT: PSS, upon optimizing the carrier concentration. This, combined with advantages such as low cost, easy synthesis, and an inherently low thermal conductivity, makes polymeric a very attractive choice for commercially viable TE applications such as large-scale Peltier coolers and electricity generation from waste heat and renewable sources. A longstanding problem in TE materials is the dependence of performance on the TE Seebeck coefficient and the conductivity. We find that numerical transport models play a key role in predicting the optimum structural characteristics and the design of novel TE materials for TE applications. In this work, we investigate the TE properties of disordered organic semiconductors, and establish the effect of carrier concentration, disorder, and correlation in energy and position on the TE Seebeck coefficient, electrical conductivity, and the Lorenz number. Our transport model is based on electron hopping between localized sites with a Gaussian disorder model for their energies. We iteratively solve the non-linear Pauli master equation to compute the time-averaged occupational probabilities of the sites from which relevant transport quantities are calculated. Our results show that large energy overlap between localized electronic states can improve the electrical conductivity without adversely affecting the Seebeck coefficient. Positional disorder affects the overlap between neighboring states and aids in the formation of conduction paths with an increased probability of carriers in high energy sites, ultimately leading to simultaneous increase in electrical conductivity and Seebeck coefficient. We introduce positional correlation to investigate the role of partial ordering and find that it negatively affects conductivity. On the other hand, energetic disorder widens the density of states and leads to increased energy gap between neighboring sites, thus hindering transport and adversely affecting both conductivity and Seebeck. Surprisingly, correlation in energies of nearby sites has an effect on the TE properties. We also find that Lorenz number increases with Seebeck coefficient, largely deviating from the Sommerfeld value and the universal trend observed across all materials exhibiting band transport. Our work provides an understanding of how short channel OTFTs were fabricated using all solution processes. We will also detail the performance advantages of short channel OTFTs as well as discuss the lifetime issues associated with dopant drift.

The authors acknowledge the NSF Scalable Nanomanufacturing program for financial support and SENER-CONACyT 291145 for Zaira I. Bedolla-Valdez’s postdoctoral fellowship.

Exciton Binding and Dissociation in Semiconducting Polymers—A Tight Binding Approach

Joel H. Bombile, Michael Janik and Scott Milner; The Pennsylvania State University, University Park, Pennsylvania, United States.

Semiconducting polymers are the subject of much interest and study as active elements in a number of electronic devices. Among these devices, organic photovoltaics are particularly attractive due to their potential light weight, low cost and mechanical flexibility. Crucial to the performance of photovoltaic devices is the generation of charge carriers, which occurs through the dissociation of excitons. A clear understanding of excition formation, dissociation, and recombination in OPVs is necessary for the design of more efficient devices. We focus on the stability of excitons and the energetics of their dissociation and separation into charge carriers that can then be transported to the electrodes. Excitons are excited electron and hole pair bound by a Coulomb interaction. For separation into individual carriers, the binding energy of the exciton must be overcome. We use a model Hamiltonian based on the tight binding approximation to describe the exciton binding energy and its dissociation potential, for an exciton confined to a 1D lattice. Our model takes into account polaronic effects arising from the reorganization of nuclei and from polarization of the surrounding dielectric, which substantially stabilize the separated carriers and affect the exciton dissociation potential. We examine the effects of an applied electric field on the dissociation potential, and relate the field strength necessary to unbind the hole-electron pair to the maximum attractive Coulomb force between them. We then study the exciton at a 1D donor-acceptor interface, which polarizes the exciton. We explain the exciton polarization by observing how its dissociation potential is altered by the interface. The interface not only polarizes the exciton but makes it easier to be unbound by an external factor, as evidenced by a reduced electric field strength necessary for charge separation.

EP05.14.42
Elucidating the Role of Molecule-Electrode Interfacial Defects in Charge Tunneling Characteristics of Large-Area Junctions

Gyu Don Kong, Junji Jin and Hyo Jae Yoon; Chemistry, Korea University, Seoul, Korea (the Republic of). 

Interfacial chemistry at organic-inorganic contact critically determines function of a wide range of molecular and organic electronic devices and other systems. The chemistry is, however, difficult to understand due to the lack of easily accessible in-operando spectroscopic techniques that permit access to interfacial structure on a molecular scale. Herein we compare two analogous junctions formed with identical organic thin film and different liquid top-contacts (water droplet vs. eutectic gallium indium alloy) and elucidate the puzzling interfacial vs. eutectic gapless. Specifically, we fine-tune the surface topography of the organic surface using mixed self-assembled monolayers (SAMs): single component SAM composed of rectifier $2,2'$-bipyridyl-terminated n-undecanethiolate; denoted as SC$_11$BPY is systematically diluted with non-rectifying n-alkanethiolates of different lengths (denoted as SC$_n$ where $n=8,10,12,14,16,18$). Characterization of the resulting mixed SAMs in wettability and tunneling currents with the two separate liquid top-contacts allow us to investigate the role of phase segregation and gauche defect in the SAM/liquid interfaces. The results reported here show the difference in length between SC$_{11}$BPY and SC$_n$ is translated into nanoscopic pits and gauche-conformer defects on the surface, and the difference in contact force—hydrostatic vs. user pressures—and hence conformity of contact accounts for the difference in wettability and rectification behaviors. Our work provides an
EP05.14.43

Deconvolution of Tunneling Current in Large-Area Junctions Formed with Mixed Self-Assembled Monolayers
Jinju Jin, Gyu Don Kong and Hyo Jae Yoon; Chemistry, Korea University, Seoul, Korea (the Republic of).

The study of charge transport by quantum tunneling phenomena across organic thin films has been actively studied for many years in various academic fields. In molecular electronics, while single-component self-assembled monolayers (SAMs) have been previously main organic component, little has been investigated on how heterogeneity of monolayer affects the charge transport behavior across it. Here we focus on binary mixed SAMs composed of two different n-alkanethiolates of different lengths formed on ultraflat template-stripped gold substrate. Electrical characterization of mixed SAMs using liquid eutectic gallium-indium alloy reveals that the surface topography of monolayer largely depends on the difference in length between the thioclates, and the surface heterogeneity is translated into the distribution of tunneling current density. As the length difference is more significant, more phase segregation takes place, leading to increase in the modality of Gaussian fitting curves. Consequently, statistical analysis permits access to deconvolution of tunneling currents, mirroring the phase segregated surface. Our work provides an insight into the role of surface topography in performance of molecular-scale electronic devices.

EP05.14.44

Crystal Structures and Superradiance of Organic Semiconductors at 2D Limit
Beilei Sun, Xin Xu, Zefeng Chen and Jianbin Xu; The Chinese University of Hong Kong, Sha Tin District, Hong Kong.

Organic semiconductors (OSCs) have attracted great attention for decades because they offer intriguing prospects for high throughput, low-temperature processing of electronic circuitry on flexible substrates. However, previous studies mainly focused on bulk single crystal or polycrystalline or amorphous thin films with disorders and grain boundaries. The intrinsic properties of OSCs in the vicinity of the device interfaces are rarely studied, although the interfaces have important influence on the electronic and optoelectronic properties of device. We have prepared high quality few-layer thin films of N,N’-dinitroxypropylene 3,4,9,10-tetracarboxylic diimide (PTCDI-C$_4$) by physical vapor transport (PVT) method and further characterized the crystal structure and optical properties of the first three layers in the proximity of the substrate. It is found that the first layer adopts a different molecular packing arrangement, whilst the overlayers exhibit different optical properties. Superradiance is observed in the single and bilayer as well as trilayer films, but decreases with the increase of film thickness and then disappears in the bulk material. The superradiance intensity shows an opposite trend as the sample temperature increased. The intensity at 140 K is about 9 times of that at 290K. The linewidth becomes narrower at lower temperature. The full width at half maximum (FWHM) drops from 10 nm at room temperature to 4.3 nm at 140 K.

EP05.14.45

Plasmon Hybridization in Self-Assembled Graphene Nanotubes
Kriti Agarwal, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota, Minneapolis, Minnesota, United States.

Graphene plasmonics has attracted widespread attention in recent years due to their rapid frequency tunability, long plasmon lifetime, and strong light confinement. However, the two-dimensional (2D) nature of graphene imposes stringent requirements on the underlying substrate and limits the plasmon enhancement modes that can be excited. One of the solutions to overcome the limited performance of 2D graphene plasmons is through the fabrication of self-assembled graphene nanotubes. We have realized the 3D graphene nanotubes using the plasma in a reactive ion etching (RIE) system to trigger a surface tension based self-folding caused by grain coalescence in a tin sacrificial hinge. The parameters in the RIE process have also been tuned to control the gap size within nanotubes, and also achieve extremely high aspect ratio (length/radius ~ 10,000) tubes. The radial coupling of plasmons at the opening of the tube creates a virtual uniform cross-section area of extremely strong field enhancement as compared to the rapidly decaying fields in 2D graphene. If small longitudinal gaps are introduced in the nanotubes, propagating surface and edge modes are achieved with intensity based on the gap length between the edges. The propagating modes in the high aspect ratio nanotubes can be utilized for plasmonic waveguides with extremely high propagation lengths. Furthermore, the self-assembled multi-layered (Al$_2$O$_3$/Graphene/Al$_2$O$_3$) nanotubes can be fabricated with an array of horizontally short discontinuous graphene segments as long as the outer layers are maintained as continuous. The smaller aspect ratio graphene segments undergo not only radial plasmon coupling but also a longitudinal coupling between the discontinuous segment openings, creating strong uniform field throughout the volume of the multi-layered tube. The lower contact area of the 3D graphene tubes with the underlying substrate leads to a lower capacitive coupling that causes significant ohmic losses through non-radiative plasmon relaxation due to coupling between plasmons and substrate carriers in metallic and semiconducting substrates. The lower plasmon damping leads to a 13 times stronger field that extends throughout the completely closed graphene tubes as opposed to corner confined weaker field in 2D ribbons on a silicon substrate. The stronger fields throughout the tube structure exhibit a fourfold enhancement in sensitivity and overcome the need to bind targeted molecules to the surface of graphene as exhibited by the example of A/G protein. The 3D graphene nanotubes achieve distinct edge and volumetric enhancement modes while simultaneously increasing the compatibility of graphene with diverse substrates without deterioration in plasmonic properties for application in novel optical and electronic devices.

Direct Measurement of the Energetic Landscape of Solution-Processed Organic Photovoltaic Devices
Vincent Lam and Yana Vaynzof; Kirchhoff-Institut für Physik und Centre for Advanced Materials, Ruprecht-Karls-Universität Heidelberg, Heidelberg, Germany.

Organic optoelectronic devices such as light-emitting or photovoltaic diodes have been under extensive investigation in the last decades, resulting in remarkable improvements in their performance. Most literature reports in this field include energy level diagrams to illustrate how the energetic landscape in the device varies through the various device layers. Consequently, these energy level diagrams are used to interpret device performance and comment on the efficiency of physical processes such as charge separation, charge injection or extraction. Despite the importance of such energy level diagrams, they are currently constructed by combining energetic values for the individual device components as obtained by different techniques, e.g. cyclic voltammetry, density functional theory calculations, Kelvin probe and photoemission spectroscopy. Additionally, these diagrams are often formed without taking into account interfacial effects, such as dipole formation or band bending, that may arise as different materials are put into contact. Herein, we demonstrate that combining ultra-violet photoemission spectroscopy (UPS) with gas cluster ion beam (GCIB) sputtering, allows for a damage-free depth profiling and hence, an accurate determination of the energetic landscape of solution-processed active layers or multi-layers. We utilize the widely investigated model material system poly[3-hexylthiophene] (P3HT) and C61-butyric acid methyl ester (PC60BM), but also demonstrate that our method is applicable to a large variety of other novel organic material systems. By fitting the obtained UPS spectral maps, we are able to not only quantify the positions of the donor and acceptor energy levels, but also obtain compositional information with a vertical depth resolution than that available from X-ray photoemission spectroscopy profiling. Our results allow us to accurately and reliably measure the ‘photovoltaic bandgap’ (the energetic difference between the lowest unoccupied molecular orbital of the acceptor and the highest occupied molecular orbital of the donor) and correlate it to the measured open circuit voltage of the device. Our method opens the way to quantify the energy losses in organic photovoltaic systems and develop new
Sensitized triplet-triplet annihilation (TTA) involves two components: a triplet-triplet annihilation (TTA) material where two triplets can fuse to a singlet for light emission, and a sensitizer material to provide the triplets to the TTA material. Typically, the sensitizer has a lower singlet energy than the TTA material, which results in singlet quenching (SQ) of the TTA signal in solid-state optoelectronic devices (such as organic light-emitting diodes), lowering the efficiency. Here, we show that a triplet diffusion and singlet blocking (TDBS) layer between the sensitizer and TTA material allows the triplet ejection to diffuse from sensitizer to TTA but blocks the singlet quenching of TTA emission by sensitizer. Obviously, the TDBS layer should exhibit a triplet energy lower than the sensitizer and higher than TTA material, as well as a higher singlet energy than both sensitizer and TTA material. The TDBS layer can be applied to several sensitizer systems, such as phosphorescent (Ph) and thermally-activated delayed fluorescent (TADF) materials whose efficient intersystem crossing (ISC) process converts singlets into triplets for sensitizing TTA emission. With incorporation of the TDBS layer into a solid-state thin film, a 6.13-times enhancement in the STTA signal was observed using a TADF-sensitizer under optical pumping. Efficient STTA emission was also observed with a Ph-sensitizer in an electrically-pumped organic light-emitting diode (OLED). The exciton dynamics were analyzed with transient electroluminescence (TrEL) and transient photoluminescence (TrPL), which provide direct evidence for reduced singlet quenching with the insertion of a TDBS layer. Finally, an electrically-pumped device that generates 75% triplet excitons in a conventional fluorescent dye can also provide sufficient triplets to be used as the sensitizer, and the overall conversion efficiency of the triplets into singlets approach 80%. Besides, the operation lifetime of the blue OLED using TTA emission was elongated by ~3x due to separation of charge recombination zone in the sensitizer layer and the emission zone in the TTA layer.
A series of novel carbazole-imidazole derivative with a large energy bandgap and triplet state over 3.4 and 2.8 eV, respectively, were synthesized conjugating three carbazole moieties and one imidazole moiety to exhibit the bipolar behavior. Their highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) were approximately at 2.3 and 3.7 eV, respectively. In particular, by well design to form the molecular structure, these compounds showed the excellent thermochemical properties with high glass transition (T_g) of more than 190 °C and high decomposed temperature of approximately 450 °C. The T_g is greater than the highest thermal specification of 150 °C for automotive electronics, corresponding to the better thermal reliability. Employing as host materials of blue phosphorescent organic light emitting device (OLED), a layer structure of indium-tin-oxide anode/4,4'-cyclohexyldenedibis[N,N-bis(4-methylphenyl)benzeneamine]/N,N-dicarbazolyl-3,5-phenylene/ host: iridiumIIIbis[6,6-(di-fluorophenyl)]pyridinato-N,C20]picolinate (Flirpic)/ diphenylbis[4-(pyridin-3-yl)phenyl]silane/lithium fluoride/ aluminum cathode. The Flirpic was well-known high efficiency blue phosphorescent emitter. Our preliminary high efficiency phosphorescent OLED exhibited the max. current efficiency of 58.7 cd/A, max. power efficiency of 59.3 lm/W, max. external quantum efficiency of 28.6%. By moving the main recombination from the region close to electron transporting layer to the center of emitting layer, the operation lifetime exhibited 2 times improvement. The further improvement in device performance is possible.

Synthesis and Characterization of Meso-Substituted BODIPYs—Exploration of the Optical and Photophysical Properties and the Formation of Thin Films Cruz Pamela1, 2; 1UNAM, Mexico city, Mexico; 2Chemistry, ICN, Mexico city, Mexico.

Four BODIPY-fluorene based fluorophores were synthetized using a donor-π-bridge- acceptor (D-π-A) motif. They were studied via their structural analysis, the measurement of their photophysical and optical properties and a theoretical DFT study, to plunge deeper into their electronic structure and transitions bestowing such features. We present four different structures as we change the π bridge, in the first one BODIPY 1, we have the BODIPY core substituted in the meso position with a fluorene moiety in the BODIPY 2 we have the BODIPY core directly attached to the ethynylfluorene moiety, in BODIPY 3 we have a phenyl group attached to the ethynylfluorene moiety, finally in the BODIPY 4 we have a phenyl group attached to an ethynylfluorene moiety. In this work, we present the synthesis of novel meso-BODIPY derivatives, the spectroscopic characterization, structural analysis of X-Ray diffraction, and the study of the photophysical properties, such as: absorption, emission, and fluorescence quantum yield. Quantum chemical calculations were performed to analyzed the conduct of the compounds in the excited state.

Investigation of Locally-Excited and Charge-Transfer Optical Transitions in a Series of Porphyrins Thomas M. Cooper1, Joy Haley1, Weije Su1, Douglas Krein2 and Jennifer Fore3; 1Air Force Research Laboratory, Dayton, Ohio, United States; 2General Dynamics Information Technology, Dayton, Ohio, United States; 3SOCHE, Dayton, Ohio, United States.

In order to investigate locally-excited and charge-transfer optical transitions in multiple-chromophore-molecular-complexes, we synthesized eight new porphyprins containing 5,15-attached diphenyl aminoporphyrin (DPA) or benzothiazolo(HT) connected to the porphyrin core either through a phenyl-alkynyl fluorene bridge or with an alkynyl-fluorenone bridge. We also synthesized a series of these porphyrins containing a central Zn atom. We will describe the effects of transitions bestowing such features. We present four different structures as we change the π bridge.

**EP05.14.56**

Tuning Excited-State Absorption of Aromatic Hydrocarbons via Structural Modifications David Stewart1, 2, Jianmin Shi1, Alexis T. Phillips1, 4, Zhenning Yu1, 3, Tristan Naranjo1, 4, Tod Grusenmeyer1, Jacob M. Artz1, 4, Christopher McCleese1, Ryan M. O’Donnell3, Thomas M. Cooper1, William M. Shensky1, Loon-Seng Tan1 and Joy Haley1; 1Air Force Research Laboratory, Dayton, Ohio, United States; 2General Dynamics Information Technology, Dayton, Ohio, United States; 3SOCHE, Dayton, Ohio, United States; 4Southwestern Ohio Council for Higher Education, Dayton, Ohio, United States; 5UES, Inc., Dayton, Ohio, United States; 6Physics, U.S. Air Force Academy, U.S. Air Force Academy, Colorado, United States.

Excited-state absorption (ESA) plays a critical role in the effectiveness of nonlinear optical processes such as reverse-saturable absorption and effective-three-photon absorption. By favorably controlling the intensity and energy of the ESA, the nonlinear performance can be enhanced. However, examples of how to tune ESA are scarce. This work shows how structural modifications across two separate series of molecules can greatly influence ESA. The first series is a group of anthanthrene derivatives to which a varying number of phenyl or t-Bu-phenyl substituents are added. The shape of the ESA spectra remain consistent but the maxima red shift from 585 nm (parent anthanthrene) to 645 nm (four t-Bu-phenyl substituents) are. There are also two oxidized derivatives, anthanthrones, which show strong, broad ESA in the visible with weaker transitions observed to nearly two μm. The anthanthrones have stronger ESA in the visible than the anthanthrenes, with ESA extinction coefficients around 30,000 M⁻¹ cm⁻¹. Another noticeable difference is that the intersystem crossing yields are also much larger for the anthanthrenes (~0.8) than the anthanthrenes (~0.3). This follows El Sayed’s rule as the anthanthrone derivatives likely contain nπ* states. The second series is a group of naphthalene carbonitrile derivatives containing electron donating groups (either dimethylamino or piperidinyl) in the 2, 3, or 4 positions. These changes dramatically change the energy of the ESA transitions, with shifts in the maxima greater than 100 nm. These modifications also impact the singlet state, as fluorescence lifetimes and quantum yields are significantly larger in the 3-substituted compounds (10.1 ns/0.76) than the 4-substituted (0.48 ns/0.05). Another significant effect of the varying substitution positions is the singlet-triplet energy gap, which can be tuned from 0.65 eV (2-position) to 1.01 eV (4-position).
The charge-transfer (CT) states appearing at the donor-acceptor interfaces in organic solar cells (OSCs) mediate exciton dissociation, charge generation, and charge recombination. Current work on OSCs based on non-fullerene acceptors (NFAs) points out that by using blends with a small energy offset between the CT state and highly luminescent local excitation (LE) state of the low-gap material it is possible to significantly minimize the voltage losses. Here we compare how the static and dynamic disorders and hybridization between the CT and LE states impact the radiative and non-radiative recombination rates and consequently the voltage losses in PTB7-Th:IEICO and PTB7-Th:PC71BM OSCs that are representative examples of small-energy offset NFA and typical fullerene-based OSCs, respectively. We have also developed a three-state vibronic model that explicitly considers the electronic and vibrational couplings between the CT and LE states and show that the use of the three-state model is mandatory in order to obtain a reliable description of the optical absorption features related to the CT states in blends with small-energy offset between CT and LE states.

All-Organic Infrared-to-Visible Up-Conversion Organic Light-Emitting Diodes with Infrared Sensitivity Beyond 1.1µm Vishal Yeddu, Gijun Seo and Do Young Kim; Materials Science and Engineering, Oklahoma State University, Tulsa, Oklahoma, United States.

Infrared (IR)-to-visible up-conversion organic light-emitting diodes (OLEDs) have attracted a great deal of research interest because they offer the potential to convert an invisible infrared image to a visible image without pixilation in the device, thus enabling a high-quality image at a significantly low cost. However, all-organic IR-to-visible up-conversion OLEDs with an organic IR sensitizer as well as an organic visible emitter show very limited IR sensitivity up to around 830 nm. Detecting photons at longer IR wavelengths requires lower bandgap organic semiconductors. Here, all-organic IR-to-visible up-conversion OLEDs with an IR sensitivity up to 1200 nm were fabricated using a novel low bandgap polymer as the IR sensitizing layer. This low-bandgap polymer showed a strong absorption in the near-IR wavelengths from 700nm to 1200nm. To evaluate the novel low bandgap polymer as the near-IR sensitizer, the near-IR photodetectors are first fabricated with a PC60BM as the acceptor in the photoactive layer. The near-IR photodetector showed detectivity higher than 10^11 Jones in the multi-spectral region (300-1100nm) and the maximum detectivity of 3.0×10^11 Jones at the wavelength of 1000 nm due to significantly reducing dark current (8.8 × 10^-6 mA/cm² at -1V). Using the novel low bandgap polymer as the IR sensitizing layer, IR-to-visible up-conversion OLEDs were fabricated with an IR sensitivity up to 1,200 nm. The IR up-conversion OLED successfully converted invisible near-IR light of 700nm-1200nm directly to visible green light with a peak emission wavelength of 520 nm. This is the very first report of all-organic IR-to-visible up-conversion OLED with near-IR sensitivity beyond 1100 nm which Si-based photodetectors cannot offer.

**TUTORIAL: Introduction to Quantum Spintronics**

November 25 - November 25, 2018

Quantum spintronics is an emerging field of spin coherence and spin correlations at or near room temperature, and their effects on a wide range of properties, including spin dynamics and light emission from color centers in solids, spin and charge transport in organic materials, spin-dependent transport in tunnel junctions, dynamic nuclear polarization, and animal sensing of magnetic fields. Room-temperature quantum spintronic systems can be much more sensitive to external perturbations than sensors that must be very near thermal equilibrium. Applications include sensing of magnetic fields in biological systems (e.g. color centers in diamond and other wide-band-gap semiconductors and insulators), control of light emission intensity from organic light emitting diodes (e.g. thermally-activated delayed fluorescence), spin injection, spin dynamics, and coherent optical interactions with single spins (color-center photonics). Highly sensitive room-temperature spin systems also feature prominently in proposals for very low power electronic logic.

This tutorial will provide an introduction to the materials and operating regimes that tend to exhibit room-temperature spin coherence and spin correlations, methods of calculating and measuring these properties, areas of initial application and critical open questions.
The theoretical criteria for a stable, room-temperature quantum coherent system will be described, and several examples will be presented. Methods of calculating the response of a quantum coherent system to external fields and perturbations will be presented, including density matrices, stochastic Liouville equations, and master equations. Recent progress in predicting specific quantum coherent systems, such as density functional theory for new color centers in wide-gap semiconductors, will be surveyed. The ideal performance of quantum spintronic devices will be compared with other sensors or information processing approaches.

2:15 PM
Quantum Spintronics of Organic Semiconductors Christoph Boehme; The University of Utah

Organic semiconductors provide a varied set of materials that exhibit quantum spintronic phenomena. The effects of spin coherence on charge conductivity in organics will be described, along with large room-temperature responses to magnetic fields. Resonant manipulation of spins in organic materials, detected by transport, will be introduced as a mechanism for a sensitive magnetometer. Spin-charge correlations in the spin Hall Effect and spin pumping will also be presented.

3:00 PM BREAK

3:30 PM
Optical Coupling to Quantum-Coherent Spins David D. Awschalom; The University of Chicago

Coherent coupling of light to spin coherent systems, especially for color centers in diamond and silicon carbide, will be described in detail. Nonequilibrium polarization/pumping, manipulation of the spin state, and efficient detection will be presented, along with criteria for pulse shaping that can be used for low-error manipulation of the spin state of a quantum coherent system.

4:15 PM
Photonics and Quantum Spintronics Evelyn Hu; Harvard University

The design, fabrication, and measurement of photonic devices that efficiently integrate a quantum coherent spin with a cavity will be described. Methods of manipulating the quantum spin to bring it into resonance with the cavity, such as through acoustic oscillations or electrical gates, will be presented. The figures of merit for spin-photon coupling will be derived and compared with state-of-the-art coupling of other quantum coherent systems.

8:15 AM *EP06.01.01
The Dawn of Quantum Networks Ronald Hanson; QuTech, Delft University of Technology, Delft, Netherlands.

Entanglement – the property that particles can share a single quantum state - is arguably the most counterintuitive yet potentially most powerful element in quantum theory. The non-local features of quantum theory are highlighted by the conflict between entanglement and local causality discovered by John Bell. Decades of Bell inequality tests, culminating in a series of loophole-free tests in 2015, have confirmed the non-locality of Nature.

Future quantum networks may harness these unique features of entanglement in a range of exciting applications, such as distributed quantum computation, secure communication and enhanced metrology for astronomy and time-keeping. To fulfill these promises, a strong worldwide effort is ongoing to gain precise control over the full quantum dynamics of multi-particle nodes and to wire them up using quantum-photonic channels.
Diamond spins associated with NV centers are promising building blocks for such a network as they combine a coherent electron-optical interface with a local register of robust and well-controlled nuclear spin qubits. Here I will introduce the field of quantum networks and discuss ongoing work with the specific target of realizing the first multi-node network wired by quantum entanglement.

8:45 AM *EP06.01.02
Spin and Orbital Resonance Driven by a Mechanical Resonator

Gregory Fuchs; Cornell University, Ithaca, New York, United States.

Creating and studying coherent interactions between solid-state quantum systems is a challenge at the intersection of atomic physics, condensed matter physics, and engineering. Efforts to create hybrid quantum systems are appealing because they enable the exploration of coherent interactions between a physical qubit and non-traditional degrees of freedom. For instance, there is a growing interest in mechanical motion as a “plastic” degree of freedom for coupling solid-state qubits, with the potential to form a coherent interface between them, and with light. This has motivated intense research into the coherent interactions between mechanical resonators and qubits formed from photons, trapped atoms, superconducting circuits, quantum dots, and nitrogen-vacancy (NV) centers in diamond, to name a few. I will describe our experiments to drive coherent resonance of NV center spins using gigahertz-frequency mechanical resonators through dynamic crystal lattice strain. In high-quality diamond mechanical resonators, we demonstrate coherent Rabi oscillations of NV center spins driven by mechanical motion instead of an oscillating magnetic field. We show that the mechanical resonator is a resource to prolog the NV center’s spin coherence. We also examine how strain can be used to control NV centers through their excited-state, either to control the spin at room temperature or the orbital states at low temperature. In particular, using resonant optical spectroscopy of an NV center coupled to a driven mechanical resonator, we demonstrate very-strongly driven orbital states. This includes the observation of coherent Raman sidebands out to nine orders, and multi-phonon Rabi coupling between two orbital states.

9:15 AM EP06.01.03
Using Microwaves to Study Charge State in NV Diamond

Diana Prado Lopes Aude Craik1, 3, Pauli Keihayias1, 2, Andrew S. Greenspon2, Xingyu Zhang3, Matthew Turner1, 2, Erik Bauch3, Jennifer Schloss4, 5, Connor Hart3, 4, Ronald Walworth1, 2, 4, and Evelyn Hu1; 1Department of Physics, Harvard University, Cambridge, Massachusetts, United States; 2Harvard-Smithsonian Center for Astrophysics, Harvard University, Cambridge, Massachusetts, United States; 3John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 4Center for Brain Science, Harvard University, Cambridge, Massachusetts, United States; 5Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

We present a novel, microwave-based technique for determining charge state of nitrogen-vacancy (NV) ensembles in diamond. The technique isolates, in situ, the spectral shape of the fluorescence contribution from neutral (NV0) and negatively-charged (NV-) defects, producing sample-specific results which take into account the effects of experimental conditions (such as illumination intensity and wavelength) and material properties (such as local strain and electric fields). Using this technique, we explore how ensemble charge state is affected by experimental and material parameters, and study the physics of NV ionization from the negative charge state. The method can also be applied to derive relative concentrations of other solid-state defects which exhibit a spin-dependent fluorescence contrast.

9:30 AM EP06.01.04
Surface Engineering for Shallow Nitrogen-Vacancy Centers in Diamond with Long Coherence Times

Sorawis Sangtawesin and Nathalie P. de Leon; Princeton University, Princeton, New Jersey, United States.

Nitrogen vacancy (NV) centers in diamond are point defects that exhibit excellent spin coherence at room temperature. When placed close to the surface, they can have strong interactions with other molecules, enabling a new form of nanoscale spectroscopy. However, surface defects can give rise to noise, and shallow NV centers exhibit rapid decoherence. We demonstrate a method for creating a well-ordered, oxygen-terminated surface that results in an improvement of NV spin coherence and magnetic field sensitivity by up to an order of magnitude. Careful control over surface morphology enables reversible and reproducible chemical termination, which we characterize using complementary surface spectroscopy tools: NV-based nanoscale spectroscopy to probe the nature of noise, and X-ray and electron spectroscopy to probe structure and chemical state. We find that the dominant contribution to NV decoherence is broadband magnetic noise arising from disorder at the surface.

Controlling Defect Spin States with Photons, Magnons and Phonons

Brian Zhou1, Paolo Andrich1, Samuel Whiteley1, F. Joseph Heremans2 and David Awschalom2, 3; 1University of Chicago, Chicago, Illinois, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.

There is a growing interest in exploiting the quantum properties of electronic and nuclear spins for the manipulation and storage of quantum information. Current efforts embrace materials with incorporated point defects, whose unique quantum mechanical electronic and nuclear spin properties allow a fundamentally different means to process information. Here we focus on recent developments in manipulating and connecting spins in both silicon carbide (SiC) and diamond. We find that defect-based electronic states in SiC can be isolated at the single spin level [1] with surprisingly long spin coherence times and high-fidelity control within a wafer-scale material operating at near-telecom wavelengths. Similarly, the spin-photon interface in diamond offers an opportunity to implement all-optical, geometrically protected quantum spin gates [2] for quantum information processing. Moreover, we present pathways for connecting isolated electronic spins using magnons and phonotors. Exploring a hybrid qubit-magnon system, we use surface-confined spin-wave modes...
in YIG thin films to perform long-range coherent control of spins in diamond nanoparticles [3]. The magnon modes amplify the oscillating field of the microwave source by more than two orders of magnitude, thereby efficiently driving remote spin states. In addition, fabricated surface acoustic wave resonators exploit both the piezoelectric and isotropic phonon properties of SiC to create Aufler-Townes splittings and mechanically drive coherent Rabi oscillations between arbitrary ground-state spin levels, including magnetically forbidden spin transitions [4].

10:45 AM EP06.02.02
Photoluminescence Characterization of Precisely Located Si Vacancies in 4H-SiC Created via Li+ Implantation

Shojan P. Pavumuny1, Edward Bieger2, Sam Carter1, Hunter Banks1, Rachael Myers-Ward1, Paul Klein1, Mathew Dejarld1, Allan Bracker1, Evan Glaser1 and D. Kurt Gaskill2; 1U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2Sandia National Laboratories, Albuquerque, New Mexico, United States; 3KeyW Corp., Arlington, Virginia, United States.

Silicon vacancies (V0) in SiC are of interest for future applications in quantum information and quantum sensing mainly due to the long electronic spin (S = 3/2) coherence times at room temperature. A key requirement for many applications is the precise placement of V0 in a photonic crystal cavity (PhC) as the resulting Purcell enhancement improves the emission rate (brightness) of the photoluminescence (PL) as well as increases photon indistinguishability. Here we show that Li+ ions, implanted with energy 100 keV using a maskless focused ion beam technique (∼25 nm diameter spot positioned with ∼25 nm accuracy and having an ion travel depth of ~400 nm), create V0 in the material. To facilitate PL characterization, arrays of locations were implanted into epitaxial 4H-SiC with doses ranging from 1018 to 1020 Li+ cm−2. Epitaxial SiC is chosen as we have shown it has no measurable V0. Using a 745 nm excitation source, we find that the PL in the range of 860 to 975 nm is dominated by the V1′, V1, and V2 lines of V0. Furthermore, the PL saturates at an excitation intensity of ~1 mW focused to a diameter of ~1 μm. The PL intensity of V1′ for a high implantation dose is found to be constant on a time scale of many hours. Additionally, the V1′ intensity is linear with implantation dose. Moreover, we will describe data that indicates single V0 formation at the lowest doses. Lastly, given the encouraging results to-date, we will discuss utilizing this approach with a PhC.

11:00 AM EP06.02.03
Spectrally Stable Defect Qubits for Quantum Communication with No Inversion Symmetry

Péter Udvarhelyi1, 2 and Adam Gal3, 4; 1Eötvös Loránd Science University, Budapest, Hungary; 2Wigner Research Centre for Physics, Hungarian Academy of Science, Budapest, Hungary; 3Budapest University of Technology and Economics, Budapest, Hungary.

In this paper, we show that the inversion symmetry is not a prerequisite criterion for a spectrally stable defect quantum emitter. An ideal quantum emitter does not couple to the stray electric fields upon optical transition but the optical transition dipole moment should be strong for bright emission. These two conditions can be simultaneously satisfied for such defect quantum emitters that exhibit identical electron density in the ground and excited state to eliminate the coupling to the stray electric fields but the sign of the corresponding wavefunctions alters accordingly to maximize the optical transition dipole moment. These properties can be principally manifested for defect qubits without inversion symmetry.

We demonstrate by means of density functional perturbation theory calculations that the so-called V1 optical center, i.e., negatively charged Si-vacancy, in 4H silicon carbide (SiC) tends to possess such favorable properties where 4H SiC can only host defects without inversion symmetry.

The support from NKFII (Grant Nos. 2017-1-1.1.1-NKP-2017-00001, NKPV_161-2016-0043 and NN127002) and the EU Commission is acknowledged.

11:15 AM *EP06.02.04
Coherence Properties of Shallow Donors in ZnO

Xiayu Linpeng1, Maria Viitaniemi1, Aswin Vishnuradh1, Y. Kozuka1, 2, Cameron Johnson1, Masashi Kawasaki1 and Ken-Mei Fu1, 2; 1University of Washington Dept. of Physics, Seattle, Washington, United States; 2Electrical Engineering, University of Washington, Seattle, Washington, United States.

Defects in crystals are leading candidates for photon-based quantum technologies, but progress in developing practical devices critically depends on improving defect optical and spin properties. Motivated by this need, we study a new defect qubit candidate, the shallow donor in ZnO. We demonstrate all-optical control of the electron spin state of the donor qubits and measure the spin coherence properties. We find a longitudinal relaxation time T1 exceeding 100 ms, an inhomogeneous dephasing time T2* of 17 ns, and a Hahn spin-echo time T2 of 50 μs. The magnitude of T2* is consistent with the inhomogeneity of the nuclear hyperfine field in natural ZnO. Possible mechanisms limiting T2 include instantaneous diffusion and nuclear spin diffusion (spectral diffusion). These results are comparable to the phosphorous donor system in natural silicon, suggesting that with isotope and chemical purification long qubit coherence times can be obtained for donor spins in a direct band gap semiconductor.

11:45 AM EP06.02.05
Room-Temperature Magneto-Optical Signatures of Defect Spins in Hexagonal Boron Nitride

Patel2, Marcus W. Doherty3 and Lee Bassett2; 1Physics, Lafayette College, Easton, Pennsylvania, United States; 2Electrical and Systems Engineering, University of Pennsylvania, Philadelphia, United States; 3Research School of Physics and Engineering, Laser Physics Centre, Australian National University, Canberra, Australian Capital Territory, Australia.

Optically addressable spins associated with defects in wide-bandgap semiconductors have emerged as leading platforms for diverse applications in quantum information science and other quantum technologies, where spin-dependent inter-system crossing (ISC) transitions facilitate optical spin initialization and readout. Recently, the van der Walls material hexagonal boron nitride (h-BN) has emerged as a robust host for quantum emitters (QEs). Compared to traditional three-dimensional semiconductors like diamond and silicon carbide, h-BN promises unique capabilities for applications where defects couple to an external environment, such as sensing or nanophotonics, since defects exist at or very near atomically flat surfaces.

An outstanding question, however, has been whether h-BN can host QEs with an accessible spin degree of freedom, which could be used as qubits similar to the diamond nitrogen vacancy center. We report* our recent observations of a room-temperature magneto-optical response from select QEs in h-BN where the strongly anisotropic photoluminescence (PL) patterns as a function of applied magnetic field are markedly different from well-known spin
defects in diamond and silicon carbide. We explore the anisotropic PL response due to an applied magnetic field through studies of an emitter’s spectral, polarization, and photo-dynamic responses. Using a theoretical approach based on simple symmetry considerations, analytical molecular orbital theory, and semiclassical simulations, we show that the field-dependent variations in the steady-state PL and photon emission statistics are consistent with an electronic model featuring a spin-dependent ISC between triplet and singlet manifolds, indicating that optically-addressable spin defects are present in h-BN, a versatile two-dimensional material promising efficient photon extraction, atom-scale engineering, and the realization of spin-based quantum technologies using van der Waals heterostructures.

This work is supported by the Army Research Office (W911NF-15-1-0589) and the Australian Research Council (DE170100169).

**Freestanding YIG Magnon Nanoresonators with Ultra-Low Damping**

**Georg Schmidt**

1 Institute für Physik, Universität Halle, Halle, Germany; 2 Interdisziplinäres Zentrum für Materialwissenschaften, Universität Halle, Halle, Germany.

Nano electromechanical systems are interesting candidates for quantum information processing technology. Typical examples are the transfer of energy between mechanical and electromagnetic oscillators [1,2], but also spin wave excitations, so called magnons, can be used. An ideal material in this respect is Yttrium Iron Garnet. It combines long lifetimes as well for spin waves (magnons) as for mechanical waves (phonons) and a coupling mechanism for both (magnetoelastic coupling or magnetostriction). In the case of magnon resonances the coupling of a single Qbit to a magnon mode in a YIG sphere has already been demonstrated and also coupling of magnons to phonons in YIG spheres of diameters of a few hundred microns has already been published[3]. However, these experiments are still limited to macroscopic YIG spheres which forbid the integration of thousands or even hundreds of thousands of devices which may ultimately be necessary if a useful quantum computer shall be realized. So making true 3D YIG nanoresonators would open up a new field of applications for nanoscillators and create new options for quantum computation. However, up to now no method was available to shape three dimensional nanostructures from monocrystalline YIG.

We have developed a process to fabricate high quality monocrystalline freestanding 3D YIG nanostructures which can be designed for example as suspended bridges or cantilevers [4]. But also suspended optical ring resonators or disks for optical whispering gallery modes or more complex structures are possible. For the fabrication we use an electron beam lithography based process which was originally designed to realize metallic air bridges by evaporation and lift-off [5]. A newly developed deposition process for YIG using pulsed laser deposition at room temperature [6] allows for the fabrication and lift-off of amorphous structures. Surprisingly subsequent annealing leads to monocrystalline bridges even if the length of the span is as large as several micrometers.

The structures were investigated using transmission electron microscopy indicating high crystalline quality. Detailed investigation of spin dynamics was done using time and spatially resolved Kerr microscopy. Here we see various standing spin waves including Damon Eshbach Modes and Backward Volume Modes. The minimum linewidth in ferromagnetic resonance at 8 GHz is as small as 140 μT while the intrinsic linewidth at zero field is 75 μT.

**Bose-Einstein Condensates of Magnons in Optical Cavities**

**Tianya Liu**

Tianjin Key Laboratory of Low Dimensional Functional Material Physics and Producing Technology and Department of Physics, Tianjin University, Tianjin, China.

Magnonics, a newly developing field of spintronics, has attracted much attention in the past decade. However, due to its large number of thermally excited magnons, most of experiments on magnonics remain in the classical regime, where incoherent magnons play an important role. By virtual of optical cavity, laser cooling of the magnon mode has been a potential step towards the quantum regime. Instead of preparing the magnon-vacuum state, here, we propose to form a macroscopically quantum coherent state of magnons—the magnon Bose-Einstein condensate (BEC)—in optical cavities made of magnetic solids. Our previous study has predicted that parametric pumping of magnons can be achieved in such a cavity with control light blue detuned from the cavity resonance. In this work, we study the dynamics of magnons excited by the optical cavity modes, and quantitatively estimate the requisite for preparing magnon BEC. By resolving magnon number states through spectroscopic measurements of cavity photons, the proposed method here may open up new directions for all-optical manipulation of quantum magnon states.

**Spin Current Drive by Thermal Nonequilibrium**

**Kevin S. E. Olsson, Kyongmo An, Jianshi zhou, Li Shi and Xiaoqin E. Li**

Univ of Texas-Austin, Austin, Texas, United States.

A central goal in spintronics is to develop devices that rely on the transfer of spin rather than charge. In magnetic insulators, magnons, quanta of collective spin excitations, carry a pure spin current and offer energy efficient information transport and processing. Several methods have been explored to generate spin currents in magnetic insulators, including spin pumping, the magnon Hall effect, and the spin Seebeck effect. Spin current is not a conserved quantity and may reduce via scattering processes involving angular momentum exchange. The spin relaxation extracted from earlier studies on YIG has yielded a value on the order of ~ 10 μs, which is rather different from the energy relaxation length. A spin current can be introduced by a large temperature gradient introduced by a heating laser. We quantify such as a thermally driven spin current and magnon-phonon nonequilibrium in YIG using spatially resolved
Brillouin light scattering technique. We obtain information on nonequilibrium spectral density and demonstrate that low-energy magnons have a longer spin relaxation length than that of high-energy magnons.

2:45 PM EP06.03.04 Coherent Magnonics in Vanadium Tetracyanoethylene Ezekiel Johnston-Halperin1, Michael Chilcote1, Harberts Megan1, Bodo Fuhrmann2, Katrin Lehmann2, Fransson Andrew1, Yu Lu1, Howard Yu1, Na Zhi1, Hong Tang3 and Georg Schmidt2; 1The Ohio State University, Columbus, Ohio, United States; 2Zentrum für Physik, Martin-Luther-Universität-Halle-Wittenberg, Halle, Germany; 3Chemistry, The Ohio State University, Columbus, Ohio, United States; 4Yale University, New Haven, Connecticut, United States.

The exploration of quantum magnonics relies implicitly on the ability to excite and exploit long lived spin wave excitations in a magnetic material. That requirement has led to the nearly universal reliance on yttrium iron garnet (YIG), which for half a century has reigned as the unchallenged leader in high-Q, low loss magnetic resonance and spin wave excitation despite extensive efforts to identify alternative materials. Recent work has identified the organic-based ferrimagnet vanadium tetracyanoethylenide (V[TCNE]2) as the first credible alternative to YIG. In contrast to other organic-based materials V[TCNE]2 exhibits a Curie temperature of over 600 K with robust room temperature hysteresis, sharp switching to full saturation, and magnetic resonance linewidths as low as 0.5 Oe at 9.86 GHz (quality factor ~ 8,000). Further, since V[TCNE]2 is grown via chemical vapor deposition (CVD) at 50 C it can be conformally deposited as a thin film on a wide variety of substrates. Here we will discuss the coherent coupling of distinct magnon modes within a V[TCNE]2 film that is templated by growth on a corrugated substrate. The resulting array of nanowire structures exhibits uniform ferromagnetic resonance (FMR) as well as a variety of exchange and dipole coupled standing wave modes defined by the lateral boundaries of the individual nanowires. Further, as the orientation of a DC applied magnetic field is varied between induced easy and hard magnetic axes we observe anticrossing behavior among these modes that indicates the constituent magnons are interacting in the strong coupling regime. In combination with low temperature CVD synthesis, these results demonstrate the unique ability to pattern on-chip high-Q magnonic structures with implications for emerging applications ranging from microwave electronics to quantum information systems.

SESSION EP06.04: Dynamics and Magnetic Structure of Thin Magnetic Films

3:30 PM *EP06.04.01 Observation of Anomalous Magneto-Optical Kerr Effect in SrRuO3 Luyi Yang1,2 and E. Michael Barmann1; 1Physics, University of Toronto, Toronto, Ontario, Canada; 2Physics, Tsinghua University, Beijing, China.

We report the observation of anomalous magneto-optical Kerr effect in ferromagnetic strontium ruthenate (SrRuO3) thin films. We measure the polar Kerr signals as a function of an applied magnetic field. Apart from conventional hysteresis loops, the Kerr signals show additional hump features at small applied magnetic fields in certain thicknesses of the thin films. Similar to topological Hall effect, these hump features indicate the formation of topological spin textures (e.g. Skyrmions) possibly induced by the gradient of the strain.

4:00 PM EP06.04.02 Current-Induced Magnetic Domain Wall Motion in Compensated Ferrimagnet Saima A. Siddiqui, Jiahao Han, Joseph Finley, Caroline A. Ross and Luqiao Liu; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Antiferromagnetic materials show promises compared to ferromagnetic materials for spintronic devices due to their immunity to external magnetic fields and their ultra-fast dynamics. However, difficulties in controlling and determining their magnetic state are limiting their technological applications. At the compensation point, the two antiparallel sub-lattices in a ferrimagnet have the same magnetic moment and the material is an antiferromagnet. Compensated ferrimagnets are expected to exhibit fast magnetic dynamics like an antiferromagnet and yet their magnetic state can be manipulated and detected like a ferrimagnet, and therefore, have been pursued as a candidate system for ultrafast spintronic applications. Previously, it was demonstrated that current-induced spin orbit torque could provide an efficient switching mechanism for a compensated ferrimagnet. However, limited by the quasi-static measurement technique, the nature of the switching dynamics in these experiments are yet to be revealed. In this work, we provide the first experimental proof of current-induced fast domain wall (DW) motion in a compensated ferrimagnet. Using a magneto optic Kerr effect microscope, we determine the spin orbit torque-induced DW motion in Pt/Co1-xTbx microwires with perpendicular magnetic anisotropy. The DW velocity is determined as a function of applied current amplitude. A large enhancement of the DW velocity is observed in angular momentum compensated Pt/Co80Tb20 microwires compared to single layer or multi-layer ferromagnetic wires. Using analytical model, we also find that near angular momentum compensation point, the domain walls do not show any velocity saturation unlike ferromagnets or uncompensated ferrimagnets since both the effective gyromagnetic ratio and effective damping diverge at this composition. Moreover, by studying the dependence of the domain wall velocity with the longitudinal in-plane field, we identify the structures of ferrimagnetic domain walls across the compensation points. The high current-induced domain wall mobility and the robust domain wall chirality in compensated ferrimagnets open new opportunities for spintronic logic and memory devices.

4:15 PM EP06.04.03 Non-Volatile Control of Anti-Ferromagnetic Néel Vector in α-Fe2O3 Through Hydrogen Doping Hariom Jani1,2, Jiajun Linghu1, Rajesh Chopdekar1, Saima A. Siddiqui1, Jiahao Han, Joseph Finley, Caroline A. Ross and Luqiao Liu; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

α-Fe2O3 hosts in-plane Antiferromagnetism (AFM) at room temperature, possessing spin canting due to the Dzyaloshinskii-Moriya interaction. Just 10°C
below zero, bulk α-Fe$_2$O$_3$ undergoes Morin transition where the AFM spins re-orient colinearly along the out-of-plane symmetry axis. This first-order transition emerges due to the competition between magnetic-dipolar and single-ion magnetic anisotropies which have different magnitudes and temperature dependences.

We have developed a catalytic process for doping hydrogen into the α-Fe$_2$O$_3$ lattice, which allows non-volatile tuning of the AFM Néel vector and the accompanying spin canting. We discover that hydrogen doping also increases the electronic conductivity of α-Fe$_2$O$_3$ by three orders of magnitude. Moreover, owing to the light mass of a hydrogen atom, our H-doping process can be performed post-growth and is also reversible.

We characterize the new α-Fe$_2$O$_3$H$_x$ phase via Reciprocal Space Mapping, Raman and UV-Vis Spectroscopy, Scanning Tunneling Electron Microscopy and X-Ray Magnetic Linear Dichroism. We use Elastic Recoil Detection Analysis to prove that hydrogenation indeed causes incorporation of H atoms in the α-Fe$_2$O$_3$ lattice. X-Ray Absorption Near Edge Structure and ab-initio calculations reveal that the hydrogenation induced magnetic and electric modulations in α-Fe$_2$O$_3$ are concomitant with electron doping and not due to any structural changes of the lattice. This Electronic doping plays a crucial role in tuning the relative magnitude of the single-ion anisotropy with respect to the magnetic-dipolar counter-part, causing the modulation of the Morin transition. Our approach opens new avenues for control of anti-ferromagnetism in oxide systems.

4:30 PM EP06.04.04
The Role of Mn and Si Co-Doping on the Ferromagnetic and Optical Properties of MOCVD GaN Layers for Spintronic Applications
N Ben Sedrine1, Vishal Saravade2, Amirhossein Ghods2, C. Zhou2 and I. T. Ferguson2; 1Departamento de Física e I3N, Universidade de Aveiro, Aveiro, Portugal; 2Missouri University of Science and Technology, Rolla, Missouri, United States.

Wide bandgap dilute magnetic semiconductors (DMS) have increasing interest due to their room temperature (RT) ferromagnetism. DMS can be integrated into existing electronic and optoelectronic devices, and are expected to support the transport and storage of spin for the next generation of electronic devices. RT ferromagnetic hysteresis has been observed in GaN doped with transition metal or rare earth ions, and that it can be controlled by different parameters such as: doping concentration, Si co-doping, and annealing. However, the mechanism behind the ferromagnetism is not well understood and needs further investigation for spintronic applications.

In this work, Mn and Si co-doping effects in GaN layers are investigated. Un-doped GaN, Ga$_{1-x}$Mn$_x$N and Mn and Si co-doped GaN layers grown on sapphire by MOCVD, with different Mn and Si concentrations, are studied using magnetometry measurements. Ferromagnetic hysteresis was recorded in the Ga$_{1-}$Mn$_x$N layers at 300 K. However, for Si-doped Ga$_{1-x}$Mn$_x$N layers, the magnetization is found to decrease when Si concentration increases. It seems that Si compensates or shifts the acceptor levels in Ga$_{1-x}$Mn$_x$N, which are introduced by Mn-doping and contribute to the ferromagnetism [1]. Photoluminescence (PL) studies performed as a function of temperature and excitation power, from ultraviolet (UV) to the near-infrared energy regions. In Ga$_{1-x}$Mn$_x$N layers, 14 K PL emissions exhibit well resolved near band edge (NBE) emission, UV luminescence (UVL), and a yellow luminescence (YL) band, while for Mn and Si co-doped layers, noticeable changes in the NBE and a suppression of the UVL were observed. For the same experimental conditions, overall PL intensity increases with increasing Mn concentration, but drastically decreases for the Mn and Si co-doped samples. For the highest Mn concentration, the 14 K NBE emission exhibits several sharp peaks, while, Mn and Si co-doping induces a broadening of the NBE.

Understanding of defects in GaN and their effects on the ferromagnetic and optical properties is a crucial step towards using GaN for spintronics.

Electronic Transport in Ballistic InSb Nanowires with Ferromagnetic Contacts
Zedong Yang1, Yifan Jiang2, Sasa Gazibegovic3, Ghada Badawy3, Paul Crowell1, Sergey Frolov2, Erik P. Bakkers1 and Vlad Pribiag1; 1University of Minnesota, Minneapolis, Minnesota, United States; 2University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 3Eindhoven University of Technology, Eindhoven, Netherlands.

InSb semiconductor nanowires (NWs) are a versatile semiconductor platform that has enabled investigations of Majorana bound states [1,2] and spin-based qubits [3]. Among their remarkable properties are large mobilities (up to ~20,000 cm²/Vs), very large Landé g-factors (up to ~50) and strong spin-orbit coupling (SOC). The large SOC and quasi-1D nature makes InSb nanowires interesting for all-electrical control of single spins, as demonstrated previously [4], and also offers the possibility to control electrically spin currents (as yet undemonstrated).

We fabricated InSb nanowire devices with ferromagnetic contacts (FM) to investigate spin transport. Conductance quantization plateaus in the back-gate sweep measurement demonstrate quasi-one-dimensional ballistic transport in these FM/NW/FM structures. We observe hysteretic features when varying the applied magnetic field, which could indicate spin injection from the FM contacts and transport in the quasi-1D InSb channel.

Trivalent rare earths (REs) exhibit fascinating spectroscopic, luminescent, and magnetic properties. REs have higher magnetic moment (Er$^{3+}$ = 9.59 mB and Yb$^{3+}$ = 4.5 mB) than transition metals. La$_2$Sr$_2$Mn$_2$O$_7$ (LSMO) is a highly spin polarized materials with room temperature ferromagnetism. In this work, we report the effect of RE co-doping (Er$^{3+}$ and Yb$^{3+}$) on photomagnetic behavior and infrared spectra of LSMO. In order to study the multifunctional effect, LSMO was co-doped with different concentrations of RE ($1\%$, $2\%$ and $3\%$) at the La-site. The microstructure, phase separation, electric and magnetic properties of LSMO was measured using energy dispersive x-ray spectroscopy (EDXS), scanning electron microscopy (SEM), X-Ray diffraction (XRD) and a physical properties measurement system (PPMS). The electronic states of the dopants are investigated by photoelectron spectroscopy (XPS). Magnetic and photomagnetic measurements were carried out using SQUID magnetometry with visible and infrared excitation. Measurements of magnetoresistance at room temperature showed that Er$^{3+}$ and Yb$^{3+}$ ions have also great influence on the magnetic and electric ordering of LSMO under the influence of UV light and they can effectively enhance the magnetotransport properties of LSMO.

Initial solid-state qubit implementations have shown great promise but currently suffer from non-robust qubit generation and significant active cooling requirements. Flying qubit designs have emerged as an approach for adding dynamic control to solid-state qubit implementations. The flying qubit approach utilizes surface acoustic (SAW) wave interaction(s) for the capture and transport of a single or few electron(s) from a reduced dimensionality electron pool. Electron transport between quantum dots over a several-microns distance has been experimentally demonstrated [1] and theoretical investigations for spin-entangled electron qubits show promise [2]. In previous work, we investigated the effect of the SAW wave longitudinal component modelled as perturbation to the k-space momentum in the transport direction for a heterostructure based finite width 1D channel using the lowest energy parameter [7].

