Machine learning and data-driven techniques are quickly being adopted to accelerate materials research in a variety of ways. In this tutorial, we introduce material scientists to a wide variety of machine learning topics which have found utility in real-world materials research. We will review fundamental topics in machine learning, including supervised and unsupervised learning, reinforcement learning, and Bayesian techniques and optimization. We will also cover practical tools and techniques for handling experimental data, in addition to extracting the relevant information from such data to make the applications of machine learning methods possible. After the tutorial, participants will have a broad understanding of machine learning in general, as well as concrete example applications of the topics to material science problems. No previous knowledge of machine learning will be required.

Predicting Colloidal Crystals from Shapes via Inverse Design and Machine Learning Yina Geng, Greg v. Anders and Sharon C. Glotzer; University of Michigan, Ann Arbor, Michigan, United States.

A fundamental challenge in materials design is linking building block attributes to crystal structure. Addressing this challenge is particularly difficult for systems that exhibit emergent order, such as entropy-stabilized colloidal crystals. We combine recently developed techniques in inverse design with machine learning to construct a model that correctly classifies the crystals of more than ten thousand polyhedral shapes into 13 different structures with a predictive accuracy of 96% using only two geometric shape measures. With three measures, 98% accuracy is achieved. We test our model on previously reported colloidal crystal structures for 71 symmetric polyhedra and obtain 92% accuracy. Our findings (1) demonstrate that entropic colloidal crystals are controlled by surprisingly few parameters, (2) provide a quantitative model to predict these crystals solely from the geometry of their building blocks, and (3) suggest a prediction paradigm that easily generalizes to other self-assembled materials.

9:15 AM GI01.01.03
Machine Learning Augmented Polymer Design—Mapping the Size and Composition of Poly(Oxazolines) to Cloud Points Jatin Kumar1, Karen Tang1, Qianxiao Li2, Amibal Gonzalez Oyarce2 and Jun Ye2; 1Institute of Materials Research & Engineer, Singapore, Singapore; 2Institute of High Performance Computing, Singapore, Singapore.

It has been long suggested that present synthetic techniques of polymers afford an excessive strain on resources, and efforts should be undertaken to devise new methods to predictively design polymers based on their desired properties.[1] One of such properties include phase behavior. Phase behavior is a unique characteristic of polymers which afford interesting assemblies and microstructure of polymer solutions, blends and films,[2] which are in turn influenced by the four key fundamentals of polymer architecture: (a) topology; (b) molecular weight; (c) composition; (d) functionality. Efforts were made by Hoogenboom and co-workers[3],[4] to systematically vary composition and molecular weight for poly(oxazoline)s so as to ascertain their relationship with cloud points – a temperature dependent phase behavior. A 3D curve of best fit was obtained correlating 2 of the numerous design parameters to cloud point. However, a 3D curve is an inaccurate correlation as there is no model that suitably fits the data, resulting in a poor fit with a loss of detail. Most importantly, the 3D curve does not cover all the parameters and is incapable of identifying the feature importance of the design parameters. In this paper, we will demonstrate the use of modern machine learning techniques which are able to correlate the various parameters describing polymer architecture, to its associated cloud point. We will demonstrate how the algorithm was trained using polymers synthesized at varying levels of precision. Finally we will demonstrate the attempt towards building an inverse design problem capable of designing a poly(oxazoline) architecture based on a required cloud point.

The true potential of additive manufacturing (AM) as a next-generation production technology will only be realized by synergy of automated machinery with predictive models of process and material performance. I will discuss our recent efforts to improve the performance of extrusion AM technology, including the design of a desktop system that achieves ~10X greater build rate than commercial benchmarks, implementation of feed-forward motion control algorithms to mitigate trajectory errors, and development of graph-based toolpath planning algorithms enabling continuous printing of lattice structures. In-process thermal imaging is used to calibrate toolpath planning algorithms for large-scale extrusion AM, mitigating deformation and strength loss due to local thermal gradients during printing. I will close with commentary on the opportunities and challenges toward autonomous manufacturing systems wherein AM is a cornerstone, and machine learning is an essential, yet currently primitive, component.
Toyota Research Institute (TRI) was founded in order to develop technology for a new world of mobility - with an overall mission to use artificial intelligence (AI) to improve the quality of human life. In the coming decades, our society will continually need better and more environmentally sustainable sources of energy storage for mobility and transportation. At TRI, the Accelerated Materials Design and Discovery (AMDD) program will accelerate discovery of energy materials through new tools, technologies, and methodologies that leverage advances in AI. The research program consists of efforts to 1) create extensive and dynamic databases of materials knowledge via high-throughput computing, high-throughput experimentation, and mining of existing literature data, 2) develop software tools to aid the human expert in extracting knowledge from large databases and 3) develop novel automated materials discovery systems by integrating simulation, machine learning, artificial intelligence, and robotics. The AMDD program is comprised of our research scientists, software engineers, and an extensive network of funded collaborators at a number of universities and research institutions. This talk will describe the vision of our research program, progress to date, challenges and early successes in applying AI to materials research for the discovery of catalysts and battery materials, and future opportunities at the intersection of materials and computer science.