With further analysis, a conclusion could be drawn that the magnetism modulation is mainly attributed to the interfacial strain level of an infinite potential well for the transverse electron confinement [3]. In the present work, the infinite potential well is replaced with a more realistic parabolic confinement in the transverse direction. Derivation of a new expression for number density enables first-time investigations of quantum channel accessibility and number density allowed occupations as a function of semiconductor effective mass. Results for devices with gallium arsenide versus gallium nitride as the confinement layer are presented.

Level Attraction—Magnon-Photon Coupling Takes a New Form

Can-Ming Hu; University of Manitoba, Winnipeg, Manitoba, Canada.

Cavity Spintronics [1] (also known as Spin Cavitronics) is a newly developing interdisciplinary field that brings together microwave cavity community with researchers from spintronics. This field started around 2014 when it was found that ferromagnets in cavities hybridize with both microwaves and light via light-matter interaction [2-6]. Since then, the emergence of this field has attracted broad interests. It connects some of the most exciting modern physics, such as quantum information and quantum optics, with one of the oldest science on the earth, the magnetism.

So far, at the center stage of this new field is the coherent magnon-photon coupling, which leads to level repulsion by producing a quasi-particle called cavity magnon polariton (CMP)[5-7]. In this talk, I will report our latest experiment that reveals magnon-photon level attraction [8]. Based on dissipative magnon-photon coupling, this effect is distinct from traditional level repulsion, resulting in the coalescence of hybridized modes at zero detuning in contrast to the Rabi gap observed in CMP systems. The experimental features of these new hybridized states can be accounted for by the magnetization back action which exists inside the cavity, and are revealed by our experiments due to the ability to control such a cavity Lenz effect. Exploiting this capability, we observe the transition between attraction and repulsion behavior, revealing the sharp transition which exists between the two effects. As observation of coherent magnon-photon coupling has spawned the field of cavity-spintronics, this new form of magnon–photon coupling may open up new avenues for exploiting the light-matter interactions using cavity spintronic approach.

Selection Rules for Cavity-Enhanced Brillouin Light Scattering from Magnetostatic Modes

James A. Haigh¹, Nicholas Lambert², Sanchar Sharma³, Yaroslav Blanter⁴, Gerrit Bauer⁵ and Andrew Ramsay¹; ¹Hitachi Cambridge Laboratory, Cambridge, United Kingdom; ²Cavendish, University of Cambridge, Cambridge, United Kingdom; ³Delft University of Technology, Delft, Netherlands.

We present measurements of enhanced Brillouin light scattering from magnons in yttrium iron garnet spheres. Optical whispering gallery modes confined at the surface by total internal reflection are coupled to the ferromagnetic resonance modes via the Faraday effect. Our experiments on optical coupling in this manner have demonstrated an enhancement in magnon Brillouin light scattering when the system is tuned to a triple-resonance point [1]. This occurs when both the input and output optical modes are resonant with those of the whispering gallery resonator, with a separation given by the ferromagnetic resonance frequency. Extending the measurements to higher order magneto-static modes [2], we have confirmed recent theoretical predictions [3] of the selection rules for scattering, dependent on the mode indices of the optical and magnetic modes. We give experimental evidence that the opto-magnonic coupling to non-uniform magnons can be higher than that of the uniform Kittel mode, due to the better spatial overlap with the optical modes.

Intrinsic Exciton Valley Dynamics in Semiconductor Monolayers and Heterostructures

Xiaqin F. Li; Univ of Texas-Austin, Austin, Texas, United States.

Monolayer transition metal dichalcogenides (TMDs) have a hexagonal lattice structure in which the extrema (i.e., valleys) of the energy-momentum dispersion curves appear at two degenerate $K$ and $K'$ points at the boundary of the Brillouin zone. Time-reversal symmetry dictates that the electron spins in the $K$ and $K'$ valleys have opposite signs, effectively locking the spin and valley DoF. Valley pseudospin has been proposed and pursued as an alternative information carrier to charge. Optical manipulation of the valley index via excitons (neutral and charge exciton) requires the knowledge of valley polarization and valley coherence dynamics. Nonlinear resonant spectroscopy studies reveal intrinsic valley ultrafast dynamics inaccessible via simple linear spectroscopy measurements such as photoluminescence. We report valley decoherence measurements associated with excitons and trions in monolayers. We also discovered an exceptionally long valley polarization time associated with intra-valley excitons. Finally, we discuss our most recent studies on interlayer excitons in TMD vertical heterostructures.

Spin Relaxation in 2D Semiconductors with an Elliptic Band Structure
Seyed Mohammad Farzaneh and Shaloo Rakheja; New York University, Brooklyn, New York, United States.

Coherent spin distribution can be used to transport information through semiconductors. The relaxation dynamics of the spin distribution is key in analyzing experimental data and enabling spin-based device applications. For most spin transport applications, a long spin relaxation time is desirable. Two-dimensional (2D) materials, such as monolayer black phosphorus (BP), have a weak intrinsic spin-orbit interaction and are expected to have long spin relaxation times, which could allow spin-encoded information to travel macroscopic distances in these materials. Moreover, an external electric field perpendicular to the plane of the 2D materials is an effective method to tune their spin-transport characteristics. Monolayer BP has a highly anisotropic band structure with an elliptic Fermi contour due to its puckered honeycomb structure. The anisotropy in the band structure leads to anisotropic momentum relaxation, anisotropic Rashba spin-orbit coupling, and, therefore, anisotropic spin relaxation. The goal of this work is to theoretically investigate spin relaxation in 2D semiconductors that have intrinsic anisotropy as well as other 2D materials in which mechanical strain results in ellipticity of the band structure. Two major relaxation mechanisms, namely D'yakonov-Perel' (DP) and Elliot-Yafet (EY), are taken into account to calculate the spin relaxation time. Within the DP theory, spin relaxation occurs due to the scattering-induced motional narrowing of spin precession about the Rashba spin-orbit field, which is the result of broken inversion symmetry in the presence of an external electric field. Per the EY mechanism, which is present in centro-symmetric structures like BP, spin flipping at momentum scattering events causes nonequilibrium spin population to relax. We model the elliptic band structure using the effective mass approximation and quantify the impact of effective mass anisotropy on the spin relaxation anisotropy. More specifically, we demonstrate how fast a spin ensemble relaxes for a given initial polarization. The results from the DP and EY mechanisms are compared to determine the dominant spin relaxation mechanism in experimental samples. Finally, the results are used to predict the impact of mechanical strain on spin relaxation.

10:30 AM EP06.07.03
Spin Relaxation in 2D Semiconductors with an Elliptic Band Structure
Seyed Mohammad Farzaneh and Shaloo Rakheja; New York University, Brooklyn, New York, United States.

In the last 20 years, several optical and electrical methods have been used to demonstrate how change in the dimensionality of a GaAs-based semiconductor system (bulk - 3D, quantum well - 2D, quantum dot - 0D) affects the spin relaxation rate over the broad range of technologically relevant doping levels (N_d above 10^{14} cm^{-3} and below 10^{10} cm^{-3}), and temperature ranges (~ 1K – 300K). This work represents advances in the use of Spin Noise Spectroscopy (SNS) [1,2] aiming to understand the level of control over the spin relaxation rate in two cases: (a) varied dimensionality of GaAs based spintronic devices with the focus on differences between the available ranges of spin relaxation values driven by the changing dimensionality of GaAs systems, and, more specifically (b) voltage and geometry control of spin relaxation rate in quasi-1D nanowires. Compared to bulk (3D), quantum wells (2D) and quantum dots (0D), there have been comparatively fewer studies that focused on spin relaxation in two other systems: (a) 1D (quantum wires), and (b) quasi-1D semiconducting nanowires. Our interest in such systems stems from the belief that quantum wires and nanowires will play important role as interconnects in future quantum devices, especially in hybrid photonic-electronic spintronic quantum devices. To this end, we fabricated the semiconductor nanowires with controllable dimensionality, so that the cross section of the NWs is in the range (10-100 nm x 10-50 nm), with length in micrometer range. We report on the spin relaxation range between 20 and 300 ns, depending on temperature, magnetic field and doping. We also report on some qualitative differences between the behavior of spin relaxation rate for quasi-1D systems on one side, and 2D and 0D systems on the other. Two additional facets of this work are: (1) electric field dependent studies, and (2) nanowire aspect ratio studies. Electric field dependence is studied after the contacts were nanopatterned at the end of nanowires, using end contacts technology [3]. It is shown that the change of the applied voltage within 1.5 V range may affect the spin relaxation rate more by 40%, for selected values within that range. Additionally, the voltage dependent study is then conducted for a variety of controllable external conditions. Changes in aspect ratio (width-to-thickness) of GaAs nanowires also affect the spin relaxation rate, pointing towards the need to optimize the NW dimensions prior to quantum spintronic devices implementation. A part of this work was supported by US DoE Office of Basic Sciences at Brookhaven National Laboratory. We acknowledge support from GRC-SRC, and partial support from 2012 KUIRF-Level 1, and 2015 ADEC-A2RE grants.

NV magnetometry has become a powerful tool for exploring magnetic properties of novel electronic systems. In this talk I will give an overview of some
of the recent work we have done to use NV center magnetometry to image skyrmions in thin magnetic films, measure the spin chemical potential in magnetic insulators, and image hydrodynamic electron flow in graphene.

11:00 AM *EP06.08.02
Exploring Magnetism at the Nanoscale with a Single Spin Microscope Vincent Jacques, Laboratoire Charles Coulomb, UMR 5221, CNRS and Université Montpellier, Montpellier, France.

In the past years, it was realized that the experimental methods allowing for the detection of single spins in the solid-state, which were initially developed for quantum information science, open new avenues for high sensitivity magnetometry at the nanoscale. In that spirit, it was proposed to use the electronic spin of a single nitrogen-vacancy (NV) defect in diamond as an atomic-sized magnetic field sensor [1,2]. This approach promises significant advances in magnetic imaging since it provides non-invasive, quantitative and vectorial magnetic field measurements, with an unprecedented combination of spatial resolution and magnetic sensitivity under ambient conditions.

In this talk, I will show how scanning-NV magnetometry can be used as a powerful tool for exploring exotic spin textures in thin magnetic materials focusing on (i) domain walls and magnetic skyrmions in ultrathin ferromagnets [3,4] and (ii) cycloidal antiferromagnetic order in multiferroic materials [5].

11:30 AM *EP06.08.03
Diamond Electronics for Quantum Sensing Mutsuko Hatano and Takayuki Iwasaki, Tokyo Institute of Technology, Tokyo, Japan.

Nitrogen-vacancy (NV) centers in diamond have superior physical properties at room temperature for quantum sensing of the magnetic field, electronic field, temperature, and pressure enabling scalable applications from atomic-scale to macroscopic range. We would like to introduce our recent progress on materials, devices, and protocols;

- Materials: Selectively-aligned (> 99%) NV ensemble formed by distinctive CVD-growth with precise depth control for scalable applications [1-3].
- Sensing devices: Charge state control of NV centers by band-gap engineering using pn junctions [4,5].
- Protocols: The iterative Qdyne protocol for wide field NMR imaging with MHz frequency resolution and nT sensitivity

For applications, we will introduce biological imaging, nano-scale NMR [3], macro-scale magnetometer [6] and its portable prototype, and internal device sensing [7].

SESSION EP06.09: Coherent Dynamics from Nuclear and Ionic Spins in Semiconductors
Session Chairs: Vincent Jacques and Amir Yacoby
Tuesday Afternoon, November 27, 2018
Hynes, Level 2, Room 204

1:30 PM *EP06.09.01
Nuclear Spin System in GaAs—Cooling, Relaxation and Spin Temperature Concept Maria Vladimirova1, Steeve Cronenberger1, Denis Scalbert1, Mladen Kotara2, Roslan Dzhioev3, Ivan Ryzhov3, Valerii Zapasskii3, Gleb Kozlov1, Aristide Lemaître1 and Kirill Kavokin2, 3; 1Laboratoire Charles Coulomb, CNRS-University of Montpellier, Montpellier, France; 2Ioffe Institute, St Petersburg, Russian Federation; 3Spin Optics Laboratory, St-Petersburg State University, St Petersburg, Russian Federation; 4Centre de Nanosciences et de nanotechnologies, CNRS, Université Paris-Saclay, Université Paris-Sud, Marcoussis, France.

Cooling of nuclear spins in doped semiconductors via their dynamic polarization by optical pumping is a powerful method for harnessing ubiquitous fluctuations of nuclear spin, which constitute a well-known decoherence channel for the electronic spins. The idea of spin cooling is based on the hypothesis of spin temperature, which states that nuclear spin system (NSS) reaches an internal thermal equilibrium long before it comes to equilibrium with the external bath (crystal lattice). Although thermodynamic framework has been successfully employed for the description of a variety of the experimental data, a rigorous check of this concept in semiconductors was impossible until recently, in particular at low magnetic field. The reason for that is the lack of experimental techniques allowing nonperturbative optical control over adiabatic transformation of the NSS.

We have recently developed such methods, based on off-resonant Faraday rotation and spin noise spectroscopy [1, 2]. Using these techniques, combined with dark-interval photoluminescence spectroscopy, we established a comprehensive picture of the nuclear spin relaxation efficiency, its magnetic field, temperature, and carrier concentration dependence in doped GaAs, a model system in the field of nuclear spin physics in semiconductors [3-5]. We also analyzed the interplay between four relevant relaxation mechanisms: hyperfine interaction, quadrupole interaction, spin diffusion and Korringa mechanisms.

Understanding of field dependence of NSS dynamics allowed us to obtain a new insight into the NSS thermodynamics, and verify the spin temperature
concept in GaAs bulk material and microcavities [6]. We have demonstrated, that NSS exactly follows the predictions of the spin temperature theory, despite the quadrupole interaction that was earlier reported to disrupt nuclear spin thermalization in quantum dots [7]. Our results open a way for the deep cooling of nuclear spins in semiconductor structures, with the prospect of realizing nuclear spin-ordered states for high-fidelity spin-photon interfaces.

This work is supported by a joint grant of the Russian Foundation for Basic Research (RFBR, Grant No. 16-52-041301-4 and National Center for Scientific Research (CNRS, PRC SPINCOOL, No. 148362).

Electrically Tunable Dynamic Nuclear Spin Polarization in GaAs Quantum Dots at Zero Magnetic Field

Marco Manca1, Gang Wang1, Takashi Kuroda2, Shivangi Shree1, Andrea Balocchi1, Pierre Renucci1, Xavier Marie1, Mikhail Durnev3, Mikhail Glazov3, Kazuaki Sakoda2, Takaaki Mano2, Saeedi Ilkhchy2, Peter Christianen3 and Ben Murdin1; 1Advanced Technology Institute, University of Surrey, Guildford, United Kingdom; 2FELIX Israel Inst of Tech, Haifa, Israel.

The control of individual spins in semiconductor quantum dots is limited by interactions with the nuclear spin bath fluctuations because the carrier and nuclear spins are efficiently coupled through the hyperfine interaction especially in III-V nano-structures with Ga, Al and In where 100 % of nuclei have non-zero nuclear spin.

On the other hand, the stable nuclear spins themselves can potentially be used as a resource for quantum information storage. Semiconductor quantum dots allow manipulating a mesoscopic ensemble of several thousand nuclear spins by optical manipulation of a single carrier spin, but commonly nuclear spin polarization manipulation is achieved in applied magnetic fields of several Tesla, a major drawback for practical applications.

In this work we show that both the sign and amplitude of optically generated dynamic nuclear polarization can be switched electrically in experiments at zero magnetic field, through the application of a bias voltage to our device based on charge tunable GaAs droplet dots grown by MBE on 111A substrates [1].

We demonstrate dynamic nuclear polarization (DNP) at zero magnetic field in a single quantum dot for the positively charged exciton X+ state transition. We tune the DNP in both amplitude and sign by variation of an applied bias voltage Vg. Variation of Vg on the order of 100 mV changes the nuclear spin polarization from -22% to +7% although the X+ photoluminescence polarization does not change sign over this voltage range. This indicates that absorption in the structure and energy relaxation towards the X+ ground state provide favorable scenarios for efficient electron-nuclear spin flip-flops, generating DNP during the first tens of ps of the X+ life-time, which is on the order of hundreds of ps.

We also present Hanle spin depolarization experiments for electrons and nuclei in transverse magnetic fields, which confirm the dependence of dynamic nuclear spin polarization on the applied bias. First results on all electrical nuclear spin manipulation at zero magnetic field are discussed for a SpinLED device [2].

Magneto-Optical Properties of Magnetically Doped Semiconductor Nanocrystals Controlled by Spin-Spin Interactions

Efrat Lifshitz; Technion-Israel Inst of Tech, Haifa, Israel.

The control of individual spins in semiconductor nanocrystals is an emerging scientific field which undoubtly play an important role in the development of new spin-based technologies. Generation of individual spins via incorporation of magnetic ions into colloidal nanocrystals became a hot topic in recent years. These diluted magnetic semiconductor (DMS) nanocrystals are subject to a size confinement on photo-generated carriers, which markedly enhances the mutual carrier-dopant spin-exchange interaction, consequently leading to a pronounced modification of the host's optical and magneto-optical properties.

Here we described the synthesis and characterization of DMS nanocrystals based on colloidal nanoplatelets, rods or spherical host semiconductor matrices, embedded with extremely low concentration of Mn2+ ions. This work includes host nanocrystals with a core/shell design (one semiconductor covered by another semiconductor) with dopant ions positioned either in the core or in the shell, using the layer-by-layer deposition. Thus, the work here discusses the influence of internal design on the magneto-optical properties of DMS colloidal nanocrystals. The research involved the use of magneto-photoluminescence (MPL) and optically detected magnetic resonance (ODMR) spectroscopy. The MPL spectra recorded at various temperatures and strength of magnetic field revealed the generation of giant magnetization (~ 30 Tesla) and g-factor (~4) of the exciton upon doping. The ODMR spectra of those samples designated a resonance line with a distinguished sextet related to the hyperfine interaction between the photo-generated electron and the surrounding nuclear spins of the dopants. The ODMR explored, for the first time, a control of nuclear spins on the magneto-optical properties of DMS nanocrystals. Furthermore, a time resolved ODMR experiment also revealed a shortening of the spin coherence time with respect to estimations, due to the hyperfine interaction. The carrier-nuclear spin may occur either directly, or mediated via the carrier-dopant electron spin (the sp-d interaction).

High Field Spin Resonance of Shallow Donors in Silicon

Gemma Chapman1, Konstantin Litvinenko1, Dmytro Kamenskyi2, Viktoria Eless2, Kamyar Saeedi Ilkhchy2, Peter Christensen3 and Ben Murdin3; 1Advanced Technology Institute, University of Surrey, Guildford, United Kingdom; 2FELIX Laboratory, Radboud University, Nijmegen, Netherlands; 3High Field Magnet Laboratory, Radboud University, Nijmegen, Netherlands.

Single impurities in silicon are a key contender in the development of quantum technology applications. Donors can be placed and isolated within silicon with atomic resolution and have exceedingly long spin and orbital coherence times, leading to many potential spin-based quantum information architectures. High magnetic fields are an important tool for the control of impurity-based qubit structures. External fields manipulate the wave-functions of bound states allowing controlled modulation of the interaction between neighbouring impurities. Additionally, it has been shown that applying a gradient magnetic field can be used to read out the spin state of a bound donor. A potential quantum computing scheme could use magnetic fields to transfer quantum information along chains of qubits, before being manipulated and read out electrically through the external magnetic field. While spin dynamics at
low field is well understood, knowledge of spin dynamics under high magnetic fields is limited.

Through the use of a tuneable microwave free electron laser and a helium-isolated bitter magnet, we have developed a scheme to investigate the spin dynamics of Group V donors in silicon in fields up to 25 T. Real-time photoconductivity measurements of the bound-exciton have demonstrated incoherent control of the population of the ground state of phosphorous impurities and resolution of the relaxation dynamics of the system.

Theory of the Circulating Current of a Single Magnetic Impurity in a Semiconductor Adonai R. Cruz1 and Michael Flatté2; 1Eindhoven University of Technology, Eindhoven, Netherlands; 2The University of Iowa, Iowa City, Iowa, United States.

The localized electron spin of a single impurity in a semiconductor is a promising system to realize quantum information schemes [1]. Coherent control of this spin depends on understanding the structure of the magnetic moment that couples the system with external fields. In this work we investigate the spin-orbit induced circulating current associated with the ground state of a single magnetic impurity in zincblende III-V semiconductor. This circulating current is dissipationless and represents an electron moving in a closed trajectory producing an orbital contribution to the magnetic moment [2]. We developed a formalism employing Green's functions obtained by the Koster-Slater technique [3] with a sp3d5s* empirical tight-binding Hamiltonian [4,5] to describe the interaction of individual atoms.

Our work provides a powerful probe of the quantum states of electron and nuclear spins for individual atoms and nanostructures. Magnetic structures built extending from dipole to exchange interactions. We find that increasing the interaction strength between the spins of two atoms enhances the degree of the mixing of quantum spin states, enabling us to create robust singlet and triplet states. We show that a two level system composed of these singlet and triplet states is insensitive to local and global magnetic field noise, resulting in longer spin coherence times compared to single atoms.

We also measured the hyperfine interactions of individual atoms on a surface. Taking advantage of atom manipulation, we show that the hyperfine splitting strongly depends on the binding site of surface atoms as well as the proximity of other magnetic atoms. The observed hyperfine spectra enable us to deduce position-dependent information about the electronic ground state, the state mixing with neighboring atoms, and properties of the nuclear spin.

Our work provides a powerful probe of the quantum states of electron and nuclear spins for individual atoms and nanostructures. Magnetic structures built using spin-1/2 atoms may serve as the smallest component for assembling custom spin chains and arrays for the exploration of quantum phases, spintronic information processing, and quantum simulation.

SESSION EP06.10: Electrical Coherence of Localized Spin States
Session Chairs: Nathalie de Leon and Michael Flatté
Tuesday Afternoon, November 27, 2018
Hynes, Level 2, Room 204

3:30 PM *EP06.10.01
Electrically-Driven Spin Resonance of Surface Atoms Yujeong Bae1, 2, 3, Kai Yang2, Philip Willke1, 2, 3, Andreas Heinrich1, 3 and Christopher Lutz2; 1Center for Quantum Nanoscience, Institute for Basic Science, Seoul, Korea (the Republic of); 2IBM Almaden Research Center, San Jose, California, United States; 3Physics, Ewha Womans University, Seoul, Korea (the Republic of).

Meticulous control of spin states is of central importance in spin-based information processing and spintronic devices. Electron spin resonance (ESR) combined with atom manipulation in a scanning tunneling microscope (STM) provides electrical access to spin structures constructed on a surface with atomic precision. In this talk, we demonstrate precise measurement and control of (i) the magnetic interactions between surface atoms and (ii) the hyperfine interaction of individual atoms.

The magnetic interactions between two spin-1/2 atoms on a surface were tailored via atom manipulation, resulting in a wide range of coupling strengths, extending from dipole to exchange interactions. We find that increasing the interaction strength between the spins of two atoms enhances the degree of the mixing of quantum spin states, enabling us to create robust singlet and triplet states. We show that a two level system composed of these singlet and triplet states is insensitive to local and global magnetic field noise, resulting in longer spin coherence times compared to single atoms.

We also measured the hyperfine interactions of individual atoms on a surface. Taking advantage of atom manipulation, we show that the hyperfine splitting strongly depends on the binding site of surface atoms as well as the proximity of other magnetic atoms. The observed hyperfine spectra enable us to deduce position-dependent information about the electronic ground state, the state mixing with neighboring atoms, and properties of the nuclear spin.

Our work provides a powerful probe of the quantum states of electron and nuclear spins for individual atoms and nanostructures. Magnetic structures built using spin-1/2 atoms may serve as the smallest component for assembling custom spin chains and arrays for the exploration of quantum phases, spintronic information processing, and quantum simulation.

4:00 PM EP06.10.02
Proposal for Measurement of Coherent Spin Dynamics of Individual Magnetic Dopants in a Semiconductor Using Low-Field Magnetoresistance of Spin-Polarized Scanning Tunneling Spectroscopy Stephen R. McMillan, Nicholas J. Harmon and Michael E. Flatté; The University of Iowa, Iowa City, Iowa, United States.

Individual magnetic impurities or small collections of magnetic impurities in III-V semiconductors can be identified via scanning tunneling microscopy (STM) [1,2], their exchange interaction can be measured [3], and they can have remarkably long spin coherence times [4]. Spin-1/2 impurities are able to be addressed individually and the eigenstates tailored allowing the construction of engineered spin networks [5]. We describe an approach to explore the coherent spin dynamics of a spin-1/2 defect coupled to an additional spin-1/2 defect via exchange interaction with a spin-polarized STM contact through low-field magnetoresistance. Our model utilizes a single site approximation and a stochastic Liouville equation allows for the calculation of steady state currents through the mediating defect. The inherent anisotropy [2,3,5,6] in conjunction with the applied magnetic field should allow one to describe a single spin Hanle curve. In addition, measurements of the spin coherence time and the local hyperfine interaction should be feasible. This analysis is then used to guide the exploration of coherent spin-dynamics involving coupled Mn-hole complexes in III-V semiconductors.

Spinning and Variable Range Hopping in a Highly Disordered Dielectric—Amorphous SiOC:H and SiOC:D

Spin dependent variable range hopping (SDVHR) is observed through changes in currents which are almost certainly due to spin dependent variable range hopping. The study includes extensive comparisons of the EDMR response as a function of voltage applied across thin films in metal-oxide-silicon structures. Comparisons of these films. The EDMR is observed through changes in currents which are almost certainly due to spin dependent variable range hopping. The study includes extensive comparisons of the EDMR response as a function of voltage applied across thin films in metal-oxide-silicon structures. Comparisons of the EDMR versus voltage response and fairly well understood band diagrams provide information about the defect densities of states. We have exploited the fact that EDMR sensitivity is very nearly independent of the field and frequency at which the measurements are made. Comparison of EDMR measurements at high (9.5GHz) and low (about 100 MHz) frequencies help to deconvolute contributions to the spectra from hyperfine and spin orbit coupling. EDMR results also include comparisons with films in which hydrogen was replaced with deuterium. These comparisons also provide information about hyperfine interactions. In these hydrogen/deuterium comparisons, some structures were subjected to ionizing radiation, a process which considerably altered the defect structures. Our results allow some (somewhat tentative) conclusions to be drawn with regard to defect structure and also provide semiquantitative information about defect energy levels as well as defect-hydrogen interactions.

Charge State of Single and Ensemble Nitrogen Vacancy Center in Diamond n-i-n Junctions

Negatively charged nitrogen vacancy center (NV–) has attracted considerable interest over the past years since it is promising for magnetometer, quantum information science and biosensors. For these applications, controlling the charge state of NV center is essential, since NV– center is sometimes unstable and may transition to NV0 in uncontrollable ways. Recently, we have demonstrated that the charge state is controlled in n-type-intrinsic-n-type (n-i-n) diamond junctions[1][2]. In this method, NV centers were formed in the undoped i-layer where impurity concentration is very low and we can control Fermi energy (EF) externally using standard band engineering techniques. Therefore, both the long spin coherence time (T2) and the stabilization of NV– centers can be obtained simultaneously. We showed that the E2 in the i-layer was controlled via the band bending at the two n-i junctions and the ratio of NV– to NV0 centers was increased by reducing the width of the i-layer between the two n-layers. However, the spatial change of charge state of NV center in depletion region and neutral region near the n-i junctions were not examined in detail and the relationship between the measured photoluminescence (PL) spectra of ensemble of NV center and a single NV center is not clear.

In this work we first predict using the k.p method and the valence band anti-crossing theory that the common III-V InAs0.85Bi0.15 /AlSb quantum well becomes a room temperature 2D topological insulator for well thickness d ≤ 6.9nm. Second, we analytically solve the correspondent BHZ model for our TI by introducing a cylindrical confinement defining cylindrical quantum dots (QDs). Surprisingly, we find for the non-topological QDs “geometrically protected” discrete helical edge states, i.e., Kramers pairs with spin-angular- momentum locking, similar to the topological protected helical edge states within the gap in the topological QDs. We calculate the circulations currents associated to both trivial and topological edge states and find no substantial difference between them. The two terminal conductance calculation for two pairs of edge states as a function of the QD radius and the gate controlling its levels with respect to the Fermi energy of the leads shows a double peak at 2e2/h for both topological and trivial QDs. In conclusion, our results blur the boundaries between topological and non-topological QDs as for the protection of the helical edge states, their calculated circulating currents and their two terminal conductance measurements.

Charge State of Single and Ensemble Nitrogen Vacancy Center in Diamond n-i-n Junctions

Maki Shimizu1, Toshiharu Makino1, Hiromitsu Kato2, Masanori Fujiwara3, Takayuki Iwasaki4, Satoshi Yamasaki2, Norikazu Mizuochi3 and Mutsuko Hatano4; 1Tokyo University of Science, Shinjuku, Japan; 2National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 3Kyoto University, Uji, Japan; 4Tokyo Institute of Technology, Meguro, Japan.

Negatively charged nitrogen vacancy center (NV–) has attracted considerable interest over the past years since it is promising for magnetometer, quantum information science and biosensors. For these applications, controlling the charge state of NV center is essential, since NV– center is sometimes unstable and may transition to NV0 in uncontrollable ways. Recently, we have demonstrated that the charge state is controlled in n-type-intrinsic-n-type (n-i-n) diamond junctions[1][2]. In this method, NV centers were formed in the undoped i-layer where impurity concentration is very low and we can control Fermi energy (EF) externally using standard band engineering techniques. Therefore, both the long spin coherence time (T2) and the stabilization of NV– centers can be obtained simultaneously. We showed that the E2 in the i-layer was controlled via the band bending at the two n-i junctions and the ratio of NV– to NV0 centers was increased by reducing the width of the i-layer between the two n-layers. However, the spatial change of charge state of NV center in depletion region and neutral region near the n-i junctions were not examined in detail and the relationship between the measured photoluminescence (PL) spectra of ensemble of NV center and a single NV center is not clear.

In this study, we fabricated multilayer of n-i-n junction to investigate spatial change of the charge state of single and ensemble of NV centers along the junction. We measured the PL spectra of ensemble NV centers by continuous laser illumination which caused the stochastic charge state transitions between NV– and NV0. We also measured the population of each charge state of single NV center by single shot measurement. The charge state depended on the band structure calculated by the Poisson equation in both of the measurements. The proportion of NV– gradually increased in the vicinity of n-i junctions where it was considered to be depletion layer, and did not change at the center. This work was supported by JST CREST Grant Number JPMJCR1333, Japan
In the Edelstein effect, a current in the crystal induces a spin polarization. It occurs in crystals without inversion symmetry, such as Rashba systems and surfaces of topological insulators. The spin polarization vanishes in equilibrium, but in the presence of the current, the electron distribution becomes off-equilibrium, giving rise to nonzero spin polarization, due to the spin-split band structure.

We propose an analogous effect for orbital angular momentum [1,2]. For example, in crystal with helical structure such as tellurium (Te) [3], we propose that a current along the helical axis induces an orbital magnetization [1,2] as well as spin magnetization. This effect is analogous to solenoids in classical electromagnetics. Within this analogy to solenoids, we quantify this effect by introducing a dimensionless parameter $\xi$, which represents a number of turns within the unit cell when regarded as a classical solenoid. Then we found that $\xi$ is largely enhanced when the system is in the Weyl semimetal phase [1,2].

Here the Weyl semimetal phase [4] is allowed by broken inversion symmetry, and it is shown that Te becomes a Weyl semimetal at higher pressure [3,5]. There are other crystal structures that allow Edelstein effects, and we also demonstrate the orbital Edelstein effect for polar systems. Moreover, we propose a similar effect appears for phonons. In crystals, each phonon eigenmode has angular momentum due to rotational motions of the nuclei, but their sum is zero in equilibrium. Meanwhile a heat current in the Te crystal induces a nonzero total angular momentum [6]. We evaluate this effect for GaN and Te by ab initio calculation, and propose experiments to measure this effect.

8:30 AM EP06.11.02 Anisotropic g-Factors of Bi-Sb Alloys Cumeet Sahin and Michael E. Flatté; Univ of Iowa, Iowa City, Iowa, United States.

Bismuth and bismuth-based materials with small band gaps and large spin-orbit couplings exhibit novel physical phenomena such as three-dimensional topological insulator phases [1] and giant spin Hall conductivities [2]. Furthermore, prediction [3] and a recent discovery of the Weyl semimetal phase [4] with the chiral anomaly in the Bi and Sb alloys demonstrate the rich physics of these materials. In this work, we calculate another spin-orbit interaction related term, the g-factor in the BiSb alloys. Early studies of the g-tensor with a two band k.p approach [5] are valid only for electrons, and a more recent multi-band k.p model [6] is accurate just for electrons and holes. The magnitude of g-factor may change dramatically in a crystal as a result of the crystal potential and the spin-orbit interaction, which makes the g-factor a band structure dependent, an intrinsic property of the crystal. Additionally, g-factor is a direction dependent property in a crystal; therefore it is a rank two tensor.

Here we present a full Brillouin zone calculation of the g-factor using a 16 band tight-binding Hamiltonian of the BiSb alloys. To calculate effective g-factors of bismuth and antimony alloys, we model electronic bands and eigenfunctions using a Slater-Koster type tight-binding technique with parameters taken from a previous study [7] and investigate the behavior of conductance and valence band edges. In addition to the tight-binding Hamiltonian, we include a spin-orbit Hamiltonian with spin-orbit couplings of 1.5 eV and 0.6 eV for Bi and Sb respectively.

We calculate the electronic band structure from the tight-binding Hamiltonian for different concentration of antimony using the virtual crystal approximation. As the antimony concentration is increased the band overlap disappears and a semimetal-semiconductor transition occurs. Further increase in the antimony concentrations leads to a faster shift in the valence band than the conduction bands. Therefore, an indirect gap opens, leading to topologically insulating (TI) phase. BiSb alloys also display a Weyl semimetal with chiral anomaly within the range of the TI phase. For bismuth, holes are located at the T point in the Brillouin zone whereas electrons are at the L point. As a result of the symmetry of the T point, $g_z$ is the only non-zero g-factor element where $z$ is along the trigonal axis. However, at the L point, we observe substantial g-tensor elements for both pure Bi and BiSb alloys that differ in magnitude. In conclusion, we show that bismuth, antimony and bismuth-antimony alloys exhibit giant anisotropic g-factors.

8:45 AM EP06.11.03 Tuning Spin-Charge Interconversion with Quantum Confinement in Ultrathin Bismuth Films Matthieu Janet1, Carlo Zucchi2, Federico Bottegoni3, Celine Vergnaud1, Thomas Guillier1, Alain Marty1, Cyrille Beigne1, Serge Gambarelli1, Andrea Picone1, Alberto Calloni2, Gianlorenzo Bussetti2, Lamberto Duò3, Franco Ciccacci4, Pranab Kumar Das1, Jun Fujii4, Ivana Vobornik4, Marco Finazzi2 and Minh-Tuan Du4; 1CEA Grenoble, Grenoble, France; 2Politecnico di Milano, Milan, Italy; 3National University of Singapore, Singapore, Singapore; 4Elettra, Trieste, Italy.

Bismuth exhibits a series of electronic properties that made it the subject of experimental and theoretical interest for decades, in particular in electronic-transport studies [Y. Fuseya et al., J. Phys. Soc. Jpn. 84, 012001 (2015)]. With a lattice structure close to that of graphene and a very large spin-orbit coupling, bismuth may have the potential to be a topological semimetal or semiconductor [L. Aguilera et al., Phys. Rev. B 91, 125129 (2015)]. In order to explore this possibility, we have grown by molecular beam epitaxy (MBE) ultrathin films of Bi on Ge[111]. Indeed, MBE gives the opportunity to grow metastable allotropic phases of Bi or to induce strain into bulk Bi which may give topological properties to this material. Moreover, the growth of such phase on germanium opens new perspectives to use the electron spin in traditional microelectronics. In this study, we have grown a bismuth wedge (0-15 nm) on Ge[111] by MBE. Using structural characterization (RHEED and x-ray diffraction), we found a critical thickness of 5 nm below which Bi exhibits an allotropic pseudocubic phase. A careful angle-resolved and spin-resolved photoemission spectroscopy study using synchrotron radiation (ELETTRA, Italy) showed that the pseudocubic phase exhibits surface states with a quasi-linear band dispersion and a characteristic helical spin texture. We have then investigated the spin-to-charge interconversion at these surface states using 3 different techniques: magneto-optical Kerr effect to probe the Rashba-Edelstein effect (REE), inverse REE using optical spin orientation in the Ge film beneath and finally spin pumping from a ferromagnetic layer grown on top of Bi separated by an Al spacer. We found a clear signature of the strong spin-to-charge interconversion in these surface states only in the regime where...
Bi grows in the form of nanocrystals on Ge(111). We could demonstrate that this effect is the result of a strong quantum confinement in the Bi nanocrystals [C. Zucchetti et al., arXiv:1805.01841].

9:00 AM EP06.11.04

Epitaxial BaTiO₃ on Ge as a Tunnel Barrier for Charge and Spin Injection Yichen Jia, Cristina Visani, Charles H. Ahn and F. J. Walker; Yale University, New Haven, Connecticut, United States.

The epitaxial integration of functional oxides on conventional semiconductor opens new opportunities for coupling their unique properties with semiconductors for post-CMOS technologies. Here we demonstrate a spin-injection device based on epitaxial BaTiO₃ on Ge (001) heterostructures. We first show spin accumulation in the p-type Ge and measure a sizeable spin lifetime in the semiconductor. The magnitude of the spin injection signal can be quantitatively explained using a two-channel spin transport model with one channel due to spin injection into germanium and the other due to injection into interfacial localized states (ILS). We also demonstrate control of the spin signal by manipulating the band profile across the heterojunction, which modulates the charge transport between impurity-assisted conduction and quantum mechanical tunneling, effectively acting as a “switch” for spin injection.

9:15 AM EP06.11.05

Spin Injection into Epitaxially-Grown β-FeSi₂ in Lateral Structural Spin-Valves Hiroki Ishimoto1, Tetsuo Taber2, Ken-ichiro Sakai2 and Tsuyoshi Yoshitake1; 1Applied Science for Electronics and Materials, Kyushu University, Kasuga-shi, Japan; 2Research Institute for Nanodevice and Bio Systems, Hiroshima University, Higashihiroshima, Japan; 3Control and Information Systems Engineering, Kurume College, Kurume-shi, Japan.

Since giant magnetoresistance (GMR) and tunnel magnetoresistance (TMR) effects were discovered, spintronics have received much attention from physical and scientific viewpoint. Spintronics is the fusion field of electronics and magnetics, which is utilizing not only the electrical charge but also electrical spin of an electron. GMR and TMR, which employ nonmagnetic metal and insulator as interlayers, respectively, have already been applied to magnetic heads and magnetic random access memories (MRAM). On the other hands, semiconductor spintronics employing semiconductor interlayer such as Si, Ge, and GaAs has actively been developed. Employing semiconductor has the following merits: (i) crystal growth and process techniques have been already matured; (ii) physical properties change significantly by control of carriers; and (iii) electronic devices and their large scale integration (LSI) techniques have been well-establish. Therefore, Spin-devices comprising semiconductors have a potential compatibility with present semiconductor devices. As fundamental preparation researches for such an application, we have studied spin injection into nanocrystalline FeSi₂ with vertical-type spin-valves. Since spin is easily scattered at grain boundaries, high purity of crystallinity is desirable for the application of the spin-devices. Semiconducting β-FeSi₂ has been attracting much attention as a possible candidate compatible with Si technologies because β-FeSi₂ can be grown epitaxially on Si (111) substrates with small lattice mismatches of -5 to 2 %. Furthermore, it has a large absorption coefficient of over 10⁴ cm at 1.5 eV, and it is a candidate semiconductor applicable to optoelectronic applications. Our laboratory has ever succeeded in the epitaxially growth of β-FeSi₂ films on Si (111) substrates at a substrate temperature of 600 °C by facing target direct current sputtering (FTDCS). So far, there have been few studies on the spin injection into β-FeSi₂. In this study, based on experimental techniques in the previous studies, lateral-type spin-valves comprising β-FeSi₂ films were fabricated, and spin injection and transport were experimentally studied. Lateral-type spin-valves were prepared by electron beam lithography combined with the deposition of semiconducting β-FeSi₂ films and ferromagnetic metal Fe films, and a mask method. The magnetoresistance (MR) curve in local-structure was measured at room temperature by a vibrating sample magnetometer (VSM). From the measurement of MR curves, it was confirmed high and low electrical resistance values are owing to the antiparallel and parallel alignments of the Fe layers magnetization are clearly realized. It was experimentally demonstrated that β-FeSi₂ is applicable to interlayers of spin valves that work at room temperature. Further systematic experiments are conducted and results will be reported at the conference.

Non-Local Opto-Electrical Spin Injection and Detection in Germanium at Room Temperature Matthew Janer1, Fabien Rortais2, Carlo Zucchet3, Lavina Ghiardini1, Celine Vergnaud1, Julie Widen1, Alain Marty1, Laurent Vila1, Jean-Philippe Attane1, Henri Jaffres1, Jean-Marie George1, Michele Celerbro1, Giovanni Isella1, Franco Ciccarel1, Marco Fina2 and Federico Bottegoni1; 1CEA Grenoble, Grenoble, France; 2University of Kyoto, Kyoto, Japan; 3Politecnico di Milano, Milan, Italy; 4Unité Mixte CNRS-Thales, Palaiseau, France.

Non-local charge carrier injection/detection schemes lie at the very foundation of information manipulation in integrated systems. The next generation electronics may operate on the spin instead of the charge and germanium appears as the best hosting material to develop such spintronics due to its compatibility with mainstream silicon technology and long spin lifetime at room temperature. Moreover, the energy proximity between the direct and indirect bandgaps allows for optical spin injection and detection within the telecommunication window. In this presentation, we demonstrate injection of pure spin currents (i.e. with no associated transport of electric charges) in germanium, combined with non-local spin detection blocks at room temperature [C. Zucchetti et al., Phys. Rev. B 96, 014403 (2017), F. Rortais et al. Appl. Phys. Lett. 111, 182401 (2017)]. Spin injection is performed either electrically through a magnetic tunnel junction (MTJ) or optically, exploiting the ability of lithographed nanostructures to diffuse the light and create an in-plane polarized electron spin population. Pure spin current detection is achieved using either a MTJ or the inverse spin-Hall effect (ISHE) across a Pt stripe. These results first show that the spin diffusion length in low-doped germanium can be as long as 10 µm and broaden the palette of tools available for the realization of opto-spintronic devices.

9:45 AM EP06.11.07

Electronic Raman Scattering in Ge Studied by Circular-Polarized Femtosecond Excitation Correlation Photoluminescence Yuhsuke Yasutake and Susumu Fukatsu; Graduate School of Arts and Sciences, University of Tokyo, Tokyo, Japan.

Germanium (Ge) has received the renewed interest in light of not only optoelectronic but also spintronic advantages. In fact, its relatively small offset between the indirect and direct valleys (ca. 140 meV) permits direct-gap optical transitions while crystal inversion symmetry, fewer nuclear spins and the fairly large spin-orbit splitting (ca. 290 meV) promise the manipulation of electron spin polarizations. Fairly large spin-orbit splitting (ca. 290 meV) promise the manipulation of electron spin polarizations.

Since spin is easily scattered at grain boundaries, high purity of crystallinity is desirable for the application of the spin-devices. Semiconducting β-FeSi₂ has been attracting much attention as a possible candidate compatible with Si technologies because β-FeSi₂ can be grown epitaxially on Si (111) substrates with small lattice mismatches of -5 to 2 %. Furthermore, it has a large absorption coefficient of over 10⁴ cm at 1.5 eV, and it is a candidate semiconductor applicable to optoelectronic applications. Our laboratory has ever succeeded in the epitaxially growth of β-FeSi₂ films on Si (111) substrates at a substrate temperature of 600 °C by facing target direct current sputtering (FTDCS). So far, there have been few studies on the spin injection into β-FeSi₂. In this study, based on experimental techniques in the previous studies, lateral-type spin-valves comprising β-FeSi₂ films were fabricated, and spin injection and transport were experimentally studied. Lateral-type spin-valves were prepared by electron beam lithography combined with the deposition of semiconducting β-FeSi₂ films and ferromagnetic metal Fe films, and a mask method. The magnetoresistance (MR) curve in local-structure was measured at room temperature by a vibrating sample magnetometer (VSM). From the measurement of MR curves, it was confirmed high and low electrical resistance values are owing to the antiparallel and parallel alignments of the Fe layers magnetization are clearly realized. It was experimentally demonstrated that β-FeSi₂ is applicable to interlayers of spin valves that work at room temperature. Further systematic experiments are conducted and results will be reported at the conference.

Ab Initio Electronic T1 Spin Relaxation Times in Silicon and Diamond Jinsoo Park, Jin-Jian Zhou and Marco Bernardi; Department of Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States.

Spin relaxation in crystals with inversion symmetry primarily occurs through the Elliott-Yafet mechanism, in which the injected spins are scattered by phonons or impurities. We present an efficient first-principles approach for computing the Elliott-Yafet electronic spin relaxation time T1 in semiconductors and insulators. Our scheme combines ab initio electron-phonon scattering with a new approach to correctly treat degenerate electronic states. Application of our approach to silicon and diamond is discussed in this talk. Our computed spin relaxation times in silicon are in excellent agreement with experiment above 150 K, and we can also resolve the phonon modes that mainly contribute to spin relaxation. The temperature dependence of the spin relaxation times in silicon and diamond are analyzed, together with the contributions from intravalley and intervalley scattering. We show that intravalley scattering dominates at low temperature, and that intravalley and f-intervalley scattering becomes comparable at room temperature. Our work enables accurate ab initio calculations of the T1 spin relaxation time in a range of materials, providing new microscopic insight into spin relaxation.

SESSION EP06.12: Novel Spin Centers in Diamond
Session Chair: Michael Flatté

Engineering Coherent Defects in Diamond Nathalie P. de Leon; Princeton University, Princeton, New Jersey, United States.

Engineering coherent systems is a central goal of quantum science and quantum information processing. Point defects in diamond known as color centers are a promising physical platform. As atom-like systems, they can exhibit excellent spin coherence and can be manipulated with light. As solid-state defects, they can be produced at high densities and incorporated into scalable devices. Diamond is a uniquely excellent host: it has a large band gap, can be synthesized with sub-ppb impurity concentrations, and can be isotopically purified to eliminate magnetic noise from nuclear spins. Specifically, the nitrogen vacancy (NV) center has been used to demonstrate basic building blocks of quantum networks and quantum computers, and has been demonstrated to be a highly sensitive, non-invasive magnetic probe capable of resolving the magnetic field of a single electron spin with nanometer spatial resolution. However, realizing the full potential of these systems requires the ability to both understand and manipulate diamond as a material. I will present two recent results that demonstrate how carefully tailoring the diamond host can open new opportunities in quantum science.

First, currently-known color centers either exhibit long spin coherence times or efficient, coherent optical transitions, but not both. We have developed new methods to control the diamond Fermi level in order to stabilize a new color center, the neutral charge state of the silicon vacancy (SiV-) center. This center exhibits both the excellent optical properties of the negatively charged SiV- center and the long spin coherence times of the NV center, making it a promising candidate for applications as a single atom quantum memory for long distance quantum communication.

Second, color centers placed close to the diamond surface can have strong interactions with molecules and materials external to the diamond, which makes them promising for nanoscale sensing and imaging. However, uncontrolled surface termination and contamination can degrade the color center properties and give rise to noise that obscures the signal of interest. I will describe our recent efforts to stabilize shallow NV centers within 5 nm of the surface using new surface processing and termination techniques. Specifically, we are able to demonstrate reversible and reproducible control over the top layer of atoms. These highly coherent, shallow NV centers will provide a platform for sensing and imaging down to the scale of single atoms.

Group-IV Defects in Diamond from First Principles Chris Ciccarino1, 2, Matthew Trusheim1, Dirk R. Englund1 and Prineha Narang1; 1John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 2Department of Chemistry and Chemical Biology, Harvard University, Cambridge, Massachusetts, United States; 3Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Color centers in diamond have emerged as leading solid-state "artificial atoms" for a range of technologies from quantum sensing to quantum networks. Concerted research activities are now underway to identify new color centers that combine the favorable spin properties of the diamond nitrogen vacancy (NV-) with the spectral stability of the silicon vacancy (SiV- ) center. Among the alternate color centers explored, the SiV- and PbV- centers, the latter of which we have investigated previously, are among the most promising candidates for application in spin-photon systems such as quantum repeaters and quantum networking. Characterizing these defect centers and their emission spectra remains an actively debated area of research. We use a combination of theory and experiment to study the PbV-, SiV- and the previously unexamined GeV- defects in diamond and determine the nature of these defect states. By leveraging theory to accurately predict vibrational effects as well as Jahn-Teller distortion, we capture experimentally accessible spectral features including the Debye-Waller factor and spin-orbit-quenched zero field splitting. Meanwhile, we identify potential experiments that can verify theoretical predictions and provide additional defect characterization data of interest, including the excited-state lifetime. Together with theory, these results provide new insight into the potential of these defect centers as single photon emitters for quantum information processing.

11:30 AM EP06.12.03
Diamond Color Centers Created by Implantation of Heavy IV-Group Elements of Tin and Lead Takayuki Iwasaki1, Yoshiyuki Miyamoto2, Takashi Taniguchi2, Petri Sivushev1, Matthias Metsch3, Fedor Jelezko4 and Matsuho Hatano5; 1Tokyo Institute of Technology, Tokyo, Japan; 2ALST (National Institute of Advanced Industrial Science and Technology), Ibaraki, Japan; 3National Institute for Materials Science, Ibaraki, Japan; 4Ulm University, Ulm, Germany.

Quantum emitters in diamond are expected to be important components toward the realization of quantum network. Although nitrogen-vacancy (NV) centers have been most intensively studied, they suffer from the low fraction of zero phonon line (ZPL) in the total fluorescence and external noise leading to the unstable emission line. To solve these problems, color centers based on the IV-group elements have recently attracted attention because of the large
ZPL and robustness of the emission line due to the inversion symmetry. Furthermore, a long spin coherence time over 10 ms has been reported for a silicon-vacancy (SiV) center at millikelvin temperatures [1]. It is expected that a heavier element with larger spin-orbit interaction can increase the ground state splitting to reduce the phonon-mediated decoherence. Thus, long spin coherence times can be expected at higher temperatures without a dilution refrigerator. In this study, we demonstrate the creation of a novel quantum emitter in diamond, called tin-vacancy (SnV) center [2], possessing a much larger ground state splitting than the SiV center, and we also discuss optical properties of diamond implanted with a heavier IV group element of lead (Pb). SnV centers were fabricated by ion implantation and subsequent high-pressure and high-temperature (HPHT) annealing over 2000 deg. Both single and ensemble SnV centers were formed. Pb ions were implanted into different diamond crystals, and the HPHT annealing was performed. The SnV center showed a sharp ZPL at 619 nm at room temperature, while it splits into four peaks at low temperatures, corresponding to split ground and excited states. The ground state splitting was estimated to be 850 GHz, which is 17 times higher than that of the SiV center. With this large value, we can expect a long spin coherence time for the SnV center in the kelvin regime. The first-principles calculations indicated the D3d symmetry of the SnV center, same as the SiV and GeV center. Thus, the stable emission of the SnV center can be also expected. Optical properties of Pb implanted diamond crystals were investigated. Note that independent works on the Pb-implanted diamonds have been very recently reported [3,4]. We observed prominent peaks at 551, 556, and 591 nm. However, we found that these peaks also appeared in a Sn implanted sample. Thus, at present, we speculate that these peaks are not related with Pb, but probably vacancies created by the implantation of the heavy atoms. Further efforts will be discussed for the fabrication of the Pb-related color center in diamond.

Lead-Related Quantum Emitters in Diamond Matthew Trusheim1, Noel Wan1, Kevin Chen1, Chris Ciccarino2, Ravishankar Sundararamam3, Eric A. Bersin1, Michael Walsh1, Benjamin Lienhard, Hassam Bakr1, Prineha Narang1 and Dirk R. Englund1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Harvard University, Cambridge, Massachusetts, United States; 3Rensselaer Polytechnic Institute, Troy, New York, United States; 4State University of New York Polytechnic Institute, Albany, New York, United States.

Quantum emitters in diamond are promising spin-photon interfaces, as they can possess both long-lived electronic spin states and coherent optical transitions. In particular, color centers based on Group IV impurities, such as the silicon vacancy center, have a crystallographic inversion symmetry that eliminates their static dipole moment and produces stable optical lines approaching the lifetime limit. This crystallographic structure, however, results in a pair of nearly degenerate orbital ground states that can scatter phonons, resulting in rapid spin dephasing for silicon- and germanium-vacancy centers at liquid helium temperatures. Here, we report on lead-related centers fabricated in ultrapure diamond following ion implantation and high temperature annealing. Cryogenic photoluminescence measurements performed on single quantum emitters in nanofabricated pillars show several transitions, most notably a pair of lines around 520 nm. The splitting of this doublet, 2 THz, is the largest reported of any Group IV-vacancy emitter in diamond. These observations are consistent with our models of the negatively charged Pb-vacancy center, which is expected to have a combination of narrow optical transitions and stable spin states that make it a promising system for quantum networking applications.

Tailored Disordered Hyperuniform Materials with Novel Properties Salvatore Torquato; Princeton Univ, Princeton, New Jersey, United States.

Hyperuniform states of matter include all perfect crystals, perfect
quasicrystals, and some exotic disordered materials. Disordered hyperuniform materials can be regarded to be new states of amorphous matter in that they behave more like crystals or quasicrystals in the manner in which they suppress large-scale density fluctuations, and yet are also like liquids and glasses because they are statistically isotropic structures with no Bragg peaks. Thus, these special correlated disordered materials possess a "hidden order" that is not apparent on short length scales, which endows them with novel physical properties.

I will describe procedures to design a variety of different disordered hyperuniform materials as well as their corresponding physical properties, including novel electromagnetic, photonic and transport characteristics.

Leonardi5, Giovanna Ruelle6, Rosalba Saija4, Paolo Musumeci2, Diederik Wiersma7, Francesco Priolo2, Matteo Galli8 and Alessia Irrera3; 1Istituto per i Processi Chimico Fisici, Consiglio Nazionale delle Ricerche, Messina, Italy; 2IMM MATIS, Consiglio Nazionale delle Ricerche, Catania, Italy; 3Dipartimento di Fisica, Università degli Studi di Pavia, Pavia, Italy; 4Dipartimento di Fisica e Astronomia, Università degli Studi di Catania, Catania, Italy; 5Università di Messina, Dipartimento di Scienze Matematiche e Informatiche, Scienze Fisiche e Scienze della Terra, Messina, Italy; 6LENS, Università di Firenze, Firenze, Italy.