11:00 AM  GI01.01.05
Accelerating the Discovery of New Energy Materials Brian Storey; Toyota Research Institute, Cambridge, Massachusetts, United States.

Toyota Research Institute (TRI) is conducting research on developing technology for a new world of mobility, leveraging artificial intelligence (AI) to improve the quality of human life. Within the coming decades, society will continually need sources of environmentally sustainable energy storage for mobility and transportation. The Accelerated Materials Design and Discovery (AMDD) program at TRI aims to accelerate energy materials discovery through innovative tools, technologies, and methodologies that harness advances in AI. The program's efforts include creating extensive and dynamic databases of materials knowledge via high-throughput experimentation and simulation, developing software tools to facilitate human expertise in extracting knowledge from large databases, and building automated materials discovery systems by integrating simulation, machine learning, artificial intelligence, and robotics. The presentation will outline the research program's vision, progress, and early successes in applying AI to materials research for the discovery of catalysts and battery materials, identifying future opportunities at the intersection of materials and computer science.

Damage Nucleation and Growth Prediction from Microstructure Spatial Characteristics Benjamin Cameron1 and C. Cam Tasan2; 1Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The vast compositional space of metallic materials provides ample opportunity to design stronger, more ductile and cheaper alloys. However, the substantial complexity surrounding microstructural deformation makes simulating new microstructures exceedingly difficult. Instead, tedious experiments are conducted to optimize properties without tools to predict how microstructures will perform. Here, we exploit recent developments in data collection capabilities and develop a purely empirical model to forecast microstructural performance in advance, entirely bypassing the challenges associated with physics based simulations. In-situ experiments are conducted using a scanning electron microscope in order obtain detailed microstructural information. 6400 12.5 μm square microstructural regions are tracked using a quasi digital image correlation algorithm and imaged throughout deformation in order to obtain sufficient data to train the model. Detailed analysis is conducted on three experimental datasets, two of dual-phase steel and one of bearing steel. The models are trained to predict crack nucleation and crack growth, a complex process with an intricate relationship to microstructural geometry. Multiple machine learning approaches are compared and contrasted including a n-point statistics and principle component analysis algorithm based on grain boundaries, a support vector machine approach, and a convolutional neural network. Using this approach, significant predictive ability is achieved and the model can accurately predict crack nucleation and crack size on a new microstructure. For example, 84.8% of microstructures predicted to crack, actually crack. Artificial microstructures with idealized properties are constructed and fed into the model in order to understand how it makes its prediction. For example, there is a major difference in cracking probability for grain boundaries aligned with the loading direction (12%) and inclined at 45° to the loading direction (72%). These results demonstrate the success of this approach and paves the pathway for use of this framework in alloy design to predict a range of behaviors.

Extraction of Capacitance Variance Mechanisms via a Neural-Net Accelerated Genetic Algorithm Venkatesh Meenakshisundaram1,2, David Yoo1,2, Andrew Gilman3, Clare Mahoney3, James R. Deneau3,1, Nicholas Glavin1 and Phil Buskohl1; 1Air Force Research Laboratory, WPAFB, Ohio, United States; 2UES, Inc., Dayton, Ohio, United States; 3UTC, Dayton, Ohio, United States.

Microscale spatial and material heterogeneities in 3D printed electrical devices present significant challenges to predictable electrical performance and device reliability. High permittivity particles are often added to dielectric inks to tailor the macro level permittivity of printed dielectric substrates and coatings. However the combined role of particle morphology, discrete spatial arrangement and material properties on variance is difficult to distinguish experimentally, due to the large parameter space of processing variables and electrical sensitivity to local heterogeneities. To address this challenge, we developed a 3D, high-fidelity finite element model of an interdigitated capacitor (IDC) with a dielectric coating of distinct spatial distributions of discrete dielectric particles. The volume fraction, particle size and permittivity distributions for each IDC was then encoded into the genome of a genetic algorithm (GA) with the objective of identifying combinations of these properties that generate high variance in the capacitance of the IDC. In addition, the genetic algorithm was guided by an artificial neural network (ANN) that recursively trains on the data produced by GA and sends suggestions back to the GA to accelerate the identification of optimized properties. This autonomous and robust optimization approach allows us to build a database with strong likelihood of high variance mechanisms, while saving on computational costs. Preliminary results indicate that large particles in dilute volume fractions generate high variability in capacitance, due to heighten influence these particles positions on excluding the electric field. Classification-based machine learning techniques were also applied to the spatial distributions of the dielectric particles to determine whether a critical spacing parameter or local clustering was a component in driving up the variance. Collectively, the study provides a useful framework to correlate electrical performance with both macro- and microstructural variation sources, which is key to accelerating the development of 3D printing materials.

11:30 AM  GI01.01.08
Machine Learned Defect Level Predictor for Semiconductors—The Example of Hybrid Perovskites Arun Kumar Mannodi Kanakkithodi, Michael Davis and Maria K. Chan; Argonne National Laboratory, Lemont, Illinois, United States.

Electronic levels introduced by impurities and defects in the middle of the band gap are critically important in semiconductors for optoelectronic, photovoltaic (PV) and quantum sensing applications. While “deep” defect levels can prove catastrophic for PV performance by causing non-radiative carrier recombination, impurity levels in the band gap could also be exploited for quantum sensing or lead to increased absorption of sub-gap photons which can enhance efficiencies. Predicting formation energies and charge transition levels for defects in semiconductors is thus paramount; density functional theory (DFT) calculations have been widely applied for such studies to overcome experimental bottlenecks. However, the requirement of large supercells and inclusion of charged states make these computations very expensive, and trends and knowledge from previous calculations are not exploited in subsequent ones. In this work, we use DFT to generate a substantial computational dataset of the formation energies and transition levels of vacancy, interstitial and substitutional point defects in many lead-based pure and mixed halide hybrid perovskites (MAPbX3, where MA = methylammonium and X = Cl/Br/I). These computations help determine the dominant intrinsic defects in any perovskite, the equilibrium Fermi level (and thus the nature of conductivity) for different chemical potential conditions, and the stable extrinsic substituents (atoms selected by screening across the periodic table). That
compensate for intrinsic defects and change the equilibrium Fermi level. Further, we apply machine learning to extract crucial design rules and predictive models of the emitters. As a result, we present a data set of small molecule donor-acceptor pairs gathered from the literature (between 2013 and 2017), for which equilibrium geometries and electronic properties have been computed at DFT level. We used electronic data in combination with Scharber’s model to calculate photovoltaic parameters of the organic solar cells. Comparison with experimental data reveals a disappointing performance of DFT. It has been shown that DFT data can be refined through Machine Learning to improve the performance of Scharber’s model to predict experimental photovoltaic parameters.

In this contribution, we present an approach to predict Organic Solar Cells Efficiency based on Machine Learning. We present a data set of small molecule donor-acceptor pairs gathered from the literature (between 2013 and 2017), for which equilibrium geometries and electronic properties have been computed at DFT level. We used electronic data in combination with Scharber’s model to calculate photovoltaic parameters of the organic solar cells. Comparison with experimental data reveals a disappointing performance of DFT. It has been shown that DFT data can be refined through Machine Learning to improve the performance of Scharber’s model to predict experimental photovoltaic parameters.

Finally, with a similar approach, we obtain direct predictions of solar cell efficiencies. We show that considering only electronic or structural parameters leads again to similar results, while considering both parameters at the same time results in improved predictions, allowing to obtain direct predictions of solar cells efficiency with a reasonable level of accuracy.

Finally, we critically assess the usefulness of the proposed approach for the discovery of new materials that have not been synthesized yet.