The optimization of novel textured nanomaterials, both ordered and disordered, plays a key role on the transport of the light towards striking optical performances based on light trapping and multiple scattering [1-2]. In this context, the production of a fractal arrangement of nanostructures represents the case of a material with a complex disorder and strong structural heterogeneities correlated at all length scales. Using Au layers at the percolation limit, that exhibit a fractal arrangement, as the catalyst of a metal-assisted wet etching process, a 2D random fractal array of vertically aligned silicon nanowires (NWs) has been obtained by means of an inexpensive, fast and maskless process compatible with Si technology [3,4]. We demonstrate as a morphological property such as lacunarity, defined as the measure of alternation of full and empty space, is the main actor in the light scattering phenomena for this material, since it is strongly related to the fluctuations of refractive index [5]. The occurrence of strong in plane multiple light scattering, resonant with the structure in a wide wavelength range, promotes a very high light-trapping efficiency across the entire visible and near infrared ranges. This strong scattering also leads to a greatly enhanced Raman signal, which is correlated at all length scales according to the spatial variations in refractive index. The forest of Si NWs so arranged, causing light to bounce around many times within the array, increases the likelihood of light absorption.

Since NWs obtained by this technique exhibit a room temperature PL [3,4], the direct consequence of the increased absorbance manifests in a very bright PL emission. Moreover, the random organization and the strong scattering performances allow for the observation of an unexpected and counterintuitive interference radiation in random media, also for the generated Raman light [6]. The Raman CBS becomes, therefore, the first experimental signature in a macroscopic scale of the coherent nature of individual Raman scattering processes, typically occurring on the scale of the phonon coherence length and time. Our results are interpreted within a simple theoretical model of mixed Rayleigh-Raman random walks, for which reciprocity is assured by the symmetry of the Raman polarizability tensor and by the short dwell time of light inside the material, far below the phonon coherence time [6,7].

Hyperuniform Disordered Photonic Networks—Band Gap Formation and Anderson Localization
Frank Scheffold; University of Fribourg, Fribourg, Switzerland.

Structured dielectric materials with a sufficiently high refractive index contrast can display partial or full photonic band gaps. This leads to dramatic changes of the optical transport properties with a strong spectral dependence. The latter is responsible for the transparency of the cornea to visible light, the iridescence of opal gems and structural colours in biology [1]. The lowered density of states may also result in increased lifetimes for embedded light emitters such as fluorescent molecules. Interestingly, it appears that many of these unique properties are not tied exclusively to crystalline structures. Florescu et al. demonstrated that particular disordered materials can also display full photonic band gaps [2]. Mapping hyperuniform point patterns with short-range geometric order into tessellations allows the design of interconnected networks that give rise to photonic properties in two and three dimensions [2]. We report here on the fabrication and characterization of such photonic network structures in three dimensions and for optical wavelengths in the shortwave infrared [3]. We first discuss the fabrication of polymer templates of the network structures using direct laser writing (DLW) lithography. Next, the mesoscopic polymer networks are converted into silicon by infiltration and double-inversion. The resulting hyperuniform materials display a pronounced photonic gap in the optical transmittance at λ>2.5μm. To obtain a deeper understanding of the physical parameters dictating the properties of amorphous photonic materials we investigate band gaps, and we report Anderson localization in hyperuniform structures using numerical simulations of the density of states and optical transport [4,5]. Our results show that, depending on the frequency of incident radiation, a dielectric material can transition from photon diffusion, localization to a bandgap crossing an intermediate regime dominated by tunnelling between weakly coupled states [4].

3:15 PM *EP07.01.04
The fundamental connection between geometrical and topological characteristics of structured photonic materials and advanced photonic functionalities is central to the design of novel photonic materials. Here, we introduce new metrics, hyperuniformity and local self-uniformity as measures of the structural order of photonic network structures. The hyperuniformity concept is built upon the properties of the structure in the reciprocal space, whereas local self-uniformity characterises the intimate connection between uniformity on local and global length scales. Hyperuniformity is associated with a constrained randomness such that density fluctuations on large scales behave more like those of ordered solids, crystals or quasicrystals, rather than those of conventional amorphous materials. On the other hand, local self-uniformity is a measure of a random network’s internal structural similarity and can be used to rank networks on a continuous scale from crystalline, through glassy intermediate states, to chaotic configurations. Despite their distinct characteristics, both metrics provide novel design strategies for achieving advanced photonic functionalities in non-periodic materials.

We then explore the connection between the hyperuniformity and local self-uniformity and the photonic band gap formation and introduce a novel photonic-network architectures, the hyperuniform amorphous diamond network and the amorphous gyroid network or triamond. We demonstrate that all architectures displaying large photonic band gaps, be they periodic or disordered, are characterized by large values of the newly introduced disordered metrics. We then explore their distinct photonic properties: photonic band gaps, localisation and waveguiding, and photon transport. A comparison between their predicted properties and recent experimental results will also be provided. In the end, a series of applications of the new disordered photonic networks will be discussed including novel structuring for solar cell absorbers, wing-scale structuring in the butterfly Pseudolycæna maryas and new designs for photonic integrated circuits and micro-opto-mechanical filters and modulators.

References
We would like to present the Ewald sphere construction for the prediction of the scattering in disordered media with small refractive index contrast. The Ewald sphere construction is a geometrical tool that is based on the first-order approximation and often used in X-ray scattering. We review the first-order derivation, explain the geometrical construction and as an example show how the Ewald sphere construction can be used to explain structural color.

Non-iridescent (i.e. angle-independent) structural colors are widely found in nature, especially in the plumage of birds. Unlike regular pigment or dye-based colors, these colors are based on the selective scattering of light instead of selective absorption. The structures responsible for this scattering appear completely disordered but they exhibit a spherical shape in reciprocal space, indicating that they are actually short-range ordered. We developed a model structure producing a spherical shell in reciprocal space. Using the Ewald sphere construction we were able to predict the scattering from a structured film. The results were checked by comparison to numerical simulations and show good agreement for light scattered in first order. The Ewald sphere construction also provides a vivid explanation for why there are many examples of structural colors in the short wavelength range while long-wavelength structural colors are barely found and have low color saturation. Finally, the results also indicate that the utilization of total internal reflection and thus frequency selective trapping of the scattered light can lead to a narrow reflection peak which may pave the way to long-wavelength structural colors.

Designing Nanophotonic Structures Using Deep Learning Sunae So and Junsuk Rho, Mechanical Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of); Chemical Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Designing structural components for desired properties has been a major challenge in the nanophotonics field. Recently, several data-driven design methods have provided novel systematic approaches[1-3], where deep neural networks are utilized to design metamaterials. However, all previous efforts have been limited to constraints where basic structures are predefined and the DNNs predict only structural parameters. Here, we report the first demonstration of designing metamaterial components that are not constrained to basic structure[4]. A deep neural network is used to learn the correlation between structural images and their corresponding reflection spectra. For given input reflection spectra, the network generates desirable designs in the form of images; this form allows suggestion of new structures that cannot be represented by structural parameters. Simulation results obtained from the generated designs agreed well with the input reflection spectrum. This method opens new avenues towards the development of nanophotonics by providing a fast and convenient approach to design complex nanophotonic structures that have desired optical properties.

Tuning Photonic Properties of Cellulose-Clay Nano Structures Ana C. Trindade, Susete Fernandes, Ville Liljestrom, Matthias Daab, Josep Breu, Maria H. Godinho and Jon O. Fossum, Norwegian University of Science and Technology, Trondheim, Norway; DCM and CENIMAT/3N, FCT/UNL, Lisboa, Portugal; University of Bayreuth, Bayreuth, Germany.

Solid films prepared from cellulose nano crystals (CNCs) present iridescence and selective reflection of left circularly polarized (LCP) light [1,2], while nano clay particles organize as lamellar structures in the solid state. It is well known that aqueous suspensions of sodium fluorohectorite (NaFh) clay biaxial platelets can form a nematic uniaxial liquid crystalline phase [3]. In this work we dissolved different quantities of cellulose nanorods in the clay nematic liquid crystalline suspensions (cellulose-NaFh nanocrystals (CNC/NaFh)) and we observed that the clay nematic structure undergoes a helical distortion by dissolving cellulose nanorods. Above a certain critical concentration the suspensions became iridescent with a left handed structure. In order to preserve the photonic characteristics of the clay/nano rods suspensions solid films were prepared. We demonstrate that not only iridescent films can be produced but also their selective reflection of LCP light channel preserved.

The colors reflected by the films can vary from blue to red depending on the amount of CNCs added to the system. This work demonstrates that the chirality-transfer, at the nano scale, induced by the CNCs on the clay nano platelets nematic phase translates into the photonic characteristics of solid films produced from aqueous CNC/clay suspensions.

Bio-Inspired Highly Scattering Networks via Polymer Phase Separation Julia Syarik, Gianni Jacucci, Olimpia D. Onelli, Hendrik Hoelscher and Silvia Vignolini; Karlsruhe Institute of Technology, Eggenstein Leopoldshafen, Germany; University of Cambridge, Cambridge, United Kingdom.

Structural colors in nature are often the result of evolutionary-optimized complex nanoscale architectures. A well-known example of multiple scattering optimizations in a low refractive index medium is observed in the scales of Cyphochilus beetles. Here, the anisotropic chitin network inside the scales,
which cover the insect’s body out-performs practically all man-made low refractive index materials. The key to this optimization lies in the tuning of the filling fraction and in the anisotropic nature of the fibrillar structure in the scales.

Inspired by these natural design principles, we fabricated highly scattering white networks solely constituted by polymethylmethacrylate (PMMA). The resulting porous films are flexible and show the shortest transport mean free path reported in the literature for low refractive index materials [1]. We demonstrated that the scattering strength of the network can be enhanced by varying the molecular weight of PMMA to achieve transport mean free paths (λ) as low as 1 μm for an incident wavelength around 500 nm. Having such a short transport mean free path yields a reflectance of 75% for a 4 μm thick film. Due to their low refractive index (close to 1.5 over the whole visible range) and porosity, the produced free-standing films can be easily index-matched with water and other conventional solvents, providing a tunable response, which transitions from white to transparent upon wetting. This property, in addition with the high flexibility of the films, allows for various coating applications. We demonstrate that the scattering properties are maintained when the porous films are grinded into powders, opening their exploitation as white enhancers in paints, paper, and cosmetics.

8:15 AM EP07.02.02
A Bio-Based Photoresist for Direct Laser Writing of Disordered Architectures Maximilian Rothammer1, Marie-Christin Angermann2, Georg von Freymann2 and Cordz Zollfrank1, 1Chair for Biogenic Polymers, Technische Universität München, Straubing, Germany; 2TU Kaiserslautern, Kaiserslautern, Germany.

The polysaccharide cellulose is next to chitin the most abundant biopolymer on earth and is considered an almost inexhaustible source of raw material for the increasing demand for environmentally friendly and biocompatible products.[1] The presented research includes the functionalization of cellulose enabling photo-crosslinking to generate biopolymer-based hierarchical architectures. This chemical modification is a prerequisite for the fabrication of two- and three-dimensional structures by direct laser writing (DLW). In combination with the inherent self-assembly capability of certain cellulose derivatives, there is the opportunity to introduce tailored disordered substructures through infiltration of the DLW-written framework and thus fabricate hierarchical architectures entirely from polysaccharides. Additionally, disorder on the nano-scale is created by the surface roughness of the DLW-written structures, which is caused by curling of the uncrosslinked ends of the cellulose chains in the resist. In contrast to common lithography, which uses photoresists based on polymers sourced from mineral oil, our approach conserves resources through replacing those polymers by sustainable materials such as polysaccharides. Polysaccharide-based photoresists have not been presented so far. We synthesized a bio-based photoresist, where a photo-reactive cellulose-derivative is dissolved in acetone together with a photoinitiator. This novel photoresist is curable by two-photon absorption (780 nm) in a DLW system (Nanoscribe Photonic Professional GT). With this setup, two-dimensional architectures with a linewidth of less than 500 nm and a feature size of 750 nm are achieved. Our bio-based photoresist allows three-dimensional structuring of cellulose on the μm scale via DLW. Curing of our cellulose derivative is generally possible in liquid and solid state via two-photon absorption.[2] This expands the operational areas of this photoresist, because writing in solid resist allows for more complicated structures, which have to be written in several disconnected sections. Additionally, this cellulose photoresist is curable via one-photon absorption with a UV-lamp (365 nm) in liquid as well as in dried state. Our resist opens up a new class of photo-curable polymers based on sustainable and renewable materials.

Direct Laser Writing of Iteratively-Designed Biomimetic Photonic Structures Exhibiting Tailored Disorder Bianca C. Datta, Sunny K. Jolly and V. Michael Bove, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Structural color phenomena exhibited by several organisms result from interference and diffraction of light incident upon multilayer nanostructures. The wings of the Morpho butterfly are a well-studied example of a biological system exhibiting structural coloration and a high degree of wide-angle iridescence due to a non-negligible degree of disorder in the photonic nanostructure. Recent work has demonstrated the fabrication of artificial, Morpho-inspired nanostructures that exhibit structural coloration effects via a variety of fabrication techniques; however, prior work has largely neglected the role of tailored disorder in generating iridescence in such bioinspired nanostructures.

Such complex biological systems require advanced fabrication techniques, and replication of nanoscale features of this complexity has been difficult. Existing methods include multi-step deposition, etching, and assembly processes. In comparison to existing fabrication methods for Morpho-inspired structures, such as interference lithography, colloidal self-assembly, sputtering, atomic layer deposition, or electron beam lithography, direct laser writing methods allow for flexible, three-dimensional, volumetric feature patterning on multiple length scales.

Here we present a comprehensive method for iterative inverse design of a biomimetic Morpho-inspired photonic structure exhibiting tailored disorder and a fabrication methodology based around direct femtosecond laser writing. Our design framework explicitly accounts for the important role of disorder in generating the iridescence effects seen in biological examples of structural coloration.

We evaluate optical properties such as spectral response, interference, diffraction, and reflectance of photonic structures fabricated using direct laser writing techniques such as two photon polymerization. We compare our model system and simulations to fabricated structures using optical microscopy, scanning electron microscopy, and angular spectrometry. This process provides a toolkit with which to examine and build other bio-inspired, tunable, and responsive photonic systems and expand the range of achievable structural colors.

The use of femtosecond laser direct writing allows for the rapid prototyping of complex, hierarchical micro- and nano-structures. When combined with the design and optimization process presented here, this method allows for the use of the Morpho structure as a baseline for iteration, both to incorporate tailored disorder, and to produce structures with extended functionality beyond existing systems. In doing so, we present a versatile approach to bio-inspired materials design and and provide a platform with applications ranging from light harvesting and steering, to chemical sensing, high performance displays, responsive products and architecture.

Bio-Inspired, Large Scale, Highly-Scattering Films for Nanoparticle-Alternative White Surfaces Julia Syurik1, Radwanul Hasan Siddique2,1, Antje Dollmann1, Marc Schneider1, Siegbert Johnsen1, Matthias Worgull1, Gabriele Wiegand1 and Hendrik Hölscher1, 1Karlsruhe Institute of Technology, Eggenstein Leopoldshafen, Germany; 2California Institute of Technology, Pasadena, California, United States.
White is the most popular color for today’s industrial products. Being the essential color for interiors, white pigments are widely found in plastics, inks, paints, cosmetics, and even food. In many of these products, their whiteness is achieved by incorporating titanium dioxide (TiO2) particles, which, due to their high refractive index, effectively scatter incoming visible light. However, fabricating white polymeric films and bulk parts with TiO2 particles causes some issues ranging from possible environmental harm to suspected health issues. Consequently, particle-free alternatives are of particular interest.

Here, we present an approach to whiten thin polymer foils via saturation by supercritical carbon dioxide (SC-CO2), which is an industrial process suitable for large-scale fabrication. We tailored the parameters for the fabrication of thin and white nano-foams made from PMMA because it is a common, often used polymer. The process parameters effectively control size, shape and wall thickness of the pores, which act as scattering elements. Although the refractive index of PMMA ($n = 1.49$) is comparable low the films are perfectly white even for thin film thicknesses in the µm-range [1]. In order to demonstrate the process-ability of our porous white films, we fabricated ultra-white micro-channels from them.

Brilliant Coloration from Tailored Photonic Disorder in Weevil Scales Michael H. Bartl, 1,2, 1Department of Chemistry, University of Utah, Salt Lake City, Utah, United States; 2Center for Energy Efficient Electronics Science, University of California, Berkeley, Berkeley, California, United States.

The world of insects displays myriad hues of colors produced by elaborate nanoscale architectures built into wings and exoskeletons. Many of these architectures display intricate hierarchical organization with varying degrees of ordering. For example, using a combination of optical and electron microscopy tools, photonic band structure calculations, and color mixing analysis, we recently discovered that the origin of the brilliant near angle-independent coloration of the weevil Eupholus chevrolati stems from tailored disorder involving multi-level photonic interactions: from diamond-based photonic crystal domains to seemingly random arrays of colored micro-pixels. This pointillist color-mixing scheme is responsible for a bright and multi-hued appearance, without the metallic sheen typical of photonic crystal colors found in many other beetles.

Disordered Tumor Spheroid Deep Optical Neural Network Davide Pierangeli, 1, Valentina Palmieri, 1, Giulia Marcucci, 1, Giordano Perini, 1, Marco De Spirito, 1, Massimiliano Papi, 1 and Claudio Conti, 1, 1Physics, Catholic University of SH, Rome, Italy; 2Physics, Sapienza University, Rome, Italy.

Light can propagate inside random media by iterative optimization of the input electromagnetic field. This training and scattering is a form of photonic machine learning, which we apply here to the special case of tumor cells. Specifically, we consider glioblastoma tumor spheroids that appear as an assembly of multiple scattering cells for a light beam. We show that by embedding these samples in an optical setup and using a feedback, the tumor cells can act as a computing reservoir and realize different optical transformation on the input light beam. The tumor cells act indeed as a multi-layered neural network that, with time, grows and gives additional deep computational layers to perform accurate and sophisticated functions. Once trained, this unconventional hybrid combination of living matter and photonic hardware returns information on its growth dynamics. For this random optical machine, we have grown glioblastoma cells in 3D spheroid architectures that represent modern model platforms for studying complex cell-to-cell interactions, anticancer therapeutics uptake and diffusion in tumor bulk. We tracked glioblastoma spheroids spontaneous evolution and their subcellular transformations stimulated by hyperthermia or chemotherapies. We demonstrated that brain tumor cells can be trained to track cancer evolution and subcellular transformation induced by external stimuli. We demonstrate that a higher resolution is obtained with this deep optical neural network compared to confocal microscopy and standard optical imaging. This hybrid photonic living system is a novel artificial disordered photonic computing machine for real-time study and unprecedented measurements of tumor dynamics.

10:15 AM EP07.03.01
Interplay of Order and Disorder in Biological Photonic Materials Ulrich Steiner; Adolphe Merkle Institute, Fribourg, Switzerland.

The generation of well defined band-gaps requires perfectly ordered transparent material, which is technologically demanding. Biological organisms, animals and plants, are however able to generate striking optical effects, with a much lower degree of order that, seemingly, should be highly detrimental to realise the colour brilliance arising from well ordered structures. On the other hand, optimised disorder is required for the multiple scattering of light that produces white, requiring a different type of structural control.

The first part of my presentation will focus on the interplay of order and disorder of grating-like topographical features found on many flower petals, the optical effects they generate and their role in insect recognition. The second part discusses biological strategies to generate whiteness employing a minimal amount of material, which is particularly important for flying insects.

10:45 AM EP07.03.02
The Cyphochilus Beetle as an Inspiration for Sustainable White Materials Gianni Jacucci, 1, Olimpia D. Onelli, 1, Giulia Syurik, 1, Matti Toivonen, 2, Hendrik Hoelscher, 3, Olli Ilkka, 3 and Silvia Vignolini, 1, 1University of Cambridge, Cambridge, Cambridge, United Kingdom; 2Aalto University School of Science, Espoo, Finland; 3Karlsruhe Institute of Technology–Institute for Applied Materials, Karlsruhe, Germany.

Whiteness arises when light interacts with disordered media, where different wavelengths are scattered with comparable intensity. Such appearance is the result of light undergoing multiple scattering events before exiting the object, i.e. when the object is optically thick. The optical thickness of a material is determined by the ratio between its physical thickness and the transport mean free path, namely the distance that light travels before losing information about its starting propagation direction. Commonly, the transport mean free path in low-refractive index white materials is about tens of micrometres long. Therefore, opacity is achieved for relatively large thicknesses (in the millimetres range) to allow a high enough number of scattering events. [91]
Nature provides an invaluable source of inspiration for the study and the manufacturing of thin opaque white materials. The *Cyphochilus* white beetle achieves a high total reflectance (~75% over the whole visible range) with a few micron thick, lightweight, anisotropic network of chitin fibres (n~1.55).

Herein, after quantifying the scattering efficiency of the chitin network via a coherent backscattering setup, we show an experimental approach to produce bio-inspired, sustainable white materials. In particular, we demonstrate that tuning the morphology of a network of polymer fibres strongly affects its optical properties: from transparent, to bright white materials. Notably, our bio-inspired materials achieve high scattering efficiency whilst being only a few micrometres thick (up to 75% reflectance while only 4 µm thick). Our study illustrates the potential of using biopolymers as building blocks to produce next-generation sustainable and biocompatible highly scattering materials. In addition, we show that it is possible to manipulate the light transport regime, moving from standard to anomalous diffusion, when a long-tailed distribution of the fibres size is introduced.  

Graphene oxide (GO) and its reduced form (rGO) are capable of inducing mesenchymal stem cells differentiation and promote bone tissue formation with efficacy depending on reductive state of the material. Thus, modulation of the osteogenic process and of bone mineral density distribution is theoretically possible by controlling the GO oxidative state. In this study, we laser-printed GO surfaces to obtain both a local photo-thermal GO reduction and the formation of nano-wrinkles along precise patterns. In the first days of culture, cells migrated and accumulated on the reduced and wrinkled surface. When possible by controlling the GO oxidative state.

The design rules we revealed have the potential to guide the creation of synthetic polymer fibres or surface microstructures which are able to mimic the skin’s light management over a broad spectral range and can be scaled to dimensions suitable for adequate synthesis routes.

Invariance of the Mean Path Length in Light-Scattering Media

2:00 PM *EP07.04.03
Light Trapping and Super Diffusion in Levy Glasses
Francesco Ueli1,2,3, Lorenzo Pattelli1,2,3, Diederik Wiersma1,2,3, and Kevin Vynck1; 1European Laboratory for Non-linear Spectroscopy, Turin, Italy; 2Department of Physics, University of Florence, Turin, Italy; 3National Metrology Laboratory INRIM, Turin, Italy; 4Institut d’Optique, Université Bordeaux, Bordeaux, France.

For wave transport in disordered systems it is known that the dimensionality of the structure plays a crucial role. In particular, for dimensions equal to two or smaller, interference will give rise to localised modes for large enough system size.

In this contribution we show that this situation is actually only correct for the limiting case of homogeneous (Gaussian) disorder. We will discuss the general case of light transport in Levy glasses, which are materials in which a large inhomogeneity of the structure leads to super diffusion.

While one would expect super diffusion to counterbalance localisation, we find the counter-intuitive result of strong localisation in coexistence with extended modes.

Invariance of the Mean Path Length in Light-Scattering Media
Romolo Savo1, Romain Pierrat2, Ulysses Najari3, Rémi Carminati4, and Sylvain Gigan1; 1Laboratoire Kastler Brossel, ENS-PSL Research University, CNRS, UPMC-Sorbonne Universités, Collège de France, Paris, France; 2ESPCI Paris, PSL Research University, CNRS, Institut Langevin, Paris, France; 3Institute for Theoretical Physics, Vienna University of Technology (TU Wien), Vienna, Austria.

Optical materials engineering lies on the assumption that the structure of a medium is inherently linked to its functional behavior. This is particularly true for light scattering properties, which depend very sensitively on whether a medium is homogeneous, structured or disordered. As opposite to this paradigm, a recent theoretical study pointed out that a very fundamental property of wave transport is extremely robust to the structure of the underlying medium [1]. This result was derived by generalizing an invariance property first found for random walks [2] to arbitrary wave scattering scenarios [2], such as for light in a disordered material. Specifically, it has been shown that, when all modes in a medium are equally excited, the mean path length <s> associated with wave scattering through a medium only depends on the medium’s boundary geometry, but not on its internal microstructure. Apart from limitation due to finite absorption the mean path length is found to be <s> = vE<t> = 4V/S for a three-dimensional geometry of volume V and surface S, where vE is the energy velocity [1].

Here [3], we experimentally consider the case of a fully disordered medium, in which the crossover between systems with different degrees of disorder can be described by the transport mean free path Φ. Applying the predicted invariance to this case would mean that any change of Φ should leave the mean path length invariant. We investigate multiple scattering of light in colloidal suspensions of particles in water and tune the mean free path by varying the concentration and size of the particles. We develop a reverse version of diffusing-wave spectroscopy to measure the mean length of light trajectories through the temporal decorrelation of the optical speckle pattern. We unambiguously observe the invariance of the optical mean path length over almost two orders of magnitude of scattering strength - from a nearly transparent to a very opaque system. The observed invariance sets rigid bounds for the optical path length enhancement in multiple scattering media and provides insights for the optimal design of light trapping and light storage devices. It crucially relies on the validity of the Equi-partition Theorem and thus provides a stringent test of this fundamental principle in scattering media. We also emphasize that our results are not restricted to light propagation, but apply basically to all wave scattering problems.

Engineering Isotropic Light Scattering for Light Emission Control
Sean Gorsky1, Kidanemariam Kebede1 and Luca Dal Negro1,2; 1Electrical and Computer Engineering, Boston University, Boston, Massachusetts, United States; 2Materials Science and Engineering, Boston University, Boston, Massachusetts, United States.

Light extraction from high-index materials is an ongoing issue in modern LED technologies. Specifically, total internal reflection (TIR) significantly limits the amount of light that can be extracted from the high-index medium into free space. Photonic crystals coupled to emitting optical materials have been shown to enhance light extraction and control directionality by scattering TIR light into free space. In particular, the use of aperiodic and isotropic, disordered patterns such as the Golden Angle (GA) Vogel spiral has been shown to be particularly advantageous compared to traditional photonic crystals such as the hexagonal lattice as it enables the extraction of a wider domain of TIR waves across a broader angular range. However, in the case of the GA Vogel spiral, isotropic diffraction comes at the cost of weaker scattering strength which diminishes the overall light extraction capability. In order to solve this problem we introduce in this talk a new disordered, isotropic point pattern which features enhanced short range order, and therefore enhanced scattering when compared to the GA Vogel spiral. In particular, we demonstrate that the first radial correlation peak of this engineered structure is 2X that of the GA Vogel spiral, while maintaining an overall isotropic character. The new pattern is created using the collective coordinate control method which allows for direct engineering of the pattern's structure factor. We pattern transparent substrates with reflective nano-pillars arranged in these new patterns and experimentally measure the structure factor by illuminating with a 405 nm laser and measuring the optical Fourier transform on a CCD camera. The surfaces were patterned using magnetron co-sputtering, electron beam lithography (EBL) and reactive ion etching (RIE) techniques. A variety of the patterns were fabricated with varying nano-pillar diameter and mean particle separations. Finally, we use a model based on the kinematic scattering to assess their potential as transparent surface patterns to increase light extraction of incoherent radiation and enhance directional emission from active, high-index materials.

Reflectivity of Finite 3D GaAs Photonic Band Gap Crystals Willem Vos1, Takeyoshi Tajiri2, Shun Takahashi3, Cornelis A. Harteveld1, Diana A. Grishina1, 4, Satoshi Iwamoto2 and Yasuhiko Arakawa2; 1Complex Photonic Systems (COPS), University of Twente, Enschede, Netherlands; 2Institute of Industrial Science, The University of Tokyo, Tokyo, Japan; 3Kyoto Institute of Technology, Kyoto, Japan; 4Thermo Fisher Scientific, Eindhoven, Netherlands; 5Institute for Nano Quantum Information Electronics, The University of Tokyo, Tokyo, Japan.

While the large majority of theoretical studies of photonic crystals pertain to infinite and perfect structures [1], any experimental study or practical device obviously concerns finite nanostructures with unavoidable deviations from perfect periodicity [2]. The quintessential property of any photonic crystal - regardless of dimensionality and the presence or not of a 3D photonic band gap - is of course the appearance of a stop gap in the dispersion relations for wave propagation in the direction perpendicular to the spatial periodicity [1]. Such a gap corresponds in real and finite structures to a stop band that is observed as a peak in reflectivity experiments. A seminal study reported the evolution of the width of stop band with crystal thickness [3]. It was found that the width of the stop gap scales inversely with the thickness, as later confirmed elsewhere [4]. However, it is still unknown how finite-size effects affect the width of stop gaps in photonic crystals that interact so strongly with light that they reveal a 3D complete photonic band gap.

We surmise that since the probed stop gap is part of complete 3D photonic band gap, the confinement is truly 3D. The confinement is then not only affected by the "thin" dimension perpendicular to the crystal slab, but also by stop gaps within the plane of the crystal structure where the crystal extent is obviously concerns finite nanostructures with unavoidable deviations from perfect periodicity [2]. The quintessential property of any photonic crystal - regardless of dimensionality and the presence or not of a 3D photonic band gap - is of course the appearance of a stop gap in the dispersion relations for wave propagation in the direction perpendicular to the spatial periodicity [1]. Such a gap corresponds in real and finite structures to a stop band that is observed as a peak in reflectivity experiments. A seminal study reported the evolution of the width of stop band with crystal thickness [3]. It was found that the width of the stop gap scales inversely with the thickness, as later confirmed elsewhere [4]. However, it is still unknown how finite-size effects affect the width of stop gaps in photonic crystals that interact so strongly with light that they reveal a 3D complete photonic band gap.

We observe that from N=2 to N=8 layers (4-fold increased thickness) the band width decreases only slightly from 4500 to 3500 1/cm (a 1.3-fold decrease). This behavior differs strongly from Bragg-like proportional one that is typical of weakly interacting photonic crystals [2,3].

We experimentally study reflectivity of 3D GaAs woodpile crystals with different number of layers N, made by advanced micro manipulation [5]. Plates with 2D arrays of parallel rods (445 nm period) of 134 nm width and 150 nm thickness are stacked one-by-one to form the 3D nanostructures. The rods are crossed between neighboring layers, and parallel and shifted by half a period in the secondary neighboring ones. The crystal thickness ranges from N=2 to N=8 layers. Optical spectra are measured with a tailor-made broadband micro-reflectivity setup with reflecting optics [6], and are interpreted with numerical results from FDTD simulations.

We surmise that since the probed stop gap is part of complete 3D photonic band gap, the confinement is truly 3D. The confinement is then not only affected by the "thin" dimension perpendicular to the crystal slab, but also by stop gaps within the plane of the crystal structure where the crystal extent is much greater than the thickness.

The interplay between disorder and nonlinearity can provide original opportunities to overcome some of the most challenging limits in the development of future optical technologies. For instance, a standard frequency doubler based on a birefringent crystal can be hardly integrated on a chip due to tight phase-matching conditions and bulky structure with non-standard etching process. Differently a disordered $\chi^2$ material would provide much more relaxed phase-matching condition and tremendous advantages in terms of fabrication, scalability and cost. Indeed, it has been shown that an effectively incoherent Second Harmonic Generation (SHG) is possible in transparent films of semiconductors and ferroelectrics that are disordered only in the spatial distribution of the second order susceptibility $\chi^{(2)}$, with a large acceptance angle and a broadband conversion [1-4].

Here we realize second-order disordered nonlinear structures by self-assembly of perovskite nanoparticles (BaTiO$_3$, LiNbO$_3$) [5] with different packing densities and geometries. Our structures show signatures of pure incoherent SHG with a nearly flat broadband conversion in the visible range ($400\text{ nm} < \lambda/2 < 510 \text{ nm}$). Very interestingly our structures are also completely opaque, so that multiple light scattering (of both $\omega$ and $2\omega$) and SHG coexist, influencing each other in a way that is still under investigation. We additionally propose an application of our methods at the wavelength scale, where second-order diffraction effects and self-assembly becomes a valuable tool to mimic bulk properties, with the advantage of a high control over the system size. We foresee that the complexity created by disorder, multiple scattering and functional Mie resonances of the scattering centers could generate unconventional mechanisms for nonlinear optical conversion and pave the way to the development of highly versatile disordered photonic devices.

Nonlinear Transmission Matrices of Random Media
Adam Fleming1, Claudio Conti2, 3 and Andrea Di Falco1; 1University of St Andrews, St Andrews, United Kingdom; 2Institute for Complex Systems, National Research Council (ISC-CNR), Rome, Italy; 3Sapienza University, Rome, Italy.

The complex light matter interaction in disordered materials mediates many intriguing fundamental light transport phenomena, enabled by a large multitude of optical modes that can carry the information through random media and that can interact during propagation [1].

In recent years, the associated large number of degrees of freedom have been used in conjunction with waveform shaping techniques, enabling breakthroughs such as diffraction limit beating focusing devices [2]. The ability to access a growing subset of the total individual channels has also enabled the acquisition of a transmission matrix (TM), which directly links input and output fields [3]. Again, this has allowed for the creation of remarkable optical devices such as fibre-based imaging and the simultaneous measurement of the spectral and polarimetric properties [4, 5].

Manipulation of the random media itself through nonlinear effects will allow the generation of even more powerful optical tools facilitated by additional degrees of control over the scattering system. For example, it is possible to use waveform shaping and two photon fluorescence to focus ultrashort pulses in both space and time, providing enhancements over and above the experimental limits in linear wavefront shaping experiments [1,6].

Here, we characterize the TM in the nonlinear regime (NLTM), to describe the effect of nonlinear processes have on the long-range correlations of photon interference, and their various transmissive channels. To do so we use a series of pump-probe experiments to exploit the high optothermal nonlinearity of Silica Aerogel (SA), an ultra-porous material made of sparse silica aggregates. SA can host extremely high temperature spatial gradients, which in turn mediates opotothermal nonlinearities on the order of $10^{-13} \text{ m}^2/\text{W}$ [7]. In addition to the measurement of the NLTM, we also demonstrate that the coupling to the transmission channels can be dynamically and reversibly tuned.

Just as the TM greatly enhanced the ability to manipulate light transport in the linear regime, we anticipate that providing access to the NLTM of a random medium will enable the creation of complex optical devices, whose characteristic behaviour can be modified directly and dynamically.

transmittance ratio between the orthogonal circular polarizations at $fa/c = 0.190$ is 1.07 and 0.11 for the direct and inverse structure, respectively. These chiral structures have circularly polarized bands that induce different transmittance between orthogonal circular polarizations [1]: circular dichroism. We find that the band structures for these two classes of chiral nanostructures differ remarkably, even at constant average refractive index, causing distinctly different circular dichroism.

The unit cell of the direct crystal consists of 3 dielectric layers each with thickness $h$. The first layer is a 2D periodic array (period $a$) of square rods with width $w$. The 2nd layer has the same periodic rod pattern, rotated by 60 degrees in the in-plane direction. The 3rd layer is empty (in practice it will have distant thin spacers). The first layer of the inverse crystal is a 2D periodic array of square pores with the same parameters as the direct structure. The 2nd layer has the same pore array rotated by 60 degrees, and the 3rd layer is homogeneous. The thickness-to-period ratio of both crystals is $h/a = 0.45$. The refractive index of the backbone is chosen as $n = 3.4$ to represent semiconductor GaAs and Si that have been processed in real structures [1-4]. For a width-to-period ratio $w/a = 0.75$, the average refractive indices of both the direct and the inverse structures are equal, whence one might expect the same band structures and optical properties. To verify this hypothesis, we calculated photonic band structures by a plane wave expansion method for the lowest four bands in the Gamma-Z direction along the chiral axis. The direct structure has a gap between normalized frequencies $fa/c = 0.147$ and 0.192. The inverse structure has a gap between 0.129 and 0.186. The difference between the gaps shows that the naive hypothesis above is invalid.

Chiral structures have circularly polarized bands that induce different transmittance between orthogonal circular polarizations [1]: circular dichroism. We calculated transmittance of circularly polarized light through the two complementary structures by a finite-difference time domain method. The transmittance ratio between the orthogonal circular polarizations at $fa/c = 0.190$ is 1.07 and 0.11 for the direct and inverse structure, respectively. These results confirm the band structures.

**Dual-Moth-Eye Structure for Sample Collection in Mid-IR Spectroscopy**

Amirhossein Nateghi, Jieun Myung, Tae Yoon Jeon and Axel Scherer;
California Institute of Technology, Pasadena, California, United States.

Mid-IR radiation covers light in the spectral region of 4000–400 cm$^{-1}$ or 2-20 um which can be used to provide information on molecular structure as well as to gain insight into a molecule’s local environment. Here, we present design and experimental demonstration of a sample collection and interrogation geometry that enables the spectroscopic measurement of materials in the mid-IR region. In this spectral region, silicon is relatively transparent, and a cuvette consisting of two silicon wafers bonded together can be made of this material. Such cuvettes however suffer from progressively higher reflectivity, resulting in low transmitted light. Although different anti-reflection methods can be used over small wavelength ranges, only few approaches work throughout the broad spectral regions needed for spectroscopy. Here we show a promising technique by micro-fabricating a geometric anti-reflection structure analogous to the moth-eye on silicon. This anti-reflection geometry can drastically reduce the reflectance from a silicon surface from ~30% to ~1% . We have built and characterized anti-reflective microstructures and have shown how our geometry can be used for sample collection on a surface of patterned silicon. Low reflectivity is measured by incorporating two moth-eye structures on both sides of a silicon wafer. This new method can be easily implemented to produce transmission efficiencies through high-reflectivity materials over a large wavelength range and still obtain large surface areas both of which are necessary for spectroscopy.

The surface of the microfabricated moth-eye structure can collect sample within the crevices between the microfabricated pillars through surface tension.

If properly designed, disordered light scatterers can trap the collected photons in a photovoltaic (PV) active layer over an extended and targeted frequency range. This is particularly beneficial for enhancing the absorption in thin-film solar cells. Proof-of-concepts have been successfully performed by fabricating nanostructures with short-range structural correlation using a slow serial writing process (e-beam lithography), hence limiting the demonstration to small areas. This shortcoming can be circumvented by tailoring the morphology of self-assemblies which inherently incorporate structural disorder, and which can be more conveniently formed over large surfaces. Polymer blend lithography (PBL), relying on the lateral phase separation of a blend made of...
immiscible polymers, is a relevant patterning technique with that respect as it can be carried out rapidly, cost-effectively and because it allows exploring a broad set of disordered configurations with tunable size distributions.

In the present communication, we first report on the development of self-assembled, high refractive index dielectric nanopillars (NP) which are introduced on the solar cell front side for improved light in-coupling and trapping. We show that they can be realized either by liquid-phase infiltration of titania nanoparticles into a disordered nanoholes array obtained by PBL, or via a lift-off process involving vacuum deposition and a similar PBL-based template. This route is exemplified by enhancing the absorption of a hydrogenated amorphous silicon (a-Si:H) absorber coupled to a rear side mirror, following the implementation of the disordered dielectric scatterers over few cm² onto the PV demonstrator.

We further demonstrate that the phase-separated nanostructures can also serve for realizing broadband light-trapping reflectors. To this end, a metallic layer is deposited atop a disordered NP array whose geometrical parameters are previously adjusted to achieve a light scattering coefficient (in air) exceeding 40% in the low absorbing region of the a-Si:H active layer. The low aspect ratio and smooth profile of the disordered NP enable a conformal deposition of the PV thin film stack onto the NP film, resulting in functional and reproducible devices. The latter exhibit a broadband absorption enhancement and a power-conversion efficiency increase of +65% relative to planar solar cells. The developed reflectors even overcome the light harvesting properties (Asahi-type) substrates based on random textures, thereby highlighting the advantage of controlling structural disorder for PV light management.

Random Laser Action in Disordered Electrospun Nanofibers Doped with Rhodamine B Dye
Lucas F. Sciutí1, Nathalia B. Tomazio1, Luiza A. Marcante2, Daniel S. Correa2, Cleber Mendonça1 and Leonardo de Boni1; 1Institute of Physics of São Carlos, University of São Paulo, São Carlos, Brazil; 2Nanotechnology National Laboratory for Agriculture, Embrapa Instrumentação, São Carlos, Brazil.

The scattering of light caused by disordered nanostructures enables the action of random laser. A random laser utilizes a disordered structure allowing multiple-scattering of light, embedded in an active media which amplifies it by stimulated emission. Random laser systems are of great interest due to their applications in speckle-free imaging, designing of photonic chips and also for identifying cancerous tissues. The search of different materials and architectures to provide the random laser mechanism is therefore highly important to support new applications.

In this work, polymeric nanofibers containing Rhodamine B (Rhb) were fabricated by the electrospinning technique. The nanofibers were electrospun having average diameter of 500 nm. In order to investigate the random laser emission in these disordered thin layer nanofibers, a 532 nm pulsed laser was used as the pump beam. Samples were kept in a way that light emitted was collected perpendicularly to the pump beam. The light beam was focused by a 5 cm convergent lens, with the possibility of varying the sample position along the beam axis. The emitted light was captured by a set of convergent lenses and coupled to an optical fiber connected to a high resolution spectrometer. Nanofiber samples containing 2%, 5% and 10% RhB-doped were investigated. As it is expected for random laser, the output intensity as a function of the pump energy should present a threshold level and a decrease in the FWHM of the spectral emission. All three nanofibers samples studied presented a change in the slope for the output intensity as a function of the pump fluency. A narrowing of the emission band, showing a characteristic laser action, was also observed. It is important to say that the results related to the 2% RhB-doped sample, in which an incoherent-like random laser emission was measured. While for 5% and 10% RhB-doped samples, the random laser emission spectra showed a coherent-like random laser with the presence of several spikes. It is important to say that the spikes position does not change from shot to shot at a fixed pump energy, which could be related to the fact that the characteristic disorder of the disordered photonic nanofiber is static over time. Consequently, the cavities formed preserve the emission wavelength during time.

Changes in the RhB concentration show to play an important role in the spectral emission characteristics, presenting a red-shift with the increase of the concentration. Moreover, the spectral emission band width also increases with the concentration. One explanation for this effect is a possible reabsorption of the RhB due to some chromophores that are not excited, making possible the tuning of the laser wavelength emission. Furthermore, the transition from incoherent to coherent random laser when increasing the RhB concentration shows that the process of doping or the presence of the dye molecule tends to increase the disorder of the nanofibers.

Light-Path Engineering in Disordered Waveguiding Systems
Paris Varytis1, Wladyslaw Hartmann1,4, Wolfram Pernice4 and Kurt Busch1,2; 1Max-Born-Institut, Berlin, Germany; 2Institut für Physik, Humboldt-Universität zu Berlin, Berlin, Germany; 3Institute of Physics, University of Münster, Münster, Germany; 4CeNTEch - Center for Nanotechnology, University of Münster, Münster, Germany.

Integrated nanophotonic circuits allow for realizing complex optical functionality in a compact and reproducible fashion through high-yield nanofabrication. Typically configured for single-mode operation in a single path, the optical propagation direction in such devices is determined by the waveguide layout which inherently requires smooth surfaces without scattering and restricts the device footprint to the limits of total internal reflection. By moving forward to multi-mode and multi-path designs in intentionally disordered waveguide structures, we will harness in-plane scattering effects to realize a new class of functional waveguiding devices. Through light-path engineering of free-standing dielectric membranes compact and broadband optical systems will be derived for operation in the classical and quantum regime. Our approach is based on multi-path interference, leading to the generation of wavelength dependent speckle patterns at the output of a tailored photonic nanostructure.

Random spectrometers represent prototypical examples for light-path engineered devices. Through exact numerical electrodynamic simulations (using a Discontinuous-Galerkin Time-Domain finite-element approach) in combination with multiple-scattering theory, we have demonstrated the feasibility of silicon-nitride-based high-resolution spectrometers in integrated optics layout for operation at near-IR and visible frequencies.

Cellulose-Based Photoresist for Curing Films with Disordered Microstructures by UV-Lithography
Andrea Obendorfer, Maximilian Rothammer and Cord Zollfrank; Biogenic Polymers, Technische Universität München, Straubing, Germany.

Cellulose is the most abundant biopolymer on earth and is considered an almost inexhaustible source of raw material for the increasing demand for environmentally friendly and biocompatible products.[1] The presented research includes the esterification of cellulose diacetate with methacrylic acid anhydride.[2] This reactive methacrylic side group is essential for a subsequent photopolymerization reaction during UV-lithography. We created a bio-based photoresist, where the above mentioned photo-reactive cellulose-derivative is dissolved in acetone together with a photoinitiator. Therefore, this photoresist can be subjected to surface patterning techniques (e.g. mold casting) to obtain surface structured films entirely made from polysaccharides via UV-curing. As a result, transparent patterned cellulose films with distinct optical properties are accessible. The imprinted diffraction pattern consists of pillars in the micron range and evokes brilliant colors, which depend on the reflection angle of the incident light. Disordered areas can be generated through swelling and random self-agglomeration of several pillars, if the UV-cured film is moistened with an organic solvent. The resulting optical properties can be tuned by altering the dimensions of the pillars or their distances, which tailor the disordered cluster size and their arrangement. Additionally, there is still a high degree of freedom for the system within certain limits, since the cellulose-based pillars are subjected to a self-organization process. This example demonstrates the versatility of fabrication of tailor-made disordered architectures from biogenic polymers. It is interesting to note that curing of this
Femtosecond Laser Structuring of Metal Oxide Thin Films for Enhanced Optical Properties

Danny Bialauschewski1, Jan Hoppius2, Evgeny Gurevich2 and Sanjay Mathur2; 1Institute of Inorganic Chemistry, Cologne, Germany; 2Chair of Applied Laser Technologies, Bochum, Germany.

Disorder in materials, either chemical or structural, often result in new and unique properties, especially regarding different light interaction and interference of ordered and disordered structures. Here, ultra short femtosecond laser pulses are used to tailor specific properties in different metal and metal oxide materials. By optimizing chemical parameters such as laser fluence, pulse duration or repetition rate, we can modify substrates on a physical or/and chemical level. In this work, we show that by inducing structural disorder in metals, for example by creating laser induced periodic surface structures (LIPSS), light harvesting properties like absorption, photoconversion and overall photoelectrochemical water splitting performance can be increased when compared to untreated substrates. This influence was investigated with and without additional top layers, regarding their spectroscopic (UV-VIS), thermoplasmonic and the ultra-thin crystalline solar cells structuring for their efficiency improvement [6].

Mie glasses are inhomogeneous solids that behave as solid dispersions of light scatterers. A novel demonstration of a Mie glass synthesized by solution processing methods and comprising a mesoporous TiO2 matrix in which crystalline TiO2 monodisperse nanoparticles are dispersed in a random manner is reported. A full optical characterization of this optically disordered material, whose behavior can be predicted prior to fabrication based on single particle considerations, has been performed to attain the key parameters that describe light propagation in random media, i.e. scattering and transport mean free paths. Herein we discuss the potential of these inhomogeneous solids for optoelectronic applications. In particular, we show that Mie glasses are able to boost light harvesting and thus power conversion efficiency in bifacial dye sensitized solar cells when the porous matrix is sensitized with a dye [1]. Also we prove that soaking the optically disordered material with fluorescent dye molecules yields brighter color conversion layers, which we attribute to a combination of resonant excitation and a better out coupling of the emitted light [2].

Bi-Phase Emulsion Droplets as Reconfigurable Optical Components Sara Nagelberg1, Lauren Zarzar2, Lukas Zeininger1, Amy Goodling2, Timothy M. Swager1 and Mathias Kolle1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2The Pennsylvania State University, State College, Pennsylvania, United States.

Micro-scale optical elements play a key role in imaging and display technologies, biosensing, beam shaping, optical switching, wavefront analysis, and device miniaturization. Recently developed multi-phase micro-scale liquid droplets with tunable morphology show a variety of interesting optical properties. The droplets are formed from immiscible oils in an aqueous medium, and the morphology of the droplets can be dynamically adjusted by varying the interfacial tensions of the liquids. As refractive elements, the droplets can behave as micro-lenses with a variable focal length that can be adjusted continuously from positive (converging lens) to negative (diverging lens) focal lengths. When a fluorescent dye is dispersed within one of the droplets’ phases, their emission profile is morphology-dependent, allowing the droplets to act as transducers in chemical and bacteria sensing systems. As reflective elements, certain morphologies of the droplets display structural color, which is also geometry dependent. A wide variety of stimuli, including altering the chemical environment, light, heat, and light, can be used to manipulate the shape and orientation of the droplets, and thus their optical properties.

9:45 AM BREAK
Physical Unclonable Functions (PUFs) are partly disordered physical systems used for identification in hardware security applications. The ‘response’ generated from a PUF depends on an externally applied ‘challenge’ and the unique and unclonable disorder present in the system. It should be difficult or impossible for an adversary to predict the response of a PUF and clone the exact disorder into another device [1]. Various types of PUFs have been implemented using electrical and optical systems [1], [2]. Optical PUFs are expected to be inexpensive and to enable strong security. Optical PUFs based on light scattering tokens using randomly placed sub-millimeter size (~500 µm) glass spheres have been reported earlier [3], [4]. Exploiting the variability in optical properties arising at micro- and nano-scales in different materials or structures can lead to new advances in the field of optical PUFs. ZnO can be a good choice of material for this purpose as it is a direct band gap material with numerous types of spontaneous and stimulated emissions [5] and it easily forms into random and intricate nanostructures.

For this study, dense ZnO nanoforests composed of nanorods of ~ 200–300 nm in diameter have been grown on SiO2 and p+ polycrystalline silicon substrates using a chemical bath deposition (CBD) technique. A relatively diluted seed solution results in high density nanorods grown mostly in the upright direction with some vertical hollow spots in between neighboring nanorods. This nanorod arrangement works as a nano-porous thin film and produces Fabry-Perot fringes under perpendicularly incident white light. Optical scattering measurements have been conducted using an optical fiber placed at ~45° angle and connected to a spectrum analyzer to collect and analyze the scattered light. The local variations in density, height, diameter, orientation angle, and hexagonal perfection of the ZnO nanorods give rise to unique and reproducible scattering spectra that vary significantly from one spot on the sample to another. Example observed scattering spectra, statistical analysis of large numbers of spectra and uses for optical PUFs will be presented.

High Brightness Laser Illumination using Macroscopic 3D Boron Nitride Architectures
Fabian Schutt1, Robert Roeder2, Maximilian Zapf2, Helge Krueger1, Juergen Carstensen1, Soeren Kaps1, Yogradra K. Mishra1, Carsten Ronning2 and Rainer Adelung1; 1Functional Nanomaterials, Kiel University, Kiel, Germany; 2Institute of Solid State Physics, University of Jena, Jena, Germany.

Laser diodes (LDs) are regarded as the next generation of ultra-efficient light sources, being able to produce more photons at high power densities than conventional light emitting diodes.[5] Even though most state-of-the-art technologies are based on a blue LD pumping a white-light emitting phosphor, an all-laser wavelength mixing approach, e.g. a combination of three (RGB) or even four (RGBY) laser wavelengths would outperform the efficiency of any other known white-light source.[2] However, in illumination applications, laser-based lighting systems still suffer from their monochromatic, low-divergent, and coherent nature, which demands a new generation of extremely efficient and versatile optical diffusers based on disordered nanostructured materials.[3] In the here presented study, we demonstrate a macroscopically expanded, three-dimensional (3D) laser light diffuser based on a highly porous (>99.99%) nanorachitecture, composed of interconnected hollow hexagonal boron nitride (h-BN) microtubes, with a wall thickness below 25 nm. The 3D hollow h-BN microtubular framework structure is synthesized by a novel template approach, which is based on a highly porous ceramic network consisting of tetrapodal-shaped microparticles.[3] The synthesis results in a highly disordered[4] and non-absorbing photonic network with thinly spread but highly effective light scattering centers, based on a combination of feature sizes greater than, equal to, and well below the magnitude of the impinging wavelength, allowing for pure light diffusion. The network structure basically resembles an artificial solid fog, but with a defined hierarchical internal structure. This enables an isotropic 3D light distribution from energetic, highly directional, as well as coherent laser light, with speckle contrasts well below the human sensitivity limit. In combination with the excellent heat management of the 3D h-BN exceptionally high laser damage thresholds (~3 J/cm²) above commercial diffuser materials can be reached. Such aero-materials enable a new generation of optical downstream components of tremendous efficiency for brightest illumination applications and open new fundamental research prospects in the field of disordered photonics.

Towards Inkjet Printing of Phase-Separated Nanostructures for Light Extraction in Organic Light Emitting Diodes
Yidenekachew J. Donie1, 2, Stefan Schlisske1, Jan B. Preinfalk1, Jocelyn Van Leeuwen1, Amos Agrios1, Jürgen Hüpkes4, Karsten Bittkau4, Gerardo Hernandez-Sosa1, 2, Uli Lemmer1, 2, 3 and Guillaume Gomard1, 2; 1Light Technology Institute, Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; 2Nanotech Biomachines, Inc., Milpitas, California, United States; 3InnovationLab, Heidelberg, Germany; 4IEK 5-Photovoltaik, Forschungszentrum Jülich GmbH, Jülich, Germany.

With only around 20% of light emitted into the ambient, organic light emitting diodes (OLEDs) suffer from detrimental optical losses arising from light trapped as (wave) guided modes and as surface plasmon polarizations. An attractive method to improve light out-coupling is to exploit the volumetric light scattering properties of composite layers based on nanoparticles that are randomly distributed in a polymer matrix. These layers promote light extraction over a broad spectral range and do not induce color distortion, which is desirable, for instance, in large area lighting applications. Moreover, it was demonstrated that they can be processed by screen- or inkjet-printing [1], making them industrially relevant in terms of fabrication throughput, design flexibility and material yield. Besides these micrometer thick layers, more compact layouts consisting of 2D planar light scatterers can be integrated in the OLED thin film stack to allow a good spatial overlap of the guided modes with the light outcouplers. Herein, structural disorder within the scatterers array (described by diameter size and inter-distance distribution functions) can be additionally tailored to optimize the light outcoupling conditions.

In this communication, we show that the up-scalable polymer blend lithography technique is a versatile platform for fabricating such 2D planar, disordered light scatterers [2]. Using spin-coating as the deposition method for a blend of two immiscible polymers dissolved in a common low boiling point solvent and by tuning the polymer blend composition and the process parameters, we first generate phase-separated nanostructures initiated by solvent extraction. Their morphology and light scattering properties are varied, and their light extraction potential subsequently tested in bottom-emitting OLEDs. We report an efficiency enhancement of up to >50% relative to non-corrugated devices, as well as an improved angular and spectral stability. Following this proof-of-concept, our approach is then adapted to make it compatible with inkjet printing by using high boiling point solvents. We present a formulation which achieves the desired phase separation and a homogenous printing over cm² pixels, and we finally introduce a route to further include a planarization layer that helps the integration of the OLED thin film stack atop the light extraction layer.

Long-Distance Transmission of Broadband near Infrared Light Guided by Semi-Disordered 2D Array of Metal Nanoparticles Hyunguk Kim1, Seon Ju Yeou2, Kinam Jung3, Jeong Je Kim1, Kwanil Lee1, Il Ki Han1 and S. Joon Kwon1; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Hannam University, Daejeon, Korea (the Republic of).

Near infrared (NIR) waveguide is a key component of planar photonic devices such as optical communication couplers, image sensors, and spectroscopy for chemical or biological molecules. Conventional NIR waveguides such as silicon-on-insulator (SOI) waveguides or channel/ridge-type metal micro-strips have been used for signal transmission. However, there are usually limitations in reducing either signal delay or signal loss in the optically integrated devices. In this study, a novel NIR waveguide composed of semi-disordered array of metal nanoparticles (sDAMNPs) on Si substrate was proposed, fabricated, and tested. The disordered metallic nanoparticles array is geometrically localized in the form of 1D metal strips, thus changing sDAMNPs to less lossy strip channel waveguides. From the measurements supported by various computational modellings, fabricated waveguides effectively operate at broadband NIR (1100-1700 nm). It does not support signal transmission ultra violet-visible spectrum due to strong signal absorption and localization effects inside the metal nanoparticles. Instead, it is capable of transmitting NIR over a distance longer than 100 mm (signal loss ~ 3.85 dB/100 μm for NIR in 1200-1600 nm), which is also sufficiently larger than the conventional surface plasmon polariton propagation distance at the metal-Si interface. Compared to the waveguide-free reference, the waveguide exhibited greatly improved signal transmission efficiency up to a factor of 7.42×10⁴ at 1367 nm. It also exhibits a high sensitivity of deflection angle of 1.89 dB/0.01 rad, thus efficiently and straightly guiding the broadband NIR signal over long distance.

11:45 AM EP07.07.12
Simultaneous Generation of Reflective Multi-Colour Using Broadband Absorber PilHoon Jung, Soo-Jung Kim, Seungho Baek, Sacheol Ju and Heon Lee; Korea Univ, Seoul, Korea (the Republic of).

Reflective multi-colour is expressed by Fabry–Perot (F-P) resonance cavities which is the interference effect in multilayer thin-films with metal–dielectric–metal. The F-P resonance is composed lossless core dielectric with partially reflective ultra-thin metal layer and optically thick, highly reflective mirror. The absorption peak of multi-colour is tunable in the visible light range just by controlling the dielectric thickness.

In this study, we fabricated the multi-absorber to realize various colours that top metal as silver (Ag) Nanocrystals (NC) solids, with dielectric layer as hydrogen silsesquioxane (HSQ) as a resist, and higly reflective mirror as thick Ag layer. As a novel material, Ag NCs solids possess optical and electrical features for electrical and plasmonic applications of comparable utility to evaporated silver, with the added advantage of enhanced stability against oxidation. Also, HSQ resist shows similar optical properties with SiO₂ and thus can be worked the dielectric layer for F-P cavities. In particular, we can adjust the residual layer of HSQ resist to obtain various colours using nanoimprint lithography (NIL). NIL has advantages over other techniques in that it forms various patterns such as nano-to-microscale structures on various substrates. Consequently, we fabricated the various full-color optical micro-images (bear, flower, words, tiger) with 5μm square pixels on rigid substrate, non-planar substrate, and flexible substrates.

Non-iridescent structural colors have a great potential to replace commercial pigments such as toxic metal oxides or organic pigments. Structural colors are generated by the refractive index distribution of the material and the observed colors result from light scattering by the structure of the material. Thus, structural colored materials show a high UV stability and can be tailored to high-temperature stability by using ceramics such as yttria-stabilized zirconia (YSZ). Non-iridescent structural colors can be generated by disordered arrangement of spheres, so-called photonic glasses (PhGs). So far, PhGs for structural coloration reported in the literature are mainly based on polymer spheres with low color saturation. Theoretical predictions showed that high saturated structural coloration can be realized by a PhG from hollow spheres with YSZ shell.[1] We successfully fabricated a YSZ hollow sphere PhG which shows structural coloration with high saturation. The fabrication of these PhGs is divided into two steps: co-deposition of polystyrene (PS) spheres and YSZ nanoparticles by drop-casting and calculation to remove the PS template. Materials based on YSZ generating structural colors are suitable for high-temperature applications and with our easy and environmental-friendly fabrication method this material can be therefore a non-toxic substitute for color pigments in ceramic processing.

We studied the effect of the YSZ hollow sphere PhG structure parameters on the optical properties regarding the color impression and the effect of high-temperature treatment on the stability of the material’s structure. High-Contrast Structural Color Based on Core-Shell Photonic Glass Guoliang Shang1, Yen Nguyen2, Kaline P. Furlan2, Lukas Maiwald1, Hagen Renner1, Dirk Jalas1, Maksym Dosta1, Rolf Janßen2, Stefan Heinrich1, Gerold A. Schneider1, Alexander Petrov1, 4 and Manfred Eich1, 5; 1Institute of Optical and Electronic Materials, Hamburg University of Technology, Hamburg, Germany; 2Institute of Advanced Ceramics, Hamburg University of Technology, Hamburg, Germany; 3Institute of Solids Process Engineering and Particle Technology, Hamburg University of Technology, Hamburg, Germany; 4ITMO University, St. Petersburg, Russian Federation; 5Institute of Materials Research, Helmholtz-Zentrum Geesthacht, Geesthacht, Germany.

Photonics glasses are disordered assemblies of monodisperse (i.e. equally-sized) spherical particles. They are commonly used in research on non-iridescent (i.e. angle-independent) structural colors. However, no sufficient color saturation has been obtained so far as the reflectivity spectra of the realized structures show no sharp transitions.

Using first-order approximation the reflection spectrum of the structure can be related to the Fourier transform of its permittivity distribution. We show that by appropriately tailoring the individual particles in a photonic glass, its Fourier transform can be drastically changed. Using core-shell particles with a non-monotonous refractive index distribution from their center through their shell and into the background material the Fourier transform of the photonic glass can be shaped in such a way that a significant increase of the color saturation can be achieved. Our theoretical predictions were confirmed by numerical simulations.

Moreover, we experimentally realized a non-optimized photonic glass with full polystyrene spheres and an optimized photonic glass made from hollow zirconia spheres. Both structures were designed in such a way that they produce a similar reflection level and a transition at a similar wavelength. UV-Vis spectroscopy measurements showed that the core-shell structure indeed produces a much sharper transition in its reflectivity.

To directly compare the resulting colors the measured reflection spectra were translated into a CIE xy chromaticity diagram. In such a diagram pure spectral colors lie on the outer arched curve while less saturated colors are positioned inside closer to the white point at the center. The optimized core-shell structure produces a point that is much closer to the outer arched curve which indicates that it causes a significantly higher color saturation.

3D Spatially-Resolved Optical Energy Density in Disordered Photonic Media Enhanced by Wavefront Shaping Oluwasemi S. Ojamhadi1, 2, Peilong
We study the transport and storage of light in a three-dimensional (3D) photonic band gap crystal doped by a single embedded resonant cavity by numerical methods. The crystal has finite support since it is surrounded by vacuum, as in experiments and devices, with a thickness of three unit cells. We employ the finite element method to model the diamond-like inverse woodpile crystal that consists of two orthogonal arrays of pores in a high-index dielectric similar to silicon. The point defect that functions as a resonant cavity is formed in the proximal region of two line defects, namely two selected orthogonal pores with a radius smaller than the ones in the bulk of the crystal.

We present a field-field cross-correlation method to identify resonances in the 3D position intensity pattern we obtain the 3D position of each nanosphere, while the total fluorescence intensity gauges the energy density. Our 3D spatially-resolved measurements reveal that the differential fluorescent enhancement changes with depth, up to 26 times near the back surface of the medium, and the enhancement scales with a strong peak versus transverse position. We successfully interpret our results with a newly developed 3D model without adjustable parameters that considers the time-reversed diffusion starting from a point source at the back surface [8].

Out of five observed cavity resonances, one is s-polarized and four are p-polarized for light incident in the X or Z directions. All cavity resonances are angle-independent, confirming the 3D confinement of light in the photonic band gap cavity. It is remarkable that quality factors up to Q ~ 1000 are found for such thin crystals, which is attributed to the relatively short Bragg length of inverse woodpile photonic crystals. As a result, the optical energy density is greatly enhanced at the cavity resonances, by up to 2400 times the incident energy density in vacuum or up to 1200 times the energy density of the equivalent effective medium. Fano resonances arise below the 3D photonic band gap due to interference between the discrete contribution of the fundamental cavity mode and the continuum of light scattered by the crystal.

We present a field-field cross-correlation method to identify resonances in the 3D position intensity pattern we obtain the 3D position of each nanosphere, while the total fluorescence intensity gauges the energy density. Our 3D spatially-resolved measurements reveal that the differential fluorescent enhancement changes with depth, up to 26 times near the back surface of the medium, and the enhancement scales with a strong peak versus transverse position. We successfully interpret our results with a newly developed 3D model without adjustable parameters that considers the time-reversed diffusion starting from a point source at the back surface [8].

We study the transport and storage of light in a three-dimensional (3D) photonic band gap crystal doped by a single embedded resonant cavity by numerical methods. The crystal has finite support since it is surrounded by vacuum, as in experiments and devices, with a thickness of three unit cells. We employ the finite element method to model the diamond-like inverse woodpile crystal that consists of two orthogonal arrays of pores in a high-index dielectric similar to silicon. The point defect that functions as a resonant cavity is formed in the proximal region of two line defects, namely two selected orthogonal pores with a radius smaller than the ones in the bulk of the crystal. We present a field-field cross-correlation method to identify resonances in the finite crystal that has resonant states within the 3D photonic band gap of the infinite crystal. Out of five observed cavity resonances, one is s-polarized and four are p-polarized for light incident in the X or Z directions. All cavity resonances are angle-independent, confirming the 3D confinement of light in the photonic band gap cavity. It is remarkable that quality factors up to Q ~ 1000 are found for such thin crystals, which is attributed to the relatively short Bragg length of inverse woodpile photonic crystals. As a result, the optical energy density is greatly enhanced at the cavity resonances, by up to 2400 times the incident energy density in vacuum or up to 1200 times the energy density of the equivalent effective medium. Fano resonances arise below the 3D photonic band gap due to interference between the discrete contribution of the fundamental cavity mode and the continuum of light scattered by the crystal. Consequently, we find that an inverse woodpile photonic band gap cavity with a suitably adapted lattice parameter reveals a substantial photonic band gap due to interference between the discrete contribution of the fundamental cavity mode and the continuum of light scattered by the crystal.

We present a field-field cross-correlation method to identify resonances in the 3D position intensity pattern we obtain the 3D position of each nanosphere, while the total fluorescence intensity gauges the energy density. Our 3D spatially-resolved measurements reveal that the differential fluorescent enhancement changes with depth, up to 26 times near the back surface of the medium, and the enhancement scales with a strong peak versus transverse position. We successfully interpret our results with a newly developed 3D model without adjustable parameters that considers the time-reversed diffusion starting from a point source at the back surface [8].

Fano resonances arise below the 3D photonic band gap due to interference between the discrete contribution of the fundamental cavity mode and the continuum of light scattered by the crystal. Consequently, we find that an inverse woodpile photonic band gap cavity with a suitably adapted lattice parameter reveals a substantial absorption in the visible range, which is relevant for photovoltaic applications and optical sensing.
A highly nonlinear M-Cresol/Nylon solution for optical shock waves

Giulia Marcucci1, 2, Phillip Cala3, Graham Siggins3, Weining Man3, Claudio Conti1, 2 and Zhigang Chen3, 4
1Physics, Sapienza University, Rome, Italy; 2Institute of Complex Systems, National Research Council, Rome, Italy; 3Physics and Astronomy, San Francisco State University, San Francisco, California, United States; 4TEDA Applied Physics Institute, Nankai University, Tianjin, China.

M-Cresol/Nylon is a chemical solution, which is made up of an organic solvent (m-cresol) and a synthetic polymeric solute (nylon). Recent experiments showed that this solution exhibits an isotropic giant self-defocusing nonlinearity, tunable by varying the nylon concentration. [1] When it is enlightened by a continuous-wave laser beam, light absorption induces heat gain, which reduces the refractive index: the material experiences a nonlinear thermo-optical effect, made nonlinear by the local temperature change. Since the temperature changes with the beam intensity, this nonlinearity follows a nonlocal Kerr model, as already known in the literature.

In optics, many phenomena are ruled by NLSE, such as soliton propagation and dispersive shock wave (DSW) generation. [2] We report experimental evidence of two-dimensional optical DSWs with an anisotropic zero-singularity. Fixing z as the longitudinal and x, y as the transverse directions, we start with a beam that has a Gaussian profile along y but a Gaussian first derivative along x, thus the intensity is null for x=0. This specific initial condition causes a new phenomenon, reported here for the first time: the shock develops undular bores on the beam external borders (as already known in literature), but around the singularity it presents an abrupt intensity discontinuity. We theoretically analyze the wave breaking along all the propagation. By a hydrodynamic model, we study the beam before the shock point: the WKB approach and the characteristic method let us predict the wave breaking both in phase and in intensity. [2] In order to model the beam propagation beyond the shock point, we use mathematical tools of time asymmetric quantum mechanics and uncover the mechanism how such an abrupt intensity discontinuity is generated. [3] We numerically simulate these results and find remarkable agreement both with experiments and with theoretical predictions.

Our outcome not only confirms previous studies on the giant nonlinear response of m-cresol/nylon, but also discloses fundamental insights on propagation of DSWs with a singular initial intensity profile.

condensates and optics, but it has never been observed. Here, we report the experimental observation of the breaking of replica symmetry in disordered nonlinear optical propagation [5]. We found that when mode interaction dominates light dynamics in a disordered photorefractive waveguide, replicated experimental realizations are found to have an anomalous overlap intensity distribution that signals a transition to an optical spin-glass phase. Specifically, a glassy state of light that emerges as nonlinear interaction overcomes a threshold and it is characterized by strong shot-to-shot variations of the speckle-like intensity distribution and the degree of spatial coherence. Surprisingly, these fluctuations are not randomly distributed but can be either completely correlated or anticorrelated. In close agreement with spin-glass theory, the Parisi overlap distribution between identical replicas incurs a nontrivial change that indicates how the same realizations of the dynamics may give rise to different physical observables. Thus, RSB here indicates a global locking of several spatial modes so that completely anticorrelated states may emerge from equivalent conditions, the signature that different metastable states underlie dynamics. These findings are general and do not depend on the specific form of disorder and character of the nonlinearity. They can be extended to a large class of optical systems including nonlinear multimode fibers and multiple pulse filamentation. Our results demonstrate that wave propagation can manifest features typical of spin-glasses, thus providing a novel platform for testing fundamental physical theories for complex systems.

Tailbot Carpets by Rogue Waves
Milivoj R. Belic; Texas A&M University at Qatar, Doha, Qatar.
Rogue waves are giant nonlinear waves that randomly appear and disappear in oceans and optics. Talbot carpets are periodic recurrent images of linear light and plasma waves. We demonstrate how to produce Talbot carpets by rogue waves. Such carpets can be used in nanoscale lithography.

Coherently Engineered Disorder in Metal Oxide Semiconductors for Superior Solar-Assisted Hydrogen Production
Sanjay Mathur1, Danny Bialusiewski2, Jian Hoppus2, Evgeny Gurevich3; 1Institute of Inorganic Chemistry, Cologne, Germany; 2Chair of Applied Laser Technologies, Bochum, Germany.
Disorder in materials often result in new and unique properties, like enhanced light absorption or electrical conductivity. Tailored chemical or structural disorder is of high technological interest for various applications especially in the energy harvesting/conversion sector. These controlled defect structures can consist of perturbed periodic patterns (correlated) or lacking of any long-range symmetry (random). Both have been reported to improve the spectral response of semiconductor films used in light harvesting applications. Available techniques to induce disorder in sample volume or surface range from mechanical processing to bombardment with high-energy particles like electrons, ions or neutrons. In order to precisely control the disorder process, ultra fast laser pulses can be used. While laser ablation or laser melting rely on long pulses of continuous wave lasers, ultra short pulses, usually below 100 femtoseconds, can be used for controlled structuring. The very beam duration with high peak intensity allow induction of surface defects at micro- and nano-scale by non-linear effects, shock wave propagation or heat-induced transport. Engineered structural and chemical disorder is even capable of turning metal oxide semiconductor thin films into highly efficient solar absorbers. By laser-assisted patterning, these substrates can be modulated in their structure and composition, which manifests in enhanced light-trapping and in-coupling, ultimately enhancing the photoelectrochemical water splitting performance.

Tailored Disorders in Photonic Crystals for Laser and Cavity QED Applications
Satoshi Iwamoto1, Yasutomo Ota2, Kazuhiro Kuruma1, Takeyoshi Tajiri3, Shun Takahashi3, Ryota Katsuma3, Masahiro Kakuda3, Katsuyuki Watanabe2, and Yasuhiko Arakawa2; 1Institute of Industrial Science, The University of Tokyo, Tokyo, Japan; 2Institute for Nano Quantum Information Electronics, The University of Tokyo, Tokyo, Japan.
Tailored disorders in a photonic crystal (PhC), which is a periodic structure in refractive index with a wavelength-scale periodicity, function as optical cavities and waveguides. Particularly, PhC nanocavities with high Q factor and small mode volume are receiving much attention because they can be applicable not only to passive optical devices such as narrow band filters but also to active photonic components, lasers, modulators, nonlinear optical devices etc. The tight confinement of photons within a tiny volume also make PhC nanocavities a fascinating platform for the study of cavity quantum electrodynamics (cavity QED) using solid state quantum emitters like semiconductor quantum dots (QDs). In this talk, we will discuss our recent experimental progresses on nanocavity lasers and quantum-dot cavity QED utilizing photonic nanocavities formed in 1D, 2D and 3D PhCs. Our long-lasting development of the fabrication technologies for high Q PhC nanocavities now makes possible the advanced studies on cavity QED phenomena in 2D PhC nanocavity embedding InAs QDs. We will discuss the successful fabrication of the QD-based vacuum Rabi oscillations measurement. The time-domain investigations also enables the investigation of carrier dynamics which have not been detected by the spectral-domain measurements. We have been also developing the micromanipulation technique for 3D PhCs. In the method, 2D plates constructing the final 3D PhC are prepared using the conventional planar nanofabrication technique first. Then the plates are precisely stacked with micromanipulators in a SEM chamber. We will briefly introduce the method and will discuss a proof-of-concept demonstration of photonic integrate circuit, in which a nanocavity laser and waveguides were simultaneously integrated in a 3D PhC. The output of nanocavity laser was guided through the two orthogonally connected PhC waveguides and was observed from the output facet of the waveguide. Finally, if time allows, a new
design approach of PhC nanocavity based on the photonic band topology will be discussed. A localized optical mode at the interface between two nanobeam PhCs with the same band structures but with different Zak phases were designed and fabricated. With optical gain of InAs QDs, we achieved the lasing oscillation utilizing the localized mode as an optical nanocavity.

Nanostars for Random Lasing Thomas A. Klar, Johannes Ziegler, Battuulga Munkhbat and Calin Hrelescu; Institute of Applied Physics, Johannes Kepler Universität Linz, Linz, Austria.

Gold nanostars in dye doped media provide a double degree of randomness. First, the position of these strong scatterers is random within the active media, making them good candidates for scattering centers in random lasers, superior to spherical or rod shaped gold nanoparticles. Second, the number, the size, and the directional distribution of the metallic tips are all random, hence making an ensemble of nanostars a broadband resonator. In fact, it is possible for gold nanostars to provide feedback over almost a full octave of visible to near IR laser wavelengths. Apart from organic dye molecules as active media, we also fabricated core-shell semiconductor quantum dots in combination with gold nanostars and demonstrated random lasing, as well. A disadvantage, though, is the high absorption of gold nanoparticles due to Förster transfer and due to the large imaginary part of the dielectric function given by the single electron transition between the d- and the sp-band. Silver would be the much better plasmonic material, however, it is seldom used due to its chemical reactivity. We have found a way to circumvent this dilemma. Starting with gold nanostars, we overgrow them with silver, such that the resulting Ag@Au nanostars show substantially smaller lasing thresholds than pure gold nanostars. Further, a 10 nm thin silica protection layer acts as a chemical passivation layer and simultaneously keeps the fluorophores away from the metallic surface. Within these 10 nm thick oxide layer, the quenching of the active material due to Förster transfer ceases, but the electric field is still enhanced at its surface. Finally, nanostars can also be used to improve the efficiency of organic light emitting diodes.

Designing and Writing Scattering Centres to Build a Random Laser Network
Niccolo Caselli, Angel Mateos and Cefe López; Consejo Superior de Investigaciones Científicas, Madrid, Spain.

Random lasers emerged as an alternative and accessible source of laser light. The noteworthy advantage relies on the low-cost and flexible fabrication approach, which is traditionally based on colloidal systems [1] or crystal powder [2,3]. Their omnidirectional emission with low spatial coherence makes them promising sources for imaging and lighting application [4]. However, control and stabilization of the emission in terms of number of the amplified modes and frequency, is an open challenge due to the absence of an optical cavity. As a matter of fact, even by employing the same fabrication design two different devices give rise to different modes.

Here, we implemented a direct laser-writing technique to engineer an optically active material (dye-doped biopolymer film) by creating circular holes that act as scattering centres for light. This approach is based on the generation of a single femtosecond-pulse that induces ablation of the polymer film on the micrometre-scale. The site-controlled fabrication allows to print holes of different dimension, depth and position inside the active medium. When a couple of identical scattering centres are drawn it is possible, by optically pumping the straight region that connect the two scatterers, to generate random laser emission due to the feedback induced by the scatterers [5,6]. The spectral properties of these home-built random laser depends on the amount of disorder of the scatterers, that varies with their size and smoothness. Therefore, by tailoring the degree of disorder, that is by engineering and reproducing identical scattering centres, we achieved random lasers with a reproducible spectral emission. As a rule of thumb, in our devices larger and rougher holes give rise to a larger number of modes. The presented technique could open new ways to design and fabricate networks of random lasers where the nodes are represented by the holes acting as scattering centres and the connections are the straight line pumped regions of the active medium.

Investigation of Random Lasing Contributions to Lasing-Spasers
Jill Tracey1 and Deirdre O'Carroll1, 2; 1Chemistry and Chemical Biology, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Materials Science and Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Lasing-spasers are physically-small metal/dielectric nanoparticle structures that emit light via stimulated emission of radiation due to amplification of surface plasmons. There have been relatively few experimental demonstrations to date, all of which have relied on ensembles of randomly arranged nanoparticles to exhibit spasing. This has lead to the possibility that it is not just solely the effects of stimulated emission of radiation by amplification of surface plasmons leading to the observed phenomenon. Potentially, a combination of effects from the amplification of surface plasmons, and the random arrangement of nanoparticles, or local interactions between nanoparticles leads to stimulated emission. It is truly necessary to analyze the effects of a single particle and small clusters of particles in order to fully determine if random lasing is contributing to or even obscuring lasing-spaser emission.

The goal of this research project is to fabricate functioning spasers utilizing silver nanoparticles and conjugated polymer gain media. Samples are fabricated by sequential deposition of the following layers on a glass substrate: poly(acrylic acid), silver nanoparticles (60 nm diameter), poly(9,9-di-n-octylfluorenyl-2,7-diyldiyl) (PFO), followed by an optical epoxy encapsulant, and, finally, another glass slide. The thickness of the PFO gain layer is controlled to be less than 70 nm to inhibit photonic waveguide modes. The sample configuration is analyzed in two ways. First, stimulated emission from a dense, random arrangement of nanoparticles coated with a thin-film of the gain medium (PFO) is analyzed, to observe the effects of ensemble measurements, and potentially the effects of random lasing, if they do indeed contribute. From initial measurements, stimulated emission has been observed in samples with polymer thicknesses ranging between 30 nm to 70 nm, and was not observed in polymer films of the same thickness when nanoparticles were not present. However, as these were ensemble measurements, it is possible that the observed stimulated emission is from a combination...
of surface plasmon amplification, as well as nanoparticle interactions. The second approach is to use a less dense nanoparticle arrangement, in order to be able to probe single nanoparticles coated with the gain medium. This approach will allow us to determine if spasing is possible from a single nanoparticle, as well as to determine the effect that the random arrangement of particles contributes to the ensemble measurement results. Scanning electron microscopy is utilized to quantify the nanoparticle arrangement. Photoluminescence spectroscopy is used to determine if stimulated emission is occurring in both configurations, with the addition of an optical microscope for the single particle studies, in order to ensure that only one particle is probed at a time.

Random Lasing in Disordered Photonic Networks
Dhruv Saxena1, Michele Gaio1, Alexis Arnaudon1, Jacopo Bertolotti1, Sophia Yaliraki1, Mauricio Barahona1, Dario Pisignano3,4, Andrea Camposeo2 and Riccardo Sapienza1; 1Imperial College London, London, United Kingdom; 2Istituto Nanoscienze-CN, Pisa, Italy; 3University of Exeter, Exeter, United Kingdom; 4Università del Salento, Lecce, Italy.

Photonic networks, where light flows in a mesh of interconnected sub-wavelength waveguides, have attracted much attention due to their potential applications in quantum optics and integrated photonics. Here we report on a laser based on a disordered planar photonic network [1]. The network is composed of interconnected polymer nanofibers that are doped with a laser dye (Rhodamine-6G). We demonstrate lasing from the network, over a wide range of frequencies corresponding to many network modes, and show that the lasing modes can be designed via the network connectivity and topology.

The complexity of the photonic network lasers brings the opportunity to control the lasing action by selectively illuminating a very small subset of the network links. This surprising result is predicted by a graph description of Maxwell’s equations, which is used to model the network laser. Our graph approach enables efficient modelling of large networks, which is not possible using conventional numerical methods of solving Maxwell’s equations. Moreover, it facilitates design of the network topology for lasing and identification of the most important edges in the network that are necessary for sustaining a particular mode.

Following this strategy, we experimentally demonstrate control over the lasing modes and single-frequency operation. The controlled network laser is a compact laser source, CMOS compatible, capable of switching the lasing output, which could become an important component for future optical computing and processing.

Nonlocal Random Laser and Replica Symmetry Breaking
Loredana Maria Massaro2, Silvia Gentilini1, Cristina Colosi2, Ilenia Viola3, Claudio Conti1,4 and Neda Ghofraniha2; 1Consiglio Nazionale delle Ricerche, Istituto dei Sistemi Complessi, Rome, Italy; 2Dipartimento di Fisica, Universita La Sapienza, Rome, Italy; 3Istituto Italiano di Tecnologia, Rome, Italy; 4Consiglio Nazionale delle Ricerche, Istituto Nanotec, Rome, Italy.

We propose a novel type of random lasers (RL) with disordered structure designed by using 3D bioprinting. Bioprinting uses a computer-controlled printing device to accurately deposit cells and biomaterials into precise architectures creating organized multicellular tissue structures [1]. In our sample we use a blend of alginate mixed with TiO2, which acts as structural template maintaining the printed multi-layer constructs without collapsing. After fabrication the printed structures are stored in a liquid medium and depending on the time spent in it they will present different final dimension. Rhodamine-B in diethylene glycol (RHB) is added as gain medium. The final result is a dyed sample with waffle-like structure made by crossing 30-100 micron thick stripes of TiO2-alginate-RHB and square empty holes.

Two different RLs with different dimension and microstructure are explored. The first one is dried and with a more compact structure inside the stripes, the second one is kept wet and with lower porosity. We use a RL set-up previously reported [2] to examine the emission and two diverse behaviors are observed.

i) The dry sample shows incoherent RL emission with the well known large narrowing spectral peak typical of other TiO2 based RLs, but with an intriguing NONLOCAL behavior: strong RL emission far from the pumping point is observed both inside the stripes (with material) and more interestingly outside in the empty holes. This can be ascribed to a wave guiding mechanism not yet reported in similar disordered materials and is a clear demonstration of the propagation of RL radiation.

ii) The wet sample presents coherent RL emission with several sub-nanometric peaks as an indication of many longitudinal modes. Strong shot to shot spectral fluctuations are observed: each time the laser is on a different composition of the many peaks is given ranging from the only fluorescence band to few very sharp narrow peaks.

We use the Replica Symmetry Breaking (RSB) analysis recently introduced [3] to quantify such fluctuations. Differently, in the present work we explore by this method the statistical mechanics of coherent RL with many resonances. We observe evident RSB of whole the spectra as well as of the single peaks as the demonstration of strong mode interaction and we define their different laser thresholds by investigating the distribution of the intensity overlaps. In this wet sample we do not observed the wave guiding mechanism present in the dry one.

The ability to manipulate light-matter interactions using complex, aperiodic electromagnetic media is at the heart of current nanophotonics and metamaterials technologies. Efficient approaches for multiscale electromagnetic field enhancement, concentration and manipulation of fields with designed spatial-frequency spectra in complex media enable the control of propagating and non-propagating electromagnetic modes in optical nanostructures with broadband/multi-band enhanced responses. Besides its fundamental interest, photonic-plasmonic interactions in complex aperiodic environments are also of great importance for a number of device applications such as multi-band nano-antennas, ultrafast optical switches, nanoscale energy concentrators, laser nano-cavities, and optical biochemical sensors. In this talk, I will discuss our work on the design and engineering of wave localization, scattering and transport phenomena in novel aperiodic nanostructures and metamaterials with controllable structural correlation properties for novel Si-compatible, on-chip devices applications. Finally, I will introduce our current work on the design and of novel dielectric nanostructures and metamaterials with anomalous scattering properties driven by the Epsilon Near Zero (ENZ) response of Si-compatible novel materials.

2:00 PM EP07.11.02
Plasmonic Properties of Ordered Arrays of Metallic Nanostructures Fabricated by Nanosphere Lithography and MeV Ion Implantation Cecilia Salinas1, Jose Miguel Zarate1, Erick Flores-Romerol2, Erika Rodriguez-Sevilla1,2 and Juan-Carlos Cheang-Wong1, 1Universidad Nacional Autonoma de Mexico, Ciudad de Mexico, Mexico; 2Catedrático CONACyT, Ciudad de Mexico, Mexico.

In nanoscale electronic, photonic and plasmonic devices, feature dimensions shrink towards a critical limit, and new experimental approaches have to be explored in lithographic patterning to create ordered arrays of metallic nanostructures with useful optical properties. In this work, spherical submicrometer-sized colloidal silica particles were prepared by sol-gel and deposited onto silica glass plates by means of a spin coater system. By combining MeV ion implantation (Au, Ag ions) and nanosphere lithography, this silica particle monolayer acts as a mask to create regular arrays of metallic nanoscale features embedded in the silica plate. By this way, after removal of the silica particles and an adequate thermal annealing of the as-implanted samples, the formation of metallic nanostructures was confirmed by the presence of the corresponding surface plasmon resonance (SPR) in the optical absorption spectra. In order to modify the shape of such quasi-spherical nanoparticles embedded in the silica matrix, some of the samples were irradiated at room temperature with 8 MeV Si ions, leading to the formation of elongated metallic nanoparticles, achieving then the tuning of the SPR and the nonlinear optical properties. The size and shape of the arrays of silica particles and the embedded metallic nanoparticles were studied by scanning and transmission electron microscopy, respectively. The long range order of both the self-assembled monolayer of silica particles and the metallic nanoparticle arrays were characterized by a Fast Fourier Transform study. The plasmonic properties of the metallic nanostructures were characterized by optical absorption measurements as a function of the Si ion irradiation experimental parameters.

Light-Induced Disorder-to-Order Transition in Dissipative Colloidal Silver Nanoparticles Fan Nan, Fei Han and Zijie Yan; Clarkson University, Potsdam, New York, United States.

Upon laser illumination, electrodynamic interactions can arise among plasmonic silver nanoparticles in solution, leading to local energy minima on the potential energy surface. The silver nanoparticles will self-assemble into ordered structures if the potential wells are deep enough to maintain the structural stability under thermal fluctuations, otherwise they tend to be disordered. Here we report a dissipative colloidal system where ordered chains involving nanoparticle oligomers (such as dimers and linear trimers) transiently arise among largely disordered silver nanoparticles illuminated by a laser beam. The transition is driven by anisotropic electrodynamic interactions coupled with electrostatic interactions, and provides new opportunities to discover new dissipative structures and build novel mesoscale structures.

3:00 PM EP07.11.04
Anderson Localization of Hybrid Plasmons in Terahertz Plasmonic Materials Sushil Mujumdar1, Ajay Nahata2 and M. Balasubrahmaniyan1; 1Tata Institute of Fundamental Research, Mumbai, India; 2Department of Electrical and Computer Engineering, The University of Utah, Salt Lake City, Utah, United States.

Disorder-induced Anderson localization of waves has been demonstrated in optical, acoustic, and matter wave domains, but lacks substantial research in the plasmonic domain due to the inherent losses. Towards a more calibrated study of plasmonic localization and dissipation, appropriate plasmonic materials need to be employed. Given that metallic losses are lower at lower frequencies, terahertz waves are promising candidates in the study of loss and localization. Our recent experiments provided evidence of Anderson localization in terahertz frequencies in a linear array of subwavelength through-holes drilled in a thin stainless steel sheet. However, the limited spectral resolution prevented access to individual localized modes and their loss. The current work reports our theoretical analysis of Anderson localization in this system from the vantage point of the dispersion characteristics of the structure. The subwavelength holes act as resonators and confine resonant fields in the air in the holes. The steel surface supports a plasmon polaron that possesses a linear dispersion at terahertz frequencies. The Kondo-hybridisation of the cavity resonance and the polariton realizes hybrid plasmons that constitute the localized quasiparticles in this system.

We further elucidate critical differences between the localization of hybrid plasmons and that of photons occurring in conventional dielectric systems. The anti-crossing of the dispersion profiles of the resonator and the polariton opens a hybridisation gap that is centered on the resonant frequency of the resonator. The resultant upper transmission band is highly radiative, but the lower band is bound to the interface and supports surface transport, and is conducive to Anderson localization. The profile of the density of states (DoS) exhibits diverging DoS at the edges of the gap. Disorder is introduced into the structure by randomizing the positions of the holes. This shifts the band-edge states into the hybridization gap, and induces their localization as evidenced by the newly-developed exponential tails. We quantify the localization length separately from the loss-length, and find that the latter is at least an order of magnitude larger. Further, we find that the maximally-shifted gap modes cannot arbitrarily transit deep into the gap, even at strongest disorder. They exhibit a propensity to remain pinned to a frequency which depends on the resonance frequency of the subwavelength cavity. As a consequence, the hybridization gap never closes even at strongest disorder, and the midgap DoS remains zero. Such a situation is in stark constrast to conventional dielectric systems, where the DoS closes through the formation of a Lifshitz tail.

In conclusion, we have analyzed Anderson localization of hybrid plasmons, which exhibits hitherto-unstudied characteristics of localization. This study emphasizes the need and potential of novel hybrid plasmonic materials in studies of fundamental phenomena.

3:15 PM EP07.11.05
Fourier-Space Spectroscopy of Disordered Plasmonic Metasurfaces Florian Sterl, Thomas Weiss, Steffen Both and Harald Giessen; 4th Physics Institute and Research Center SCoPE, University of Stuttgart, Stuttgart, Germany.
The optical properties of plasmonic nanoparticle ensembles are not only determined by the particle shape and size, but also depend on the arrangement of the nanoantennas. The angle-dependent transmission/reflection characteristics of a rectangular nanoparticle array are strongly influenced by lattice diffraction effects, while these effects are absent in a completely randomized ensemble. By introducing short- or long-range disorder into a nanoparticle lattice, one can furthermore strongly influence the optical properties.

We present both computational and experimental approaches to gain a better understanding of the impact of disorder on the bidirectional reflectance distribution function (BRDF) of complex plasmonic metasurfaces. We treat the nanoantennas as dipoles, and we simulate the electric field based on dipole-dipole coupling. We can then extract the wavelength-resolved far-field response [1] and convert it into RGB colors, to construct the optical appearance. Similarly, we can extract the wavelength-resolved Fourier space image, providing the angle-resolved far-field response. Varying the incident angle provides the full wavelength-resolved BRDF.

To compare the simulations to experimental data, we develop a designated back focal plane microspectroscopy setup, based on a modified 4-f setup [2]. This allows us to record the real- as well as Fourier-space images generated by nanoparticle ensembles at spot sizes down to 50 µm. The resulting image can either be projected onto an RGB CCD camera, or onto the entrance slit of an imaging spectrometer. In this way, the full wavelength- and angle-resolved far-field response can be recorded. By furthermore varying the incident angle, we can record the full BRDF of such microscopic metasurfaces. In the case of ‘frozen-phonon disorder’, each element is displaced from its initial lattice position by a random amount in a random direction [3]. We can go from a fully ordered to a fully disordered arrangement in several steps by increasing the range of the displacement. We also consider correlated disorder, where the displacement of any element affects the surrounding elements with a certain correlation length and function. We aim to derive a correlation of these results with the two-point correlation function resulting from the spatial arrangement. Thus, we will be able to extract disorder kind and strength from our measurements, and, in turn, design the visible appearance of a metasurface by tailored disorder.

SYMPOSIUM EP08

TUTORIAL: Ultra-Wide-Bandgap Semiconductors—From Materials to Devices
November 25 - November 25, 2018

* Invited Paper

The Ultra-Wide-Bandgap (UWBG) materials represent the next chapter in the history of semiconductor physics, with potential applications to optoelectronics, radio-frequency electronics, power switching electronics, electronics and sensors for harsh environments, platforms for quantum information processing, and possibly as-yet-unforeseen areas. Such applications are enabled by the properties of the materials and the novel device structures enabled by those properties. The first part of this tutorial will focus on the unique physical properties of the key UWBG semiconductors (AlN, BN, Ga2O3, diamond, etc.) as well as the challenges in their growth and manipulation (substrates, doping, defects, etc.) The second part will focus on potential applications and the device structures appropriate for those applications (LEDs, vertical and lateral transistors, etc.) as well as the challenges associated with the design and processing of such devices (metal-semiconductor contacts, surface passivation, etc.) The goal is to provide a comprehensive overview of the key aspects of this new and exciting field.

Investigation of Process Techniques for Ga2O3 Based Diodes  
Fan Ren¹, Jiancheng Yang¹, Stephen J. Pearton¹, Marko Tadjer² and Akito Kuramata³; ¹University of Florida, Gainesville, Florida, United States; ²U.S. Naval Research Laboratory, Washington DC, District of Columbia, United States; ³Tamura Corporation and Novel Crystal Technology, Inc, Sayama Saitama, Japan.

Monoclinic β-phase Ga2O3 has outstanding potential for power electronics, and high quality, large diameter bulk crystals and epitaxial layers of Ga2O3 are already available with a range of controllable n-type doping levels by edge-defined film-fed (EFG) growth using iridium crucibles, by Czochralski or by float zone. The direct energy bandgap of Ga2O3, ∼4.9 eV, yields a very high theoretical breakdown electric field (∼8 MV/cm). For power electronics, the Baliga figure-of-merit proportional carrier mobility, critical electric field and breakdown voltage, is almost four times higher for Ga2O3 than for GaN. Currently, the major limitation for Ga2O3 based device fabrication is the lack of low resistance Ohmic contacts, low damage dry etching process, and thermally stable Schottky contacts. In this work, we report a technique by employing Aluminum Zinc Oxide (AZO) to improve Ohmic contacts on Ga2O3, studies of etch rates and etching induced damages with Cl2/Ar and BCl3/Ar based discharge, surface treatment prior to Schottky metal deposition as well as Ni/Au and Pt/Au Schottky contacts, and demonstration of 2300 V breakdown voltage Ga2O3 Schottky diode.

Ga2O3 has emerged as a noteworthy ultrawide bandgap semiconductor in the past five years. Owing to excellent material properties based on an extremely large bandgap of over 4.5 eV and the commercial availability of native wafers produced from melt-grown bulk single crystals, Ga2O3-based electronic devices are promising candidates for various applications in power switching, RF, and harsh-environment electronics.

First, this presentation will give an overview of our state-of-the-art lateral depletion-mode (D-mode) Ga2O3 metal-oxide-semiconductor field-effect transistors (MOSFETs) [1]. The devices demonstrated an off-state breakdown voltage of over 750 V, a drain current on/off ratio of more than nine orders of magnitude, stable device operation at temperatures up to 300°C, and negligibly small DC–RF dispersion. Furthermore, the bulk Ga2O3 channel exhibited strong gamma-ray tolerance by virtue of showing very little on-resistance degradation and threshold voltage shift, thereby demonstrating the strong potential of Ga2O3 devices for radiation-hard electronics [2]. We will also present RF and thermal characteristics of the lateral MOSFETs [3-5].

In the second part, we will discuss our recent developments of vertical D-mode Ga2O3 MOSFETs [6, 7]. The devices had a current blocking layer formed by Mg- or N-ion implantation and successfully demonstrated drain current modulation by an applied gate bias. However, the devices were still at a primitive development stage and had some severe issues to be resolved.

This work was partially supported by Council for Science, Technology, and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Next-generation power electronics” (funding agency: NEDO).

The layer was fabricated into a vertical Schottky photodiode with a Pt/n(-)Ga2O3/n(+)Ga2O3(010) structure. A 30Å semitransparent Pt metal was used on the

In this paper, we report performance comparisons between Silicon Dioxide (SiO2) and Aluminum Oxide (Al2O3) as gate dielectrics for beta-Gallium Oxide transistors based on β-Ga2O3 with promising results for the development of high efficiency power converters. In order to electrically isolate such electronic devices based on β-Ga2O3 for high efficiency power electronics of the next generation.

The ultra-wide bandgap semiconductor β-Ga2O3 has received great attention in recent years due to its potential to become an attractive alternative to conventionally used materials for future power electronic applications. The estimated dielectric strength of 8 MV/cm in combination with the expected Baliga’s figure of merit are promising indicators to pave the way for the realization of power devices with even higher breakdown voltages and efficiencies than their SiC and GaN counterparts. Up to now several studies have demonstrated the successful realization of Schottky barrier diodes and field-effect transistors based on β-Ga2O3 with promising results for the development of high efficiency power converters. In order to electrically isolate such electronic devices from each other dry etching of mesa structures into the β-Ga2O3 is commonly carried out. On the other hand device isolation by ion implantation of Ga2O3 has not yet been investigated and the applicability of this technology in terms of processing boundary conditions on β-Ga2O3 is still unknown to date. In this study we report on the application of multiple energy nitrogen ion implantation for the electrical isolation of electronic devices on monoclinic β-Ga2O3. By the introduction of uniformly distributed midgap damage-related levels in the β-Ga2O3 crystal lattice we are able to increase the sheet resistances by more than 9 orders of magnitude to ≥1011 Ωsq which remains electrically stable up to annealing temperatures of 600 °C carried out for 60 seconds under nitrogen atmosphere. At higher annealing temperatures the damage-related trap levels are being removed causing a significant drop of the sheet resistance down to 4 x 105 Ωsq after annealing at 800 °C. This effect is preceded by a structural recovery of the implantation damages via the recrystallization of the crystal lattice at already 400 °C as verified by x-ray diffraction measurements. The extracted activation energies of the deep states responsible for the high resistive β-Ga2O3 layer after implantation is in the range of 0.7 eV. It shows a strong correlation with the annealing temperature dependence of the sheet resistance and thus supports the theory of a damage-induced isolation mechanism. The outcome of this work is an important step towards a more robust fabrication method of electronic devices based on β-Ga2O3 for high efficiency power electronics of the next generation.

We report on the MOCVD growth of controllably doped device quality β-Ga2O3 and β-(AlGaxGa1-x)2O3 epitaxial layers with carrier concentration between 1E15 and 1E20 1/cm³. For the realization of β-Ga2O3, based high performance power electronics with high breakdown voltages and low on-resistance, the low background impurity concentration and high electron mobility are critical. However, one of the challenges in the MOCVD growth of β-Ga2O3 is the presence of unintentional background concentration which is mainly attributed to carbon and hydrogen impurities that incorporate into the epilayers primarily from the metalorganic precursors. Here, we present an in-situ and ex-situ methods used to reduce the incorporation of these impurities. Optimization of the MOCVD growth condition, including O₂ flow rate, chamber pressure, and temperature were found to be critical to control the incorporation of these impurities, hence the background concentration and electron mobility in the film. With optimal growth conditions, films with record electron mobility of up to 176 cm²/Vs and ~3500 cm²/Vs were measured at room temperature and 54 K, respectively [1]. Low background concentration of ~1.5E15 1/cm³ was obtained. A short post growth annealing of the β-Ga2O3 in an oxygen atmosphere was also found to reduce the background concentration in the films with no influence on the electron mobility. Si doping of β-Ga2O3 and β-(AlGaxGa1-x)2O3 alloys using silane and tetrachlorosilane (TEOS) was systematically investigated with the carrier concentration ranging between 1E15 and 1E20 1/cm³. The effect of using silane and TEOS on the incorporation of carbon and hydrogen impurities in the doped layers will be discussed. The growth of high-quality strained β-(AlGaxGa1-x)2O3-β-Ga2O3 heterostructures and superlattices on (010) β-Ga2O3 substrates will be presented. The structural quality, abruptness of hetero-interfaces, surface morphology and electrical properties of the heterostructures will be discussed.

mobility two-dimensional electron gas (2DEG) at the AlGaN/GaN heterointerface. In the power switching domain, AlGaN/GaN based HEMTs are believed to make an impact similar to what Si MOSFETs did in 1970s in switching power supply applications by replacing BJTs. However, a major challenge with this device technology is the normally-ON nature which reduces their efficiency in power systems. There have been multiple instances of overcoming this issue by various (post growth) processing methods [1][2]. Here we show, for the first time, the integration of a body-diode based back-gate control in AlGaN/GaN HEMTs to shift the threshold voltage to normally-OFF regime and dynamically control the device performance with a fourth back-gate terminal. This approach is similar to the body-bias technique of threshold voltage control in CMOS [3].

We experimentally demonstrate the role of the back-gate voltage in controlling the performance of HEMTs in both ON and OFF states of the device. The HEMT structure used in this study has been epitaxially grown using metal organic chemical vapor deposition technique. To incorporate body-diode, conventional HEMT structure was epitaxially grown on p-type GaN. The role of Mg activation in the p-GaN layer on the electrical properties of the device has been studied and will be discussed. With the integration of body-diode, the 2DEG current shows modulation with the change in magnitude and polarity of the back-gate voltage. An increase in 2DEG current is measured with the application of a positive back-gate voltage and a decrease is measured under a negative back-gate bias. Moreover, a positive/negative shift in the threshold voltage is observed with the application of negative/positive back-gate voltage. The modulation of 2DEG density is attributed to the modulation of the body-diode depletion width. Along with extensive results of such modulation, a comprehensive study demonstrating 3-terminal and 4-terminal output/transfer characteristics and capacitance-voltage characteristic of this novel device structure will be presented.

11:45 AM EP08.02.06 InGaN Nanowire Light Emitting Diode Integrated with Field Effect Transistor Matthew Hartensveld and Jing Zhang; Microsystems, Rochester Institute of Technology, Rochester, New York, United States.

Current display technology is reaching its practical limitations as the Thin-Film-Transistors (TFTs) that make up displays are struggling to be reduced further in size. Emerging technologies such as Augmented and Virtual Reality are also challenged to find transparent and high-resolution displays. Nanowire (NW) Light Emitting Diodes (LEDs) are appearing as the solution due to higher efficiencies (70% vs. 5%), high reliability, and the ability to be manufactured at nanoscale. Though NW LEDs are being pursued, there are key issues in monolithically integrating Field Effect Transistors (FETs) with these LEDs. Common solutions include growth on Silicon to incorporate Complementary Metal Oxide Semiconductor (CMOS) technology, layer regrowth for High Electron Mobility Transistors (HEMTs), and deposition of classical TFTs on top of the LEDS. Nevertheless, all these approaches would sacrifice display area and device performance to introduce FETs to LEDs.

Presented here is a novel monolithic integration scheme to vertically combine GaN NW FETs with InGaN NW LEDs. Novel to this work, the layer of unintentionally doped GaN (u-GaN), serving as a template to LED growth, is used for FET channel. This makes the FET in series with an NW LED for switching. Our approach allows for straightforward fabrication, no loss of display area, and eliminates device degradation. Many different types of FETs can be realized, and here a Static Induction Transistor (SIT) is selected due to the ease of fabrication.

To start, a conventional LED structure is used consisting of sapphire, u-GaN, n-type GaN, InGaN quantum wells, and p-type GaN. The NWs are fabricated through a top-down method utilizing Reactive Ion Etching (RIE) to etch down into the u-GaN layer. The etched NWs are then immersed in a KOH solution to crystallographically wet etch the wires, shrinking the diameters along with removing etch damage. Titanium is next evaporated at the base of the wires and annealed. Annealing creates nitrogen vacancies which construct the n-i-n structure common to modern transistors. Following the anneal, Polydimethylsiloxane (PDMS) is deposited and etched back to provide an insulating layer. Nickel is then evaporated creating a 30 nm schottky gate on the u-GaN. A second layer of PDMS is then coated and etched back to reveal the NW tips, followed by a deposition of Indium Tin Oxide (ITO) for top contact. These preliminary devices show good gate control with the ability to switch on/off the NW LEDs. As the gate becomes reverse bias the depletion region of the gate pinches off the current flow through the u-GaN layer, switching off the LED. Silvaco simulations are additionally performed to investigate and model device operation. This monolithically integration of NW LED and SIT can open the door to the next generation of display technology with the ability to be fabricated at diameters smaller than 100 nm, along with the inherent ability to be fully transparent.

SESSION EP08.03: Oxide Devices II

1:30 PM *EP08.03.01 Electrical and Thermal Studies of β-Ga2O3 Nano-Membrane Field-Effect Transistors on Different Substrates Peide P. Ye; Purdue University, West Lafayette, Indiana, United States.

β-Ga2O3 is an emerging wide bandgap semiconductor for the next generation power devices to replace GaN and SiC. It has an ultra-wide bandgap of 4.8 eV and a corresponding high breakdown field of 8 MV/cm. However, the β-Ga2O3 bulk substrate has a low thermal conductivity (k) of 10-25 W/mk and thus severe self-heating effects (SHE) can be observed. In high-power electronic devices, the output power density and the maximum drain current can be significantly limited by the elevated channel temperature caused by SHE and it has become a key challenges in β-Ga2O3 research. To suppress severe self-heating at high powers, we herein demonstrate top-gate nano-membrane β-Ga2O3 field effect transistors on a high thermal conductivity diamond substrate. The devices exhibit enhanced performance, with a record high maximum drain current of 980 mA/mm for top-gate β-Ga2O3 field effect transistors and 60% less temperature increase from reduced self-heating, compared to the device on sapphire substrate operating at the same power. With Improved heat dissipation, β-Ga2O3 field effect transistors on a diamond substrate are validated using a newly developed ultrafast high-resolution thermoreflectance imaging technique, Raman thermography, and thermal simulations. The work is in close collaborations with Dr. Marko Tadjer’s team at NRL and Prof. Ali
Heat dissipation has become an increasingly critical technological challenge in modern electronics and photonics. To address this challenge, discovering new high thermal conductivity materials that can efficiently dissipate heat from hot spots and improve the device performance of gallium nitride based electronics are urgently needed. Recent theoretical work including ab initio has predicted a new class of thermal materials, however, experimental demonstration has been challenged by materials synthesis and thermal characterization. Here, we describe our current progress in developing and characterizing these emerging high thermal conductivity materials [1-3].

We have chemically synthesized high-quality boron phosphide single crystals and measured their thermal conductivity as a record-high 460 W/mK at room temperature[1]. We have, for the first time, experimentally measured the phonon mean free path spectra of boron phosphide and analyzed experimental results by solving three-dimensional and spectral-dependent phonon Boltzmann transport equation using the variance-reduced Monte Carlo method. The experimental results are in good agreement with that predicted by multiscale simulations and density functional theory, which together quantify the heat conduction through the phonon mode dependent scattering process.

Our findings underscore the promise of the emerging high thermal conductivity material for advanced thermal management and provides a microscopic-level understanding of the phonon spectra and thermal transport mechanisms. The study aims to enable a rational design of thermal materials and nano- to multiscale devices, including the heat management of wide-bandgap electronics.

References:
phase. The band offset of the (Al,Ga)O alloy mainly arises from the discontinuity in the conduction band. Consequences for designing modulation-doped field effect transistors (MODFETs) based on (Al,Ga)O/GaO are also discussed.

β-Ga2O3 Nano-Electronic Devices
Jhvan Kim, Korea University, Seoul, Korea (the Republic of).

The preparation of nanowayer β-Ga2O3 flake by a mechanical exfoliation method and its fabrication into various types of electron and optoelectronic devices will be presented. Firstly, we will show a heterostructure n-channel depletion-mode β-Ga2O3 junction field-effect transistor through a van der Walls bonding with an exfoliated p-WSe flakes. β-Ga2O3 and hexagonal boron nitride hetrostructure-based metal-insulator-semiconductor field-effect transistors (MISFETs) are achieved by integrating mechanical exfoliation of quasi-two-dimensional materials with dry transfer process, where nano-thin flakes of β-Ga2O3 are utilized as the channel region of the MISFET. We will present a β-Ga2O3 metal-semiconductor field-effect transistor with a high off-state breakdown voltage (344 V), based on an exfoliated β-Ga2O3 field-plated with hexagonal boron nitride. This heterostructured ultra-wide bandgap nanodevice shows a new route toward high power nano-electronic devices.

4:00 PM EP08.03.07
Anisotropic Optical Properties in Zn2GeO4 and Ga2O3 Nanowires
Jaime Dolado1, 2, Manuel Alonso-Orts1, Íñaki Lopez2, 3, Pedro Hidalgo2, Emilio Nogales1 and Branci Mendez1, 4; 1University of Complutense, Madrid, Spain; 2Istituto Nazionale di Ottica, Florence, Italy.

Zinc germanate (Zn2GeO4) and gallium oxide (Ga2O3) are wide band gap semiconductors (Eg = 4.5 and 4.9 eV, respectively) with promising applications due to their matching with UV radiation in UV photodetectors, phosphors in flat panel displays or photo catalysis. In addition, Ga2O3, in particular, is becoming an emerging material for high power devices while Zn2GeO4 is a good candidate to be used in Li-ion batteries. In both oxides, the electronic and optical properties have been investigated recently, and an active research is going on. For example, there is still controversy about the origin of the visible luminescence of these oxides, usually attributed to oxygen vacancies, which are mainstream defects in oxide materials. Furthermore, doping oxides to modify electronic conductivity or luminescence property is a challenge because of the interplay of impurities with native defects, which add more complexity to the physical properties. On the other hand, nanowire morphologies of a number of compounds have been recently studied on the view of particular applications, such as optical microcavities or vertical devices designs. Since optoelectronic properties are intrinsically related to the electronic levels in the band gap, high-energy electron and UV light are suitable probes to test these properties. In this work, we explore the optical properties of undoped Zn2GeO4 and Zn doped Ga2O3 and nanostructures synthetized by a thermal evaporation method. We will carry out polarization dependent luminescence and Raman measurements to get some insight into their luminescence features and their correlation with their chemical and structural configuration at atomic scale level.

4:15 PM EP08.03.08
Gallium Oxide Nanowires for Gas Sensing Applications—Growth, Device Fabrication and Gas Response
Guillem Domenech-Gil1, 2, Irmina Peiró1, Jordi Sama1, 2, Paolo Pellegrino1, 2, Sergi Hernández1, 2, Mauricio Moreno1, 2, J.D. Prades1, 2, Isabel Gràcia3, Carles Cané3, Sven Barth4 and Albert Romano-Rodríguez1, 2; 1Department of Electronic and Biomedical Engineering, Universitat de Barcelona (UB), Barcelona, Spain; 2Institute of Nanoscience and Nanotechnology (IN2UB), Universitat de Barcelona (UB), Barcelona, Spain; 3CNM, Bellaterra, Spain; 4TUW, Wien, Austria.