REFERENCES
Metal-organic frameworks (MOFs) are promising solid-state adsorbents thanks to their high gravimetric capacities. However, realizing a high volumetric $H_2$ adsorption capacity, balanced with a high gravimetric density, is one of the main barriers of the successful application of MOFs as solid-state adsorbents. A large database of half-a-million MOFs consisting of real and hypothetical compounds was compiled and screened using semi-empirical and atomistic (grand canonical Monte Carlo) techniques. Several machine learning (ML) algorithms were benchmarked for their ability to predict hydrogen storage in MOFs at multiple conditions. The top performing algorithm, extremely randomized trees, was applied to rapidly identify MOFs with high usable $H_2$ storage capacities across the entire database. A combinatorial approach was then used to understand the importance of crystallographic properties and training set size. This approach identifies the number and combination of crystallographic features needed to achieve the most accurate predictions. Finally, we assess multilinear regression models for their ability to out-perform the well-known Chaline rule for predicting $H_2$ uptake.

**Functional Defects by Design—A High-Throughput Approach to Energy Materials Discovery**

Janakiraman Balachandran, Jiuli Ding, Xiaohan Sung, Wei Guo, Shreyas Muralidharan, Jonathan Anchell, Gabriel Veith, Craig Bridges, Yongqiang Cheng, Christopher Rouleau, Jonathan Anchell; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2University of California, Berkeley, California, United States.

Defects and impurities introduce localized heterogeneities in solids and decisively control the behavior of a wide range of energy technologies. Fuel cell materials, especially proton conducting fuel cells, are a quintessential example in this regard. Designing and developing solid oxide materials that can selectively transport protons will enable us to develop the next generation proton conducting solid oxide fuel cells. Protons require less activation energy compared to oxygen ions which results in a lower operating temperature, higher operating efficiency and better material reliability. In this work [1,2,3,4] we focus obtaining fundamental insights on how properties of host material structure along with dopants, disorder and strain influences proton transport properties in solid oxides by coupling high-throughput computations with functional imaging, neutron spectroscopy and transport measurements.

We initially focus on the perovskite family of compounds (such as doped BaZrO$_3$). We benchmark our calculations against a wide range of experimental measurements such as kelvin probe force microscopy (KPFM), inelastic neutron scattering (INS) and atom probe tomography (APT). To obtain better insights on why certain cubic perovskite/dopant combinations are better at conducting protons compared to others, we developed a high-throughput framework to perform $ab$ _initio_ calculations. The high-throughput framework can scale massively to tens of thousands of nodes to fully exploit the computational capability of Titan at OLCF supercomputing facility. We employ this approach to calculate proton transport properties in several cubic perovskite materials with different host atoms and dopants. The results obtained from these calculations enables us to obtain better insights on how material structure – such as atomic properties (electronegativity, ionic radius) and lattice properties (sub-lattice distortion) influences proton transport. The results obtained from this high-throughput analysis is being employed to develop a machine learning framework to predict structure-property correlations on a larger set of perovskites materials. Finally, we explore the role of disorder on proton transport by studying for example fluorite based lanthanum tungstate materials.

3:45 PM GI01.02.06

**Polymer Genome—A Data-Powered Polymer Informatics Platform for Property Predictions**

Chinho Kim, Anand Chandrasekaran, Huan Tran, Deya Das, and Rampi Ramprasad; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2University of Connecticut, Storrs, Connecticut, United States.

The recent successes of the Materials Genome Initiative has opened up new opportunities for data-centric informatics approaches in several subfields of materials research, including in polymer science and engineering. Polymers, being inexpensive and possessing a broad range of tunable properties, are widespread in many technologically applications. The vast chemical and morphological complexity of polymers though gives rise to challenges in the rational discovery of new materials for specific applications. The nascent field of polymer informatics seeks to provide tools and pathways for accelerated property prediction (and materials design) via surrogate machine learning models built on reliable past data. We have carefully accumulated a dataset of organic polymers whose properties were obtained either computationally (bandgap, dielectric constant, refractive index and atomization energy) or experimentally (glass transition temperature, solubility parameter and density). A fingerprinting scheme that captures atomistic to morphological structural features was developed to numerically represent the polymers. Machine learning models were then trained by mapping the fingerprints (or features) to properties. Once developed, these models can rapidly predict properties of new polymers (within the same chemical class as the parent dataset) and can also provide uncertainties underlying the predictions. Since different properties depend on different length-scale features, the prediction models were built...
on an optimized set of features for each individual property. Furthermore, these models are incorporated in a user friendly online platform named Polymer Genome (www.polymergenome.org). Systematic and progressive expansion of both chemical and property spaces are planned to extend the applicability of Polymer Genome to a wide range of technological domains.