Gallium oxide (Ga2O3) is a wide band gap semiconductor material that has been widely studied during the last three decades in the form of thin films for its high-temperature sensing properties towards oxygen and reducing gases. Its optical and sensing properties have been largely studied and several improvements for its use as gas sensor have been achieved introducing different modifications. These changes, that include surface functionalization, material doping or nanowire (NW) morphology, allow working at low temperatures where the sensing mechanisms are supposed to be deactivated. The high surface-to-volume ratio attributed to nanowire morphology decreases the power consumption of the devices, while allowing to sense at lower temperatures than thin films. In our study, devices containing a single Ga2O3 NW are studied as humidity sensors, working at room temperature. β-Ga2O3 nanowires were fabricated via a metal-assisted vapor-liquid-solid process using a carbothermal reduction and the synthesized nanowires were structurally and optically characterized using X-ray diffraction, scanning and transmission electron microscopy and related techniques as well as photoluminescence and X-ray photoelectron spectroscopy. Measurements revealed a crystalline material, different photoluminescence emission peaks in the visible range, and a transition band gap of 4.2 eV that suggests the presence of a high density of intraband states. UsingFocused Electroan Beam Induced Deposition techniques, nanowires were individually contacted for their use as gas sensors. The fabricated devices have been tested, from room temperature up to 200 °C, in environments with different concentrations of relevant gases for air quality monitoring, such as nitrogen dioxide and carbon monoxide, as well as oxygen and water vapor. Fast, stable and reproducible response was measured towards water vapor at room temperature (25 °C) using power consumptions between 0.25 and 250 nW. Tests under nitrogen ambient revealed that, at room temperature, the pre-adsorption of oxygen ions at the NW surface is mandatory for the water vapor sensing and that oxygen, even at low concentrations, is rapidly re-adsorbed at the surface of the material in a lapse of one minute. Furthermore, the presence of carbon at the surface of the nanowires, result of the growth process, plays an important role in sensing capabilities and will be discussed.

4:30 PM EP08.03.09
New Perspective of Room-Temperature Gas Sensor Using Ionic Conduction Based SnO2 Nanorods
Young Geun Song1, 2, Young-Sook Shim3, Jun Min Suh4, Ho Won Jang4, Byeong-Kwon Ju1 and Chong-Yun Kang1, 2; 1Center for Electronic Materials, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2College of Engineering, Korea University, Seoul, Korea (the Republic of); 3Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 4Seoul National University, Seoul, Korea (the Republic of); 5KU-KIST Graduate School of Converging Science and Technology, Korea University, Seoul, Korea (the Republic of).

Gas sensors with intelligent systems have become a core part of the complete Internet of Things (IoT) since they offer continuous information on the presence of specific gases in the ambient atmosphere. As a representative gas sensor, semiconducting type has attracted much attention due to their cost effectiveness, simplicity in fabrication, high response and easy integration with electronic circuits. Generally, the semiconducting gas sensors require a high operating temperature of 150–400°C for adsorption and desorption of target molecules. However, high temperature reduces sensor stability and life time due to thermally induced growth of grains, and can lead to risks of ignition when detecting flammable explosive analytes. Furthermore, it can also affect interconnect electronic and requires high power consumption that is an important parameter for the new generation of battery-loaded wireless sensors, resulting in reluctant practical application. Hence, one of the most important challenge and issue in gas sensor society is to make a high-performance gas sensor that operates at room temperature for high stability and low-power consumption. Over the past decade, there are various approaches to enhance the sensing performance at room-temperature using metal additives or heterojunctions and two-dimensional materials. Despite these extensive efforts, there remain challenging including poor response and incomplete recovery because electronic conduction based sensing mechanism is limited by insufficient reaction energy between the analytical molecule and sensing material at room-temperature. Herein, we suggest a new strategy for a room temperature gas
sensor using the ionic conduction based gas sensing mechanism. Glancing angle deposition (GLAD) method was used to fabricate highly porous
SnOxnanorods. The ionic conduction induced by humidity was confirmed using impedance spectroscopy, I-V characteristic and XPS analysis. The relation
between the sensing properties and relative humidity was systematically investigated. Our experimental results show that the response of SnO2 nanorods to
5 ppm NO2 has a maximum response over 1400 at RH 20%. Also, it is observed that the response rate and recovery rate are accelerated as relative humidity
increases. The gas sensing mechanism can be demonstrated based on the principle of the ionic conduction, humidity sensor, and water splitting. We believe
that the ionic conduction based SnO2 nanorods open a new direction for developing the room temperature gas sensor.

4:45 PM EP08.03.10
Doping Dependence of Electrical Characteristics of Zn-O-N Thin-Film Transistors Hiroshi Tsuji, Tatsuya Takei, Mitsuru Nakata, Masashi Miyakawa
and Yoshihide Fujisaki; NHK Science & Technology Research Labs, Tokyo, Japan.

Thin-film transistors (TFTs) that utilize oxide semiconductors as channel materials have become a key technology for various applications such as displays,
sensors, and memory devices due to their superior characteristics, which include high mobility, low off-current, low processing temperature, and applicability
to large-area production. Zn-O-N (ZnON) [1] has recently received attention as a channel material for high-mobility TFTs, especially those
employed in demanding applications such as large ultra-high definition organic light-emitting diode displays. ZnON-TFTs exhibit much higher field-effect
mobilities (>50 cm²/Vs) [2] than conventional oxide TFTs. However, ZnON-TFTs have some drawbacks that must be addressed, including a negatively
shifted threshold voltage (Vth), a large subthreshold swing (SS), and Vt instability when stored in air. We have recently reported that Si doping of ZnON is
effective for improving the switching characteristics and long-term stability of ZnON-TFTs [3].

In the present work, the effects of impurity doping on the electrical characteristics of ZnON-TFTs are further investigated by co-sputtering of Zn and other elements
(Ta, Zr, or In). The results indicate that doping with Ta or Zr, both of which have a high bond-dissociation energy with nitrogen, is effective for
overcoming the drawbacks of ZnON-TFTs, as in the case of Si doping [3]. In particular, Ta-doped ZnON-TFTs with an optimal doping level exhibited a high
field-effect mobility of 49 cm²/Vs, improved switching behavior (less negative Vth and smaller SS), and better Vt stability than non-doped ZnON-
TFTs. On the other hand, the use of In doping enhanced the mobility of ZnON-TFTs, and this could be attributed to the electron pathways formed by the
broad 5s orbitals of In. In-doped ZnON-TFTs exhibited a high field-effect mobility of up to 59 cm²/Vs, although a more negative Vt was also observed.
These results indicate that impurity doping is an effective approach to improving and enhancing the performance of ZnON-TFTs.

SESSION EP08.04: Oxide Growth

8:30 AM *EP08.04.01
Bulk Crystal Growth and Devices Fabrication of β-Ga2O3 Xutang Tao; Shandong University, Jinan Shandong, China.

At present, silicon based devices have gradually reached their theoretical limits. Wide-bandgap semiconductors have been considered as the candidates for
high-performance electronic devices and deep UV optoelectronic devices.[1] The bandgap of β-Ga2O3 is as large as 4.7 eV, as a new type of ultra-wide
bandgap semiconductor, it is attracting more and more attention in recent years. β-Ga2O3 has the advantages of higher breakdown field, bigger Baliga FOM
and shorter UV cutoff edge compared to the traditional wide-bandgap semiconductors including ZnO, SiC and GaN. Furthermore, large size and high
quality β-Ga2O3 crystals could be grown by Czochralski method or edge-defined film-fed growth (EFG) method such as Si and GaAs.[2] Therefore, β-
Ga2O3 is a desirable material for high voltage, high power, low loss power devices and deep UV optoelectronic devices, such as: deep UV photodetectors,
transparent thin film transistors, light-emitting diodes (LEDs), Schottky diodes, high voltage transistors and high temperature gas sensors.
In recent years, the basic research and commercialization of β-Ga2O3 develop quickly. The size of bulk crystals is enlarging, the quality of epitaxial films is
improving and the performance of semiconductor devices keep breaking records. However, as a novel semiconductor material, the research of β-Ga2O3 is
still in the early stage. The crystal quality, basic physical properties, physical properties optimization and devices performance optimization are still need
be systematically studied.
In this work, we focus on the crystal growth of high quality β-Ga2O3 to meet the requirements of different devices. The crystal growth methods and
equipment modification, crystal growth process optimization, electrical properties optimization and crystal wafer processing are systematically studied.
Furthermore, high-performance UV detector and Schottky diodes have been obtained based on high quality single crystal wafers.

Epitaxial Lateral Overgrowth of α-Ga2O3 on Sapphire Substrates Riena Jinno, Nobuhiro Yoshimura, Kentaro Kaneko and Shizuo Fujita; Kyoto
University, Kyoto, Japan.

Ga2O3, which is one of the ultra wide-bandgap (UWBG) semiconductors, has attracted attentions as a next-generation material of power devices [1].
Among their six different phases (α, β, γ, δ, ε, and κ), the α-phase is the most suitable for bandgap engineering due to its crystal structure of corundum,
although it is the metastable phase. Alloys with α-Al2O3 and α-In2O3 enabled the bandgap engineering from 3.7 to 8.7 eV[2]. However, we must consider
dislocations in α-Ga2O3 formed due to large lattice mismatch to sapphire substrates. In this study, epitaxial lateral overgrowth (ELO) of α-Ga2O3 was
conducted on sapphire substrates, aiming at reducing the dislocation density in α-Ga2O3.
Stripe-patterned dielectric masks of SiO2 were formed on sapphire substrates. The both widths of openings and masks were 5 μm. The various orientations
of substrates (c-, c-, m- and r-planes) and openings were used. All the growth of α-Ga2O3 was conducted on the patterned substrates by using the mist-CVD
method. Ga2O3 was adopted as a Ga source, which enables the growth rate of α-Ga2O3 as high as 7 μm/hour. The growth temperature was changed between
500 and 700 °C.

References
α-Ga2O3 was selectively grown on the openings at the temperatures higher than 550 °C, while the deposition on masks was observed at 500 °C irrespective of the orientations of substrates and openings. When α-Ga2O3 was grown on c-plane sapphire substrates, the triangular stripes with (10-11) and (10-12) facets were observed for (10-10)-type stripe, while the rectangular cross section with a (0001) top facet and (11-20) sidewalls was observed for (10-10)-type stripes. Although the shapes of the features depended on the orientations of substrates and openings, all the facets were formed by (10-11), (10-12), (11-20) and (0001), which are consistent with stacking of oxygen and gallium layers. These planes were considered to be stable under the oxygen rich growth condition by the mist-CVD method. The growth of α-Ga2O3 on a-plane sapphire with <10-10> stripes showed the largest ratio of the lateral and vertical growth rates, that is, 0.87. Under this condition, the coalescence of two adjacent wings was achieved. TEM observations were conducted to discuss dislocation structure in the α-Ga2O3. The cross sectional TEM images revealed that the dislocation density in the α-Ga2O3 was successfully reduced, while the dislocations on the openings were propagated without bending. From these results, the ELO technique is useful to reduce the dislocation density in α-Ga2O3. We need to investigate the growth conditions with bending dislocations on openings to decrease the dislocations on openings effectively.

We report on growth studies and germanium doping of heterogeneous and homoepitaxial beta-Gallium Oxide using low pressure chemical vapor deposition technique. Gallium oxide has attracted a lot of attention because of its potential applications in high power devices. The main advantage of Ga2O3 over other wide band gap materials is the availability of a high quality commercial substrates and shallow n-type dopants. A variety of growth techniques exist for growth of Ga2O3 thin films including MBE, MOCVD, HVPE etc. Low pressure CVD [1] is a simple, cost-effective technique to grow high-quality Gallium Oxide with sufficiently high growth rates and low impurity concentration, as the precursors are ultrapure Gallium, oxygen gas and Argon carrier gas.

To calibrate the growth rates and understand the growth regimes, we characterized gallium oxide thin films grown on sapphire substrates as a function of growth temperature, oxygen flow rate and Argon flow rate. The nominal growth rate (characterized using cross sectional SEM) varies from 2.5 µm/hr to 3.5 µm/hr for temperature between 850 °C – 950 °C, for chamber pressure of 1.5 Torr. At low oxygen concentrations, the growth rate doesn’t show significant variation with oxygen flow rate indicating a mass transport limited growth, at the substrate temperature of 935 °C. With flow rates higher than 6 sccm (Ar flow rate of 140 sccm), gallium oxide power formation was observed which resulted in much thinner films. Ga2O3 films were grown on both c-plane and vicinal sapphire substrates, thin films on vicinal sapphire were much smoother than c-plane wafers. Also, the roughness of these films dropped with increasing oxygen flow rate. Using a two-step growth technique, surface roughness was reduced to as low as 10 nm for a 10 micron thick LPCVD grown film. Using CV characterization on undoped films grown on Sn-doped n-type bulk substrates, background carrier concentration as low as 1×10³ cm⁻² was obtained. Solid Ge source was used to explore n-type doping. Using transfer length method (TLM) structures fabricated using annealed Ti (50 nm)/Au(100 nm)/Ni(100 nm) metal stack, resistivity ranging from 0.1 to 7.5 ohm-cm was obtained. Temperature dependent hall mobility and carrier concentration, activation energy for Ge dopants in Ga2O3 will be presented. These results indicate the promise for controlled high quality growth of Ga2O3 with high growth rates for high power performance electronics.

High-Bias-Stability in Atomic-Layer-Deposition Al2O3 by Post-Deposition-Anneal on Wide- and Ultra-Wide-Bandgap Semiconductors Kiyotaka Horikawa1, Atsushi Hirawat2, Satoshi Okubo2, Taitsu Kegeura2 and Hiroshi Kawarada1; Waseda University, Tokyo, Japan; 2 Nagoya University, Nagoya, Japan.

The metal-insulator- Wide- and ultra-wide-bandgap semiconductor field-effect transistors (MISFETs) are expected to realize good characteristic in terms of high breakdown voltage and low-loss features. However, it was difficult to form a thermally SiO2 film as a gate insulating or passivation film on Wide- and ultra-wide-bandgap semiconductors. Various insulators have been investigated using atomic layer deposition (ALD), which forms films with unparalleled uniformity and reproducibility. Among those films, ALD-Al2O3 is an attractive candidate, having a wide bandgap of 7eV [1], a high dielectric constant of 9 [2], etc. A major challenge for the Al2O3 in practical applications is Al2O3-related bias instability (BI) needs to be reduced. This study is concerned with achieving better performance by reducing the dislocations on openings effectively.

Part of this work was supported by the New Energy and Industrial Technology Development Organization (NEDO).

β-Ga2O3 has attracted a lot of attention because of its potential applications in high power devices. The main advantage of Ga2O3 over other wide band gap materials is the availability of a high quality commercial substrates and shallow n-type dopants. These results indicate the promise for controlled high quality growth of Ga2O3 with high growth rates for high power performance electronics.
The intrinsic structural and electronic properties of Ga2O3 suggest that it may ultimately outperform existing wide-gap semiconductors such as SiC for Army Research Laboratory, Adelphi, Maryland, United States.

β-(AlxGa1-x)2O3 epitaxial layers were grown using ultra-high vacuum pulsed laser epitaxy at 500 °C, using a KrF excimer laser (λ=248nm) operating at 4 J/cm2, and metal-organic vapor phase epitaxy (MOVPE) using Ge as n-type dopant in β-Ga2O3 (010) films, and obtained a wide range of electron concentration (1×1017 cm−3 - 1×1020 cm−3)[8]. Mobility of 97 cm2/Vs was achieved for a charge density of 1.6×1018 cm−3 using Ge as dopant. This mobility is two times higher than the mobility achieved for a similar charge density using Sn.

Using β-Ga2O3 as the intentional donor, we recently demonstrated modulation doping in β-(AlxGa1-x)2O3/β-Ga2O3 heterostructures. The formation of 2DEG was confirmed by capacitance-voltage measurements. Modulation doping field effect transistors were fabricated. A maximum current density of 20 mA/mm, with a pinch of voltage of ~0V was achieved on the sample with a 2DEG sheet charge density of 1.2×1013 cm−2.[9]

In this talk, I will discuss the above-mentioned progress in detail.

High-Quality β-(AlxGa1-x)2O3/Ga2O3 (010) and Si-Doped β-(AlxGa1-x)2O3/Ga2O3 (010) Heterostructures Grown by Pulsed Laser Epitaxy
Shaneq Pacley, Shin Mou, Adam Neal, Kurt Eynk, Krishnamurthy Mahalingum, Lawrence Grazulis, Eric Heller, Brandon M. Howe, Kelson Chabak and Gregg Jessen, Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States.

Here, we present the results of a fundamental growth investigation into the effects of Al-alloying and delta doping using Si on the structural and electronic properties of β-(AlxGa1-x)2O3 heterostructures grown on semi-insulating Fe-doped β-Ga2O3 (010) single crystals. High quality β-(Al0.8Ga0.2)2O3 and Si-doped β-(Al0.8Ga0.2)2O3 epitaxial layers were grown using ultra-high vacuum pulsed laser epitaxy at 500 °C, using a KrF excimer laser (λ=248nm) operating at 4 Hz and a fluence of ~3 J/cm2. Targets with an Al content ranging from x = 0.175 - 0.5 were used for undoped layers of β-(AlxGa1-x)2O3, while targets with an Al content of x = 0.175, 0.225 and a Si content of 0.1% were used for the doped heterostructures. The Al content was varied to increase the bandgap, and Si was used in the heterobuffer of β-(AlxGa1-x)2O3 for modulation doped field-effect transistors. High-resolution X-ray diffraction (HRXRD) and high-resolution transmission electron microscopy (HRTEM) confirmed both β-(AlxGa1-x)2O3 and Si doped β-(AlxGa1-x)2O3 films. Both HRXRD and HRTEM showed we were able to obtain high quality epitaxial films of β-(AlxGa1-x)2O3 up to x = 0.225, which was confirmed by X-ray photoelectron spectroscopy (XPS). However, HRTEM suggests we were able to obtain β-(Al0.8Ga0.2)2O3 up to 50%, but the stability of this phase is still under investigation. As a result of this research, we demonstrate that pulsed laser deposition can be used to grow both β-(Al0.8Ga0.2)2O3/Ga2O3 and Si-doped β-(Al0.8Ga0.2)2O3 heterostructures for wide bandgap electronic devices and specifically, modulation doped transistors. Finally, Hall transport and capacitance-voltage will be used to characterize the heterojunction electrical properties, and XPS will be used to correlate Al content with band offset.

TEM-EELS Analysis of Ga2O3/SiO2 and Ga2O3/Al2O3 Interface Structures with Electron Beam Induced Crystallization of Al2O3 Gate Layer
Christopher Klingshirn1, Asanka Jayawardena2, Sarit Dhar2, Tsvetanka Zheleva3, Aivars Leis3 and Lourdes G. Salamanca-Riba4; 1Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; 2Physics, Auburn University, Auburn, Alabama, United States; 3U.S. Army Research Laboratory, Adelphi, Maryland, United States.

The intrinsic structural and electronic properties of Ga2O3 suggest that it may ultimately outperform existing wide-gap semiconductors such as SiC for certain metal oxide semiconductor (MOS) device applications, especially at very high power. However, as with SiC, interfacial defects at the Ga2O3 / gate oxide interface adversely affects the performance of Ga2O3-based MOS devices. The various choices of gate oxide material for Ga2O3-based devices, such as SiO2 and Al2O3, present their own trade-offs in terms of electrical properties (bandgap and breakdown strength) and interface abruptness and stability. Previous work on SiC has shown that a narrower transition layer at the SiC/ SiO2 interface correlates to decreased interface trap density and enhanced channel mobility.

In this work, we discuss chemical and structural features of interfaces between Ga2O3 and SiO2 and Al2O3 investigated using high resolution transmission electron microscopy (HRTEM) and high angle annular dark field scanning TEM (HAADF-STEM) combined with electron energy loss spectroscopy (EELS SI). STEM and EELS measurements allow identification of the width, composition, and bonding characteristics of the interface region. Hyperspectral decomposition of EELS signals using machine learning techniques reveal components corresponding to Ga2O3, Ge or Si and Al. Gate dielectric deposition and post-deposition annealing (PDA) conditions are found to affect interface quality, with higher temperature processing correlated with interfacial roughness. The Ga2O3 / Al2O3 interface is not fully abrupt and contains an interfacial region likely corresponding to interdiffusion between Ga and Al. Additionally, rapid crystallization of the Al2O3 gate oxide layers, outward from the interface, was observed during TEM imaging despite remaining at a lower temperature than during the gate deposition or PDA processes. Contributions of thermal gradient, strain and radiolysis to this beam-induced crystallization effect will be presented.

Scanning Transmission Electron Microscopy of Gallium Oxide Materials and Interfaces
Jared M. Johnson, Yuewei Zhang, Md Rezaul Karim, Hongqing Zhao, Siddharth Rajan and Jinwoo Hwang; Ohio State University, Columbus, Ohio, United States.

We perform a microscopic investigation of ultra-wide bandgap (UWBG) β-Ga2O3 materials and interfaces using atomic resolution scanning transmission electron microscopy (STEM). Our goal is to establish fundamental understanding on the atomic to nanoscale structure and defects that directly affect the
basic materials properties and device performance of β-Ga2O3, which is essential to advance β-Ga2O3 to many technologically important UWBG applications. Here, we present the details of our STEM investigation and the experimental results from various β-Ga2O3 materials and heterostructures. First, we will present the unique technical challenges in the STEM characterization of β-Ga2O3 due to its high structural anisotropy and TEM sample preparation. Second, we will show the detailed structure, formation, and dynamics of extended defects that can directly influence the properties of various homo- and hetero-β-Ga2O3 interfaces. Finally, we will present our ongoing development of the new STEM imaging mode that uses the electron channeling effect to image individual point defects (both intrinsic and extrinsic) in β-Ga2O3. The imaging mode can utilize the new-generation pixelated fast STEM detector, which can capture the channeling signals at a narrowly confined scattering angle and determine the position and structure of point defects with high precision.

Topics in the Ab Initio Theory of Ga2O3, Mainly the ε Phase
Barbara Maccioni1, Roberta Farris1, Paola Alippi2 and Vincenzo Fiorentini1; 1University di Cagliari, Monserrato, Italy; 2CNR-ISM, Rome, Italy.

This presentation is about ab initio calculations in the area of Ga2O3 and thereabouts. I will first discuss the anisotropy of absorption in the β phase of Ga2O3, and a revised mixing phase diagram of InGaO phases including strain. I will then concentrate on the newly-synthesised ε (epsilon) phase of Ga2O3, in particular in relation to its polarization properties (is this a pyro- or a ferro-electric ?), electronic structure (first ARPES spectra, Seebeck and Peltier coefficients), and phonons (dispersion, thermal conductivity, thermoelectric ZT, and core lineshapes).

Characterizing the Influence of Impurities and Dopants on the Electrical Properties of Ga2O3 Through Hybrid Functional Calculations
Joel B. Varley; Lawrence Livermore National Laboratory, Livermore, California, United States.

Gallium oxide has emerged as a promising candidate for next-generation power electronics due to a number of favorable properties such as its large band gap, controllable conductivity and the availability of large single-crystal substrates grown from the melt. Despite the rapid surge of interest in this material, there are still a number of outstanding questions as to how various defects, i.e. native point defects and extrinsic impurities, influence the properties of this material. In this talk we use hybrid functional calculations to elucidate the role of common impurities that have been identified in Ga2O3 single crystals and epitaxial films. Particularly we discuss the role of Fe and Ir impurities, which we find to be highly soluble in Ga2O3 and both electrically and optically active defects depending on the conditions. Our results identify that Fe impurities act as a highly soluble deep acceptors that are commonly observed in Ga2O3 bulk samples, while Ir is a deep donor that can degrade optical performance in insulating samples. We discuss our results in the context of recent experimental evidence of properties correlated with the presence of these impurities.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Dynamically Modeled Current Conduction in Atomic-Layer-Deposited Al2O3 on Wide- and Ultra-Wide-Bandgap Semiconductors
Atsushi Hiraiwa; 1, Kiyotaka Horikawa2, Satoshi Okubo2 and Hiroshi Kawarada2; 1Tokyo Branch, Nagoya University, Tokyo, Japan; 2Waseda University, Tokyo, Japan.

Wide- and ultra-wide-bandgap semiconductors are promising power-device materials due to their high blocking capability. The wide bandgap, however, poses a serious challenge of gate insulation and surface passivation, because the insulator barrier against carrier emission from the semiconductors is inevitably small requiring wide-bandgap insulators. Although having the widest bandgap and well established in Si industry, thermal SiO2 is not amenable here. Therefore, atomic-layer-deposited (ALD) Al2O3 is the most promising insulator owing to wide bandgap (7 eV), relatively high dielectric constant (9), and good uniformity/reproducibility specific to ALD [1]. To promote the practical application of this AL2O3, Al2O3-related bias instability (BI) needs to be reduced. This study aims to achieve this through investigating the current conduction process in ALD Al2O3.

The current conduction in Al2O3 follows the space-charge-controlled field emission (SCC-FE) process [2], which, however, is hitherto only suitable for low-field analysis, imposing a limitation on its BI analysis. To solve this problem, the charged state of Al2O3 is assumed to dynamically change with bias voltage and is investigated by alternately measuring current-voltage (I-V) and capacitance-voltage (C-V) characteristics of Al2O3 metal-insulator-semiconductor capacitors, with the stop voltage of the I-V measurements increasing successively. The Al2O3 charged states in the I-V measurements, except for the first one, remain unchanged until the stop voltage and, therefore, the barrier height is accurately extracted based on the static SCC-FE process. Then, the sheet of Al2O3 charge is estimated as a function of bias voltage and, using the flat-band voltages obtained from the C-V characteristics, the sheet of charge at the Al2O3/substrate interface is given as a function of bias voltage. In this way, we compared the charged states of four kinds of Al2O3 deposited by varying the oxidant (H2O or O3) and the temperature (200 or 450 °C). This comparison was made for different substrates: Si, GaN and Ga2O3. The Al2O3 films on GaN and Ga2O3 have smaller barrier heights than those on Si but allow smaller leakage currents because of less Al2O3 positive charge. Despite a large leakage current, high-temperature H2O-grown Al2O3 is found to exhibit the highest bias stability, irrespective of the substrates, due to the excellent Al2O3/substrate-interface stability against biasing. Therefore, together with the longest dielectric-breakdown lifetime [3], this Al2O3 is the most promising insulator for high-reliability gate insulation and passivation.

This research is supported by the “Program for research and development of next-generation semiconductor to realize energy-saving society” of the Ministry of Education, Culture, Sports, Science and Technology, Japan.

The recombination of photoexcited carriers with electrons or holes bound to point defects results in many experimentally observed optical phenomena in wide gap systems, such as ultra-violet, yellow, green, and red luminescence in GaN. Such processes are usually explained with reference to a particular defect state and often such states are studied systematically via computational techniques. The balance between different defect states, however, which may be metastable but relevant in the time-scale of optical processes, is frequently omitted from such analysis. Here we study how different configurations of electrons and holes, whether bound to defects in well-localised 'compact' states, or in extended 'diffuse' states, can alter the observed luminescence in GaN. For our calculations we employ the hybrid quantum mechanical/molecular mechanical embedded cluster method, which offers advantages over more commonly-applied supercell-based techniques when modelling defects in wide gap materials. The analysis regarding the balance between compact and diffuse states, however, is not dependent on the computational technique we employ. Our results allow us to account for various photoluminescence peaks observed routinely in doped and nominally undoped GaN samples. In particular, we attribute the 3.46 eV and 3.26 eV ultraviolet emission peaks to nitrogen vacancies binding compact and diffuse holes respectively, and describe processes related to gallium vacancy complexes that result in yellow, green and red luminescence. We demonstrate that the competition between these differently bound carrier states is key to understanding the luminescence properties of GaN, a point that also has implications for wide gap oxides. Indeed, we show that taking into account the diffuse states associated with oxygen vacancies in In$_2$O$_3$, ZnO and SnO$_2$ helps explain the different intrinsic conductivity properties of these transparent conductors.

Impact of Neutron Irradiation on Deep Levels in Ge-Doped (010) β-Ga$_2$O$_3$ Layers Grown by Plasma-Assisted Molecular Beam Epitaxy Esfmat Farzana$^1$, Akhil Mauze$^2$, James S. Speck$^2$, Aaron R. Arehart$^1$ and Steven A. Ringel$^1$; $^1$The Ohio State University, Columbus, Ohio, United States; $^2$Materials Department, University of California, Santa Barbara, California, United States.

Monoclinic gallium sesquioxide ($\beta$-Ga$_2$O$_3$) belongs to the transparent semiconducting oxides. It is distinguished by its large band gap of about 4.7 eV, which is the reason for an optical transparency range extending deep into the ultraviolet and for a high electrical break down field estimated at 8 MV/cm. Combined with the feasibility of n-type doping by Sn, Si, or Ge, ($\beta$-Ga$_2$O$_3$) has great potential as a material for solar-blind photodetection and for power electronics where it might outperform GaN and SiC. To fully exploit the favorable properties of $\beta$-Ga$_2$O$_3$, single-crystalline material of high structural perfection and controlled electrical characteristics is a prerequisite. In particular, it is necessary to find out how the material can be doped in a controlled manner. Not only the selection of suitable dopants plays a role, but also the formation of compensating defects, including the introduction of unwanted impurities, must be understood.

Here we present a critical review of these doping issues. While p-type conduction might be impossible to be achieved due to intrinsic obstacles such as self-interstitials and holes of large effective hole mass, intentional n-type doping has to cover wider ranges, must be reproducible and thermally stable. In this context, we discuss own and recently reported results of temperature dependent Hall effect measurements, deep level transient spectroscopy, local vibrational mode spectroscopy, electron paramagnetic resonance spectroscopy, and electronic Raman scattering investigations. Silicon, germanium, and tin are revealed to be effective-mass-like shallow donors without any peculiarity such as DX behaviour. Compensation of shallow donors by gallium vacancies interacting with hydrogen is proposed as an alternative to other compensation mechanisms. In thick crystals grown from the melt additionally transition metal impurities must be taken into account as compensating acceptors. Furthermore, we show that the deterioration of n-type doping in epitaxially grown material may be due to extended defects rather than due to point defects and can be overcome under proper growth conditions. In cases of point defects, latest theoretical predictions of charge state transition levels and formation energies are compared with experimental values of energy levels and defect concentrations.
Interpreting the behaviour of all electronic devices, Herbert Kroemer coined the famous phrase “the interface is the device” in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with wide-bandgap materials being no exception. If anything, wide bandgap materials are more vulnerable to defect states purely due to their larger bandgap. Understanding gained for the bulk behaviour of semiconductors can often not be extended to the behaviour of materials in structured film stacks where interfaces play a vital role. SiC/SiO₂ is a prototypical wide-bandgap semiconductor/dielectric interface, which represents the challenges faced by many such material systems. A multitude of different defects leads to unacceptably large defect densities exceeding 10¹¹ cm⁻² eV⁻¹ in the vicinity of the conduction band of 4H-SiC. The management of interfacial defects still remains a topic of lively discussion and current interest. The main reasons for the ongoing struggle in understanding and controlling such defects lies in the lack of direct probes for chemical states at interfaces. Interfaces present a special challenge for physical characterisation techniques due to the spatial confinement of defects in a narrow region, the fact that by their nature interfaces are buried beneath a variety of overlayers, and the starkly different behaviour of chemical species at interfaces compared to surfaces and bulk. Advanced X-ray spectroscopy methods can tackle some of these issues, and X-ray Photoelectron Spectroscopy (XPS) in particular can deliver great insight into interfaces as it combines both qualitative and quantitative information on elemental distributions, chemical environments, and valence states.

Here, we present a systematic study of the 4H-SiC/SiO₂ interface in industrially manufactured samples with a particular focus on the effects of nitridation in a variety of atmospheres, to reduce interface defect states. Clear differences are found in both spectroscopy and electrical behaviour after high temperature treatments in N₂, NO, NH₃, and NO+NH₃ atmospheres. Si 2p, C 1s, O 1s, and N 1s core level spectra are analysed to give a complete picture of chemical environments present in the oxide and carbide layers as well as at the interface. Several species are found only at the interface providing insight into defect states and how they are compensated by nitridation. Mixed silicon oxy-carbides (SiOxCy) and oxynitrides (SiOxNy) as well as Si-C-N species from reaction of N with dangling C defects on the SiC side of the interface are identified. The findings from XPS are used to explain changes in the electrical behaviour of these device stacks.

Ultimately, the detailed understanding of advanced spectroscopy results in combination with electrical characterisation can be applied to a wide range of materials, particularly to wide- and ultra-wide-bandgap materials.

High-Resolution Observation of Defects at SiO₂/SiC Interfaces by Local Deep Level Transient Spectroscopy Based on Time-Resolved Scanning Nonlinear Dielectric Microscopy

Interface Chemistry and Electrical Characteristics of 4H-SiC/SiO₂ After Nitridation in Varying Atmospheres

Anna Regoutz1, Gregor Pobegen2 and Thomas Aichinger1; 1Imperial College London, London, United Kingdom; 2Kompetenzzentrum für Automobil- und Industrieelektronik GmbH, Villach, Austria; 2Infineon Technologies Austria AG, Villach, Austria.

Interfaces govern the behaviour of all electronic devices. Herbert Kroemer coined the famous phrase “the interface is the device” in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with wide-bandgap materials being no exception. If anything, wide bandgap materials are more vulnerable to defect states purely due to their larger bandgap. Understanding gained for the bulk behaviour of semiconductors can often not be extended to the behaviour of materials in structured film stacks where interfaces play a vital role. SiC/SiO₂ is a prototypical wide-bandgap semiconductor/dielectric interface, which represents the challenges faced by many such material systems. A multitude of different defects leads to unacceptably large defect densities exceeding 10¹¹ cm⁻² eV⁻¹ in the vicinity of the conduction band of 4H-SiC. The management of interfacial defects still remains a topic of lively discussion and current interest. The main reasons for the ongoing struggle in understanding and controlling such defects lies in the lack of direct probes for chemical states at interfaces. Interfaces present a special challenge for physical characterisation techniques due to the spatial confinement of defects in a narrow region, the fact that by their nature interfaces are buried beneath a variety of overlayers, and the starkly different behaviour of chemical species at interfaces compared to surfaces and bulk. Advanced X-ray spectroscopy methods can tackle some of these issues, and X-ray Photoelectron Spectroscopy (XPS) in particular can deliver great insight into interfaces as it combines both qualitative and quantitative information on elemental distributions, chemical environments, and valence states.

Clear differences are found in both spectroscopy and electrical behaviour after high temperature treatments in N₂, NO, NH₃, and NO+NH₃ atmospheres. Si 2p, C 1s, O 1s, and N 1s core level spectra are analysed to give a complete picture of chemical environments present in the oxide and carbide layers as well as at the interface. Several species are found only at the interface providing insight into defect states and how they are compensated by nitridation. Mixed silicon oxy-carbides (SiOxCy) and oxynitrides (SiOxNy) as well as Si-C-N species from reaction of N with dangling C defects on the SiC side of the interface are identified. The findings from XPS are used to explain changes in the electrical behaviour of these device stacks.

Ultimately, the detailed understanding of advanced spectroscopy results in combination with electrical characterisation can be applied to a wide range of materials, particularly to wide- and ultra-wide-bandgap materials.

High-Resolution Observation of Defects at SiO₂/SiC Interfaces by Local Deep Level Transient Spectroscopy Based on Time-Resolved Scanning Nonlinear Dielectric Microscopy

Interface Chemistry and Electrical Characteristics of 4H-SiC/SiO₂ After Nitridation in Varying Atmospheres

Anna Regoutz1, Gregor Pobegen2 and Thomas Aichinger1; 1Imperial College London, London, United Kingdom; 2Kompetenzzentrum für Automobil- und Industrieelektronik GmbH, Villach, Austria; 2Infineon Technologies Austria AG, Villach, Austria.

Interfaces govern the behaviour of all electronic devices. Herbert Kroemer coined the famous phrase “the interface is the device” in his 2000 Nobel Prize lecture, and we are still applying tremendous effort to understand interfaces in new material generations, with wide-bandgap materials being no exception. If anything, wide bandgap materials are more vulnerable to defect states purely due to their larger bandgap. Understanding gained for the bulk behaviour of semiconductors can often not be extended to the behaviour of materials in structured film stacks where interfaces play a vital role. SiC/SiO₂ is a prototypical wide-bandgap semiconductor/dielectric interface, which represents the challenges faced by many such material systems. A multitude of different defects leads to unacceptably large defect densities exceeding 10¹¹ cm⁻² eV⁻¹ in the vicinity of the conduction band of 4H-SiC. The management of interfacial defects still remains a topic of lively discussion and current interest. The main reasons for the ongoing struggle in understanding and controlling such defects lies in the lack of direct probes for chemical states at interfaces. Interfaces present a special challenge for physical characterisation techniques due to the spatial confinement of defects in a narrow region, the fact that by their nature interfaces are buried beneath a variety of overlayers, and the starkly different behaviour of chemical species at interfaces compared to surfaces and bulk. Advanced X-ray spectroscopy methods can tackle some of these issues, and X-ray Photoelectron Spectroscopy (XPS) in particular can deliver great insight into interfaces as it combines both qualitative and quantitative information on elemental distributions, chemical environments, and valence states.

Here, we present a systematic study of the 4H-SiC/SiO₂ interface in industrially manufactured samples with a particular focus on the effects of nitridation in a variety of atmospheres, to reduce interface defect states. Clear differences are found in both spectroscopy and electrical behaviour after high temperature treatments in N₂, NO, NH₃, and NO+NH₃ atmospheres. Si 2p, C 1s, O 1s, and N 1s core level spectra are analysed to give a complete picture of chemical environments present in the oxide and carbide layers as well as at the interface. Several species are found only at the interface providing insight into defect states and how they are compensated by nitridation. Mixed silicon oxy-carbides (SiOxCy) and oxynitrides (SiOxNy) as well as Si-C-N species from reaction of N with dangling C defects on the SiC side of the interface are identified. The findings from XPS are used to explain changes in the electrical behaviour of these device stacks.

Ultimately, the detailed understanding of advanced spectroscopy results in combination with electrical characterisation can be applied to a wide range of materials, particularly to wide- and ultra-wide-bandgap materials.

Recent Progresses in Deep Depletion Diamond MOSFET
Cedric Masante1, Toan Thanh Pham1, Nicolas Rouger2, Gauthier Chicot1, David Eon1, Etienne Gheeraert1, Daniel Araujo2 and Julien Pernot1; 1University Grenoble Alpes, CNRS, Grenoble INP, Institut Néel, Grenoble, France; 2Univ. Grenoble Alpes, CNRS, Grenoble INP G2Eah, Grenoble, France, Grenoble, France; 3Department of Engineering, The University of Cambridge, Cambridge, Cambridge, United Kingdom; 4Université de Toulouse; LAPLACE; CNRS; INPT; UPS, Toulouse, France; 5Dpto. Ciencia de los Materiales, Universidad de Cadiz, Cadiz, Spain.

Diamond is a fascinating semiconductor with exceptional physical properties such as a wide band gap, a high breakdown electric field (10 MV/cm), an outstanding thermal conductivity (20 W/cm/K) and high carrier mobilities. These exceptional properties, or more precisely, the combination of some of these properties makes diamond an ideal semiconductor for high power and/or high frequency electronics which should surpass other materials like silicon, silicon carbide or gallium nitride. Numerous diamond field effect transistors are under investigation: H-terminated accumulation FET, O-terminated inversion channel FET, metal-semiconductor FET and junction FET.

In this work, we propose a new transistor concept in order to exploit the full potentialities of diamond material. The deep depletions concept will be described and proposed for MOSFET devices. A proof of concept of deep depletion diamond MOSFETs will be presented. Finally, the recent progresses achieved in terms of device performances will be discussed.

High Frequency, High Voltage and Vertical Diamond MOSFETs Using Two-Dimensional Hole Gas
Hiroshi Kawarada1, Nobutaka Oi2, Shoichiro Imanishi1, Masayuki Iwataki1 and Atsushi Hiraiwa2; 1Waseda University, Tokyo, Japan.
2Universidad de Cadiz, Cadiz, Spain.

Low SBH for 2DHG:
Diamond has superior properties as p-type conducting compared with other wide bandgap semiconductors. Among them P-type Schottky barrier height (SBH) is very low (<0.1eV) on the hydrogen terminated (C-H) diamond surface in high work-function metal such as Au [1]. This property enables hole injection smoothly from metal to diamond subsurface when surface electron potential is high (surface band bends upward). It is realized by negatively charged surface or negative surface voltage bias. Then, 2 dimensional hole gas (2DHG) is produced by hole injection from metal. It is desirable for high speed FET operation [1].

High Frequency FET:
The first GHz operation in diamond [2] has been realized by metal semiconductor (MES) FET, where Au is used for source and drain contacts and Al for Schottky gate on the same C-H diamond surface. Al shows the SBH of 0.6 eV, because Al work function is lower than Au by 0.7 eV. The work function dependence of SBH indicates that C-H diamond surface has low surface states density, necessary for MOSFET. In addition to MESFET [3], MOSFETs [4,5] exhibited GHz operation up to 70 GHz [6] in fC (cutoff frequency) and >100GHz [3] in fmax. The power density is now 3.8 W/mm2 [7] at 1GHz obtained by high bias voltage (~50V). Its electric field is above 2×10^(5) V/cm, where the hole velocity is nearly saturated in an entire FET. The power density is lower than AlGaN/GaN HEMT, but higher voltage operation can enhance it much further.

High Voltage FET:
C-H diamond MOSFETs are uniquely designed for high-voltage (~1000V) and high-temperature (up to 400°C) operation using the high temperature (450°C) ALD Al2O3 as gate oxide and passivation of gate-drain (drift) region. The maximum breakdown voltages (Vbr) are above 1500 V [8] obtained at long drift region (Ld > 15 µm). Vbr/Ld is –1.0 MV/cm, which is equivalent to those of SiC MOSFET and AlGaN/GaN HEMT. The drain current density is comparable to SiC, but 3-4 times lower than AlGaN/GaN at similar Vbr. Conductivity in drift region must be improved by mobility enhancement.

Vertical FET:
The first vertical diamond MOSFETs have been developed using 2DHG layer on trench structure [9]. Hole conduction at the trench side wall (3-4 µm depth) acts as drift region and is electrically connected to p+ substrate (drain). The drain current density of active planar area has reached to 5000 A/cm^2 [10], which is comparable to those of SiC or GaN MOSFET. Specific on resistance is 5 mΩcm^2 at present.

The potential mechanisms for this performance enhancement and future implementation of these techniques to enhance the performance and robustness of the devices, further improving device performance. As a semiconductor, diamond possesses many unique properties that make it attractive for the production of high performance devices such as robust, high power RF FETs. Such properties include a large bandgap of 5.5 eV, high thermal conductivity of up to 20 W cm⁻¹ K⁻¹ and high carrier saturation velocity of 2 × 10⁷ cm s⁻¹ for electrons and 0.8 × 10⁷ cm s⁻¹ for holes. Development of electronic diamond devices has been largely limited however by the immaturity of existing doping processes used to introduce mobile charge into its naturally insulating crystal structure. ‘Transfer doping’ of hydrogen-terminated diamond (H-diamond) presents a potential solution to this challenge which has allowed for the production of high performance FETs. Stability issues associated with traditional transfer doping, which relies on the presence of atmospheric species on the diamond surface, has limited the maturity of device technologies that exploit these doping techniques. More recently, various work has demonstrated the potential to improve the stability and efficiency of transfer doping in diamond utilising electron acceptor oxide materials on the diamond surface. In this work, we apply the electron oxide acceptor material V2O5 into H-diamond FET technology and demonstrate substantial performance improvement in comparison with traditional atmosphere-exposed devices. These performance figures include the highest reported drain current and transconductance for a H-diamond FET to incorporate an electron acceptor oxide such as V2O5. Furthermore, a 400°C anneal stage utilised in the process flow for devices (as required to ensure stability of the V2O5 layer) is also found to reduce the ohmic contact resistance and increase the carrier concentration beneath the gate of the devices, further improving device performance. The potential mechanisms for this performance enhancement and future implementation of these techniques to enhance the performance and robust operation of H-diamond FET technology will be discussed. Higher power, higher frequency RF transistors than those possible using the III-nitride semiconductors are desired for large data (high bandwidth) information transmission, highly advanced radar detection, and more efficient communication. We are developing hydrogenated diamond surface conduction field effect transistors (FETs) for use in these next generation RF systems accessing diamond’s wide bandgap (5.47 eV) extremely high thermal conductivity (> 20 W/cm) and impressive breakdown field (10 MV/cm). Our latest unpассивated, atmospheric transfer doped FETs have maintained high current density performance (up to 700 mA/mm at 10 V) with occasional testing over an 8 month period indicating very limited degradation in an indoor environment and the ability to maintain DC operation powers of ~ 7 W/mm. Optimising RF surface channel FETs is most effectively done using device physics information obtained directly from the same device that the RF measurements are made on. This best connects the influence of material, fabrication steps and structure on performance. In this regard, we obtained the hole velocity in the FET channel using a delay time measurement and this is we believe the first ever discussion of velocity obtained in this way applied directly on a diamond RF FET. This will be related to carrier density and effective mobility obtained from RF FETs. RF small signal characteristics (current and power gain cutoff frequencies (Ft, Fmx)) and large signal characteristics (power, gain and efficiency) from load pull measurements will also be discussed for the same devices. Transit time values obtained from a delay time measurement indicates these FETs have a hole velocity in the channel = 5 × 10⁷ cm/s and drain depletion region delay = 2.5 ps. On wafer RF measurements for intrinsic current gain cutoff frequency indicate an opposite trend with gate length of Ft = 70 GHz (Lg = 50 nm), 49 GHz, (100 nm), and 10 GHz, (500 nm) when Vds = 10V. With improved contact and access region resistances we expect the frequency bandwidth to increase. Load pull measurements indicate RF output power densities increased 30% as the drain and gate bias voltage pulse spacing increased (a duty cycle reduction from 5% to 0.5%) suggesting that RF output power is affected by heating of the transfer dopant in unpassedivated FETs. These measurements also demonstrate a peak RF output power density of 0.66 W/mm at 2 GHz. We have also observed that the Schottky barrier heights for the atmospheric transfer doped devices with good gate control are over 0.38 eV and range up to 0.63 eV, however, the ideality factor is quite high (between 1.5 and 7.3). This may be an indication of the roughness of the surface and challenge contacting a hydrogenated region that the gate finger metal sits on. As the gate length reduced from 3 micron down to 50 nm the FET current density increased six fold, and knee voltage reduced uniformly by 50%.
A diamond semiconductor with a bandgap of 5.47 eV is expected to be the ultimate power device because of its exceptional physical properties, such as a high breakdown field (>10 MV/cm), high mobility, and highest thermal conductivity [20 W/(cm K)]. We previously reported high radio-frequency (RF) power performance of diamond field-effect transistors with a power-gain cutoff frequency $f_	ext{MAX}$ of 120 GHz and an RF output power of 2.1 W/mm at 1 GHz. In this talk, we focus on very recent progress in two basic technologies related to diamond electronics: wafer technology and carrier doping technology.

To overcome the size limitation of diamond crystals, diamond heteroepitaxy technology has progressed rapidly. A 1-inch heteroepitaxial diamond has been demonstrated. In heteroepitaxy, epitaxial overgrowth technology is used to drastically decrease the dislocation density. Furthermore, micromechanics technology has been proposed and demonstrated as a method to delaminate heteroepitaxial diamond from its substrate without cracking. [1] In the final process of heteroepitaxy technology, chemical mechanical planarization of the heteroepitaxial diamond surface is important for obtaining a damage-free and smooth surface. The full-width at half-maximum of the (004) plane was as low as 0.03°, and the curvature was 0.29 m, indicating the world’s highest quality heteroepitaxial diamond. The size and quality of diamond crystals is improving. We have fabricated diamond field-effect transistors on heteroepitaxial diamond, and the resultant device shows the same drain-current level as conventional homoepitaxial diamond on a HPHT substrate.

Concerning carrier doping technology in diamond, Kubovc and Kasu previously reported NO$_2$ p-type doping, which they used to fabricate FETs; that is, NO$_2$, O$_2$, NO, and SO$_2$ molecules adsorbed onto H-diamond generated hole carriers and the hole sheet concentration was as high as $1 \times 10^{14}$ cm$^{-2}$ at room temperature. [2] Shiraishi and Kasu explained this phenomenon as the LUMO/SOMO orbital energies in the inorganic molecules adsorbed onto H-diamond being below the valence-band top of H-diamond, resulting in electron transfer from H-diamond to these molecules. Recently, Geis and Wade at the Massachusetts Institute of Technology investigated the NO$_2$–H-diamond surface further by surface chemical techniques such as Fourier transform infrared spectroscopy and elucidated the surface reaction and states. Their reports surprisingly agree with our previous findings. Recently, we used synchrotron X-ray photoelectron spectroscopy/X-ray absorption near-edge spectroscopy and capacitance and conductance measurements to determine the energy band diagram and found oxygen-related states and boundary states in the metal-oxide-semiconductor interface.

Transfer doping of hydrogen terminated diamond (Diamond:H) with various molecular-like surface acceptors suffers from low efficiency and temperature instability. In contrast, high electron affinity transition-metal oxides (TMOs) (i.e. MoO$_3$, WO$_3$, V$_2$O$_5$ and ReO$_3$), when employed as surface acceptors for transfer doping on Diamond:H, have recently yielded improved p-type sheet conductivity and remarkable thermal stability even with only a few monolayers of coverage. [4]. Despite these properties, the realization of Diamond:H electronic devices using TMOs remains very challenging. [8]. This is due to undesirable changes in the physical and electronic characteristics of the TMO caused by the device fabrication process. In particular, stoichiometry reduction, crystalline phase transitions and structural morphology aggregations take place.

In this work, we will discuss how different TMOs’ physical parameters affect the electrical properties of the resulting diamond:H/TMO-based transistors, and how these undesirable effects can be minimized. Electrical and surface characterization monitored before and after transistor fabrication reveal TMO oxygen reduction and a change in its oxidation state leading to electrical conductivity degradation. Based on these findings, we propose and demonstrate a way to improve diamond:H/TMO transistor performance and stability.

H-terminated diamond with 2 dimensional hole gas (2DHG) provides a promising surface channel for high-power and high-frequency applications due to its excellent properties for FETs. From 2001, mile stones of RF performance of diamond FETs are first GHz operation in MESFETs [1], MISFETs with cutoff frequency ($f_c$) > 20 GHz [2], high power density > 2.0 W/mm [3], maximum oscillating frequency ($f_	ext{MAX}$) > 100 GHz [4] and $f_c$ > 50GHz [5]. Particularly, the power density of diamond FETs (up to 2.2 W/mm) [3, 6] is higher than that of GaAs and LDMOS. However, the operating voltage was as low as 15 ~ 20 V because of low breakdown voltage. Power density would be much more improved by realizing high voltage operation. Recently, we reported high average electric field [7] in MOSFETs with Al$_2$O$_3$ deposited as gate insulator [6, 8] and passivation layer [9] by high temperature atomic layer deposition (ALD) [10]. In this work, we fabricated ALD-Al$_2$O$_3$ 2DHG diamond MOSFETs, whose structure is capable of withstand high voltage, and evaluated small signal and large signal performance at high voltage operation ($|V_{DS}| \leq 60$ V). As a result, the highest power density of 3.8 W/mm was obtained in diamond.

We fabricated ALD-Al$_2$O$_3$ 2DHG diamond MOSFETs with 100 nm Al$_2$O$_3$ film on Ilα-type polycrystalline diamond substrate with a <110> preferential growth surface. The source-gate length, gate length ($L_G$) and gate width were fixed to 0.5, 0.5 and 100 μm, respectively and gate-drain length ($L_{GD}$) was ranged from 1 to 3 μm.

The drain current density ($I_{DS}$) was 730 mA/mm at $V_{GS} = -20$ V and $V_{DS} = -40$ V and the transconductance was 15 mS/mm at $V_{GS} = 12$ V and $V_{DS} = -40$ V for $L_{GD} = 1$ μm. Extrinsic $f_t$ and $f_{MAX}$, including parasitic pad capacitances and inductances, were 30 GHz and 27 GHz at $V_{GS} = 16$ V and $V_{DS} = -60$ V.
for $L_{CD} = 3 \mu m$, $f_1 = 30 \text{ GHz}$ @ $L_d = 0.5 \mu m$ corresponds the saturation velocity of $1 \times 10^7 \text{ cm/s}$. It is the first report that diamond FET reaches its saturation velocity. The large signal performance was evaluated using load pull system. The large signal performance was evaluated using load pull system. The large signal performance was evaluated using load pull system. The large signal performance was evaluated using load pull system. The large signal performance was evaluated using load pull system.

Heteroepitaxial Diamond—Scaling of an Ultra-Wide-Bandgap Material to Wafer Dimensions Matthias Schreck\textsuperscript{1}, Stefan Gsell\textsuperscript{2}, Martin Fischer\textsuperscript{2}, Michael Mayr\textsuperscript{3} and Björn-Christoph Gallheber\textsuperscript{4}; \textsuperscript{1}University of Augsburg, Augsburg, Germany; \textsuperscript{2}Augsburg Diamond Technology GmbH, Augsburg, Germany.

In the field of power devices, diamond’s intrinsic physical properties suggest that they can facilitate ultimate device performance. Just as for other wide-bandgap materials, the availability of wafer-size diamond substrates with high single crystal quality is an indispensable prerequisite. There are two approaches which start from opposite points: First, homoepitaxial growth on carefully selected rather small single crystals with minimum dislocation densities can be performed in such a way that the available area is increased step by step while the dislocation density is kept low. By a similar approach, 4H-SiC has progressively been scaled over 20 years starting from small Acheson platelets to 6” wafer size \cite{1}. The second alternative is based on heteroepitaxy which starts on large areas but with high dislocation densities (DDs). The challenge here consists in a controlled decrease of the DD by several orders of magnitude while preserving the initial size. This presentation is focused on heteroepitaxy of diamond on Ir/YSZ/Si(001) which has recently provided the first single-crystal diamond wafer with a diameter $> 3.5”$ and a total weight of 155 carat \cite{2}. All relevant steps for the wafer preparation will be described. First applications of the material will be presented and the potential for further applications will be discussed.

Engineering Doped Single Crystal Diamond Films for Electronic and Quantum Applications Jocelyn Achar\textsuperscript{1}, Riadh Issaoui\textsuperscript{1}, Alexandre Tallaire\textsuperscript{1, 2}, Ovidiu Brinza\textsuperscript{2}, Vianney Mille\textsuperscript{2}, Audrey Valentin\textsuperscript{2}, André Tardieu\textsuperscript{2} and Fabien Bénédic\textsuperscript{2}; \textsuperscript{1}LSPM-CNRS, Villetaneuse, France; \textsuperscript{2}IRCP - Ecole Nationale Supérieure de Chimie de Paris, Paris, France.

Diamond is a transparent wide band gap material with outstanding optical and electronic properties that are attracting a lot of attention for the development of the next generation of devices. Indeed single crystal diamond provides an ideal host material to incorporate different types of impurities that can drastically modify its properties. The use of dopants such as boron can for example allow tuning the electrical conductivity of the film up to the metallic. Concerning the schottky barrier diodes (SBDs) on heteroepitaxial diamond (001) films, the specific on-resistance of 0.2 Ω-cm$^2$ and high rectification of
10^6 (±5 V) were obtained which are comparable for SBDs on homoepitaxial diamond films. The sensor devices using nitrogen-vacancy (NV) centers were formed in the heteroepitaxial diamond (111) films. The NV centers could be preferentially aligned of the NV axis to the one direction and be leading to improving the sensitivity was confirmed. This work was supported in part by JST-CREST Grant No. JPMJCR1333, KAKENHI (17H01262 and 18H01472), and JSPS Bilateral Open Partnership Joint Research Projects.

Diamond’s extreme properties make it a prime candidate for next-gen electronic devices, including high frequency and high power operation. While monolithic diamond devices based on doped monocrystalline layers, enabling both unipolar as well as bipolar design schemes, have great potential, the currently obtainable substrate size and quality leave several years of scientific and technological development. The fact that diamond has an extremely high thermal conductivity and can be deposited on non-diamond substrates, opens up an intermediate pathway for hybrid power devices that integrate diamond with other wide bandgap materials such as SiC or GaN. The main goal in such cases is to achieve an enhanced reliability of the latter active materials by providing superior cooling minimizing thermal hotspots and withstanding large break down electric fields.

Here, the case of diamond on GaN-based HEMT structures is considered. First, the deposition of thin CVD diamond layers will be discussed, including the surface chemistry governing the nanodiamond particle seeding, the deposition conditions, and the use of different microwave-based CVD techniques, including resonant cavity and linear antenna technology. Cross-sectional TEM and EELS mapping of the stacks are employed to discuss the structural and morphological properties and to extract possible changes in composition in the underlying Si/N/AlGaN/GaN interfacial layers induced by the substrate temperature during diamond deposition. Finally, the evaluation of the effective thermal conductivity of the thin diamond layers is discussed. The contactless transient thermoreflectance technique, used to study the heat spreading capabilities, shed light on the thermal conductivity and interfacial thermal boundary resistance.

Semiconducting diamond is an attractive candidate for the next generation of high voltage and high frequency power devices, thanks to his exceptional properties in terms of wide bandgap, high breakdown field and thermal conductivity. In the literature, several diamond-based field-effect-transistors (FETs) have already revealed good on state performance and high blocking voltage capability (~2kV) in a wide range of operating temperatures. The possibility of generating an inversion regime in diamond metal-oxide-semiconductor FET (MOSFET), and the new Deep Depletion regime (D2MOSFET) specific to wide bandgap semiconductors pave the way for a new generation of power devices. The critical part of the transistor is the gate oxide, with electrical charge traps located within the oxide or at its interface with the semiconductor. These traps can screen the gate potential and shift the threshold voltage, making the devices unusable. The reduction of the trap density is a major concern in all MOS technologies, as well as its stability with time under bias stress. The latest results about diamond MOS transistors prepared in the framework of the European GreenDiamond project will be presented, and the evolution of the diamond MOS properties with time will be reported for the first time.

The properties of diamond (high mobilities and ultra-gap) suggest different current transport modes that can support high current operation which is sustained and actually improved at high temperatures. This study presents experimental results of forward current density vs voltage which shows a V^2 dependence indicative of injection mode transport. The Schottky-PIN devices show high values of forward current density (> 500A/cm^2 at 3 V) that is stable and actually improves at elevated temperature. Perhaps the most stunning aspect of these results is that the diode specific on-resistance (RonS) decreases as the voltage increases. The results indicate a new mode of operation of high mobility diamond power devices where the high carrier mobilities and low phonon scattering will support current injection and drift with a reducing resistance as the current is increased. We present a comparison between diodes that operate in injection mode and the more conventional doped drift layer. We discuss modifications of the standard power electronics figure of merit for projecting the operation of diamond devices that operate in the injection transport mode. This research is supported through the NASA HOTTECH program.

Diamond Power Electronics—Drift Layer Doping vs Injection Mode Transport Robert J. Nemanich, Raghuraj Hathwar, Manpuneet Benipal, Franz A. Koeck, Mohamad Ali Malikoustian, Srabanti Chowdhury and Stephen M. Goodnick; 1Arizona State University, Tempe, Arizona, United States; 2Advent Diamond, Tempe, Arizona, United States; 3University of California - Davis, Davis, California, United States.
AlGaN+As channel high electron mobility transistors (HEMTs) are ideal for high-temperature/voltage/power applications. Their increased breakdown field and thermal conductivity with Al-alloy composition, leads to a much higher Baliga Figure of Merit [1]. We have recently reported on AlGaN+As channel MESFETs [2][3]. Polarization Doped FETs (PDFETs) [4] and high electron mobility transistors (HEMTs) [5] grown on low-defect AlN/sapphire templates. For these devices the channel electron mobility was a strong function of the Al-composition and decreased with higher doping. Thus, for the lowest channel sheet resistance, an undoped heterojunction FET (HFET) is the preferred device design. However, this design, makes the ohmic-contact formation very challenging leading to a contact resistivity well over 20 $\Omega\cdot$mm. Doping the barrier to reduce the contact resistivity leads to excessive gate-leakage currents. These limitations, till recently, the limited the highest demonstrated currents in undoped AlGaN+As HFETs to 0.1-0.3 A/mm. Now, our group has explored a new doped barrier high-Al channel HFET design with PECVD SiO2 and ALD TiO2 as gate-insulators to reduce the leakage current [6]. For these n-AlxGa1-xN, n=0.45 AlxGa1-xN MOSHFETs perfectly linear ohmic contacts were achieved with a resistivity as low as 1.6 $\Omega\cdot$mm. A record peak current as high as 0.6 A/mm was measured for devices with a gate-length of 1.75 $\mu$m in a 6 $\mu$m source-drain opening. In addition, the gate-leakage currents at room-temperature were four orders of magnitude lower than Schottky-gate devices. The ON/OFF current ratio which was more than 107 at room-temperature, remains as high as 108 for operation up to 250 $^\circ$C. Using temperature-dependent $I_{DS}$-$V_{DS}$ and ($C_{GS}$-$V_{GS}$) characteristics, we show $n_t$ to be ($1\times10^{13}$ cm$^{-2}$) and nearly temperature independent. The room temperature mobility was around 430 cm$^2$/V-s and decreased with increasing temperature and $n_t$. These mobility values were considerably higher than those predicted by the theoretical model in [7]. We believe the discrepancy to be from a smaller contribution of alloy scattering than the one used in the model of reference 7. In this paper we will present the detailed results of the comparative study of AlGaN channel MOSHFETs with PECVD SiO2 and ALD TiO2 and ZrO2 gate-insulators. Initial results of a comparative study of breakdown voltages for passivated and un-passivated devices will also be discussed.

We gratefully acknowledge the support from the DARPA-DREAM program (ONR Contract N00014-18-1-2033, Program Manager Dr. Paul Maki). Many thanks to Virginia Wheeler and Charles Eddy for the AlD oxide depositions.

Reverse-Bias-Induced Virtual Gate Phenomenon in N-Polar GaN HEMTs Takayuki Saenituka, Kiattivut Prasertsak1-3, Tomoyuki Tanikawa2, Takeshi Kimura2, Shigei Kudo2 and Takashi Matsuo3; 1Center for Innovative Integrated Electronic Systems, Tohoku University, Sendai, Japan; 2Institute for Materials Research, Tohoku University, Sendai, Japan; 3Thai Microelectronics Center, National Electronic and Computer Technology Center, Chachoengsao, Thailand.

N-polar GaN high-electron-mobility transistors (HEMTs) are a promising candidate for high-frequency power transistors for millimeter-wave and beyond because of its stronger carrier confinement by the natural back-barrier and its potential to achieve lower ohmic resistance by means of the direct contact between the GaN channel and ohmic electrodes in comparison with conventional Ga-polar HEMTs. A grand challenge in N-polar GaN HEMTs is to achieve a high-performance and highly-stable MIS (metal-insulator-semiconductor) gate structure because Schottky gates suffer from a large gate leakage current due to the low barrier height and a large background charges by oxygen impurities in the GaN channel layer so far. In Ga-polar GaN HEMTs, a reverse bias annealing (RBA) is reported as an effective approach to stabilize the MIS interface and to reduce anomalous behaviors such as hysteresis in the current-voltage and capacitance-voltage characteristics. We confirmed, however, that RBA causes a significant decrease in the maximum drain current density and the transconductance in N-polar GaN HEMTs which were not observed in Ga-polar counterparts. In this study, in order to understand the physics behind such a difference between Ga- and N-polar GaN HEMTs, a 2D numerical analysis was performed to calculate the potential profiles inside the devices.

The device structure of the N-polar GaN HEMTs consists of a 30-nm-thick GaN channel, a 25-nm-thick AlGaN barrier with an Al mole fraction of 0.32, and a 2-μm-thick GaN buffer on a 0.8°-offcut sapphire substrate from top to bottom. For comparison, the Ga-polar GaN HEMTs consisting of a 7.7-nm-thick AlGaN barrier with an Al mole fraction of 0.33, a 1-nm-thick AlN spacer, and a 2-μm-thick GaN channel/buffer on a sapphire substrate are also prepared. For both samples, a 10-nm-thick SiN is utilized as a gate dielectric film. The gate length and width are 10 and 50 μm, respectively. RBA was performed at 200°C for 1 h with a negative gate bias voltage of ~10 V. The source and drain electrodes were grounded during RBA. The 2D analysis of the potential profile inside the devices revealed that the electrons injected from the gate electrode are able to accumulate near the SiN/GaN interface at the access region adjacent to the gate electrode in the N-polar GaN HEMTs. This could cause the electron trapping in deep levels at the SiN/GaN interface and the resulting negative charges of the trapped electrons act as a virtual gate to increase the access resistance of HEMTs. In contrast, in Ga-polar GaN HEMTs, the AlGaN barrier layer prevent electrons from accumulating near the SiN/GaN interface. Based on this finding, an AlGaN cap layer on the GaN channel could be a possible way to minimize such a RBA-induced virtual gate phenomenon and to achieve more stable N-polar GaN HEMTs. This work is partly supported by the funding from JSPS KAKENHI JP16H04341.

Investigation on the Trap States at p-GaN MIS (Insulator) Interface with Different Gate Dielectric Layers Liwen Sang; NIMS, Tsukuba, Japan.

Recent progresses in the GaN-based electronic devices have demonstrated them as excellent candidates for the high power supply and switching systems, due to their unique characteristics, such as the high blocking voltage, wide bandgap, large electron saturation velocity and high thermal stability. Compared to Si-based electronic devices, higher output currents can be achieved at higher frequencies by using GaN system. To fulfill the potential of GaN electronic devices, integration of GaN power devices and their gate driving circuits is needed to minimize the chip-to-chip parasitic inductance, thus reduce the switching loss, ringing and reliability issues. Monolithic complementary metal-oxide (insulator)-semiconductor (MOS) transistors with both n-channel and p-channel for the integrated circuits is desirable to ultimately reduce the power consumption. However, the development of p-channel field effect transistors (FETs) is still in its infancy in comparison to the n-channel ones. Recently, our group has achieved p-channel MOSFETs based on polarization induced two dimensional hole gas at the InGaAs/GaN heterojunctions. It is found that the performance of p-channel FET was restricted by the poor-quality p-GaN MOS interface. As a result of Mg accumulation to the p-GaN surface, a large surface band bending of 1.2-1.6 eV was observed for the native p-GaN, which lead to in an interfacial Mg-Ga-O disordered region with high-density trap states on the order of 1013 cm-2 using Al2O3 gate dielectric layer. The high-density traps resulted in the serious electrical hysteresis in both current-voltage (I-V) and capacitance-voltage (C-V) characteristic, bringing about the threshold voltage instability. The surface pre-treatment could not effectively remove the surface oxides on p-GaN as a result of re-oxidation in the following atomic-layer deposition process for Al2O3. Therefore, to ultimately enhance the performance and stability of p-channel FETs, proper oxygen-free gate dielectric layer and high-quality p-GaN MIS interface with lower interface state density and less trapping states is in great demand. In this paper, we investigated the p-GaN MIS and MOS capacitors with different gate dielectric layer such as CaF2, SiN, SiO2, and Al2O3. The interface quality and traps behaviors are evaluated with regard to the microstructure and electrical characteristics. The oxide and oxygen-free gate dielectric layers were compared for the performance of p-GaN electronic devices.

Hyperspectral Quantum Rod Thermal Imaging of GaN Electronic Devices Bahar Oner, James W. Pomeroy, Serge Karboyan and Martin Kuball; University of Bristol, Bristol, United Kingdom.

The peak junction temperature in electronic devices is a key parameter in determining the mean time to failure (MTTF). However, accurate temperature measurements becomes increasingly more challenging as devices are miniaturised and operating power densities increase, generating large temperature gradients on the sub-micron length-scale. Existing thermography methods either have limitations in spatial resolution, e.g., IR thermography, or require time consuming complex calibration and specialised equipment, e.g., Raman thermography, transient thermoreflectance or SThM. There is a clear need for high resolution, fast, simple and low cost thermal imaging technique. To address this, we have developed a high spatial resolution and cost-effective thermography technique, Hyperspectral Quantum Rod Thermal Imaging (HQTI), demonstrated on GaN high electron mobility transistors (HEMTs), with sub-micrometer spatial resolution.
The technique exploits the temperature dependent emission wavelength of nanoparticles, i.e. quantum rods or dots deposited onto the device under test, using a low cost hyperspectral camera. Quantum dots/rods are ideal temperature sensors for this application because they have low thermal mass and surface area, quickly reaching thermal equilibrium with the surface. Core/shell nanoparticles also have a high quantum efficiency and bright emission, enabling short image acquisition times. Temperature images are obtained by imaging the nanoparticle emission wavelength in the unbiased (reference) state and biased (on) state, and applying the known emission wavelength temperature dependence of the particles used. In this way the measurement is generic and does not require any re-calibration when the particles are deposited onto different materials.

The HQTI technique has been applied to GaN HEMTs for demonstration; a technology where high temperature gradients are generated in the channel region due to the localised high power dissipation density. An optical resolution of ~0.6 μm has been achieved using an 0.5 numerical aperture objective lens and temperature resolution of ~2°C, which can be further improved by numerical image processing techniques. Measured temperatures were within ~15% of a three dimensional finite element model. In comparison, the temperature was underestimated by ~50% using the lower resolution IR thermography method. This new generic measurement technique is expected to be a step-changing characterisation tool not only for micro-electronic devices, but also for any other micro/nano scale thermal measurement applications, such as biomedical devices and nanocomposites.

Point Defect Management in Ultra-Wide Bandgap Materials Zlatko Sitar1, 2, Pramod Reddy2 and Ramon Collazo1, 3, North Carolina State University, Raleigh, North Carolina, United States; 2Adroit Materials, Apex, North Carolina, United States.

Achieving control of electrical conductivity in n- and p-AlGaN over all doping levels of interest has proven to be challenging. AlGaN exhibits a decrease in free carrier concentration as the dopant concentration increases above a critical doping concentration. This behavior is attributed to the formation of compensating defects due to lowering of their formation energy during doping. These compensators also contribute to impurity scattering, limiting the carrier mobility.

A novel scheme to control point defects in wide bandgap semiconductors is presented. The scheme uses above bandgap UV-illumination to change the position of the quasi Fermi levels in a semiconductor, and, thus, increase the formation energy of compensating defects leading to a decrease in incorporation. Using AlGaN as a model system, we demonstrated that over an order of magnitude improvement in the electrical properties could be achieved in these materials by using this scheme for controlling the incorporation of point defects.

In n- and p-doped AlGaN films grown by MOCVD, point defects such as hydrogen, carbon, nitrogen or metal vacancies and their corresponding complexes lead to dopant compensation, resulting in a high resistivity and a low mobility in these films. Generally, the energy of formation of a point defect is a function of the process conditions, as described by the chemical potentials of the species involved. In addition, the energy of formation of charged point defects is also a function of the Fermi energy, or the electrochemical potential. We have developed a non-equilibrium process scheme in which the Fermi level is controlled by external excitation in a steady-state condition. We introduce above-bandgap illumination as the excitation source for enhancing the doping capabilities, by controlling the energetics of point defects via Fermi level control during growth. This presentation will focus on the details of the theoretical background and related calculations. In addition, the discussion will also focus on the used experimental setup and influence of UV-light on the growth condition and possible gas-phase interaction. The proposed point defect control scheme is of great interest for all semiconductors in which compensation is the main limiting factor in obtaining the desired free carrier concentrations and conductivity.

11:00 AM EP08.08.09
Impact of Ge Doping on Growth Stress and Dislocation Microstructure in AlGaN Anushka Bansal and Joan M. Redwing; The Pennsylvania State University, University Park, Pennsylvania, United States.

Intentional n-type doping of AlGaN,N has been widely studied given its critical role in light-emitting diodes and ultra-wide bandgap devices. Silicon has been the most intensively investigated donor in AlGaN,N since it enables low resistance n-type films, however, Si doping induces bending of edge-type threading dislocations which generates tensile stress and cracking with increasing film thickness. Germanium (Ge) has been investigated as an alternative to Si for n-type doping of GaN. Its impact on dislocation inclination and film stress, however, is unclear particularly for the growth of AlGaN,N alloys. In this study, we employ in-situ wafer curvature measurements combined with post-growth structural and electrical characterization to investigate the impact of Ge doping on film stress and doping efficiency in AlGaN,N (x=0.0-0.51) layers grown by metalorganic chemical vapor deposition (MOCVD) as compared to Si doping.

AlGaN,N layers were grown on semi-insulating Si-face (0001) 6H-SiC substrates in a vertical cold wall MOCVD reactor equipped with in-situ wafer curvature measurements. The precursors used for growth and doping included trimethylaluminum, trimethylgallium, NH3, SiH4 and GeH4. Growth of AlGaN,N was carried out at 1150°C and 100 Torr reactor pressure using a thin (~90 nm) AlN buffer layer. SiH4/group III inlet ratio of 2 x 10−3 resulted in an electron concentration of ~8.2 x 1010 cm−3 for Si doping while a GeH4/group III ratio of 0.5 was required to achieve a similar Ge doping level. The film microstructure was investigated on cross-sectional samples using bright field imaging and [110] and [0002] weak-beam dark-field imaging. High resolution X-Ray Diffractionmetry (HRXRD) in a triple-axis geometry was used to measure the film composition and threading dislocation density. Room temperature (RT) Hall measurements were used to measure the carrier concentration and mobility of Ge doped AlGaN,N layers.

In-situ wafer curvature measurements employed during growth provided information on the evolution of film stress with doping. It was observed that Ge doping does not induce additional tensile stress into the film in contrast to Si doping. This is consistent with the inclination angle of the edge dislocations which was measured to be 6.9° and 7.5° for undoped and Ge doped Alx50Ga50,N,N films, respectively, indicating only a minor change in dislocation bending with doping. The electron concentration decreased a small amount going from GaN to AlGaN,N (x=0.21-0.41). However, at x=0.51, the resistivity increased by a factor of 40, and the electron concentration decreased sharply consistent with theoretical predictions of the onset of DX centers in Ge doped high Al content AlGaN,N.

The results demonstrate that Ge is a viable n-type dopant for AlGaN,N (x=0.5) enabling the growth of highly doped, low resistivity layers without significant modification of film stress.

11:15 AM EP08.08.09
Heteroepitaxy of Thick GaN on Si and Improvement of Electrical/Material Characteristics by Defect Annihilation Atsunori Tanaka, Woojin Choi, Renjie Chen, Ren Liu and Shadi Dayeh; Univ of California-San Diego, La Jolla, California, United States.

A major challenge in vertical power devices in GaN and other large bandgap materials is the high defect density that compromises the performance, reliability and yield. We are developing selective area growth approaches that have successfully reduced the densities of these defects on scalable and cheap substrates to a comparable level of native substrates. With these new approaches to material growth, we are able to demonstrate devices whose performance correlates well with the improved material quality. Our choice of material for studying these growth approaches is GaN that while have been extensively studied for decades suffer from large defect densities on large-scale commercially viable Si substrates. Recently, bulk GaN crystal growth techniques such as Na-flux, Hydride Vapor Phase Epitaxy and ammonothermal methods have been developed and, homoepitaxial vertical GaN devices have made it possible to achieve thick drift layers and low dislocation densities but at significant cost. Issues of reliability and uniformity over large areas
Boron containing GaN and AlN materials constitute emerging members of the III-Nitrides alloy family. They are candidate materials for a number of technological applications such as a back barrier in AlGaN/GaN high electron mobility transistors or to achieve lattice matched InGaN layers to SiC or GaN. However, a major challenge towards exploiting the full potential of B containing III-Nitride alloys is the limited B incorporation. More specifically, the B bulk solubility does not exceed 2% and 3% in GaN and AlN at 1000 °C, respectively. A potential route to overcome the limit set by bulk solubility is to employ surface engineering. Surface break the bulk translational symmetry, offer efficient strain relaxation and may provide different coordination and rehybridization than bulk [1]. The key idea underlying surface engineering is to employ surface structures with compositions higher than the bulk solubility limit which are kinetically stable and do not change their composition when overgrown. Therefore, understanding the atomistic mechanisms at surfaces is a prerequisite to fully control the composition of epitaxially grown alloys.

In the present work a potential route to achieve B contents well above the bulk solubility limit is investigated and identified. We employ total energy and force calculations within density functional theory (DFT). Specifically, we investigate the effect of surfaces on the properties and composition of epitaxially grown BGaN and BAlN alloys. In total more than 200 different B containing and B free surface structures have been implemented. Based on these calculations phase diagrams for both BGaN and BAlN surfaces are derived. These diagrams reveal that under typical MOCVD growth conditions as high as 25%. Furthermore, an interesting outcome is that ordering in the form of 2×2 and 2√3×2√3R30o patterns is introduced at the surface. Based on the aforementioned calculations we will present and discuss in detail the physics governing the above mentioned mechanism. Specifically, we will elaborate on RHEED and/or HRTEM fingerprints of B induced ordering as well as possible routes to optimize the growth of BGaN and BAlN alloys with high B content.

The emerging class of ultra-wide bandgap semiconductor (UWBGS) materials, including AlN, diamond, GaO₃, and cubic BN, have been of recent interest to electron device developers because of their desirable ability to withstand high electric fields. Despite numerous experimental demonstrations of this breakthrough strength, UWBGS materials still generally suffer from the fundamental challenge of being able to get large densities of mobile carriers into their conduction or valence bands. In cases where impurity doping is possible, there is typically only one impurity type (donor or acceptor) with small ionization energy in the material system, and this prevents or limits bipolar device realization.

Given the difficulties associated with impurity doping in UWBGS materials, our team has been investigating the epitaxial integration of lattice-matched crystalline conductors and superconductors to replace heavily doped semiconductor layers in device heterostructures. To accomplish this task, we have used an RF plasma-assisted molecular beam epitaxy system equipped with an electron beam evaporator source to study the thin film growth of single crystal transition metal nitride (TMN) materials, such as NbN, and TaN, and their integration with AlN and GaN. Cross-sectional transmission electron microscopy shows that TMN/III-N interfaces are atomically abrupt with no evidence of interdiffusion of the host elements. We anticipate that the device applications of these metallic films are quite broad ranging from selective etching of sacrificial layers for epitaxial lift-off of processed III-N devices, to buried metallic or superconducting electrodes for Josephson junction devices, to optical mirrors and waveguides for improved optoelectronics. This talk will present our recent work involving TMN development and applications that will enhance wide and ultra-wide bandgap semiconductor devices. This work was supported by the Office of Naval Research.

2:00 PM EP08.09.02
Gadolinium-Doped Gallium Nitride for Room Temperature Spintronic Applications
Vishal Saravade, Amirhossein Ghods, Naishadhal Raval, C. Zhou and I. T. Ferguson; Department of Electrical and Computer Engineering, Missouri University of Science and Technology, Rolla, Missouri, United States.

Gallium nitride (GaN) is a candidate material for room temperature (RT) spintronic applications considering its electrical and magnetic properties. MOCVD-grown Gd-doped GaN (GaGdN) exhibited RT ferromagnetism and anomalous Hall effect (AHE) in which the mechanism seems to be free carrier-mediated [1]. Observation of ferromagnetism only in GaGdN from a (TMHD)₃Gd precursor that contains oxygen points to the role of oxygen especially oxygen interstitials in stabilizing the ferromagnetism. GaGdN from a Cp₃Gd precursor that does not contain oxygen did not show ferromagnetism. In this work, the mechanism for the ferromagnetism in GaGdN will be further investigated. The role of oxygen in the magnetic properties will be examined using GaGdN implanted with oxygen. Carbon-implanted GaGdN will also be studied as carbon can also introduce interstitial sites in GaGdN [2]. AHE measurement will be done and relationship between the anomalous Hall resistivity and longitudinal resistivity will be determined to better understand the responsible mechanism for the ferromagnetism. Furthermore, GaGdN based spin-LEDs will be fabricated and difference between the left and right circularly polarized light intensities will be determined using magnetic circular dichroism measurement. These would help towards understanding spin injection in GaGdN devices and to determine the suitability of GaGdN for spintronic applications.

MOCVD Growth and Characterization of Er Doped III-Nitride Epilayers and Quantum Well Structures
Talal Al Tahtamouni1, Hongxing Jiang2 and Jingyu Lin2; 1Qatar University, Doha, Qatar; 2Texas Tech University, Lubbock, Texas, United States.

Er doped materials have attracted much attention for their applications in photonics, especially in the area of optical communications. Doped in a solid host, Er³⁺ ion has allowable intra-4f shell transition from its first excited state (4I_{13/2}) to the ground state (4I_{15/2}) and the transition corresponds to a wavelength of minimum optical loss in silica based optic fibers at 1.54 µm. Thus, Er-doped materials are ideal candidates to make amplifiers for optical communications.

It has been observed that the 1.54 µm emission from Er doped semiconductors of smaller bandgaps has a low efficiency at room temperature due to a strong thermal quenching effect. In general, the thermal stability of Er emission increases with an increase of the energy gap and ionicity of the host materials. III-nitride semiconductors are excellent host materials for Er-ions due to their structural and thermal stabilities. III-nitride wide bandgap semiconductors have demonstrated excellent performance for electronic and optoelectronic devices.

AIN has a large bandgap (6.1 eV). Therefore, it is expected that AlN as a host material will result in lower thermal quenching of Er emission. AlN is of great technological significance because of its physical and chemical properties such as low dielectric constant, excellent thermal conductivity, electrical resistivity, excellent mechanical strength and chemical stability. These reasons make AlN an excellent host material for device applications. Despite the reports of fabrication of light emitting diodes based on Er doped III-nitride epilayers operating in the infrared region. However, further improvements in the quantum efficiency of the 1.54 µm emission in Er-doped III-nitrides are still needed to enable practical photonic devices. One way to improve the quantum efficiency of these device structures is to improve the excitation efficiency of the Er ions via the enhancement in the carrier density around Er³⁺ ions. This could be achieved by implementing quantum well structures.

A-plane AlN epilayers doped with erbium (AIN:Er) have been grown on r-plane sapphire substrates by MOCVD. The 1.54 µm emission properties were probed by photoluminescence (PL) emission spectroscopy and compared with those of c-plane AIN:Er. It was found that the emission intensity from a-plane AIN:Er is higher than that from c-plane AIN:Er for above and below energy gap, as well as resonant excitation. The intensity of the 1.54 µm emission was found to increase with increasing Er molar flux. A-plane Er-doped AIN epilayers exhibit a smaller thermal quenching effect.

Erbium doped GaN/AIN multiple quantum wells (MQWs:Er) have been grown by MOCVD. The 1.54 µm emission properties from MQWs:Er were probed by PL and compared with those of GaN:Er epilayers. It was found that the emission intensity from MQWs:Er is 9 times higher than that of GaN:Er epilayers. The influence of the well and the barrier widths on the PL emission at 1.54 µm was studied.

2:30 PM EP08.09.04
Coalesced, Centimeter-Scale GaN Films on Amorphous Substrates via MOCVD Growth on a Silicon Seed Layer Fabricated by Aluminum-Induced Crystalization
Mel Hainey1, Yoann Robin2, Hiroshi Amano2 and Noritaka Usami1; 1Materials Process Engineering, Nagoya University, Nagoya, Japan; 2Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan.

The fabrication of III-nitride semiconductor thin films on substrates such as glass and oxidized Si(001) is of significant interest for LED and CMOS integration applications. However, direct epitaxy on these substrates is difficult because their amorphous structure offers no template for III-nitride thin
In recent work, the growth of GaN on amorphous and polycrystalline substrates was demonstrated by using a silicon seed layer fabricated by aluminum-induced crystallization (AIC).[1] While c-axis oriented GaN with threading dislocation densities of ~5x10^9/cm² was demonstrated, the coalesced area realized was only ~1mm² on a 1cm² fused quartz substrate, and was even smaller for other substrates. For large-scale applications, scalable fabrication of fully coalesced GaN films is required, and methods for evaluating the crystal quality of the underlying AIC-Si thin film prior to GaN growth should be developed.

In this report, GaN films with reduced tilt and improved coalescence are grown from AIC-Si seed layers on cm-scale fused quartz and oxidized Si(100) substrates. In the first part of this process, optimized annealing conditions producing the most uniformly oriented AIC-Si silicon thin films are developed. Based on pole figures taken from electron backscatter diffraction of the AIC-Si films, reducing annealing temperatures from 500°C to 425°C results in reduced Si(111) surface misorientation and increased grain size. In the second part, AIC-Si films with reduced Si(111) misorientation are used as seed layers for GaN growth, and the reduced Si misorientation translates into reduced GaN in-plane misorientation. Full-width at half maximum values (FWHM) of x-ray rocking curves measured on the GaN (00-2) peak were found to be reduced from 3° to roughly 2° on fused quartz substrates, and <1° on oxidized Si(100) substrates. Note that this marks a significant improvement over previous reports of GaN growth on glass, where (00-2) FWHM values of over 3° were reported.[2,3]

While the initial GaN growth process was able to produce highly oriented films, these films remained heavily pitted and grew as islands on their underlying AIC-Si grains. However, by increasing the growth temperature, GaN films became smooth and formed nearly coalesced films over areas of ~1cm². These coalesced films should enable device fabrication using conventional III-nitride device processing processes.

Quantification of Indium Fluctuations in InGaN/GaN Quantum Well LEDs Using Electron Energy-Loss Spectroscopy
Sarah A. Goodman1, Akshay Singh1, Zhibo Zhao1, Dong Su1, Kim Kisslinger2, Parijat Deb3, Eric A. Stach2 and Silvija Gradecak1; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 3Lumileds LLC, San Jose, California, United States.

InGaN/GaN quantum well (QW) light emitting diodes (LEDs) have high efficiencies and demonstrate wide wavelength tunability, but their internal quantum efficiency (IQE) decreases with increasing current – a phenomenon known as efficiency droop – which limits the use of these devices for high power applications. Mitigating droop requires a thorough understanding of inhomogeneities within the QWs, including indium fluctuations and crystalline defects. Electron energy-loss spectroscopy (EELS) within the scanning transmission electron microscope (STEM) is well-suited to probe material composition and optoelectronic properties on the sub-nanometer scale. However, it has been shown that electrons with energies above the knock-on threshold for indium (~120 keV) induce indium fluctuations within the QWs. As such, it is critical to obtain imaging conditions that do not induce induced artifacts from intrinsic materials properties.

Although carbon deposition particularly impacts characterization of InGaN due to the proximity of the C edge to the In and N edges, this artifact impacts motivated the need to develop new methods to study the indium distribution. Here, we use an aberration-corrected STEM to induce indium fluctuations within the QWs. As such, it is critical to obtain imaging conditions that do not induce induced artifacts from intrinsic materials properties. Although carbon deposition particularly impacts characterization of InGaN due to the proximity of the C edge to the In and N edges, this artifact impacts

Correlation of Structural and Optoelectronic Properties of V-pits in InGaN/GaN Quantum Well Heterostructures Grown on Silicon Substrates via Cathodoluminescence in Scanning Transmission Electron Microscopy
Zhizhao Su, Sarah A. Goodman1, Akshay Singh1, Govindo J. Syaranamual2, Saurabh Srivastava2, Jing Y. Chung2, Abdul Kadir3, Li Zhang2, Soo-Jin Chua2, 3, Abdul Kadir2, Li Zhang2, Soo-Jin Chua2, 3, Eugene Fitzgerald4, Stephen Pennycook2, 3 and Silvija Gradecak1; 1Department of Materials Science and Engineering, National University of Singapore, Singapore, Singapore; 2Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 3Lumileds LLC, San Jose, California, United States.

Over the past two decades, InGaN/GaN quantum well (QW) heterostructures have set the industry standard for high-efficiency inorganic blue light emitting diode (LED) devices. The highest quality InGaN/GaN-based LEDs are grown on sapphire substrates as opposed to silicon substrates, to overcome difficulties associated with thermal expansion mismatch and decrease the density of crystalline defects in the QW region. Growth of these devices on Si substrates would allow for their incorporation into integrated circuits, expanding their range of potential applications. A shift from sapphire to cheaper Si substrates would also allow cost reductions between 40-60% at the die level and enable the development of large-area LEDs using semi-automated CMOS processes. Despite the advantages in GaN-on-Si epitaxy, commercial adoption of GaN-on-Si technology remains limited due to a degradation in...
crystalline material quality in comparison to incumbent sapphire technologies. Although InGaN-based LEDs are highly resilient to non-radiative recombination at dislocations and V-pits, local optical properties around such defects remain ambiguous. Correlating optoelectronic properties with nanoscale defects remains critical to improved GaN-on-Si LEDs.

In this work, we use cathodoluminescence in scanning transmission electron microscopy (CL-STEM) to map nanoscale optical properties around V-pit defects found in InGaN/GaN QW heterostructures grown on Si substrates. The heterostructures consist of 13 periods of 2.5 nm InGaN QWs separated by 10 nm GaN barriers and emit at 472 nm. We find that the radiative recombination localized around the V-pits in the QW region is blue shifted compared to the QW emission, occurring at 375-395 nm. We attribute the blue-shift to radiative recombination in the QWs near the V-pit which are thinner and are hypothesized to contain fluctuations in indium concentration. Dislocation analysis in the TEM shows that the V-pits luminescence regardless of dislocation character (screw, edge, or mixed). In addition, hyperspectral CL-STEM mapping reveals strong spatial variations in the wavelength and emission intensity from the V-pit core to the facet.

This work provides a foundation for identifying how defects in the InGaN/GaN QW heterostructure region of an LED can influence the optoelectronic properties of the device. Understanding the correlation between structure and emission of V-pits on the nanoscale will be critical to further development of both incumbent GaN-on-sapphire and next-generation GaN-on-Si LED technologies.

AlN Capacitors for High Temperature Systems
Piujsh K. Ghosh1, Mirsaeid Sarollahi2, Rahul Kumar1, Samir K. Saha2, Gregory J. Salamo2 and Morgan E. Ware3
1Electrical Engineering, University of Arkansas-Fayetteville, Fayetteville, Arkansas, United States; 2Physics, University of Arkansas-Fayetteville, Fayetteville, Arkansas, United States.

The recent trend towards higher power and smaller size has necessitated a renewed attention to the thermal budget in power conversion systems. Increased temperatures can reduce efficiency and ultimately can lead to failure. Capacitors are particularly sensitive to high temperature failure and are in many cases held remotely from the main power devices increasing system size and complexity. Currently, off-the-shelf, general purpose capacitors limit their operating temperature range to below ~100°C. Newly developed ceramic capacitors based on BaTiO3 and CaZrO3 demonstrate very good properties at temperatures up to ~200°C, however still suffer at high temperatures from both break down and instability. Their capacitance, although very large, changes by several times and subsequently vanishes at high temperature as the ferroelectric dielectric undergoes a phase change. Although, these do have very good properties for applications in high power modules which may see very high temperatures, there are two main factors we would like to improve upon by the introduction of AlN deposited by MBE on n-type 4H-SiC as the dielectric material of the capacitor. 1) The AlN capacitors should be able to operate at high temperature, high voltage, and high frequencies in a single device, whereas the ceramic devices have different constructions optimized for each. 2) More importantly, with a look to the future of integration, the AlN based capacitors could in principle be directly integrated at the chip level with high power transistors and the associated control electronics based on GaN and SiC materials and technology. AlN is an ultrawide band gap semiconductor with very stable dielectric properties up to at least 600°C and well suited for both RF and high-power devices. At the same time there are no known phase changes within usable operating temperatures. We will present the extreme temperature stability of these AlN based capacitors over the wide temperature range from 240K to 600K, along with their high capacitance density of ~ 10μF/cm2. Finally, current efforts to increase the usable voltage range and at the same time reduce leakage current will be presented.

Substrate Induced Chemically Stabilized Large Area Wurtzite-BN Epitaxial Thin Film
Babri Vishal1, 2 and Ranjan Datta1, 2; 1International Centre for Materials Science, Jawaharlal Nehru Centre for Advanced Scientific Research, Bengaluru, India; 2Chemistry and Physics Of Materials Unit, Jawaharlal Nehru Centre for Advanced Scientific Research, Bengaluru, India.

We report for the first time on chemically stabilized the metastable wurtzite phase boron nitride (w-BN). Single crystalline epitaxial wurtzite w-BN thin film grown on c-plane sapphire by pulsed laser deposition (PLD) under slow kinetic condition. Wurtzite phase boron nitride have wide band gap of 5.81 eV (E→X). Experimental investigation into the properties of w-BN is scarce because of the difficulty in synthesizing sufficiently large and pure crystals of it, which usually requires extremely conditions (1730-3230°C, ~108 torr) in various methods e.g. static high-pressure, shock-wave compression method, direct conversion from h-BN. We have grown w-BN phase on a thin film under relatively low temperature (800°C) and pressure (~10-5 torr). The thin film shows no traces of other allotropes such as cubic (c) or hexagonal (h) BN phases and confirms by high-resolution transmission electron microscopy (HRTEM), X-ray diffraction and Raman spectroscopy. Sapphire substrate plays a significant role to stabilize metastable w-BN in unusual PLD growth condition, and explained based on density functional theory (DFT) calculation using Quantum Espresso (QE). DFT confirms the phase transition occurred due to a chemical interaction between Boron and Oxygen atoms leading to staggering in flat h-BN layer transforming to the w-BN structure at the O-terminated (0001) plane of sapphire. HRTEM and electron diffraction confirms film is relaxed and the lattice parameters of w-BN are approximately a = 2.58 Å and c = 4.29 Å. Epitaxial relationship is w-BN(001)-∥ Al2O3(-2-1-1-1) with ~6.1 % lattice mismatch. Theoretical predictions indicate that w-BN is the second hardest material (114 GPa) after lonsdaleite (~152 GPa). The hardness (H) and the elastic modulus (E) of the w-BN film are 37 & 339 GPa, respectively measured by indentation along <0001> direction. The hardness of the film is 37 GPa lower than theoretical prediction due to indentation along <0001> direction, thin film geometry and defects present in the film. It is also possible that structure may not have undergone bond flipping intermediate structural transitions during indentation and gives lower H. wide bandgap w-BN is a new unexplored phase which can open the opportunities as an active material for the energy applications and optoelectronic as its 2D layered counterpart h-BN to improve properties of graphene and 2D MoS2, WS2, ReS2, heterostructures in various device application. On the other hand, the results are extremely promising in advancing the microelectronic and mechanical tooling industry.
Temperature Dependence of Gate Leakage Current in p-GaN/AlGaN/GaN HEMTs

The transient study (on-state stress) includes two parts, one is to measure the current transient at fixed Q-points for 100 sec, another one is to measure the current transient while switching back to Q-point of 100 mA/mm and 28 V for 100 sec. All transient measurements were done under different temperatures (25, 40, 50, and 60 °C) for activation energy analysis.

In the fixed Q-points study, the transient currents decrease with time at high current Q-points (230 – 450 mA/mm) showing a significant trapping effect. The transient currents increase or decrease with time at medium current Q-points (~ 100 mA/mm) showing both trapping and detrapping effects. At low current Q-points (< 80 mA/mm), most transient currents increase then decrease with time. Based on the measurements, the trapping effect dominates at high current Q-points which hot carriers would inject into adjacent layers (AlGaN and/or GaN) for trapping. And the trapping effect is not strong function of temperatures indicating tunneling behaviors.

In the switching back to Q-point of 100 mA/mm and 28 V study, if the previous biased current (pre-stressed) is larger than 100 mA/mm, the transient currents decrease with time showing trapping effects. If the previous biased current (pre-stressed) is smaller than 100 mA/mm, the transient currents increase with time showing detrapping effects. Both trapping and detrapping behaviors are not strong function of temperatures too.

All current transient measurements (on-state stress) in this study showed complicated trapping and detrapping behaviors at different Q-points and substrate temperatures. This observation would strongly relate to the performance of GaN HEMT power amplifiers, further investigation and correlation are necessary.

Temperature Dependence of Gate Leakage Current in p-GaN/AlGaN/GaN HEMTs

In this study, on-state stress in AlGaN/GaN HEMTs is to investigate the current transient characteristics while transistors are biased at different quiescent points (Q-points) and under different substrate temperatures.

AlGaN/GaN HEMTs with two 0.25-μm T-gate fingers and width of 125-μm were investigated in this study. All HEMTs were grown on 4-inch SiC substrates and fabricated by a commercial foundry. SiN stack layers were used for passivation and source field-plate was adopted.

The transient study on-state stress) includes two parts, one is to measure the current transient at fixed Q-points for 100 sec, another one is to measure the current transient while switching back to Q-point of 100 mA/mm and 28 V for 100 sec. All transient measurements were done under different temperatures (25, 40, 50, and 60 °C) for activation energy analysis.

In the fixed Q-points study, the transient currents decrease with time at high current Q-points (230 – 450 mA/mm) showing a significant trapping effect. Both trapping and detrapping behaviors are not strong function of temperatures too.

All current transient measurements (on-state stress) in this study showed complicated trapping and detrapping behaviors at different Q-points and substrate temperatures. This observation would strongly relate to the performance of GaN HEMT power amplifiers, further investigation and correlation are necessary.
using Hi-Low method improved from $-2.0 \times 10^{-13}$ to $-7.0 \times 10^{-11}$ (eV cm$^2$/arb.) (at Ec-Et: 0.2 eV). The reliability by time dependent dielectric breakdown shows that the electric field difference in a photoconductive field was increased by about 25% at 1000°C.

From thermal Desorption Spectrometry profiles, HPWVA sample shows higher desorption of H$_2$O and smaller desorption of C$_6$H$_6$ and CO$_2$ than the w/o HPWVA. Therefore, HPWVA leads to improvement of the termination with OH group to defect of Al$_2$O$_3$ films and reducing the residual hydrocarbon. In addition, X-ray Photoelectron Spectroscopy profile of Ga2p at the Al$_2$O$_3$/GaN interface shows that the Ga-O binding increased after HPWVA.

Finally, through defect termination of OH groups and reduction of residual carbon by HPWVA, high quality Al$_2$O$_3$ were produced leading to reduction of N$_{t}$ and improvement of reliability. The low Dit is considered to be due to the termination of defects at the Al$_2$O$_3$/GaN interface by oxidizability of HPWVA. This research would contribute to realizing GaN MOSFET including high quality Al$_2$O$_3$/GaN interface for power semiconductor devices.

Ultrahigh-Yield Growth of GaN via Halogen-Free Vapor-Phase Epitaxy

Daisuke Nakamura and Taishi Kimura; Toyota Central R&D Labs Inc, Nagakute, Japan.

To realize commercially feasible vertical GaN-based power devices, a sustainable supply of high-quality, large-diameter GaN wafers at low cost is required. Particularly, the cost of GaN wafers should be made comparable to that of Si and SiC wafers. Therefore, efficient incorporation of Ga into GaN crystals in the growth process (i.e., a high material yield of Ga) is critically important for reducing the total cost of GaN wafers as it would minimize Ga consumption in the production of GaN wafers. We demonstrated the HF-VPE GaN growth of high-quality thick GaN layers at the relatively high growth rate of ~100 μm/h. HF-VPE employs a simple reaction scheme \[\text{Ga} (g) + \text{NH}_3 \rightarrow \text{GaN} (s) + \frac{3}{2}\text{H}_2\], it can lead to an efficient reaction, a low reverse reaction rate, or both. The present study investigates the critical growth parameters and mechanisms that govern the material yield of Ga in HF-VPE GaN growth, and demonstrates ultrahigh-yield HF-VPE GaN growth.

The setup employed here for HF-VPE GaN growth was almost the same as that described in previous reports. A total of 27 growth experiments were carried out using a 2”-diameter substrate as a seed. The growth parameters of concern were the seed substrate holder temperature, the Ga crucible temperature, the background pressure $p$, the gas flow rates, and the seed-to-crucible-outlet distance $d$; their effects on the material yield of Ga, $Y_{Ga}$, during HF-VPE GaN growth were investigated. A linear multivariate analysis was conducted to find the critical growth parameters that govern $Y_{Ga}$. The $Y_{Ga}$ values are in the range of 14–23%, which are considerably higher than those for conventional HVPE GaN growth (5–10%). The critical growth parameters identified in the best model for the multivariate analysis were $d$, $p$, $Q_{Ar}$, $Q_{NH}_3$, $Q_{Ga}$, and $Q_{H}_2$. Based on the regression coefficients for the critical growth parameters, the regression equation for calculating $Y_{Ga}$ was formulated.

The dependence of $Y_{Ga}$ on $d$ suggests that the gas-stream pathways for Ga vapor nearer to the seed substrate surface are a dominant factor in achieving a higher $Y_{Ga}$. With a low $p$ and a small $d$, most of the gas-stream pathways for Ga vapor (denoted by blue arrows) almost reach the seed surface owing to their high gas-stream velocity and the short seed-to-source distance. Considering the above discussion on the gas-stream pathways of Ga vapor, we employed larger-diameter seed substrates (3”- and 4”-diameter sapphire substrates) to demonstrate the suppression of Ga vapor escape and the resultant higher $Y_{Ga}$. $Y_{Ga}$ increases almost linearly with increasing seed substrate diameter, with an ultrahigh $Y_{Ga}$ of ~47% obtained for the 4”-diameter substrate. With this ultrahigh material yield, we believe that HF-VPE can be used to produce a sufficient number of GaN wafers for high-power vertical GaN devices at moderate prices without depleting the global Ga supply.

Aluminum Nitride Nanowire Flexible Ultraviolet Photodetectors

Yassir A. Ali and Kasif Teker; Electrical and Electronics Engineering, Istanbul Sehir University, Istanbul, Turkey.

One-dimensional nanostructured wide bandgap (WBG, typically between 3 eV – 6 eV) semiconductor materials are good candidates as building blocks for photovoltaic device applications such as UV photodetectors, phototransistors, and photodiodes. Furthermore, high UV light sensitivity, small size, very short response time, low power consumption, and high efficiency are the most important features of nanodevices for new and superior applications in optoelectronics. AlN nanowires, an important III-V WBG semiconductor, have aroused significant interest due to its large direct bandgap (6.28 eV), low electron affinity, high thermal conductivity, high melting point (above 2300°C), and chemical stability. Despite its intrinsic superior properties, one-dimensional nanostructured wide bandgap (WBG, typically between 3 eV – 6 eV) semiconductor materials are good candidates as building blocks for photovoltaic device applications such as UV photodetectors, phototransistors, and photodiodes. Furthermore, high UV light sensitivity, small size, very short response time, low power consumption, and high efficiency are the most important features of photodiodes for new and superior applications in optoelectronics. AlN nanowires, an important III-V WBG semiconductor, have aroused significant interest due to its large direct bandgap (6.28 eV), low electron affinity, high thermal conductivity, high melting point (above 2300°C), and chemical stability. Despite its intrinsic superior properties, challenges in synthesis of defect-free and uniform morphology AlN nanostructures persist, thereby limiting the number of electronic and photonic device studies.

This paper presents the fabrication of a flexible ultraviolet (UV) photodetector from free-standing catalyst-free AlN nanowire (AlNNW) films via a direct transfer method through a very low-cost non-lithographic fabrication scheme. The device has demonstrated very fast photoresponse rise and decay times of ~100 μs and ~10 μs, respectively. The photocurrent measurements have been conducted for bias voltages from 1V to 20V. In fact, the flexible AlNNW photodetector is very sensitive to the UV illumination even at low bias voltages (as low as 1V) indicating very high sensitivity.

One-dimensional nanostructured wide bandgap (WBG, typically between 3 eV – 6 eV) semiconductor materials are good candidates as building blocks for photovoltaic device applications such as UV photodetectors, phototransistors, and photodiodes. This paper presents the fabrication of a flexible ultraviolet (UV) photodetector from free-standing catalyst-free AlN nanowire (AlNNW) films via a direct transfer method through a very low-cost non-lithographic fabrication scheme. The device has demonstrated very fast photoresponse rise and decay times of ~100 μs and ~10 μs, respectively. The photocurrent measurements have been conducted for bias voltages from 1V to 20V. In fact, the flexible AlNNW photodetector is very sensitive to the UV illumination even at low bias voltages (as low as 1V) indicating very high sensitivity and capability of operating at low voltages. Moreover, the photocurrent has decayed to the dark current value rapidly, after the exposure ended, suggesting the absence of defect-related traps. Consequently, the facile fabrication scheme is very cost-effective, readily scalable; and offers broad integration capabilities in various flexible photonic and electronic applications including wearable devices.
layers by PLD at room-temperature in $10^{-3}$ Pa of O$_2$ using a β-Ga$_2$O$_3$ sintered target. The amorphous Ga$_2$O$_3$ films were subsequently irradiated 500–1000 pulses of the KrF excimer laser using laser-induced plasma-enhanced atomic layer deposition (ELA). A six-axis diffractometer in SR-XRD was used to evaluate the lattice parameters and to measure the reciprocal space map, such as out-of-plane -201 and in-plane 002 for Ga$_2$O$_3$ thin film, 111 and 1-11 including reflectivities for NiO seed layers, 0006 and 11-23 for α-Al$_2$O$_3$(0001) substrates. The epitaxial β-Ga$_2$O$_3$(0-1) thin films with six-fold in-plane symmetry were obtained on rocksalt-type buffer layers after the ELA procedure, while the films on wurtzite-type buffer remained uniaxial oriented and planarly isotropic. Although, the crystallization did not propagate to the surface in case of excessive precursor thickness, while insufficiently thick films remained amorphous. The d-spacing of NiO seed layers having different thickness shows a constant value because of the high-quality epitaxial growth of their layers on sapphire substrates. On the other hands, the d-spacing of the β-Ga$_2$O$_3$ thin films shrank in the in-plane direction and expanded in the out-of-plane direction. β-Ga$_2$O$_3$ thin film with NiO of 2 nm thick showed the best epitaxial quality when we judged from FWHM values of rocking curves. The results suggested importance of total consumption of energy above a threshold via photothermal process as well as a trigger of effective absorption of the reached excimer laser at the interface between amorphous and crystallized regions or the buffer layer, that optical absorption of the precursor amorphous Ga$_2$O$_3$ films well agreed the Lambert-Beer Law.

Solid-State Synthesis of Hexagonal Boron Nitride Crystals
Clint D. Frye, James H. Edgar and Rebecca Nikolic; Lawrence Livermore National Laboratory, Livermore, California, United States; Chemical Engineering, Kansas State University, Manhattan, Kansas, United States.

Ultrawide bandgap (UWBG) semiconductors such as diamond, AlN, Ga$_2$O$_3$, and AlGaN are emerging electronic and optoelectronic materials. However, material quality and availability remain immature and lag conventional semiconductors such as silicon or even silicon carbide and gallium nitride. Hexagonal boron nitride (hBN) has many of the same advantages of other UWBG materials such as low chemical reactivity, high temperature operation, and high critical electrical field, but it also has a layered 2D structure and been shown to emit light at 215 nm. These properties are valuable for a wide array of applications such as deep ultraviolet (DUV) optoelectronics, neutron detection, electronics in harsh hot environments, and as the preferred substrate and dielectric for 2D electronics (graphene, MoS$_2$, etc.). Crystal growth of hBN, however, is relatively unexplored, and a lack of high quality crystals has limited device fabrication. In this work, hBN crystals were grown by a wholly solid-state process. 300 nm of NiCr was sputter deposited onto pyrolytic BN and then annealed in a rapid thermal annealer in Ar at 900 °C for 3–15 min. During the annealing, B and N from the pyrolytic boron nitride substrate dissolved into and diffused across the NiCr film. As the samples cooled, hBN precipitated on the top side of the NiCr film. The NiCr metal serves simultaneously as a solvent, template, and catalyst. hBN platelets up to 1 μm in diameter were grown as confirmed by Raman analysis. NiCr was selected because it has been used as a liquid solvent for hBN growth and has a small lattice mismatch of 0.4%. Cr, which has a strong affinity for N, was alloyed with Ni to increase N solubility as pure Ni has a very low N solubility. The chromium content in the NiCr films was varied from 0–40 mol%. This growth technique uses readily available materials, common vacuum processing equipment, relatively low temperatures, and has the potential to be scaled up to wafer scales or made into a steady state crystal growth process. A roadmap will be presented on how to scale up the size of the crystal platelets to wafer scales. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-753061.

EP08.10.09
Fabrication of MIM Diodes by Atmospheric Pressure Spatial Atomic Layer Deposition (AP-SALD) System
Abdullah Alshehri, Kissan Mistry, Khaled Ibrahim, Vu Thi Huong Nguyen, David Munoz, Mustafa Yavuz and Kevin Musselman; Mechanical Engineering, University of Waterloo, Waterloo, Ontario, Canada; Mechanical Engineering, Prince Sattam bin Abdulaziz University, Alkhari, Saudi Arabia; Laboratoire des Matériaux et du Génie Physique, Grenoble, France.

A novel quantum metal-insulator-metal (MIM) diode is fabricated by atmospheric pressure spatial atomic layer deposition (AP-SALD) system. This scalable method was used to produce MIM diodes with high-quality, pinhole-free Al$_2$O$_3$ film more rapidly than by conventional ALD. MIM diode fabricated by AP-SALD system shows lower effective barrier height (1.27 eV) between electrode-insulator interface than that of MIM by conventional ALD (1.44 eV) resulting lower turn on voltage ($\phi_{ON}=1$ V) and better asymmetry and nonlinearity values 4.5, 8 respectively, and demonstrate that clean room fabrication is not a prerequisite for quantum-enabled devices.

EP08.10.10
Atomic Layer Etching for Selective Area Doping of GaN
Kevin A. Hatch, Houqiang Fu, Jesse Brown, Xingye Wang, Mei Hao, Yuji Zhao and Robert J. Nemanich; Arizona State University, Tempe, Arizona, United States.

The development of high efficiency GaN power devices using vertical architectures is hindered by the ability to achieve selective area doping of the $p$–$n$ junction. This process may be improved by the removal of surface damage caused by the conventional inductively coupled plasma (ICP) etching and regrowth method, which may create defects, impurities, and surface states that impact the junction properties. We have demonstrated surface etching of GaN allowing controlled material removal. Our technique uses $in situ$ remote plasma-enhanced atomic layer oxidation of the ICP etched surface followed by oxide removal through H-plasma etching. The removal of damaged layers at the surface resulted in an increase of the surface band bending to a value 0.5 ± 0.1 eV for previously ICP etched $n$-type GaN and 0.7 ± 0.1 eV for non-etched $n$-type GaN. The variation in band bending indicates continued removal of damage over several cycles of this repeated process for the etched material whereas the non-etched GaN displayed no change in the band bending after the first cycle, consistent with dry cleaning of surface contamination. This work was supported by ARPA-E, grant No. DE-AR0001691.