High-Throughput Materials Discovery and Development—Breakthroughs and Challenges in the Mapping of the Materials Genome
Marco Buongiorno Nardelli and Jeria Silva; University of North Texas, Denton, Texas, United States.

High-Throughput Quantum-Mechanics computation of materials properties by ab initio methods has become the foundation of an effective approach to materials design, discovery and characterization. This data driven approach to materials science currently presents the most promising path to the development of advanced technological materials that could solve or mitigate important social and economic challenges of the 21st century. In particular, the rapid proliferation of computational data on materials properties presents the possibility to complement and extend materials property databases where the experimental data is lacking and difficult to obtain. Enhanced repositories such as AFLOWLIB open novel opportunities for structure discovery and optimization, including uncovering of unsuspected compounds, metastable structures and correlations between various properties. The practical realization of these opportunities depends almost exclusively on the the design of efficient algorithms for electronic structure simulations of realistic material systems beyond the limitations of the current standard theories. In this talk, I will review recent progress in theoretical and computational tools for data generation and advanced characterization, and in particular, discuss the development and validation of novel functionalities within Density Functional Theory and of local basis representations for effective ab-initio tight-binding schemes.

4:30 PM GI01.02.08
Feature-Based Data Analysis for Localized Characterization of Electroactive Materials
Nikolay Borodinov1, Anton V. Ievlev1, Jan-Michael Carrillo1, Andrea Calamari2, Marc Mamak2, John Mulcahy2, GiCommunication, Joshua Agar1, Lane W. Martin1, Bobby G. Sumpter1, Sergei V. Kalinin1, Olga Ovchinnikova1 and Petro Makaryovych1; 1Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Research and Development, Procter & Gamble, Cincinnati, Ohio, United States; 1University of California Berkeley, Berkeley, California, United States.

Effective research and development efforts in the field of electroactive materials are critically dependent on the characterization methods that can generate information about the physical properties at the relevant scale. When the scope of these efforts includes engineering materials, fundamentally new challenges arise as the intrinsic complexity of industrial-grade samples requires decoupling of the observed phenomena. The characterization of the materials response in this case is impossible to be directly reflected using a single parameter. In order to tackle this challenge, we adopted a different strategy which included expanded representation of the analyzed materials with subsequent multivariate analysis. Its results were used to extract relevant features that may be intrinsic to a specific composition or instead may span across the sample library. We demonstrate this feature-centric approach for the rapid identification of the materials ability to develop triboelectric charge, observation of the electric charge migration on industrial-grade polyethylene terephthalate (PET) samples and property-driven analysis of effective piezoelectric coefficients observed across PZT-PZO (lead zirconate titanate - lead zirconate) phase diagram. We have employed multivariate adaptive regression splines, principal component analysis, large-scale molecular dynamics simulations, finite element analysis, multivariate Naïve Bayes classifier as parts of our method. Resulting insights allow for the isolation of the common features of the dataset reflecting specific piezoelectric and electrostatic phenomena as well as identification of the samples satisfying certain criteria. We believe that feature-base analytics demonstrated in this work can be successfully applied in other materials science fields where the nanoscale behavior of the relevant materials needs to the understood.

4:45 PM GI01.02.09
The Search for P-Type Transparent Conducting Chalcogenides
Rachel Woods-Robinson, Shyam Dwarknath and Kristin A. Persson; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Despite our increasing demand for renewable energy materials over the past decade, as well as recent advances in photovoltaics and transparent electronics, progress in the field of high-performing p-type transparent conductors (TCs) has been relatively slow. All TCs used in industry are still n-type, since state-of-the-art n-type TCs have figures of merit orders of magnitude higher than p-type analogues due to the localized, 2p character of valence bands and doping difficulties in wide-gap oxides. Both n-type and p-type TCs are conventionally oxides but, due to energetics of the chalcogen 2p orbitals, chalcogenide (S, Se, Te) semiconductors have shown promise of higher hole transport and greater p-type doping propensity than oxides (in exchange for a decreased band gap).