EP08.10.11
Observation of Slow and Controllable Growth of Filament in Conducting-Bridge Memory
Atsushi Shimizu, Hiroshi Sato, Sohta Hida and Kentaro Kinoshita; Faculty of Science, Tokyo University of Science, Katsushika, Japan; Tottori University, Tottori, Japan.

Resistive switching memories are drawing attention as memories that can overcome miniaturization and other performance limits facing conventional memories. Among them, filament growth-based resistive switching memories especially show high performance and are largely categorized into anion diffusion-type, which is generally called resistive random access memory, ReRAM, and cation diffusion-type, which is called conducting-bridge RAM, CBRAM. Although they tend to be mixed up in the category of a filament type resistive switching memory and both of them are expected as a non-volatile memory for next generation, it is important to elucidate intrinsic difference of their performances to select appropriate applications. In this paper, the difference of filament growth characteristics between them are discussed using ReRAM and CBRAM of top electrode(TE)/metal oxide(MO)/bottom.
A ZnO layer with a thickness of 25 nm was deposited on a Pt (100 nm)/Ti (20 nm)/SiOx (100 nm)/Si(650 nm) substrate using an RF sputtering method. Then, both Cu and Pt top electrodes were deposited on the ZnO film by an RF magnetron sputtering method. Accordingly, Cu/ZnO/Pt CRAM structures (ZnO - CRAM) and Pt/ZnO/Pt OrRReRAM structures (ZrO2 - ReRAM) were fabricated sharing the same ZrO2 layer as a memory layer. We succeeded in observing the transient of the resistance from high resistance state, HRS, to low resistance state, LRS, of the CRAM device, by inserting a load resistance. The load resistance should have an appropriate resistance value to divide a voltage applied to the CRAM device, $V_{bias}$, to the load resistance when set switching is caused. It is noticeable that CRAM resistance continues to decrease even when $V_{bias}$ is decreasing unless a current is increasing, which is consistent with a widely received picture that the growth of filaments is retarded to ionic current, i.e., the flow of cupper ions in the present case. On the other hand, the increasing rate of a resistance is too rapid to be detected within the sampling rate of 10 μs, meaning that the resistance of ReRAM device decreases to the resistance value lower than the load resistance within 10 μs after the occurrence of set switching. The difference of the observability of the transient state between CRAM and ReRAM devices strongly suggests the difference of the switching speed between them. Fast switching speed of ReRAM causes large surge current through the parasitic capacitance of a measurement circuit, although the same measurement circuit was used for both devices. The large surge current enhances the growth of filaments and makes a reset current, $I_{reset}$, large. On the other hand, slow switching speed of CRAM highly enhances the controllability of $I_{reset}$ ranging more than six orders of magnitude, 0.1 nA - 1.0 mA.

EP08.10.12
Theoretical Study on Oxygen Vacancies in Crystal Grains in Polymeric Alumina HfO: Thin Film
Sohita Hida1,2, Takumi Morita2, Takahiro Yamasaki3, Jun Nara1, Takahisa Ohno1 and Kentaro Kinoshita1; 1Graduate School of Sustainability Science, Tottori University, Tottori, Japan; 2Faculty of Science, Tokyo University of Science, Katsushika, Japan; 3National Institute for Materials Science, Tsukuba, Japan.

Metal oxides such as HfO2 are widely received as materials for the fabrication of memory layers of Resistive Random Access Memory (ReRAM) [1]. It is theoretically reported that electric characteristics were changed by introducing vacancies into HfO2 single crystal or grain boundary [2, 3]. In these studies, they suggested that resistive switching is caused by diffusion and aggregation of oxygen vacancies (Vo's). However, no one demonstrates the whole of the process during the resistive switching, i.e., detailed movement of Vo's between high and low resistance states. In this paper, the first principles molecular dynamics (FPMD) program PHASE/0 [4] was used to discuss the generation and movement of Vo's. We calculated the generation energy of Vo's ($E_{vo}$) on the surface and far from the surface of HfO2 periodic slab which was modeled based on our experimental results [5]. $E_{vo}$ for the former and the latter are 9.043 eV and 9.807 eV, respectively. Therefore, Vo's are easily generated near the surface than far from the surface.

We theoretically observed the process of structural relaxation and the effects of changing charge states of Vo's and raising a temperature to 1000 K, by FPMD. When the charge state of Vo's changes from divalent (Vo2+) to neutral (Vo0), Vo's are attracted each other and aggregate. On the other hand, when the charge state of the Vo's changes from Vo0 to Vo2+, Vo's are repelled against each other and disperse. The difference of the static energy between the aggregated and dispersed states was 0.67 eV. In addition to the result above, we previously reported that slight displacements of small amounts of atoms alter the surface electric state from conductive to insulating or vice versa [6]. Therefore, resistive switching of ReRAM can be caused by aggregation and dispersion of Vo's depending on the charge state of Vo's, with the assistance of Joule heat. The location at which resistive switching takes place is near the surface of crystal grains where Vo's are expected to move easily due to the symmetry of bulk crystal is broken. This type of resistive switching can be caused by applying voltage to a metal/metal oxide structure, which changes Fermi level and causes injection (extraction) of electrons from (to) the metal to (from) the metal oxide layer.

EP08.10.13
The Nitrogen Impurity in Wide-Band-Gap Oxide Semiconductors
Inttuo Chaturatna1, Pakpoom Reunchan1,2 and Andersson Ianotti3; 1Department of Physics, Kasetsart University, Bangkok, Thailand; 2Thailand Center of Excellence in Physics (ThEP Center), Commission on Higher Education, Bangkok, Thailand; 3Department of Materials Science and Engineering, University of Delaware, Newark, Delaware, United States.

Wide-band-gap oxide semiconductors are promising for various device applications, yet controlling the electrical conductivity and achieving p-type doping remains challenging. Among the possible acceptor impurities, N would be the most promising due to atomic size considerations. We use hybrid density-functional calculations to study the effects of the nitrogen impurity on the electronic and optical properties of the wide-band-gap oxides ZnO, SnO2, In2O3, TiO2, SrTiO3 and BaTiO3. In ZnO, SnO2, In2O3, and TiO2, we find that N incorporating on the O site (NO) introduces donor and acceptor levels in the gap, with the donor level below the acceptor level, as in an AX center. In BaTiO3 and SrTiO3, NO is, however, a negative-U center, with a (+/-) level in the gap. Therefore, N incorporation in SnO2 is, however, a negative-U center, with a (+/-) level in the gap. In this paper, we discuss the generation and movement of NO's depending on the charge state of NO's, with the assistance of Joule heat. The location at which resistive switching takes place is near the surface of crystal grains where NO's are expected to move easily due to the symmetry of bulk crystal is broken. This type of resistive switching can be caused by applying voltage to a metal/metal oxide structure, which changes Fermi level and causes injection (extraction) of electrons from (to) the metal to (from) the metal oxide layer.

EP08.10.14
Preparation of Wide Gap n-Type Sn2Ta2O7 Polycrystalline Films by Magnetron Sputtering
Shunich Suzuki1,2, Naoko Kikuchi2, Yoshihiro Atsua1 and Keisuke Nishio1; 1Materials Science and Technology, Tokyo University of Science, Katsushika, Japan; 2Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Transparent conductive oxides (TCOs) have a potential in various applications to electronic devices. Actually n-type TCOs such as tin-doped indium oxide (ITO) have been used for displays, solar cells and so on. On the other hand, p-type TCOs have not been practicable due to low hole mobility. The reason for low hole mobility for many transparent conductors is localized valance band maximum (VBM) composed of O2p. For realizing the p-type TCOs, the VBM composed of delocalized orbitals of metal elements is essential. Our group focused on Sn2Ta2O7 of which VBM is composed of Sn5s and succeeded in preparation of p-type and n-type Sn2Ta2O7 bulks depending on annealing condition. Hole and electron carriers were also found to be generated by Sn4+ -on-Nb substitutional defects and oxygen vacancies, respectively. For the application of new transparent electronic devices based on the p-n junction, preparation of Sn2Ta2O7 films is indispensable. However there is no report on conductive Sn2Ta2O7 films as of today. In this study, we report the preparation of n-type polycrystalline thin films of Sn2Ta2O7, and the effect of annealing conditions on their electrical properties.
Sn$_2$Ta$_2$O$_7$ polycrystalline thin films were fabricated by magnetron sputtering. Dense Sn$_2$Ta$_2$O$_7$ was used as a target. The sputter deposition was performed at an Ar gas pressure of 0.5 Pa with an rf power of 100 W. Sn$_2$Ta$_2$O$_7$ films were deposited on SiO$_2$ glasses at a substrate temperature of 848 K and followed by annealing under N$_2$ gas flow at 773-973 K for 6 h in tubular furnace. Crystalline phases were identified by X-ray diffraction (XRD). Band gap ($E_g$) of the films were estimated from the transmission spectra using the Tauc plot. Resistivity and Hall measurements were carried out at room temperature. $E_g$ of the films was estimated to be 3.2 eV, indicating high transparency in visible range. After the annealing over 873 K for 6 h under N$_2$ gas flow, the thin film samples showed n-type conductivity. Electrical resistivity, carrier density and mobility were 1.2 ohm cm, 5.4×10$^{10}$ cm$^{-2}$, 3.9×10$^2$ cm$^2$V$^{-1}$s$^{-1}$. Sn$_2$Ta$_2$O$_7$, with small amount of Sn$_2$Ta$_2$O$_8$x and SiO$_2$, as impurity phases was found in XRD patterns. The amount of impurity phases increased with increasing temperature. In summary, we succeeded in preparation of wide-gap, n-type Sn$_2$Ta$_2$O$_7$ films which showed both p- and n-type conductivity in powder samples.

**EP08.10.15**
Surface Band Bending of Polar ZnO by Hard X-Ray Photoemission Combined with X-Ray Total Reflection Shigenori Ueda; National Institute for Materials Science, Hyogo, Japan.

ZnO is known as a polar semiconductor due to an alternating stacking of Zn and O layers along the c-axis. Ohashi et al. [1] showed that the valence band spectral shapes of ZnO single crystals strongly depended on the crystalline orientation from hard X-ray photoemission spectroscopy (HAXPES) measurements. In general, HAXPES is a bulk-sensitive probe [2], and take-off angle (TOA) dependent of photoelectron gives depth information [3]. However, the decrease of the photoemission intensity occurs in lower TOA, and the valence band spectra depend on TOA [3] due to the matrix element effect [4].

In this work, HAXPES combined with X-ray total reflection (TR-HAXPES) [5] was used to obtain a depth-resolved electronic structure instead of TOA dependent measurements. We have measured the core-level and valence band HAXPES spectra of commercially available bulk single crystalline ZnO for Zn- and O-polar faces in the case of effective inelastic mean free path of 2.0, 4.1, and 8.0 nm by tuning the X-ray attenuation length. Undoped n-type ZnO crystals with fine polished surfaces were used. The valence band spectra of ZnO showed the clear polarity dependence as reported in Ref. [1]. The depth dependence of the valence spectra showed the nearly flat band behaviors for the Zn- and O-polar ZnO faces, in contrast to those for the Ga- and N-polar GaN faces [5]. The Zn 3s and O 1s core-level spectra also showed the nearly flat band behaviors for both the Zn- and O-polar faces. These nearly flat band behaviors are attributed to the pining by the states located at the Fermi-level. We will discuss the band bending behaviors and electronic structures of ZnO in comparison with those of GaN.

Fabrication of Rocksalt-Structured MgZnO/MgO Layered Structures and Their DUV Light Emission Properties Kyohbei Ishii1, Mizuki Ono2, Takeyoshi Onuma3, Kentaro Kaneko2 and Shizuo Fujita2; 1Electronic Science and Engineering, Kyoto University, Kyoto, Japan; 2Photonics and Electronics Science and Engineering Center, Kyoto University, Kyoto, Japan; 3Applied Physics, School of Advanced Engineering, Graduate School of Engineering, Kogakuin University, Tokyo, Japan.

Recently, deep ultraviolet (DUV) light sources using wide bandgap materials attract much attention because they can substitute for gas sources due to their small-size, low cost, and capability of arbitrary tuning the emitting wavelength. Our group has been focusing on rocksalt-structured MgZnO (RS-MgZnO), possessing the maximum bandgap energy of 7.8 eV[3], as a candidate capable of emitting DUV light of the wavelength range shorter than 200 nm, which cannot be realized by AlGaN.

At first, MgZnO thin films were grown on MgO (001) substrates by the mist CVD method. Magnesium chloride hexahydrate (MgCl$_2$·6H$_2$O) and zinc chloride (ZnCl$_2$) were used as precursor sources of Mg and Zn, respectively. The source molar ratio of [Mg]/[Zn] was 90:10. Then, MgZnO/MgO layered structure samples were fabricated. The structure consists of four periods of MgO barrier and MgZnO well layers. X-ray diffraction (XRD) 2θ/ω scan profile of the MgZnO thin film indicated that the RS-MgZnO without other crystalline phases was successfully grown. Atomic force microscopy (AFM) observation showed a smooth surface with a root-mean-square (RMS) roughness of 0.20 nm. Additionally, step-terrace structure was observed on the film surface, where the step height was 0.42 nm corresponded to the diatomic length. Cross-sectional transmission electron microscope (TEM) observation do not show the generation of misfit dislocation at the interface, i.e., only dislocation lines originated from the MgO substrate exist in the MgZnO film. The dislocation density in the MgZnO film is estimated to be less than 10$^7$ cm$^{-2}$. The improvements of crystalline quality resulted in the observation of predominant DUV emission peak at 5.86 eV (212 nm) at 6 K and 5.71 eV (217 nm) at 300 K in the cathodoluminescence (CL) spectra. Other peaks at the longer wavelengths, which were remarkable in our previous report [2], were negligibly reduced.

Moreover, in optical quality may be attributed to the use of carbon-free sources instead of the acetate sources as used in the previous study[2]. Spectrally integrated CL intensity at 300 K over that at 6 K ($I_{300}/I_{6}$) was estimated to be 2.5%. CL spectra of MgZnO/MgO layered structure exhibited a peak at 5.96 eV (208 nm) at 6 K and 5.90 eV (210 nm) at 300 K. Apparent increase in the peak energies of 0.1 eV (0.19 eV) at 6 K (300 K) were confirmed. Moreover, $I_{300}/I_{6}$ of 16% was 6 times higher than that of the MgZnO thin film. Further research toward the vacuum ultraviolet (VUV) emission at the wavelength range shorter than 200 nm is in progress.

Novel P-Type Oxide Semiconductors of α-Ir$_2$O$_3$, α-Ga$_2$O$_3$, and Gallium Oxide Electronics Kentaro Kaneko1, Shinichir Kani1, Shu Takemoto1, Isao Takahashi1, Masahiro Sugimoto2, Takashi Shinno1a and Shizuo Fujita1; 1Kyoto University, Kyoto, Japan; 2FLSOFE INC., Kyoto, Japan.

Gallium oxide (Ga$_2$O$_3$) electronics, owing to ultra-wide bandgap of Ga$_2$O$_3$, is one of the most emerging fields in electronic materials research because some of the materials properties of Ga$_2$O$_3$ are advantageous over SiC and GaN for power device applications. Ga$_2$O$_3$ takes several different crystal structures, among which monoclinic Ga$_2$O$_3$ (β-Ga$_2$O$_3$) is the thermally stable phase, and marked progress for device applications are reported [1].

On the other hand, rhombohedral corundum-structured α-Ga$_2$O$_3$ (α-Ga$_2$O$_3$) is attractive in view of bandgap engineering from 3.7 to ~9 eV by alloying with corundum-structured α-Al$_2$O$_3$ and α-In$_2$O$_3$. With mist CVD growth, high-quality α-Ga$_2$O$_3$ is grown on sapphire (α-Al$_2$O$_3$) substrates [2], followed by evolution of Schottky barrier diodes with extremely low on-resistance [3]. However, the lack of p-type oxide semiconductors acting as a counterpart of n-type α-Ga$_2$O$_3$ has obstructed high-performance power devices based on α-Ga$_2$O$_3$.

\[ E_g = 3.7 \text{ eV} \]
Our attention has been focused on corundum-structured $n$-(Rh,Ga)$_2$O$_3$ [4] and $\alpha$-Ir$_2$O$_3$. An $n$-(Rh,Ga)$_2$O$_3$ thin film showed clear $p$-type conductivity by Hall-effect measurements with the hole mobility of 1.0 mV/cm$^{-1}$ and the hole concentration of $7.6 \times 10^{17}$ cm$^{-3}$. On the other hand, $\alpha$-Ir$_2$O$_3$ was reported as a $p$-type oxide confirmed by thermoelectric power measurement with a band gap of 2.6 eV[5]. Almost reports about $\alpha$-Ir$_2$O$_3$ were poly crystals, multi-domain crystals, or oxidation layer generated at Ir metal surface[6-8].

Single-crystalline $\alpha$-Ir$_2$O$_3$ thin films were fabricated on c-plane sapphire (0001)-Al$_2$O$_3$ substrates by mist CVD technique. The growth rate was accomplished up to 7.5 mm/h. A lattice mismatch between $\alpha$-Ir$_2$O$_3$ and $\alpha$-Ga$_2$O$_3$ was calculated as 0.3% along a-axis from cross-sectional TEM observations. Obtained $\alpha$-Ir$_2$O$_3$ and $\alpha$-(Ir,Ga)$_2$O$_3$ showed clear $p$-type conductivity, especially for $\alpha$-(Ir,Ga)$_2$O$_3$, it has a hole density and a mobility of 3.7-$5.0 \times 10^{17}$ cm$^{-3}$ and 2.9 cm$^2$/Vs, respectively.

These results pave the way to fabricate pn junctions with an n-type $\alpha$-Ga$_2$O$_3$ layer and a $p$-type $\alpha$-Ir$_2$O$_3$. Highly-doped $\alpha$-Ga$_2$O$_3$ (n$^+$) and $\alpha$-Ga$_2$O$_3$ (n$^-$) layers were fabricated on $\alpha$-Ir$_2$O$_3$ (p$^+$) thin film on sapphire substrate. The junction showed rectification properties. From the current-voltage measurement, depletion layer was mainly spread into the $\alpha$-Ga$_2$O$_3$ (n$^-$) from $\alpha$-Ga$_2$O$_3$ (n$^+$)/$\alpha$-Ir$_2$O$_3$ (p$^+$) interface because of the large value of hole concentration in the $\alpha$-Ir$_2$O$_3$ (p$^+$).

Part of this work was supported by “Strategic Innovation Program for Energy Conservation Technologies” of the New Energy and Industrial Technology Development Organization (NEDO).

EP08.10.18 Controlled p-Type Doping of CuSCN Ajith DeSilva$^1$, G. R. A. Kumara$^1$, K. Tennakone$^2$ and Unil Perera$^2$; $^1$University of West Georgia, Carrollton, Georgia, United States; $^2$Physics and Astronomy, Georgia State University, Atlanta, Georgia, United States; $^3$National Institute of Fundamental Studies (NIFS), Kandy, Sri Lanka.

Solution processable optically transparent p-type semiconductors are rare. Copper (I) thiocyanate (CuSCN) having a direct band gap of ~ 3.9 eV has been identified as one of the most promising materials of the above category. CuSCN is extensively studied as the hole collector material for perovskite and dye-sensitized solar cells and simple techniques are available for casting thin films under ambient conditions. The p-type conductivity of CuSCN depends on stoichiometric excess of SCN normally introduced during the method of preparation via reaction of aqueous solutions CuSO$_4$ and KSCN in the presence of a reducing agent. Ultraviolet irradiation and chlorination introduce excess SCN enhancing the conductivity, but drawback here is introduction of impurities. A methods developed for controlled doping of CuSCN, using solutions of CuSCN$_3^-$ in organic solvents will be discussed giving the details of the procedures and results of conductivity measurements of thin films. The method enable introduction of measured quantities of excess SCN into CuSCN without introduction of impurities.

EP08.10.19 Controlling the Polarity of Aluminum Nitride Thin Films Using Si-Based Dopants Sri Ayu Anggraini, Masato Uehara, Hiroshi Yamada and Morio Akiyama; AIST, Fukuoka, Japan.

Aluminum nitride (AIN) is a promising wide band-gap material particularly for various electronic applications due to its unique combination of electrical, thermal, acoustic and piezoelectric properties. The functionality of AIN-based thin film can be tuned not only by having a highly c-oriented thin film but also by controlling its polarity. Stacking two AIN-based thin films with different polarities has been reported to improve the performance of a solid mounted BAW resonator [1]. Thin films with an inverted polarity could be obtained by controlling the deposition parameter, such as oxygen concentration [2], sputtering pressure [3], cathode power [4], or it can be also obtained by employing seed a layer to promote the growth of AIN thin films in a certain direction [5]. However, since these techniques often resulted in crystallinity deterioration and require precise control, we propose the use of Si or MgSi dopants to control the polarity of AIN thin film as an alternative method to control the polarity of AIN thin films.

The polarity of the thin film was investigated by examining the piezoelectric response (d$_{33}$) of the resulting thin films. Incorporating 1-14 at.% of Si could inverse the polarity of thin films from positive (Al-polar) to negative (N-polar) without massively reducing the magnitude of the piezoelectric response. The piezoelectric response of non-doped thin film is 6.9 pC/N, while that of Si$_{10}$Al$_{90}$Si$_{10}$O$_{7}$ is found to be ~6.2 pC/N. In case of MgSi-doped AIN, the polarity of the thin films is governed by the ratio of Mg to Si. When the Mg/Si ratio is lower than 1, the negative d$_{33}$ values suggest that the thin films are predominantly N-polar. On the contrary, higher Mg/Si ratio (> 1) yielded a positive d$_{33}$ value which indicates that the thin films are main Al-polar. Despite of polarity changes, significant enhancement in piezoelectric response by alloying AIN with MgSi was not observed. The effect of Mg and Si addition into AIN is further investigated and elucidated by investigating the change of chemical states, morphology and crystallinity of the thin films.

EP08.10.20 Solution-Processed Cubic GaN for Potential Lighting Applications Aakash K. Jain$^1$, Sushma Yadav$^4$, Meenal Mehra$^3$, Sameer Sapra$^2$ and Madhusudan Singh$^1$; $^1$Electrical Engineering, IIT Delhi, New Delhi, India; $^2$Chemistry, IIT Delhi, New Delhi, India; $^3$Momente Performance Materials (India) Pvt. Ltd., Bengaluru, India; $^4$Institut für Physikalische Chemie und Elektrochemie, Leibniz University, Hannover, Germany.

Cubic gallium nitride (GaN) is a wide bandgap semiconductor exhibits high crystallographic symmetry resulting in a lower inbuilt polarization which is useful for more efficient phosphor-free green light-emitting diodes. It has been grown using molecular beam epitaxy (MBE) and metal-organic chemical vapor deposition (MOCVD), which produce highly ordered thin films on compatible substrates. In this work, we report the chemical synthesis of cubic GaN using chemical metathesis reaction in diethyl ether with lithium nitride and anhydrous gallium chloride as precursors, inside a nitrogen glove box at the room temperature. The resulting product was washed to remove lithium chloride and dried before vacuum annealing in a furnace at 850°C. Powder X-ray diffraction (XRD) scans of the as-prepared and annealed product reveal cubic phase of GaN. Energy dispersive X-ray spectroscopy (EDX) measurements show a nitrogen-poor product, which correlates well with the nearly black color of the powder. Diffuse reflectance spectroscopy (DRS)
measurements were carried out with the product on a barium sulfate substrate in a Perkin-Elmer 1050 spectrophotometer to obtain strong absorbance below 400 nm and the Tauc plot for the bandgap estimate of 3.3 eV, which is in good agreement with the known excitonic bandgap of cubic GaN. Initial photoluminescence (PL) measurements with an excitation wavelength of 310 nm reveal a weak emission at 440 nm corresponding to the known defect centers (D2X) in GaN. Further development of this process to form an ink is expected to provide an alternate pathway to producing flexible phosphor free lighting devices.

**Heteroepitaxial Growth of Sn-Doped Ga2O3/Sapphire(0001) Thin Films Using Powder Sputtering Method** Ha Ram Lee1; Su Yong Lee2; and Hyon Chol Kang3; 1Chosun University, Gwangju, Korea (the Republic of); 2PAL, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Ga2O3 thin films have been widely investigated for use in optoelectronic and photonic devices as well as gas sensors because of a wide bandgap of 4.9 eV and good thermal stability up to its melting point (~1800 °C). Many efforts have focused on demonstrating the performance of electronic devices by varying the doping elements and concentrations. We report the heteroepitaxial growth of Sn-doped Ga2O3 thin films deposited using radio frequency magnetron sputtering onto sapphire(0001) substrates. The crystalline orientation of the films was examined using high-resolution synchrotron x-ray diffraction. The Sn-doped Ga2O3 thin films were grown with remarkably high crystallinity and negligible mosaic structure. We found that the corundum α- and monoclinic β-phases of Ga2O3 coexisted in the as-grown samples. Azimuthal angle scans of the in-plane [0020] and [0130] Bragg peaks revealed that the α-Ga2O3 and β-Ga2O3 both showed 12-fold in-plane rotational symmetry and, in particular, that the 30° rotated α-Ga2O3 domains in the in-plane direction were tilted ±3° to the surface direction. It is noteworthy that only 6-fold symmetry has previously been reported for most α- and β-Ga2O3 thin films. Finally, the optical bandgap of the as-grown film with a thickness of 185 nm was estimated at 5.03 eV, and it gradually decreased to 4.52 eV as the film thicknesses increased to 1.6 μm, which is attributed to the increased amount of Sn atoms. This might also be affected by the crossover of the dominant phases from the initial alpha phase to the later beta phase.

**EP08.10.22**

**Growth Mechanism of In-Doped β-Ga2O3 Nanowires Deposited by Radio Frequency Powder Sputtering** Su Yong Lee1 and Hyon Chol Kang1; 1Chosun University, Gwangju, Korea (the Republic of); 2PAL, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

In the last decade, various techniques have been proposed for synthesizing one-dimensional nanostructures such as nanowires (NWs) and nanobelts. In particular, monoclinic gallium oxide (β-Ga2O3) has received considerable attention for use in NWs owing to its wide bandgap of 4.9 eV, high breakdown field (> 8 MV/cm), and high optical transparency to visible and ultraviolet radiation. Recently, applications of β-Ga2O3 NWs in optoelectronic and photonic devices, as well as gas sensors, have been widely explored. Moreover, doped β-Ga2O3 NWs have attracted even greater interest as doping is an effective way to tune the physical properties of such structures. Many of these efforts have focused on demonstrating the performance of NW-based devices by varying the types and concentrations of the doping elements used, with Eu, Cr, Mn, Sn, and In having been examined. Among them, In is regarded as a promising dopant for significantly enhancing the sensitivity and quantum efficiency in nanobelt-based photodetectors. The synthesis of In-doped β-Ga2O3 NWs is typically carried out by thermal evaporation and vapor transport, using a mixture of either In and Ga2O3 powders or Ga and In2O3 powders as source materials. Recently, we reported the growth of β-Ga2O3 NWs using radio frequency (RF) powder sputtering. The deposition of non-stoichiometric Ga2O3, under an oxygen-deficient atmosphere was essential for facilitating the growth of β-Ga2O3 NWs by a self-catalytic vapor-solid-liquid (VSL) process using self-assembled Ga seeds. In this work, we examine the growth mechanism of In-doped β-Ga2O3 NWs synthesized by powder sputtering. In particular, the role of In atoms in determining the growth mechanism and the structure of NWs is investigated. Although the growth sequence of the doped NWs is similar to that of the undoped β-Ga2O3 NWs, the formation of self-assembled In clusters is more favorable compared to Ga clusters. Clusters of In as seeds for initiating the growth of In-doped β-Ga2O3 NWs through a self-catalytic VLS mechanism, while Ga seeds initiate the growth of undoped β-Ga2O3 NWs by the same mechanism. We also observed zigzag NWs formed by alternating NW growth directions.

**EP08.10.23**

**Investigation of Luminescence Characteristics of ZnO with Cycled Exposure to Electron Beams Using Cathodoluminescence in Transmission Electron Microscopy** Young-Woon Kim1; Yonghee Lee1; Sungdae Kim2; Samdong Kim3; and Mi-Hyang Sheen1; 1Seoul National University, Seoul, Korea (the Republic of); 2Dongguk University, Seoul, Korea (the Republic of); 3Korean Institute of Materials Science, Changwon, Korea (the Republic of).

ZnO is one of the strong candidates for the electrodes, sensors and detectors for the UV emission. Luminescence characteristics of nano-wire and thin-film ZnO was investigated using cathodoluminescence in transmission electron microscopy. Ultraviolet (UV) emission revealed reduction with time under electron beam, while the visible light did not show degradation of the luminescence intensity. UV luminescence decreased exponentially leaving 30% of intensity after 200 seconds exposure with electrons of 200keV, 12 pA/cm² current density. The luminescence intensity was partially recovered when the electron beam was temporarily off. Half-life of the luminescence was measured by turning electron beams ON and OFF for a fixed duration. For the first and second cycles of the electron beam showers, half-life time was measured as 26 seconds. Luminescence degradation from near-band-edge emission (3.29 eV), donor-acceptor-pair transition(3.17 eV), and emission from defects (~2.33 eV) were compared. In-situ luminescence of electrically biased ZnO thin film was characterized using TEM-CL, where localized luminescence was observed.

**EP08.10.25**

**Epitaxial Growth and Band-Offset Measurement of β-Ga2O3/GaN Heterojunction** Sunan Ding; Suzhou Institute of Nano-Tech and Nano-Bionics, CAS, Suzhou, China.

Ga2O3 is a kind of ultra-wide-bandgap semiconductor, which have been attracting more and more interests due to its super chemical and thermal stabilities. Since the band gap of β-Ga2O3 is about 4.9 eV, corresponding right to ultra-violet (UV) emission, β-Ga2O3 has been considered as the most promising candidate for UV/Deep-UV (DUV) LED and detectors. On the other hand, GaN-based devices are being well developed and widely used in high power electronics and photo-electronics. If combining Ga2O3 with GaN together in one structure, it will be possible to greatly promote their applications in the devices. However, the major challenges for Ga2O3 are material quality and p-type doping.

In this work, we have successfully grown crystalline β-Ga2O3 on GaN (0001) thin films by using plus laser deposition (PLD) and atomic layer deposition (ALD) techniques respectively. The atomic structure, interface properties, morphology, and composition of the oxide films were characterized by X-ray diffraction (XRD), atomic force microscope (AFM), transmission electron microscope (TEM) and X-ray photoelectron spectroscopy (XPS), which confirmed the epitaxial growth of highly oriented β-Ga2O3 thin films on GaN films in a wide range of temperature. By using our unique UHV connected system, the MOVCD grown GaN films were directly transferred through an UHV tube from its glove box to the ALD chamber for quick β-Ga2O3 deposition, without exposing the as-grown GaN surface to air. Therefore, a clear interface between Ga2O3 and GaN was achieved and the band offset of the β-Ga2O3/GaN heterojunction was directly measured by using XPS core levels and valence band spectra, which also indicate that the band
offset value varies with the interface conditions and the Ga$_2$O$_3$ crystallization.

As the recent progress in our studies, we demonstrated high quality epitaxial growth of β-Ga$_2$O$_3$ films on GaN(0001) by using PLD and ALD techniques at various temperatures, and experimentally determined the valence band offset of 1.40±0.06eV at the β-Ga$_2$O$_3$/GaN heterojunction. All of these results should be benefit to explore DUV devices based on Ga$_2$O$_3$/GaN heterojunctions.

**EP08.10.26**

**High-Performance of Low-Voltage Flexible UV Photodetectors Assembled with ZnO-ZnGa$_2$O$_4$ Heterostructure** Qiannian Du, Kun Tang, Shunming Zhu, Jiandong Ye, Youdou Zheng and Shulin Gu; Nanjing University, Nanjing, China.

Over the past decade, many efforts have been made to optimize the photoelectric devices because of their promising potential for biological and environment detection, optical communication and so on[1-3]. Photodetectors based on low-dimensional nanostructures exhibit superior performance owing to the large surface to volume ratio and tunable surface morphologies. Zinc gallate (ZnO$_x$Ga$_{1-x}$O$_y$) is an ultra-wide band gap semiconductor with a direct band gap of 4.4-4.7 eV. And it has attracted significant attention because of its high chemical stability and outstanding optical properties, which is the potential candidate of the deep ultraviolet photodetectors[4, 5]. In this study, we have fabricated ZnO:ZnGa$_2$O$_4$ heterojunction microwires by a simple chemical vapor deposition(CVD) method. Firstly, as evidenced from EDX, XRD and SEM analyses, we find the component of ZnO and ZnGa$_2$O$_4$ can be modulated by changing the ratio of the source materials (ZnO: Ga$_2$O$_3$) or the flow of O$_2$. The ZnO:ZnGa$_2$O$_4$ heterojunction photodetectors are fabricated on both the rigid SiO$_2$/Si and the flexible polyethylene terephthalate (PET) substrates, exhibiting excellent photoresponsivity to UV light illumination with high photoconductive gain. And it is noteworthy that the prepared flexible devices show good flexibility, high stability, reproducibility, and folding endurance.

**Structural Tuning and Photocatalytic Performance of Three-Dimensional Ga$_2$O$_3$ a-b Hetero-Phase Junction Arrays for Solar Water Splitting** Can Cui, Liaoyong Wen and Puxian Gao; University of Connecticut, Willimantic, Connecticut, United States.

Widely studied and utilized wide-bandgap semiconductors such as SiC and GaN have met the intrinsic bottleneck of electronic performance due to the limit in break-down strength and thermal stability. As a result, even wider bandgap and thermally stable semiconductors are called upon to replace these semiconductors. An emerging candidate, Gallium Oxide (Ga$_2$O$_3$) has drawn much attention lately due to its superb stability[1] and wider band gap (~4.9 eV), as well as its five polymorphic structures in nature, i.e., α-, β-, γ-, δ-, and ε phases[2, 3]. Up to date, the full understanding of Ga$_2$O$_3$ is still lacking on their structural evolution, physical and chemical characteristics, as well as functional properties, calling for more and more studies.

In this work, the tuning of the crystal structure and morphology of Ga$_2$O$_3$ has been investigated via a facile solution preparation of Ga$_2$O$_3$ based nanowire arrays on planar surfaces that could carry various functions such as sensing, catalysis, and others. A hydrothermal deposition process has been successfully carried out with controllable parameters to produce GaOOH nanorod arrays with adjustable diameter and length. The phase evolution of Ga$_2$O$_3$ nanorods was studied starting from precursor GaOOH nanostructures under thermal annealing in detail. As a result, the pure α, the α-b hetero-phase junction, and the pure β Ga$_2$O$_3$ arrays have been realized with mesoporous surface structure and adjustable porosity by such a well-controlled post-annealing process. The relationship of evolution of these nanostructure ensembles and the resulting photocatalytic performances are verified via a demonstration of solar water splitting reaction. The results revealed a higher photocatalytic efficiency (~4.27 mmol·h$^{-1}$·cm$^{-2}$) in α-b hetero-phase junction arrays, as compared with that of pure α (~2.13 mmol·h$^{-1}$·cm$^{-2}$) and pure β (~1.78 mmol·h$^{-1}$·cm$^{-2}$) phases, respectively. The catalytic performance enhancement through these phase junctions may be due to a charge carrier separation caused by an offset of electronic structure between alpha and beta Ga$_2$O$_3$, which allows a more efficient charge utilization for the hydrogen evolution.

CVD Diamond Synthesis—How to Meet Our Device Expectations? Philippe Bergonzo1, 2; 1Seki Diamond Systems, San Jose, California, United States; 2Electronic and Electrical Engineering Dpt, University College London, London, United Kingdom.

Diamond is an exceptional material combining superlative properties like superhardness, superconductivity, high thermal conductivity, biocompatibility, radiation resistance, and unique optical properties etc. These advantages make diamond an excellent material to reply to a broad range of applications, that include thermal coatings, electrodes, windows, sensors, detectors, electronic devices, as well as quantum devices for a variety of applications. The synthesis of diamond is now a well-established technique, and especially when using CVD (Chemical Vapor Deposition) with a range of diamond growing machines readily commercially available at reasonable prices, as demonstrated by the exceptional recent rise of diamond foundries created to reply to a booming synthetic gemstone market.

Still, beyond gemstone fabrication, advances in growth technologies have made it possible to purposely grow synthetic diamond with tuned performances that go beyond that of other materials, and ultimately well below those of more conventional diamonds. This includes for example large area doped diamond films coatings on non-diamond substrates, or films of specific crystalline structures, or with control defect incorporation, at the nanoscale level, or also isotopically purified diamonds for quantum applications, etc.

The step from conventional diamond growth to optimized materials has required a range of technological solutions that have been developed, including for example the possibility to perform 3D structuration of diamond films, as well as the patterning of diamond growth over large area substrates, or the fabrication of ultrathin diamond membranes structured as photonics crystals, or of flexible diamond foils for implant applications, etc. All such approaches have been made compatible with clean room nanotechnology environments to be able to tune the material to the ultimate device fabrication needs. This presentation will review a portfolio of such technological approaches in order for the diamond grower to be able to conceive devices that reply to his application needs.

9:00 AM *EP09.02.02
Single Crystal Diamond Plates Grown by a Combination of Mosaic Technique and Lateral Growth Ramon D. Diaz1, Aaron Hardy2, Elias Garratt3, 4 and Timothy A. Grojohn3, 4; 1Michigan State University, East Lansing, Michigan, United States; 2Fraunhofer Center for Coatings and Diamond Technologies, East Lansing, Michigan, United States.

The electrical, mechanical, and thermal properties of diamond make it a promising material for new generation electronic devices. One of the challenges is the need for fabricating larger size Single Crystal Diamond (SCD) wafers with minimal defects. In this study, SCD plates were successfully grown based on the mosaic technique combined with conditions known for enhanced lateral growth. In earlier works [1] the plates were tiled together using substrates created by a process consisting of ion implantation followed by growth and electrochemical separation. The approach in this work is different in that a starting substrate is cut in two, then each of the two pieces are grown laterally followed by a growth that stitches them back together with a larger area. A series of steps were taken to ensure good crystallographical orientation, starting with laser cutting the tiles from the same 3.5 mm x 3.5 mm x 1.4 mm HPHT (High Pressure High Temperature) seed. The original area of the two substrates was increased by growing a layer of diamond via MPACVD (Microwave Plasma-Assisted Chemical Vapor Deposition) using a pocket configuration which favors lateral growth [2][3]. The grown tiles are polished and kept in aligned contact by their base with a polycrystalline diamond plate used as reference on the holder during growth. This step produced a
continuous layer diamond across the two pieces. The grown together substrate was then re-polished and re-grown multiple times by MPACVD process until the contact (stitched region) interface disappeared, effectively merging the tiles back into a single crystal. Defect densities from the grown layers were analyzed by etch pit counting and birefringence measurements. X-ray rocking curve mapping of the sample shows a maximum misorientation spread of 0.2 degrees, with an average mosaicity of 0.019 ± 0.008 degrees along the surface, demonstrating the feasibility of combining the developed mosaic technique with known lateral growth conditions for increasing the area of SCD wafers.

The authors would like to acknowledge funding for this work from MIT Lincoln Laboratory. X-Ray rocking curve measurements were provided by Rigaku, and X-Ray topography measurements were performed at APS, Argonne National Laboratory.

Development of Kinetic Monte Carlo Modelling and Visualisation of CVD Diamond Growth Max D. Williams1,2, Neil L. Allan1 and Paul W. May1; 1 School of Chemistry, University of Bristol, Bristol, United Kingdom; 2Diamond Science and Technology CDT, University of Warwick, Coventry, United Kingdom.

Using a simplified kinetic Monte Carlo (kMC) model of CVD diamond growth, the diamond and computational chemistry groups at the University of Bristol have previously reported simulating many atomic layers of diamond growth at relatively low computational cost. These simulations have been found to reproduce many of the growth features seen experimentally, including growth rates, while keeping the computational time required on the order of hours, in contrast to more complicated models. However, one limitation of such a simplified model is the use of a cubic representation of the diamond atomic lattice. Although this allows low calculation times and simplified methods, the geometries of specific adsorbates or surface defects thought to be important in the diamond growth mechanism cannot be correctly modelled.

We now report on progress in transitioning the simulation from a simple cubic lattice to a true tetrahedral diamond structure, inheriting some of the methods and approximations on which the original model relied for maximum performance and simplicity. This more realistic representation for the diamond lattice allows implementation and testing of more complicated CVD growth reaction schemes, with application of modern software developmental strategies maintaining the model’s computational efficiency. Visualisation of the diamond surface as CVD growth progresses in true tetrahedral co-ordination is also now possible, allowing robust and powerful analysis of implemented reaction schemes and their effect on surface morphology development as a function of time.

In this presentation we shall use animations and videos of the simulations to show how the model can be used to test potential reaction schemes, as well as understand growth mechanisms and the associated energy barriers from literature, and determine their contribution to growth rate, surface morphology and defect formation. The ultimate aim of this work is to use measured parameters from a diamond CVD system (gas mixture, pressure, temperature, etc.), to predict accurately the expected growth rate, morphology, grain size, and even defect types and locations within a CVD diamond film.

High Quality CVD Diamond Growth on Gallium Nitride Using a Novel 2-Step Micro/Nano Diamond Seeding Method Afaa Habib Piracha1, Edmund Smith1, 2, Paul W. May1, Chao Yuan1, Fabien Massabuau1 and Martin Kuball1; 1 School of Chemistry, University of Bristol, Bristol, United Kingdom; 2 Center for Device Thermography and Reliability, University of Bristol, Bristol, United Kingdom; 3 Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom.

Diamond films deposited onto GaN are useful for heat dissipation in GaN microwave electronics, in particular GaN based MMICs and HEMTs. GaN on diamond will underpin future high-power radio frequency and microwave communications, space and defence systems, paving the way towards 5G and 6G mobile-phone networks and more comprehensive radar systems. However direct deposition of CVD diamond onto GaN (i.e. without a barrier layer being present) is difficult due to the etching of the GaN in the hot CVD environment and poor film adhesion. Moreover, the standard seeding method using detonation nanodiamond results in the first few nm of the diamond film being composed of nm-sized grains with poor thermal conductivity. This creates an undesirable thermal barrier between the active GaN device and the higher quality diamond deposited at later stages of growth which acts as the heat spreader.

To overcome this issue, a novel seeding method was developed to improve the coverage of diamond particles onto GaN on silicon wafers while maintaining an effective thermal interface between the diamond and the GaN.

We describe the optimised seeding procedure as well as the procedure to grow diamond films onto epitaxial GaN. A seeding was performed using an electrospRAY technique in which the wafers were mounted on the rotating copper disk and diamond solution was filled in a tube that sprayed on the targeting wafers by applying high accelerating voltage. This method results in a uniform distribution of diamond solution onto the wafers and eventually dried to give a homogeneously covered mixture of nano/micro diamond particles on GaN wafer.

A method whereby a 2-step seeding process is used to ensure a high thermal conductivity layer is deposited on a GaN substrate: (1) Seed the surface using microdiamonds (1-10 μm), using any standard method optimised for dense monolayer coverage. This provides the high thermal conductivity interface. (2) Seed a second time, this time using nanodiamonds (4 nm), using any standard method optimised for dense monolayer coverage. This fills in the voids and prevents the GaN from etching in the subsequent diamond deposition process. Diamond growth was done in both standard hot filament CVD reactor (HFCVD) and microwave plasma CVD reactor (MPCVD) and the results were compared. We will present results including SEM and thermal measurements showing continuous high-quality diamond layers without pinholes. Diamond films were grown after 2-step seeding method with thickness ranging from 1-50 μm. 2-step seeding seems to work nicely, with reasonably adherent, conformal diamond layers up to 50 μm thick being deposited onto GaN.
The use of diamond grown on patterned gold substrates for Fourier Transform Infrared (FTIR) spectroscopy has proved to be an effective characterization method for undoped diamond functionalized with biomolecules, however insulating diamond substrates cannot be used for electrochemical grafting, which requires a conducting substrate. In this study, we have grown well-adhered boron doped nanocrystalline diamond (B:NCD) thin films on continuous gold (Au) substrates, which form Au nanoparticles (AuNPs) during the initial stages of growth. These AuNPs were then subsequently overgrown by the diamond films. The formation of AuNPs by annealing thin films of gold has been of significant recent interest, for use as catalysts for growing nanowires and for plasmonics. Arrays of AuNPs could be used to maximize the absorption in the active layer of photovoltaic (PV) cells, where the particle size and shape are critical for precisely tuning the light scattering and trapping to maximize the PV performance. Thin film annealing is a high throughput, low contamination method of AuNP formation, but the diameter range of the particles obtained this way is still broad, and their position is uncontrolled, so a better understanding and control of the formation method of thin film annealed AuNPs is needed.

AuNPs of approximately 1 μm diameter formed during microwave plasma assisted chemical vapour deposition (MPACVD), and these were overgrown by diamond. We will show that the formation of AuNPs is affected by the surface treatment. The initial nucleation of the particles can be decreased by pretreatment with water or UV-ozone oxygen treatment. The size of the AuNPs under the diamond film can be increased to approximately 2 μm in diameter by UV-ozone treatment of the surface prior to growth.

Low temperature diamond growth (LTDG) is an area of active research interest, as processing at low temperatures is important for growth on substrates with properties such as high thermal expansion coefficients, low melting temperatures, and high thermal diffusivities. Among the possible routes, surface wave plasma linear antenna (LA) deposition with oxygen-containing gases (such as CO₂) in the gas mixture is considered to be the most promising LTDG growth process. We will show that growing a 50 nm NCD nucleation layer at low temperature in the presence of CO₂ in a LA reactor suppresses the formation of AuNPs under the diamond film, even after subsequent B:NCD overgrowth. We are therefore able to grow B:NCD over Au substrates, with control over the formation and size of overgrown AuNPs.

Diamond can be used for a wide range of applications, not only for jewelry. Diamond has a lot of attentions to be an ultimate semiconductor material because of its physical properties like as the wide band gap and high carrier mobility. The ultimate semiconductor devices, such as high frequency device and high-power transistor, are also expected application by those physical properties. In semiconductor device fabrications, damage- and roughness-free substrate surface is essential. For this purpose, in conventional semiconductors, chemical mechanical polishing (CMP) is widely used. However, in diamond there are very few reports of CMP. In this work, we perform CMP on single-crystal diamond substrates and investigate its effect on the surface properties.

The samples were HPHT single crystal diamond (001) (4 x 4 x 0.5 mm). First, all the surfaces were mechanically polished (MP) to adjust the thickness, the off angle, the roughness. Next, CMP was performed on the diamonds with different processing time; 0 h (MP only), 5 h, 50 h and 100 h. The surface roughness before DC plasma CVD growth was less than 0.2 nm. Finally, the diamond films were homoepitaxially grown on the MP and CMP-treated diamond substrates for 10 hours by DC-plasma CVD method.

In synchrotron radiation X-ray topography observation, we have found different contrast between the substrate subsurface with and without CMP. Further, we confirmed pits on the CVD diamond surface grown on the substrate without CMP. However, as the CMP process time increased, the pit density decreased. Eventually, on the surface for 100 h CMP, no pits were observed. From these results, we concluded that the subsurface damage leads to pit formation in homoepitaxial growth, and CMP on the substrate is effective to prevent pit formation in CVD diamond growth.

The sheet resistance was carried out by Hall effect measurement. We found that the sheet resistance decreased with increasing CMP time. CMP is important technique for diamond device.

The Effect of Methane Concentration on Surface Morphology and Doping Efficiency of Heavily Boron-Doped Single Crystal Diamond Layers

To develop diamond-based high-power electronics, several challenges must be overcome. One of these is the growth of high quality heavily (p+) B-doped single crystal diamond (SCD) layer. It has been reported that deterioration of film morphology, due to the presence of defects, prevents achieving high boron concentration (10²¹ cm⁻³) in the diamond lattice.

The impact of [C]/[H] ratio on the surface quality and electrical properties of B-doped SCD grown by microwave plasma-enhanced CVD (MW PE CVD) is investigated in this study. Heavily B-doped SCD layers were grown in a home-built CVD reactor on 33 mm² Ib (100)-oriented HPHT substrates. Growth was performed in a conventional [CH₄]/[H₂] plasma (0.5%, 1%, 2%, and 3%), investigated in this study. Heavily B-doped SCD layers were grown in a home-built CVD reactor on 33 mm² Ib (100)-oriented HPHT substrates. Growth was performed in a conventional [CH₄]/[H₂] plasma (0.5%, 1%, 2%, and 3%), with trimethylboron as the boron source, with a constant 997 ppm [B]/[C] ratio used for all samples. The aim was to analyze the effect of methane concentration on the electrical properties of grown films. Diamond deposition by CVD constitutes a delicate balance between diamond growth and etching by hydrogen. Atomic force and optical microscopes confirmed that etching was dominant for B-doped diamond growth at lower [C]/[H] ratio (0.5%), as seen in the morphology from the appearance of etch pits. This effect was observed at the lower [B]/[C] ratio than what has been previously observed in literature.

At a higher [C]/[H] ratio (1%), high-quality p+ B-doped SCD layers were obtained. In Raman spectra, a broad peak was observed at the wavenumber 500 cm⁻¹, the width of which is proportional to the boron concentration in diamond. Fourier transform Infrared (FTIR) spectroscopy also gives an estimate of boron content as has been demonstrated by several research groups for p+ B-doped samples. The boron concentrations estimated by Raman and FTIR spectroscopies were compared to the results of Hall effect which gave high boron incorporation levels but lower than what was estimated by the Raman and FTIR methods. The underestimated boron concentration could be due to the imperfect transmission through the samples and the possible error in the measurement of grown thickness. Even with this error, the boron concentrations which were measured by Hall effect showed the same [C]/[H] ratio dependence as determined by the Raman and FTIR methods, with the sample grown at 3% [CH₄]/[H₂] showing a higher boron incorporation than those grown at lower [CH₄]/[H₂].

A cell is a precision microsystem made up of a variety of micro- and nanocomponents, such as organelles and biomacromolecules. The cell system is governed by nanometer-scale physical and chemical properties with spatial and temporal variations. This means that the nanoscale measurements can provide a wealth of information about biological functions. However, the sensitivity and stability of measurement heavily depend on the sensor size. Therefore, nanometer-sized small sensors that can be used in cells were generally unreliable. Here, we describe intracellular measurement techniques using fluorescent nanodiamond as a quantum sensor for nanoscale chemical and physical properties. The nanodiamond quntum sensors are promising not only in advancing knowledge in fundamental science but also in technological applications, in the same way that small sensors empowered smartphones and self-driving cars, and thus, has to potential to open new avenues for bioscience and nanoindustry.

Superconducting quantum interference device (SQUID), which is composed of superconducting loop with Josephson junction, is widely used for ultra-high sensitive magnetometers. One of the current problems is that conventional superconducting material like Nb is fragile. Superconducting boron-doped diamond is robust and resistant to contact, oxidation, and deterioration, so it is suitable material for robust SQUID. We previously fabricated step-edge structure Josephson junction [1], but the superconducting transition temperature (Tc) was lower than 4.0K. It is essential to operate above liquid helium temperature (4.2K) for application to SQUID. So in this research, we report the Josephson junction composed only of (111) film with operating up to 7.0K. We fabricated a Josephson junction with weak links in intermittent (111) plane. Weak links were formed at the interfaces of the (111) superconducting diamonds across trench region. This trench was formed on the (111) diamond substrate by Focused Ion Beam. The trench had a width of 200 nm and a depth of 30 nm. Then a superconducting boron-doped layer with a thickness of 500 nm was selectively grown across the trench by microwave plasma enhanced chemical vapor deposition method.

We investigated the temperature dependence of resistance (R-T), two-step superconducting transitions were observed at 10.2K and 7.0K, corresponding to Tc of the boron-doped diamond grown from the substrate and the trench, respectively. This operating temperature is nearly twice the previous value [1] and is also comparable to that of Josephson junction with Nb, which is generally used for SQUID. This is because this Josephson junction was composed of only (111) diamond with Tc=10K whereas the step-edge structure included (001) with Tc=4K [2]. The I-V characteristic had no hysteresis and showed DC Josephson effect. The critical current (Ic) was 0.03 mA and Ic / 2eΦ0 was 0.15 mV at 4.2K. This value is comparable to that of Nb SQUID. Shapiro steps were observed up to 7.0K more clearly than before. The interval between steps was in good agreement to the theoretical value calculated from the frequency of microwave and flux quantum (Φ0=2×10-15 Wb).

We fabricated the Josephson junction composed only of (111) diamond and observed both the DC and AC Josephson effect up to 7.0K. These results mean that this Josephson junction has the capability of operating above liquid helium temperature. We strive to demonstrate the operation of the SQUID and assemble this SQUID into a Scanning microscope.

Nitrogen vacancy (NV) center in diamond is expected as a highly sensitive magnetic sensor for nanoscale NMR [1]. Since signal decays as 1/r3, where r is the distance from a magnetic field source, shallow NV centers must be fabricated. In order to improve properties of shallow NV centers, surface terminations such as O-terminations [2, 3] have been focused on. Recently, a theoretical calculation implied that N-terminated surface shows positive electron affinity (PEA) and contributes to stabilization of negatively charged state of shallow NV centers [4]. We have already reported that N-termination by nitrogen radical exposure to stabilization of negatively charged states of shallow NV centers [5]. The next step of our research is to investigate the applicability of N-terminated surface to NMR detection. In the previous study, N2 gas which contains 10% H2 gas was used as the radical source intending by nitrogen radical exposure leads to stabilization of negatively charged states of shallow NV centers [5]. The next step of our research is to investigate the applicability of N-terminated surface to NMR detection. In the previous study, N2 gas which contains 4%-H2 gas was used as the radical source intending by nitrogen radical exposure leads to stabilization of negatively charged states of shallow NV centers [5]. We previously fabricated step-edge structure Josephson junction [1], but the superconducting transition temperature (Tc) was lower than 4.0K. It is essential to operate above liquid helium temperature (4.2K) for application to SQUID. So in this research, we report the Josephson junction composed only of (111) film with operating up to 7.0K. We fabricated a Josephson junction with weak links in intermittent (111) plane. Weak links were formed at the interfaces of the (111) superconducting diamonds across trench region. This trench was formed on the (111) diamond substrate by Focused Ion Beam. The trench had a width of 200 nm and a depth of 30 nm. was used as the radical source. Charge stability of shallow NV centers was evaluated by measuring the decay rate of the NV^− and the shallow donors, including hydrogenic donors. The NV^− ion was produced by a 400−eV electron irradiation at room temperature. The 1H-NMR detection was conducted on the N-terminated surface. The coherence time of the NV center in diamond was estimated from the 1H-NMR signal [7] was 10.0 nm. In conclusion, negatively charged states of shallow NV centers were stabilized by N radical exposure using 100%-N_2 gas, and we successfully detected 1H-NMR on the N-terminated surface by shallow NV centers.

Raman and Photoluminescence Characterization of Arsenic-Doped Diamond by Ion-Implantation Kajuve Wang1, Yufei Zhang2, Huijun Wang2 and Hong-Xing Wang2; Xi’an Jiaotong University, Xian, China; 2Taiyuan University of Science and Technology, Taiyuan, China.