Here, we use high throughput computation to screen a large database of over 10,000 chalcogenide compounds for binary, ternary, and quaternary chalcogenides likely to have a high hole conductivity and high optical transparency. The first round of screening uses GGA and GGA+U functionals from the Materials Project database to calculate band gaps and hole effective mass derived from the BoltzTraP code. Refined screenings use additional transport and HSE calculations. Our ultimate goal is to synthesize promising compounds in the laboratory for use in stable devices, so we also apply a proxy for structural thermodynamic stability.

From these criteria, we discover a large set of computationally stable multi-anionic compounds. Several compounds studied previously as TCs emerge from our screening, including ZnS and sulfanitites TaCu3X4 (X = S, Se, Te). We further pare down this list for synthesis by selecting only single anionic compounds, removing compounds with toxic and highly reactive elements, and estimating p-type dopability. A refined list of ten top experimentally-favorable candidates emerges and includes spinal ZnAl2S4, distorted rocksalt BaS3Sn2S2, and several other rocksalt structures.

We delve deeper into the bonding characteristics of the valence band that give each predicted candidate its low calculated effective mass, and discuss these computed structures and our screening metrics in the context of state-of-the-art p-type and n-type transparent conductors. Additionally, we discuss defect calculations and dopant selection for the most promising structures, present our initial attempts to combinatorially synthesize and characterize a few of the candidates, and lay out a roadmap for a future high-throughput screening, synthesis, characterization, and device paradigm for new p-type transparent conducting chalcogenides.
The Role of Theoretical Prediction in Data-Driven Materials Development

Ruth Pachter; Materials and Manufacturing Directorate, Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States.

Development of two-dimensional materials, including graphene and 2D transition metal dichalcogenides (TMDs), has greatly advanced. For example, engineered defective structures are of interest, where graphene meshes were used for sensing, while defective monolayer TMDs exhibited single-photon emission, potentially useful for quantum information processing. Here, we first discuss the theoretical prediction of defect-induced Raman signatures in graphene by a combined first principles-tight binding approach, to be integrated within a data-driven experimental system for defect engineering. Our predictions of D and D’ Raman band intensities demonstrated that it is possible to distinguish between defect types, which also assists in characterization of realistic materials. Next, we note that to overcome limitations in photon-extraction efficiency and integration within photonic circuits when using bulk solid-state materials, the 2D geometry emerged as potentially useful as a single-photon source. In aiming to achieve localized excitons in monolayer WS2 due to defects, we found theoretically that calculated defect excitons red-shift significantly for experimentally observed patterns. However, although development of databases of 2D materials beyond graphene is progressing, so far the focus is on discovery of materials with low excitation energies. We provide a perspective on database development and machine learning for 2D materials with defects.

Rapid Screening of Potential Inorganic Scintillator Chemistries Using Physics-Informed Machine Learning

Ghanshyam Pilania, Kenneth McClellan, Chris Stanek and Blas P. Uberuaga; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Applications of inorganic scintillators—activated with lanthanide dopants, such as Ce—are found in diverse fields. As a strict requirement to exhibit scintillation, the 4f ground state (with the electronic configuration of [Xe]4f^{n}5d^{0}) and 5d_{1} lowest excited state (with the electronic configuration of [Xe]4f^{n-1}5d^{1}) levels induced by the activator must lie within the host bandgap. This talk will discuss a new machine learning (ML) based screening strategy that relies on a high throughput prediction of the lanthanide dopants’ ground and excited state energy levels with respect to the host valance and conduction band edges for efficient chemical space explorations to discover novel inorganic scintillators [1]. Building upon well-known physics-based chemical trends for the host dependent electron binding energies within the 4f and 5d energy levels of lanthanide ions and available experimental data [2,3], the developed ML model can rapidly and reliably estimate the relative positions of the activator's energy levels relative to the valance and conduction band edges of any given host chemistry. Using a set of perovskite oxides and elpasolites (a class of double perovskite halides) as examples, it will be demonstrated that the developed approach is able to (i) capture systematic chemical trends across host chemistries and (ii) effectively screen promising compounds in a high-throughput manner. While a number of other application-specific performance requirements need to be considered for a viable scintillator, the present scheme can be a practically useful tool to systematically down-select the most promising candidate materials in a first line of screening for a subsequent in-depth investigation.

Prediction of Glass Dissolution Kinetics Using Physics-Informed Machine Learning

Mathieu Bauchy; 1University of California, Los Angeles, Los Angeles, California, United States; 2Department of Civil Engineering, Indian Institute of Technology Delhi, New Delhi, India.

Predicting the dissolution kinetics of silicate glasses is of paramount importance to ensure the long-term integrity of vitrified nuclear wasteform. However, this is a complex task as the underlying corrosion mechanism(s) are poorly understood and the dissolution kinetics can depend on a large number of intrinsic and extrinsic factors. Here, we assess the potential of data-driven models based on machine learning to predict the dissolution rates of various aluminosilicate glasses exposed to a wide range of solution pH values, from acidic to caustic conditions. We show that, although “blind” machine learning yield promising results, the incorporation of physical space explorations into the machine learning framework greatly enhance the accuracy of the model, both in terms of interpolating and prediction far from the training set. This demonstrates how “physics-informed” machine learning can overcome the limitations of informatics approaches based on limited datasets.

Machine Learning vs Physical Insight in the Discovery of Molecular Materials for Organic Photo-Voltaics

Alessandro Troisi; Department of Chemistry, University of Liverpool, Liverpool, United Kingdom.

A number of proposals have been put forward to describe the properties required to improve the efficiency in organic solar cell. The number of experimental data available allow an evaluation of these proposal in a strict statistical sense, e.g. a good sampling of the space of the experiment can provide support to a given physical hypothesis. Alternatively, one can abandon any hope of physical insight and use a battery of machine learning approaches trying to correlate descriptor and photovoltaic efficiency. This lecture compares the two approaches and consider two specific problems (i) identification of high efficiency electron-acceptor and (ii) identification of high efficiency electron-donors.

In this work, we focused specifically on solid state synthesis of materials and used various natural-language processing [Collobert et al. J. Mach. Learn. Res. 2011] techniques to a) find relevant synthesis paragraphs, b) resolve materials entities referring to starting compounds, environment and final products, yet to c) obtain synthesis operations and firing temperatures. As a preliminary result of our work, we extracted 17,500 papers describing solid state synthesis procedure and obtained ~16,000 unique codified recipes. We analyzed these recipes using deep learning algorithms to relate materials features and their synthesis conditions. Our results present a first step toward predictive synthesis theory, and provide insights into further development.

Automated Extraction of Phase Diagram Features for Identifying Candidate Binary Alloy Systems for Metallic Glasses Aparnita Dasgupta1, Connor Mack1, Bhargava U. Kota2, Ramachandran Subramanian2, Scott Broderick1, S. Setlur2, Venugopal Govindaraju2 and Krishna Rajan1; 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The use of machine learning techniques to expedite the discovery and development of new materials is an essential step towards the acceleration of a new generation of domain-specific highly functional material systems. In this paper, we use the test case of bulk metallic glasses to highlight the key issues in the field of high throughput predictions and propose a new probabilistic analysis of rules for glass forming ability using rough set theory. We demonstrate the use of automated machine learning methods that go far beyond text recognition approaches by also being able to interpret phase diagrams. When combined with structural descriptors, this approach provides the foundations to develop a hierarchical probabilistic prediction tool that can rank the feasibility of glass formation.

Machine Learning of “Codified Synthesis Recipes”—Making Steps Toward Predictive Synthesis of New Materials Olga Kononova1, Haoyan Huo1, Tanjin He1, Ziqin Rong2, Tiago Botari1, Vahe Tshitoyan2 and Gerbrand Ceder1, 2; 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

In the past decade, first-principles methods for high-throughput computational screening and design of new materials have proven to be effective and indispensable for various applications [Curtarolo et al. Nature, 2013; Curtarolo et al. Phys. Rev. Lett. 2003]. Moreover, the design and optimization of novel materials has been transformed by the emergence of genomic approaches, where materials properties of many tens of thousands of materials can be modeled, catalogued in searchable databases, and analyzed for trends. However, knowing the structure and properties of a novel material is not enough for its successful production. Often, even knowing what material to make, an obstacle emerges how to make it, which results in the slow and tedious experimental process of trials and errors due to high complexity of materials synthesis procedure. Therefore, predicting conditions under which a specific experimental compound or crystal structure can be synthesized is an unresolved and fundamental problem in materials science, which imposes significant constrains on facile design and production of novel advanced materials. Yet, no any universal theory of synthesis exists which would relate synthesizability of materials and their obtained and computable parameters.