Due to its wide band gap, high thermal conductivity, high carrier mobility and high breakdown voltage, diamond has been attracting much interest as the potential material of high-frequency high-power electronic device[1-3]. The device requires a high concentration of acceptors or donors, which could be obtained by the methods of doping. There are a great number of works on the doping of diamond. For n-type diamond, the nitrogen is the most common observed donor impurity and usually exists in natural diamond[4]. However, the quite-deep donor level of 1.7 eV is formed between the intermediate of diamond forbidden band, which makes it useless for semiconductor devices at room temperature[5]. As the same group V elements, arsenic is the shallower doping and expected as a more promising substitutional donor candidates[6]. The theoretical works showed that the substitutional arsenic provides the shallower donating level than phosphorus, at 0.4 eV below the bottom of the conduction band [7,8].

As an important material, diamond is extensively investigated by technology of low temperature photoluminescence, and some new results were presented and discussed. A slice of ultrapure colorless diamond was involved which was synthesized by MPCVD. The (100) surface orientation of the sample was implanted with arsenic ions at 300K, with an energy of 150keV and a dose of 10^{14} ions cm^{-2}, and then annealed at temperatures of 400C, 800C and 1500C. The Photoluminescence examination was performed by Renishaw micro-Raman spectrometers fitted with Linkam liquid nitrogen cooled stages at an excitation wavelength of 532 nm.

4:15 PM EP09.04.04
Application of Laser-Induced Doping to Singlecrystalline Diamond Abdelehaman Z. Ahmed1, Eslam Abubakri2, Yuki Katamen2, Shinya Ohmagari2 and Tsuyoshi Yoshitake2; 1Advanced Power Electronics Research Center, National Institute of Advanced Industrial Science and Technology (AIST), Osaka, Japan; 2Frontier Research Academy for Young Researchers, Kyushu Institute of Technology, Fukuoka, Japan; 3Department of Applied Science for Electronics and Materials, Kyushu University, Fukuoka, Japan.

Diamond is a wide bandgap material with extreme thermal, electrical and optical properties that receives unprecedented attention since it is expected to handle more power with higher efficiency than conventional semiconductors. However, due to the intrinsic difficulties, device fabrication has serious problems in achieving n-type doping under good conditions. Moreover, diamond is not easily modified like other semiconducting materials that can be treated thermally after deposition.

Recently laser-induced doping has been applied to other wide band gap semiconductor (SiC) and its effectiveness is experimentally proved. In this work, we applied laser-induced doping to singlecrystalline diamond, for the first time to our knowledge. The doping of phosphorus and Boron into singlecrystalline diamond is discussed from the chemical compositionally and electrically viewpoints.

In this work, Singlecrystalline diamond (100) plate (Ib) was immersed in a phosphoric acid solution (85%) and Boric Acid. ArF excimer laser (Gigaphoton Inc. wavelength: 193 nm) beams were irradiated on it. The laser beam irradiation was carried out at a frequency of 1 Hz and at different laser fluences up to 3.9 J/cm².

The results indicate that SC diamond hardly damaged on the plate surface by optical images even at a maximum fluence of 3.9 J/cm². Electrically, the electrical conductivity increases with increasing fluence and number of laser shots. Moreover, Phosphorus depth profile was investigated by Secondary-Ion Mass Spectrometry (SIMS), in which the Incorporation of Phosphorus up to 30 nm was achieved by increasing number of shots and reducing time interval between successive shots.

Further systematic experiments are conducted, such as Raman, I-V measurements, and theoretical simulations, results will be reported at the conference. This study was partially supported by JSPS KAKENHI Grant Numbers: JP15H04127, JP16K14391, and JSPS Fellow Grant JP17F17380.

Doping Level Determination of HPHT Diamond Substrate Using Electron Beam Induced Current Cedric Masante1, Fabrice Donatini2, Nicolas Rouger3 and Julien Pernot3; 1University Grenoble Alpes, CNRS, Grenoble INP, Inst. NEEL, Grenoble, France; 2Université de Toulouse; LAPLACE; CNRS; INPT; UPS, Toulouse, France.

For diamond power electronic applications, such as transistors and diodes, substrate quality is a key factor to obtain the best performances, influencing the properties of the epi-layers. Moreover, understanding the properties of the substrate, especially doping level, is often necessary to design the devices accordingly.

In this work, Electron Beam Induced Current (EBIC) technique is used to visualize the lateral expansion of the depletion region of a Schottky contact (Ti/Pt/Au stack) deposited on a (100) HPHT high quality substrate provided by New Diamond Technology. A comparison with finite element simulation has been performed in order to quantify key parameters. This method, requiring a single lithography process, is demonstrated to be efficient to extract doping levels below 10^{14} cm^{-3} whereas SIMS measurements are only efficient for doping levels higher than this value. This method will be compared to previous measurements done by cathodoluminescence. The example presented in this work is a substrate having a p-type (Boron) doping level evaluated around 3.10^{15} cm^{-3} near the surface (up to a few micrometers away from the surface). Diffusion lengths of a few micrometers are extracted and compared with recent measurements done on boron doped epi-layers [2]. This method will also be applied to Nitrogen compensated substrates as a mean to test their electrical activity, prior to their use for devices.

References
Diamond has excellent electrical characteristics as a wide gap semiconductor, and is expected as a high-performance power semiconductor for various applications as electric vehicles and trains etc. Boron doping by ion-implantation has been applied to achieve low resistivity of p-type diamond [1, 2]. Tsubouchi reported that doping efficiency of about 50% was achieved by annealing at 1600 °C after Boron implantation at 400 °C [2]. However, the doping efficiency is still not enough. Therefore, we propose a high-temperature annealing over 1600 °C by protecting the surface of diamonds as the effective recovering of implantation damage to achieve a high doping efficiency and crystallinity.

Boron was implanted at 500 °C by several accelerating voltages to form homogeneous Boron distribution profile in (001) diamond made by micro-wave plasma CVD. The density and the thickness of implantation layer was 5×10^{19} cm^{-3} and 400 nm, respectively. To protect the surface of diamond, diamond-like carbon with 80 nm thickness was deposited on a surface of implanted diamond by plasma CVD. Post-implantation of Boron elemental diamond was carried out in Argon atmosphere at a range from 1500 to 1850 °C. The surface morphology was evaluated by optical microscope. The damage of implantation was evaluated by Rutherford backscattering (RBS). The annealing for 10 minutes at 1850 °C was performed without degrading the surface morphology. It was clearly demonstrated that implantation damage can be reduced due to increase the temperature and the duration of annealing. Minimum channeling yield of the diamond annealed at 1500 °C for 60 minutes estimated by RBS was 6.6 %, and of the diamond annealed at 1800 °C for 30 minutes was 4.6 %, which is one of the lowest value after high dose boron implantation into diamond. Compared with annealing condition at 1500 °C, of that annealed at 1800 °C decreased almost by half. It indicates that the damage of implantation was fully recovered and almost the same as the un-implanted diamond without damage was obtained. At the same sample, the electrical resistivity measured by van der Pauw method was 64 Ωcm, and high doping efficiency over 90 % was also obtained in heavily Boron doped diamond layer. The high dose implantation can be applicable to form source and drain region by self-alignment process.

detected by an electron multiplying CCD (EMCCD) camera with high spatial resolution (410 nm per pixel).

Optically detected magnetic resonance (ODMR) spectra were imaged in an area of 150 μm² in the device while applying a reverse bias of 400 V. The width between the ODMR dips increased upon the bias application due to the Stark effect of the NV centers [4]. We also observed several dips in the spectra, corresponding to different NV axes. The highest electric-field of approximately 1.4 MV/cm was obtained at the edge of the patterned n⁺-cathode, in agreement with three-dimensional device simulation. We confirmed that the electric-field decreased as the position was far away from the n⁺-cathode, and became 0.3 MV/cm at 2 μm from the cathode. Accordingly, these facts indicate that two-dimensional distribution of the internal electric field in the device can be measured by using the NV centers. This technique will lead to the deep understanding and reliable devices.

Continuous-Wave Double Resonance of Electric Spin Triplet of NV Centers in Diamond and Its Application to High-Frequency AC Magnetic Field Sensing
Junko Ishi-Hayase¹, Soya Saio¹, Tatsuma Yamaguchi¹, Yuichiro Matsuzaki², Shiro Saito², Hideyuki Watanabe³ and Norikazu Mizuochi⁴; ¹Keio University, Yokohama, Japan; ²NTT Basic Research Laboratories, Atsugi, Japan; ³National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; ⁴Kyoto University, Uji, Japan.

Nitrogen-vacancy (NV) centers in diamond have received much attentions as highly-sensitive quantum sensors for detecting magnetic fields at room temperature. Pulsed optically detected magnetic resonance (ODMR) is typically used to detect AC magnetic fields, but can only be implemented after careful calibration that involves measuring continuous-wave (CW) ODMR, determining the Rabi frequency, and setting the microwave phase. In contrast, CW-ODMR can be simply implemented by continuous application of a green CW laser and a microwave field. However, CW-ODMR can be used to detect DC or low-frequency (kHz-range) AC magnetic fields. In this work, we report a method that uses NV centers and CW-ODMR to detect high-frequency (MHz-range) AC magnetic fields[1]. The proposed method involves a double resonance excitation of three level system of electric spin triplet states of NV centers. Unlike conventional methods, the proposed method does not require a pulsed sequence; this greatly simplifies the procedure and apparatus needed for implementation. In the experiment, we applied continuous green laser, microwave (~2.8 GHz), and radio wave (~4 MHz) to NV center ensemble created by CVD growth and He ion implantation. We clearly observed the change in CW-ODMR spectrum with and without radio wave (~4 MHz), which is in good agreement with the theoretical calculation. This result demonstrates to detect AC magnetic field with high frequency (~MHz) by measuring CW-ODMR spectrum. The estimated sensitivity is to be of the order of μT/Hz1/2 for our present experimental apparatus. The sensitivity is currently limited by inhomogeneous broadening and low measurement contrast of samples used and by the low collection efficiency of the optical setup, both of which could be improved in the future. Thus, this simple alternative to existing AC magnetic field sensors paves the way for the development of a practical and feasible quantum sensor. Furthermore, we measured the intensity and frequency dependence of CW-ODMR spectra by applying MHz-radio wave. We found that the CW-ODMR spectra are significantly modulated due to the double resonance excitation by GHz-microwave and MHz-radio wave. We will discuss the involved physics by analyzing double resonance spectra of NV centers in detail.

Investigation of Tin Vacancy Centers in Diamond for Realization of Spin-Photon Interfaces
Johannes Goerlitz¹, Morgane Gandil¹, Dennis Herrmann¹, Philipp Fuchs¹, Takayuki Iwashaki¹, Takashi Taniguchi¹, Tatsuya Yamaguchi¹, Yuichiro Matsuzaki², Shiro Saito², Hideyuki Watanabe³ and Norikazu Mizuochi⁴; ¹Saarland University, Saarbruecken, Germany; ²National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; ³Kyoto University, Uji, Japan.

Color centers in diamond have received large recent attention as versatile tools for solid-state-based quantum technologies such as quantum information processing and quantum-enhanced sensing and metrology. They provide individually addressable spins with very long coherence times, narrow optical spectra and bright single-photon emission. In this context, impurity-vacancy color centers based on group-IV elements (SiV, GeV, SnV, PbV) have emerged as interesting systems promising to combine all desired favorable properties. As a prime example, the negatively charged SiV center in diamond features an advantageous electronic structure and superior spectral properties [1]: At liquid helium temperatures, the SiV exhibits a narrow zero phonon line (ZPL) with a four-line fine structure and lifetime-limited linewidths on the order of 120MHz [2]. In addition, due to its small Huang-Rhys factor, up to 80% of the fluorescence is emitted via the ZPL. Moreover, the SiV offers an optically accessible Λ-type level structure with a large orbital level splitting allowing for fast all-optical control of its orbital [3] and spin [4] states. However, as a tradeoff, the SiV reaches millisecond spin coherence times only at millikelvin temperatures due to phonon-driven decoherence processes [4,5]. Motivated by these ongoing results, there have been efforts in order to find a color center in diamond with both excellent optical properties (i.e. optically accessible Λ-level scheme) and long spin coherence times even at elevated temperatures (at least liquid Helium temperatures, i.e. 4K). Thus the heavier homologues of the SiV should be interesting candidates, because their orbital level splitting is considerably larger, thereby reducing phonon-induced decoherence processes. A very promising candidate is the tin vacancy center (SnV) emitting at 619nm and indeed showing a similar fine structure as the SiV center, but with a much larger ground and excited state splitting (850GHz and 3000GHz, respectively) [6].

Motivated by these ongoing results, there have been efforts in order to find a color center in diamond with both excellent optical properties (i.e. optically accessible Λ-level scheme) and long spin coherence times even at elevated temperatures (at least liquid Helium temperatures, i.e. 4K). Thus the heavier homologues of the SiV should be interesting candidates, because their orbital level splitting is considerably larger, thereby reducing phonon-induced decoherence processes. A very promising candidate is the tin vacancy center (SnV) emitting at 619nm and indeed showing a similar fine structure as the SiV center, but with a much larger ground and excited state splitting (850GHz and 3000GHz, respectively) [6].

Here, we present recent results on spectroscopy of both SnV ensembles and single SnV centers in high quality bulk diamond, from room temperature down to liquid helium temperature. We find bright single photon emission from individual SnV centers from unstructured bulk material with saturation count rates up to 100,000 counts/second. We further explore their optical and spin properties, including lifetime, polarization, spectral features from photoluminescence and photoluminescence excitation, as well as spin coherence times, paving the way for assessing the suitability of the SnV center in diamond for spin-based photonic quantum technologies.

Solid-state quantum emitters embedded in a semiconductor environment are potentially scalable platforms for quantum optical networks operated at room temperature. Prominent representatives are nitrogen-vacancy (NV) centers in diamond showing coherent entanglement and interference with each other. However, a remaining challenge is how to regulate NV centers efficiently. Here, we demonstrate that the implementation of nitrogen, oxygen or sulfursulfur into H₂/CH₄ plasma to tailor the intensity of NV centers. Higher crystal quality of epitaxial films is first confirmed by comparing the FWHM of the diamond first-order Raman peak with the HPHT diamond substrate. By the engineering of nitrogen flow into the plasma, we find that the intensity of NV centers increases with the flow of nitrogen simultaneously, and the growth rate of epitaxial films first increases and then tends to be stable, while the intensity of NV centers decreases with the flow of sulfur and the growth rate of epitaxial films also keeps decreasing. However, the intensity of NV centers and growth rate show different trends when oxygen is added into the H₂/CH₄ plasma. The regulation of oxygen on the NV centers is first promoted and then suppressed. Only when the flow of oxygen is less than 0.4% (H₂+CH₄), oxygen promotes the intensity of NV centers. Due to the competition mechanism of oxygen and nitrogen in H₂/CH₄ plasma, the growth rate decreases with the increasing flow of oxygen, and finally tends to zero when the flow of oxygen reaches 1% (H₂+CH₄). Our study demonstrates NV centers as an adjustable defect for quantum photonics architecture relying on single photon source and qubits.

Secondly, we demonstrate a vector magnetic field sensing using our scheme with higher sensitivity using confocal and wide-field experiment system. Our scheme can be performed on (113)-orientated slabs of diamond to investigate ideal surface termination for hosting NV center. We considered hydrogen, oxygen, fluorine, and mixed terminations. Results show that different chemical termination of diamond could significantly change its electronic and chemical properties. Fluorine and oxygen terminations on diamond (113) surface could eliminate surface states intrusion in deep bandgap thus stabilize the fluorine, hydroxyl, nitrogen, and mixed terminations. Moreover, the oxygen terminated (113) diamond surface could form ordered and smooth surface thereby avoid surface spin caused by surface fluctuation. The stability calculation indicates it may achieve oxygen termination on (113) diamond surface during the experimental demonstration, we confirm the sensitivity of our scheme becomes 2 times better than the sensitivity of conventional scheme. Moreover, by changing the two frequencies of spin reversal, the x, y and z components of the magnetic field can be measured directly. The most important advantage of our scheme is that the sensitivity can be improved for regardless of NV center sample orientation and pulse measurement methods.

Our theoretical calculation, we showed the sensitivity of our scheme can be improved 2–4 times better than the sensitivity of conventional scheme[1]. In the experimental demonstration, we confirm the sensitivity of our scheme becomes 2 times better than the sensitivity of conventional scheme. Moreover, we demonstrate a vector magnetic field sensing using our scheme with higher sensitivity using confocal and wide-field experiment system. Our scheme can be applied to various type of pulse sequences for magnetic field sensing and enables us to improve the sensitivity by simultaneous manipulation of spin states with four orientation axes. This work was supported by JSPS KAKENHI (Grant No. 15K17732) and MEXT KAKENHI (Grants No. 18H01502, 15H05868, 15H05870, 15H03996, 26220602, and 26249108[HI4]), and Spin-NRI.

First-Principles Investigation of Nitrogen Vacancy Center in Diamond (113) Surface Song Li¹, Jyh-Pin Chou¹, Jie Wei¹, Minglei Sun², Alice Hu¹ and Adam Gal³; ¹City University of Hong Kong, Kowloon Tong, Hong Kong; ²School of Mechanical Engineering, Southeast University, Nanjing, China; ³Wigner Research Centre for Physics, Budapest, Hungary.

The nitrogen vacancy (NV) center in diamond demonstrates promising future in quantum simulator and sensor applications. Nevertheless the shallow NV center under surface could be significant influenced by surface termination and thus limit its sensitivity. The first-principles calculations have been performed on (113)-orientated slabs of diamond to investigate ideal surface termination for hosting NV center. We considered hydrogen, oxygen, fluorine, hydroxyl, nitrogen, and mixed terminations. Results show that different chemical termination of diamond could significantly change its electronic and chemical properties. Fluorine and oxygen terminations on diamond (113) surface could eliminate surface states intrusion in deep bandgap thus stabilize the fluorescent state of negatively charged NV. Moreover the oxygen terminated (113) diamond surface could form ordered and smooth surface thereby avoid surface spin caused by surface fluctuation. The stability calculation indicates it may achieve oxygen termination on (113) diamond surface during conventional diamond CVD growth condition.

Nitrogen-vacancy centres in diamond are being widely employed to measure magnetic fields. We performed theoretical calculations showing that the precision of NV magnetometry can be vastly improved by using diamond material with high NV densities as a laser medium and making use of the intrinsic amplification and high collection efficiency of a laser system. In this way quantum-limited sensitivities could become competitive with ultra-sensitive SQUID sensors.
Motivated by this result we investigated experimentally the properties of stimulated emission of NV centre ensembles in diamond. Combining green (532nm) pump light with red (~700nm) stimulating light, we measured spontaneous and stimulated emission and characterised the occurrence of induced absorption channels.

Placing NV diamonds in optical cavities we measured an amplification of red light transmitted through the cavity, when a green pump laser was added, by a factor of 3. We furthermore identified material properties and improvement challenges and strategies for CVD growth of diamond tailored to the realisation of an NV centre laser and laser threshold magnetometry.

The Interface Properties of Al2O3/NO2/H-Diamond in MOSFET Structure Studied by Capacitance and Conductance and Synchrotron XPS/XANES Measurements
Niloy C. Saha1, Kazutoshi Takahashi2, Satoshi Masuya1, Masaki Imamura1 and Makoto Kasu1; 1Electrical and Electronic Engineering, Saga University, Saga, Japan; 2Synchrotron Light Application Center, Saga University, Saga, Japan.

Diamond with a wide band-gap of 5.47 eV and high break-down field of ~10 MV/cm is expected to be best semiconductor material for high-power and high-frequency transistors. Diamond field effect transistor (FET) exhibited high RF output power density of 2 W/mm at 1 GHz, transition frequency (fT) of 45 GHz and the cut-off frequency of power gain (fMAX) of 120 GHz. Inorganic gases, such as O3, NO2, NO, and SO2 adsorbed on H-diamond surface and generate hole carriers. This phenomenon can be explained as the inorganic molecule accommodate electrons and induce holes due to the lower molecular orbital energy of these gases than diamond valence band maximum (VBM) [1]. The NO2 p-type doping increases hole sheet concentration up to ~1x10^14 cm^-2. Recently, M. Geis et al. reported that presence of NO2 peak on NO2-adsorbed H-diamond [2]. For FET, we have been using NO2-p-type doping in H-diamond. However, Al2O3/NO2/H-diamond interface structure is yet to be identified more clearly.

Al2O3/NO2/H-C, Al2O3/NO/H-C, and Al2O3/NO2/H-C structures were investigated by XPS/XANES measurements, where valence band offsets were determined to be 3.9, 3.7 and 3.5 eV, respectively, suggesting decomposition of exposed gases. Oxygen-derived interface state was detected but no N or S peak was found at the interface.

In the C-V measurements, the flat-band voltage of Al2O3/NO2/H-C MOS structures shifted towards positive voltage side by 2 V compared to that of Al2O3/H-C MOS. We also found that exposure of inorganic gases reduces the work function of H-diamond surface and shifted flat-band voltage towards the positive side. Interfacial properties were measured using conductance method by measuring parallel conductance from 1 kHz – 1 MHz. By fitting the parallel conductance, we separated border trap density in Al2O3 layer and interface state density. values are ~5.7 × 10^12 and ~4.8 × 10^12 cm^-2 eV^-1 respectively for the Al2O3/NO2/H-C and Al2O3/H-C MOS structures at room temperature.

In conclusion, we have identified oxygen-state at the interface of Al2O3/NO2/H-C structure using XPS/XANES measurements which is also confirmed by measuring conductance and compared to that of Al2O3/H-C structure. This investigation provides the information that NO2 exposure does not incorporate directly into interfacial states as the values in both cases are within the same range. A comprehensive demonstration will be discussed.

Vertical-Type 2DHG Diamond MOSFETs Over 5000 A/cm² and Low On-Resistance 6 mΩcm²
Masayuki Iwataki1, Nobutaka Oi1, Kiyotaka Horikawa1, Shotaro Amano1, Taisuke Kageura1, Masafumi Inaba2, Atsushi Hiraiwa2, 1 and Hiroshi Kawarada1, 3; 1Waseda University, Shinjuku, Tokyo, Japan; 2Synchrotron Light Application Center, Saga University, Saga, Japan.

We have reported excellent characteristics of high breakdown voltage and stable operation in wide temperature range in 2 dimensional hole gas (2DHG) diamond metal-oxide-semiconductor field effect transistor (MOSFET) with Al2O3 gate insulator and passivation film by high temperature atomic layer deposition (ALD) method [1][2]. 2DHG is preserved by ALD-Al2O3 near the interface of hydrogen terminated diamond [3][4]. The 2DHG is induced independent on crystal orientation. So, the trench side wall is used for drift region [5]. We have also reported vertical-type 2DHG Diamond MOSFET with trench structure [5] and obtained high current density and on/off ratio by forming the nitrogen doped layer as a block layer [6]. For vertical GaN devices, high current density over 2000 A/cm² and low on-resistance of 1.8 mΩcm² have been reported [7]. The same level performance is also required for vertical diamond devices. In this work, we further miniaturized vertical-type 2DHG Diamond MOSFET with trench opening length 2 or 4 µm and incorporated overhanging gate electrode structure on the source electrode for improvement of on-current density.

The fabrication process is follows. First, the 2 µm nitrogen doped layer is grown to suppress leakage current on the boron doped layer by microwave plasma chemical vapor deposition method. The nitrogen concentration is changed stepwise from 2.0×10^14 – 8.0×10^14 cm^-3 in order to assuage the electric field overconcentration. The trench is formed by Inductive Coupled Plasma Reactive Ion Etching. The trench opening length is 2 or 4 µm and the depth is 3 ~ 4 µm. After forming the trench, undoped layer (200 nm) is grown epitaxially again to induce the 2DHG layer. 200 nm Al2O3 is deposited high temperature ALD method [1][2]. 2DHG is preserved by ALD-Al2O3 near the interface of hydrogen terminated diamond [3][4]. The 2DHG is induced independent on crystal orientation. So, the trench side wall is used for drift region [5]. We have also reported vertical-type 2DHG Diamond MOSFET with trench structure [5] and obtained high current density and on/off ratio by forming the nitrogen doped layer as a block layer [6]. For vertical GaN devices, high current density over 2000 A/cm² and low on-resistance of 1.8 mΩcm² have been reported [7]. The same level performance is also required for vertical diamond devices. In this work, we further miniaturized vertical-type 2DHG Diamond MOSFET with trench opening length 2 or 4 µm and incorporated overhanging gate electrode structure on the source electrode for improvement of on-current density.

The fabrication process is follows. First, the 2 µm nitrogen doped layer is grown to suppress leakage current on the boron doped layer by microwave plasma chemical vapor deposition method. The nitrogen concentration is changed stepwise from 2.0×10^14 – 8.0×10^14 cm^-3 in order to assuage the electric field overconcentration. The trench is formed by Inductive Coupled Plasma Reactive Ion Etching. The trench opening length is 2 or 4 µm and the depth is 3 ~ 4 µm. After forming the trench, undoped layer (200 nm) is grown epitaxially again to induce the 2DHG layer. 200 nm Al2O3 is deposited high temperature ALD method. The gate length is 2 µm and part of the gate electrode has an overhanging structure which is liable to be placed on the source electrode. So, the length between source and gate electrode is 0 µm and also the device size itself is miniaturized. We defined the device active area is calculated the length of between both source electrodes (6 ~ 16 µm) and the channel width (25 µm).

The drain current density is ~200 mA/mm at VDS of -50 V and VGS of -20 V. In the active area 1.5×10^4 cm² device, the maximum drain current which is normalized with respect to active area is ~6000 A/cm² at VDS of -50 V and VGS of -20 V and the specific on-resistance is 5.8 mΩcm². The on/off ratio is 10⁶.

Specific on-resistance and normalized current density are much more improved by the miniaturization of device area.

Diamond is expected to be the next generation of power device material as wide band gap semiconductor with special properties such as high thermal conductivity and high breakdown field. Hydrogen-terminated diamond MOSFETs with a reported high breakdown voltage characteristic [1] and stable operation in wide temperature range [2] have been reported in previous research. Diamond MOSFETs use Two-Dimensional Hole Gas (2DHHG) which is induced by negative adsorbates or passivation film on hydrogen-terminated surface. In general, 2DHHG diamond MOSFETs are normally-on since 2DHHG channel is induced without gate bias. Power devices are required to be normally-off for safety. Normally-off diamond MOSFETs have already been reported for C-H diamond MOSFETs with partial C-O channel [1], HfO2-gated diamond MOSFETs [3] and inversion channel diamond MOSFETs. In this study, we demonstrate normally-off MOSFETs by the insertion of thin SiO2 layer in diamond/Al2O3 interface. SiO2 which do not have negative charge is not induced 2DHG. So, normally-off is achieved by insertion of SiO2 into MOS structure. In addition, we could suppress the deterioration of drain current density.

The fabrication process was as follows. Undoped homoepitaxial diamond layer was deposited on Ib (001) diamond substrates by Chemical Vapor Deposition, and electrodes were deposited as source and drain. 1st Al2O3 film was deposited as gate passivation by high-temperature ALD [4] after hydrogen-termination. Al2O3 is partially etched in the 20% (2μm) of channel area, where C-H surface is exposed in part. Si thin film (1nm) was deposited directly on the clean C-H surface at 723 K, and the Si film was fully oxidized by air and the subsequent 2nd Al2O3 deposition. The 2nd Al2O3 film was deposited as gate insulator by the same high-temperature ALD [4]. Finally, gate electrode was deposited form MOS structure where 20% of channel C-H surface is directly covered Al2O3 without surface negative charge which cause 2DHG. The gate threshold voltage (Vth) of the device was -2.0 V which is suitable for power device application. Vth, control and normally-off operation were achieved. The maximum drain current density was -67 mA/mm at VDS = -50 V when VGS was 0 V. The device of size was L=2 μm, W=10 μm and L2D=2 μm. In addition, normally-off devices were achieved in various size. The size of device was L=2 μm, W=10 μm, L2D=5 and 10 μm. Vth were -5.8 and -5.7 V. The maximum drain current density (VDS = -50 V, VGS = -40 V) were -52 and -53 mA/mm, which are larger other diamond normally off devices.

Diamond's unique chemical stability allows it to be used as an electron emitter under unusual conditions, including in water. However, the large bandgap of diamond makes it a poor absorber of light even at short wavelengths. The emission of electrons from diamond can be improved by creating novel types of heterojunctions with metals, semiconductors, and by integrating metal nanoparticles directly into the diamond film. The incorporation of silver nanoparticles directly into diamond films confers significant changes in optical properties as well as changes in electron emission characteristics. We have evaluated the electron emission characteristics of diamond-based heterojunctions as a function of wavelength, diamond film thickness, and other variables in order to understand how to achieve the most effective electron emission. In this talk I will present recent data comparing photoelectron emission from diamond and diamond-based heterostructure devices, with the goal of facilitating the use of diamond as an electron emitter operating under ambient environments.

The ability to form a negative electron affinity (NEA) surface on diamond is of interest for electron emission applications. These surfaces form when atoms electropositive relative to carbon terminate the surface. Simple H-termination gives NEA but hydrogen desorption occurs at elevated temperatures (>700 °C). This makes H-terminated diamond unsuitable for high-temperature applications.

Previous work has studied NEA surfaces generated by termination from group I, II and transition metals (TMs). Larger group I metals do not have thermal stability but smaller group I and II metals, such as Li and Mg, show promise. Computational work on various first-row TMs including Cu, Ni, Ti and Zn, suggest carbide-forming TMs give larger NEA and experimental work has shown <10 Å thin films of various TMs can give NEA.

Density functional theory calculations simulate the addition of up to 1 ML of aluminium on the diamond surface. Aluminium is a carbide-forming metal that bonds sufficiently well to be used for Ohmic and Schottky contacts, and here we show it is of interest for NEA applications as well. For certain Al coverages, for example 0.25 ML coverage on the (100) O-terminated surface, we find adsorption energies were observed to be larger than for H-termination whilst maintaining a NEA.

The hydrogen peroxide reduction on boron doped diamond electrodes modified by silver nanoparticles in a neutral phosphate buffer solution shows a CE mechanism. A diffusion oxygen layer is formed firstly along with water via the disproportionation of hydrogen peroxide on silver nanoparticles, and then reduced to hydrogen peroxide during electrochemistry process. Cyclic voltammetry and simulation are combined to confirm the mechanism, demonstrating the electrochemical reduction signal depends on the interacting time between silver and hydrogen peroxide via the disproportionation step which occurs before the voltammetric analysis.

Theoretical study on Termination Dependent Redox Reactivity of Boron-Doped Diamond / Water Interface Shota Iizuka, Keisuke Natsu, Yasuaki Einaga and Yoshitaka Tatayama; National Institute for Materials Science, Tsukuba, Japan; Keio University, Yokohama, Japan.

Boron doped diamond (BDD) is a promising electrode material, which has wide potential window and low background current. Our experimental studies so far demonstrated that the electrochemical characteristics of BDD can be modified by different surface terminations. Recently, the electrochemical properties of hydrogen (H), hydroxyl (OH), and fluoride (F)-terminated BDD were compared with the cyclic voltammogram measurement of anionic, neutral and cationic redox targets [1]. It is then observed that the oxidation and reduction current densities decrease for F-BDD, compared to H- and OH-BDD. Especially, the current density for anionic target was significantly suppressed in the case of F-BDD. Also, the oxidation potential for each target monotonously shifted toward the positive direction. To understand such differences in the electrochemical behavior, we calculated H-, OH-, and F-terminated BDD/water interfaces, employing Car-Parrinello molecular dynamics based on density functional theory. In the calculated electronic structures of H-, OH-, and F-BDD/water interfaces, we found that valence band maximum (VBM) of H-BDD is located at highest energy position, while F-BDD has much lower band position. For redox reactions with the targets, the Fermi level, nearly VBM, of p-type semiconductor BDD should coincide with the target redox potential according to the Fermi’s golden rule. With the hypothesis of surface band-edge pinning, VBM in H-BDD does not need to go up from the open circuit condition, while that in F-BDD needs significant upward shift. This causes large downward band bending in the subsurface region of BDD, which plays a barrier role for the electron / hole tunneling between the BDD electrode and the redox target. This is not the case in H-BDD in fact, and the observed redox behaviors are roughly accounted for by this mechanism. For more comprehensive explanation, we also analyzed distribution of interfacial water on H-, OH-, and F-BDD/water interfaces, and the interfacial charge. Regarding H-BDD and F-BDD, oxygen atoms of water distributed farther from the BDD surface than OH-BDD. This suggests that H- and F-BDD surfaces are hydrophobic. This hydrophobicity increases the tunneling length of electron / hole between BDD and the target in water. We also found that F-BDD has more negative surface than the others, reflecting large electronegativity of fluorine atom. This indicates that it is difficult for anionic target to approach the BDD surface and the tunneling length becomes larger.
We propose a new electric wireless communication under the sea; it utilizes diamond solution-gate FETs (SGFETs) [1] where the semiconductor surface is directly immersed in solution (e.g. seawater), and drain current (\(I_D\)) is remotely controlled by electric signals (\(V_G\)) of a reference electrode.

Seawater wireless communication has been required for many purposes. The electromagnetic waves are heavily attenuated in the seawater due to highly ionized media [2]. In general, the acoustic waves and visible light are used for seawater communication. However, these seawater communication means are not appropriate for mobile seawater robots; the reasons are that acoustic waves induce transmission problems such as Doppler shifts, and that the visible light requires accurate alignment between a transmitter and a receiver [2]. On the other hand, electric signals have relatively low attenuation and isotropic distribution of electric field due to electrical conductivity of seawater. Thus, electric seawater wireless communication has potential for mobile seawater robots [3]. In this work, we mainly investigated two points; first, how far the electric signals are transmitted, and second, what the maximum operation frequency of SGFETs is in the vast sea.

This communication setup consisted of two components; a reference electrode as a transmitter and SGFET as a receiver. The reference electrode, which was remote from the SGFET, applied electric signals (\(V_{SGFET}\)) via seawater. Then, the SGFET received the electric signals (\(V_{SGFET}\)) via seawater. Also, each of the source potentials was common ground in order to obtain stable reference potential. \(I_{DS\text{-}V_{DS}}\) and switching characteristics of the SGFETs were measured.

The electric signals (\(V_{SGFET}\)) of the reference electrode propagated without attenuation in the sea. In both 1 and 10 m, ideal \(I_{DS\text{-}V_{DS}}\) characteristics were obtained by electric signals (\(V_{SGFET}\)). Moreover, the switching times for \(T_{ON}\) and \(T_{OFF}\) were both less than 1 \(\mu s\). Therefore, between 100 kHz-1 MHz, this setup was capable of communicating within 10 m in the sea. The limit of frequency governed by a long ground line. The operation frequency can be increased further by considering a new ground. The 10 m is not a limit of this wireless communication, but can be extended much more, because the signal does not differ from 1 m to 10 m.

We adopted diamond SGFETs to establish new electric seawater wireless communication. This communication method using SGFETs is applicable for mobile seawater robots because electric signals have relatively low attenuation and isotropic distribution of electric field.

Diamond is a fascinating semiconductor with exceptional physical properties such as a wide band gap, a high breakdown electric field (10 MV/cm), an outstanding thermal conductivity (20 W/cm/K) and high carrier mobilities. These exceptional properties, or more precisely, the combination of some of these properties makes diamond an ideal semiconductor for high power and/or high frequency electronics which should surpass other materials like silicon, silicon carbide or gallium nitride. Numerous diamond field effect transistors are under investigation: H-terminated accumulation FET, O-terminated injection smoothly from metal to diamond subsurface when surface electron potential is high (surface band bends upward). It is realized by negatively charged surface or negative surface voltage bias. Then, 2 dimensional hole gas (2DHG) is produced by hole injection from metal. It is desirable for high speed FET operation [1].

Low SBH for 2DHG:
Diamond has superior properties as p-type conducting compared with other wide bandgap semiconductors. Among them P-type Schottky barrier height (SBH) is very low (< 0.1eV) on the hydrogen terminated (C-H) diamond surface in high work-function metal such as Au [1]. This property enables hole injection smoothly from metal to diamond subsurface when surface electron potential is high (surface band bends upward). It is realized by negatively charged surface or negative surface voltage bias. Then, 2 dimensional hole gas (2DHG) is produced by hole injection from metal. It is desirable for high speed FET operation [1].
High Frequency FET:
The first GHz operation in diamond [2] has been realized by metal semiconductor (MES) FET, where Au is used for source and drain contacts and Al for Schottky gate on the same C-diamond surface. Al shows the SBH of 0.6 eV, because Al work function is lower than Au by 0.7 eV. The work function dependence of SBH indicates that C-H diamond surface has low surface states density, necessary for MOSFET. In addition to MESFET [3], MOSFETs [4,5] exhibited GHz operation up to 70 GHz [6] in fT (cutoff frequency) and >100GHz [3] in fmax. The power density is now 3.8 Wmm⁻¹ [7] at 1GHz obtained by high bias voltage (~50V). Its electric field is above 2x10⁵ Vcm⁻¹, where the hole velocity is nearly saturated in an entire FET. The power density is lower than AlGaN/GaN HEMT, but higher voltage operation can enhance it much further.

High Voltage FET:
C-H diamond MOSFETs are uniquely designed for high-voltage (~1000V) and high-temperature (up to 400°C) operation using the high temperature (450°C) ALD Al₂O₃ as gate oxide and passivation of gate-drain (drift) region. The maximum breakdown voltages (VBR) are above 1500 V [8] obtained at long drift region (LDrift = 15 μm). fT × fmax = ~1.0 MV/cm, which is equivalent to those of SiC MOSFET and AlGaN/GaN HEMT. The drain current density is comparable to SiC, but 3-4 times lower than AlGaN/GaN at similar VBR. Conductivity in drift region must be improved by mobility enhancement.

Vertical FET:
The first vertical diamond MOSFETs have been developed using 2DHG layer on trench structure [9]. Hole conduction at the trench side wall (3-4 um depth) acts as drift region and is electrically connected to p+ substrate (drain). The drain current density of active planar area has reached to 5000 Acm⁻² [10], which is comparable to those of SiC or GaN MOSFET. Specific on resistance is 5 mΩcm⁻² at present.

9:30 AM EP09.08.03/EP08.06.03 Integration of V2O5 into H-Diamond MOSFETs for Enhanced Device Performance David Macdonald1, Kevin Crawford1, Alexandre Tallaire2, Riadh Issaoui2 and David A. Moran1; 1University of Glasgow, Glasgow, United Kingdom; 2LSPM-CNRS, Université Paris, Paris, France.

As a semiconductor, diamond possesses many unique properties that make it attractive for the production of high performance devices such as robust, high power RF FETs. Such properties include a large bandgap of 5.5 eV, high thermal conductivity of up to 20 Wcm⁻¹K⁻¹ and high carrier saturation velocity of 2 × 10⁷ cm⁻¹s⁻¹ for electrons and 0.8 × 10⁷ cm⁻¹s⁻¹ for holes. Development of electronic diamond devices has been largely limited however by the immaturity of existing doping processes used to introduce mobile charge into its naturally insulating crystal structure. ‘Transfer doping’ of hydrogen-terminated diamond (H-diamond) presents a potential solution to this challenge which has allowed for the production of high performance FETs. Stability issues associated with traditional transfer doping, which relies on the presence of atmospheric species on the diamond surface, has limited the maturity of device technologies that exploit these doping techniques. More recently, various work has demonstrated the potential to improve the stability and efficiency of transfer doping in diamond utilising electron acceptor oxide materials on the diamond surface. In this work, we apply the electron oxide acceptor material V2O5 into H-diamond FET technology and demonstrate substantial performance improvement in comparison with traditional atmosphere-exposed devices. These performance figures include the highest reported drain current and transconductance for a H-diamond FET to incorporate an electron acceptor oxide such as V2O5. Furthermore, a 400°C anneal stage utilised in the process flow for devices (as required to ensure stability of the V2O5 layer) is also found to reduce the ohmic contact resistance and increase the carrier concentration beneath the gate of the devices, further improving device performance.

The potential mechanisms for this performance enhancement and future implementation of these techniques to enhance the performance and robust operation of H-diamond FET technology will be discussed.

9:45 AM EP09.08.04/EP08.06.04 Diamond Surface Conduction FET RF Performance Correlated to Internal Charge Carrier Characteristics Pankaj Shah, James Weil, Khamsouk Kingko, Kevin Crawford, Mahesh R. Neupane, Anthony G. Birdwell, Edward Viveiros and Tony Ivanov; Army Research Laboratory, Adelphi, Maryland, United States.

Higher power, higher frequency RF transistors than those possible using the III-nitride semiconductors are desired for large data (high bandwidth) information transmission, highly advanced radar detection, and more efficient communication. We are developing hydrogenated diamond surface conduction field effect transistors (FETs) for use in these next generation RF systems accessing diamond’s wide bandgap (5.47 eV) extremely high thermal conductivity in drift region (~1.0 MV/cm, which is equivalent to those of SiC MOSFET and AlGaN/GaN HEMT. The drain current density is comparable to SiC, but 3-4 times lower than AlGaN/GaN at similar VBR. Conductivity in drift region must be improved by mobility enhancement.

9:45 AM EP09.08.04/EP08.06.04 Diamond Surface Conduction FET RF Performance Correlated to Internal Charge Carrier Characteristics

We have also observed that the Schottky barrier heights for the atmospheric transfer doped devices with good gate control are over 0.38 eV and range up to 1.0 eV. This best connects the influence of material, fabrication steps and structure on performance. In this regard, we obtained the hole velocity (~1.0 MV/cm, which is equivalent to those of SiC MOSFET and AlGaN/GaN HEMT. The drain current density is comparable to SiC, but 3-4 times lower than AlGaN/GaN at similar VBR. Conductivity in drift region must be improved by mobility enhancement.

The potential mechanisms for this performance enhancement and future implementation of these techniques to enhance the performance and robust operation of H-diamond FET technology will be discussed.

Optimizing RF surface channel FETs is most effectively done using device physics information obtained directly from the same device that the RF measurements are made on. This best connects the influence of material, fabrication steps and structure on performance. In this regard, we obtained the hole velocity in the FET channel using a delay time measurement and this is we believe the first ever discussion of velocity obtained in this way applied directly on a diamond RF FET. This will be related to carrier density and effective mobility obtained from RF FETs. RF small signal characteristics (current and power gain cutoff frequencies (fT, fmax)) and large signal characteristics (power, gain and efficiency) from load pull measurements will also be discussed for the same devices.

Transit time values obtained from a delay time measurement indicates these FETs have a hole velocity in the channel 5×10⁷ cm/s and drain depletion region delay = 2.5 ps. On wafer RF measurements for intrinsic current gain cutoff frequency indicate an opposite trend with gate length of fT = 70 GHz (Lg = 50 nm), 49 GHz, (100 nm), and 10 GHz, (500 nm) when Vds = 10V. With improved contact and access region resistances we expect the frequency bandwidth to increase. Load pull measurements indicate RF output power densities increased 30% as the drain and gate bias voltage pulse spacing increased (a duty cycle reduction from 5% to 0.5%) suggesting that RF output power is affected by heating of the transfer dopant in unpassivated FETs. These measurements also demonstrate a peak RF output power density of 0.66 W/mm² at 2 GHz.

We have also observed that the Schottky barrier heights for the atmospheric transfer doped devices with good gate control are over 0.38 eV and range up to 1.0 eV.
0.63 eV, however, the ideality factor is quite high (between 1.5 and 7.3). This may be an indication of the roughness of the surface and challenge contacting a hydrogenated region that the gate finger metal sits on. As the gate length reduced from 3 micron down to 50 nm the FET current density increased six fold, and knee voltage reduced uniformly by 50%.

Diamond Power Electronic Devices—Schottky Diodes Timothy A. Grotjohn1,2, John Albrecht1, Michael Becker2, Ayan Bhattacharya1, Ramon Díaz1, Aaron Hardy2, Timothy Hogan1, Matthias Muehle1, Robert Rechenberg2, Thomas Schuelke1,2 and Steven Zajač1; 1Michigan State University, East Lansing, Michigan, United States; 2Fraunhofer USA Center for Coatings and Diamond Technologies, East Lansing, Michigan, United States.

This paper will overview the status and prospects of diamond for power electronics applications. Both the potential and the current/future challenges will be discussed. The particular example of diamond Schottky diodes for power electronics will be explored in more detail. The authors have worked on diamond diodes by developing high quality substrates, low-defect doped epitaxial layers and diamond microfabrication processes. Two diode structures studied are the vertical Schottky diode and the pseudo-vertical diode. The vertical diode requires a thick (>250 µm) p+ doped substrate and the pseudo-vertical diode requires an undoped substrate with low dislocation defect density. Part of this effort is directed at providing substrates of p+ diamond to thicknesses >250 µm and providing p+ epitaxial layers for the pseudo-vertical devices. Improvement of the p+ epitaxial layer deposition was studied by reducing the particles landing on the surface during deposition and increasing the time the diamond CVD reactor can run before soot formed that required the run be terminated. The soot formation is a known problem for diamond deposition using microwave plasma-assisted CVD due to the high boron level added to the deposition process. The boron doped p+ layer is the region that provides the breakdown voltage of the Schottky diode. The p+ region needs to be deposited/grown with low dislocation defect density, controlled doping, controlled thickness and low compensation from impurities like nitrogen. The p+ layer was grown at 800°C with a feedgas of hydrogen, methane (4%), oxygen and a small amount of diborane as needed for the desired p-type doping concentration. The addition of the oxygen helps to improve the quality of the p+ epitaxial layer and reduce passivation of the boron doping by hydrogen. Schottky diodes fabricated showed breakdown voltages exceeding 1800 V. The 1800 V diodes showed forward current densities of up to 300 A/cm². Other diamond diode work will also be overviewed.

11:00 AM*EP09.08.06/EP08.06.06
Recent Progress in Diamond Field-Effect Transistor Technologies Makoto Kasu; Saga University, Saga, Japan.

A diamond semiconductor with a bandgap of 5.47 eV is expected to be the ultimate power device because of its exceptional physical properties, such as a high breakdown field (>10 MV/cm), high mobility, and highest thermal conductivity [20 W/(cm K)]. We previously reported high radio-frequency (RF) power performance of diamond field-effect transistors with a power-gain cutoff frequency, fMAX, of 120 GHz and an RF output power of 2.1 W/mm at 1 GHz. In this talk, we focus on very recent progress in two basic technologies related to diamond electronics: wafer technology and carrier doping technology.

To overcome the size limitation of diamond crystals, diamond heteroepitaxy technology has progressed rapidly. A 1-inch heteroepitaxial diamond has been demonstrated. In heteroepitaxy, epitaxial overgrowth technology is used to drastically decrease the dislocation density. Furthermore, microneedle technology has been proposed and demonstrated as a method to delaminate heteroepitaxial diamond from its substrate without cracking. [1] In the final process of heteroepitaxy technology, chemical mechanical planarization of the heteroepitaxial diamond surface is important for obtaining a damage-free and smooth surface. The full-width at half-maximum of the (004) plane was as low as 0.03°, and the curvature was 0.29 m, indicating the world’s highest quality heteroepitaxial diamond. The size and quality of diamond crystals is improving. We have fabricated diamond field-effect transistors on heteroepitaxial diamond, and the resultant device shows the same drain-current level as conventional homoepitaxial diamond on a HPHT substrate.

Concerning carrier doping technology in diamond, Kubovic and Kasu previously reported NO2 p-type doping, which they used to fabricate FETs; that is, NO2, O2, N2O, NO, and SO2 molecules adsorbed onto H-diamond generated hole carriers and the hole sheet concentration was as high as ~1 x 10^14 cm^-2 at room temperature. [2] Shiraishi and Kasu explained this phenomenon as the LUMO/SOMO orbital energies in the inorganic molecules adsorbed onto H-diamond being below the valence-band top of H-diamond, resulting in electron transfer from H-diamond to these molecules. Recently, Geis and Wade at the Massachusetts Institute of Technology investigated the NO2–H-diamond surface further by surface chemical techniques such as Fourier transform infrared temperature. [2] Shiraishi and Kasu explained this phenomenon as the LUMO/SOMO orbital energies in the inorganic molecules adsorbed onto H-diamond the physical and electronic characteristics of the TMO caused by the device fabrication process. In particular, stoichiometry reduction, crystalline phase heteroepitaxial diamond, and the resultant device shows the same drain-current level as conventional homoepitaxial diamond on a HPHT substrate. The size and quality of diamond crystals is improving. We have fabricated diamond field-effect transistors on heteroepitaxial diamond, and the resultant device shows the same drain-current level as conventional homoepitaxial diamond on a HPHT substrate.

Diamond:H/Transition Metal Oxides Transfer-Doping Efficiency and Transistors Performance Mosleh Tordeman1, Zongyou Yin2, youngtack Lee2, Alon Vardi2, Rafi Khalish3 and Jesus A. del Alamo1; 1Technion–Israel Institute of Technology, Haifa, Israel; 2Microsystems Technology Laboratories, Massachusetts Institute of Technology, Boston, Massachusetts, United States; 3Research School of Chemistry, The Australian National University, Canberra, Australian Capital Territory, Australia.

Transfer doping of hydrogen terminated diamond (Diamond:H) with various molecular-like surface acceptors suffers from low efficiency and temperature instability. In contrast, high electron affinity transition-metal oxides (TMOs) (i.e. MoO3, WO3, V2O5 and ReO3), when employed as surface acceptors for transfer doping on Diamond:H, have recently yielded improved p-type sheet conductivity and remarkable thermal stability even with only a few monolayers of coverage. [4, 5]. Despite these properties, the realization of Diamond:H electronic devices using TMOs remains very challenging. [6] This is due to undesirable changes in the physical and electronic characteristics of the TMO caused by the device fabrication process. In particular, stoichiometry reduction, crystalline phase transitions and structural morphology aggregations take place.

In this work, we discuss how different TMOs' properties affect the electrical properties of the resulting diamond:H/TMO-based transistors, and how these undesirable effects can be minimized. Electrical and surface characterization monitored before and after transistor fabrication reveal TMO oxygen reduction and a change in its oxidation state leading to electrical conductivity degradation. Based on these findings, we propose and demonstrate a way to improve diamond:H/TMO transistor performance and stability.

The drain current density (I_D) ranged from 1 to 3 μm.

Particularly, the power density of diamond FETs (up to 2.2 W/mm) [3, 6] is higher than those of GaAs and LDMOS. However, the operating voltage was as low as 15 ~ 20 V because of low breakdown voltage. Power density would be much more improved by realizing high voltage operation. Recently, we reported high average electric field [7] in MOSFETs with Al2O3 deposited as gate insulator [6, 8] and passivation layer [9] by high temperature atomic layer deposition (ALD) [10]. In this work, we fabricated ALD-Al2O3 2DHG diamond MOSFETs, whose structure is capable of withstanding high voltage, and evaluated small signal and large signal performance at high voltage operation (|V_D| < 60 V). As a result, the highest power density of 3.8 W/mm was obtained in diamond.

We fabricated ALD-Al2O3 2DHG diamond MOSFETs with 100 nm Al2O3 film on IIa-type polycrystalline diamond substrate with a <110> preferential growth surface. The source-gate length, gate length (L_G) and gate width were fixed to 0.5, 0.5 and 100 μm, respectively and gate-drain length (L_DG) was ranged from 1 to 3 μm.

The drain current density (I_D) was ~730 mA/mm at V_GS = ~20 V and V_GS = ~40 V and the transconductance was 15 mS/mm at V_GS = 12 V and V_GS = ~40 V for L_DG = 1 μm. Extrinsic f_T and f_max, including parasitic pad capacitances and inductances, were 30 GHz and 27 GHz at V_GS = 16 V and V_DS = ~60 V for L_DG = 3 μm. f_T > 30 GHz @ L_DG = 0.5 μm corresponds the saturation velocity of 1x10^7 cm/s. Hz is the first report that diamond FET reaches its saturation velocity. The large signal performance was evaluated using load pull system. The bias point for A-class operation were V_GS = 12 V, V_DS = ~50 V and I_D = ~405 mA/mm, respectively. The power density reached 3.8 W/mm at 1 GHz with associated gain of 11.6 dB and power added efficiently of 23.1 % for L_DG = 2 μm. The power density is the highest ever reported for diamond FETs.

3.8 W/mm Power Density at 1GHz for ALD-Al2O3 2DHG Diamond High Frequency MOSFETs

H-terminated diamond with 2 dimensional hole gas (2DHG) provides a promising surface channel for high-power and high-frequency applications due to its excellent properties for FETs. From 2001, milestones of RF performance of diamond FETs are first GHz operation in MESFETs [1], MISFETs with Al2O3 deposited as gate insulator [6, 8] and passivation layer [9] by high temperature atomic layer deposition (ALD) [10]. In this work, we fabricated ALD-Al2O3 2DHG diamond MOSFETs, whose structure is capable of withstanding high voltage, and evaluated small signal and large signal performance at high voltage operation (|V_D| ≤ 60 V). As a result, the highest power density of 3.8 W/mm was obtained in diamond.

Heteroepitaxial Diamond—Scaling of an Ultra-Wide-Bandgap Material to Wafer Dimensions

In the field of power devices, diamond’s intrinsic physical properties suggest that they can facilitate ultimate device performance. Just as for other wide-bandgap materials, the availability of wafer-size diamond substrates with high single crystal quality is an indispensable prerequisite. There are two approaches which start from opposite points: First, homoepitaxial growth on carefully selected rather small single crystals with minimum dislocation densities can be performed in such a way that the available area is increased step by step while the dislocation density is kept low. By a similar approach, 4H-SiC has progressively been scaled over 20 years starting from small Acheson platelets to 6” wafer size [1]. The second alternative is based on heteroepitaxy which starts on large areas but with high dislocation densities (DDs). The challenge here consists in a controlled decrease of the DD by several orders of magnitude while preserving the initial size.

This presentation is focused on heteroepitaxy of diamond on Ir/YSZ/Si(001) which has recently provided the first single-crystal diamond wafer with a diameter > 3.5” and a total weight of 155 carat [2]. All relevant steps for the wafer preparation will be described. First applications of the material will be presented and the potential for further applications will be discussed.

drastically modify its properties. The use of dopants such as boron can for example allow tuning the electrical conductivity of the film up to the metallic conduction which could allow to produce highly boron doped substrates and develop vertical components whose design and architecture for the realization of more complex function is simpler. In addition nitrogen or silicon are some of the elements that can be introduced in the crystal in order to create optically active centres such as the well-known NV (nitrogen-vacancy) and SiV (silicon-vacancy). Both defects exist in different charge states that can be stabilized depending on the doping level of the diamond.

In this presentation, we will focus more specifically on the production aspects of doped monocrystalline diamond films by chemical vapour deposition assisted by microwave plasma with either boron or nitrogen, highlighting all the constraints inherent to the targeted field of application. In the case of boron doping, particular attention will be paid to showing the plasma conditions which it is essential to maintain in order to obtain a sufficiently thick and doped film leading to on state resistances compatible with their use in vertical components. It will be shown in particular the importance of the gas composition to inject high microwave power allowing coupling high material quality with high growth rate. With regard to nitrogen doping, the conditions for optimizing the formation and orientation of NV colour centres will be discussed and the role of temperature, substrate orientation and gas composition will be highlighted.