In our work, we approach the predictive synthesis problem by trying to answer the question how well synthesis can be learned from existing data. To address it, we developed a data mining pipeline which extracts information about synthesis of inorganic compounds from available scientific publications using machine learning techniques. The most important steps of pipeline include: i) collecting of research articles available on-line, ii) extraction of experimental sections and identification of paragraphs describing ceramics synthesis, iii) extraction of so-called “codified recipes” of the synthesis procedures, iv) accumulating all recipes in the database and their mining.

In this work, we focused specifically on solid state synthesis of materials and used various natural-language processing [Collobert et al. J. Mach. Learn. Res. 2011] techniques to a) find relevant synthesis paragraphs, b) resolve materials entities referring to starting compounds, environment and final products, yet to c) obtain synthesis operations and firing temperatures. As a preliminary result of our work, we extracted 17,500 papers describing solid state synthesis procedure and obtained ~16,000 unique codified recipes. We analyzed these recipes using deep learning algorithms to relate materials features and their synthesis conditions. Our results present a first step toward predictive synthesis theory, and provide insights into further development.
Polymer nanocomposites have great advantages in achieving improved performance with relative low cost compared with traditional materials. By integrating material science, informatics and information technology, efforts on Material Genome Initiative (MGI) have produced different database infrastructures, material data schemas and ontologies as well as material design tools across different material fields including polymer nanocomposite materials. Under the concept of MGI, we have developed a nanocomposite data resource: NanoMine, which consists an online material database, data-driven analysis tools and physics-based simulation tools for polymer nanocomposite data sharing, analysis and design. To appropriately capture the full suite of possible data for nanocomposites, a nanocomposite schema is designed and served as the templates to ingest data from scientific literatures and in-house experiments. The data schema consists six major sections: data source, materials, processing, characterization, property and microstructure. The current database population and curation mainly relies on the manual data abstraction from scientific literatures by humans with expert knowledge, which is an expensive, labor-intensive and error-prone process.

In order to accelerate the data curation, reduce the possible errors and provide more insights on nanocomposite material synthesis, we take a step toward fully automated data extraction by applying recent machine learning and natural language processing methods and develop an end-to-end framework to extract material processing and synthesis information from full-length journal articles. Our method starts from building a paragraph classifier which is able to select the relevant paragraphs containing the material processing information from the whole paper. Then, individual sentences from those relevant paragraphs are further classified into different categories (e.g., material characteristics, experimental action, irrelevant information etc.) using a hierarchical attention neural network based on their semantic meanings. The network is trained on a set of over one hundred human annotated literatures created by material scientist while reading through the material synthesis sections. Lastly, the learning from the attention network is combined with the outputs from grammar parser and different heuristic rules are applied in order to extract the material processing actions and parameters. The extracted material processing steps and parameters are then postprocessed in order to create a machine readable and compatible data structure (XML in our case) so that the data is ready to be populated to the database.

**Natural Language Processing for Materials Discovery**
John Dasgupta1, 2, Leigh Weston2, Vahe Tshitoyan2, Gerbrand Ceder1, 2, Kristin A. Persson1, 2 and Anubhav Jain2; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The majority of all materials data is currently scattered across the text, tables and figures of millions of scientific publications. We present recently developed natural language processing and machine learning techniques to extract materials knowledge by textual analysis of the abstracts of several million journal articles. We describe our use of Word2Vec to map words in our corpus to vector representations, which we then use as inputs to named entity recognition (NER) classifiers to extract materials, structures, properties, applications, synthesis methods, and characterization techniques from the abstracts in our database. With this information, we have created new tools for materials literature review such as: searching within chemical systems, filtering articles by experiment/theory, summarizing the known attributes of a material, or finding similar materials to a target. Furthermore, we report how these techniques can be used not only to automatically summarize existing knowledge, but enable new ways of discovering novel materials such as thermoelectrics or ion-conductors by revealing previously undiscovered relationships between materials and their properties.

1:30 PM *GI01.04.01*
**Autonomous Science Using Robot Scientists**
Ross D. King1, 2; 1University of Manchester, Manchester, United Kingdom; 2Artificial Intelligence, The National Institute of Advanced Industrial Science and Technology, Tokyo, Japan.

A Robot Scientist is a physically implemented robotic system that applies techniques from artificial intelligence to execute cycles of automated scientific experimentation. A Robot Scientist can automatically execute cycles of hypothesis formation, selection of efficient experiments to discriminate between hypotheses, execution of experiments using laboratory automation equipment, and analysis of results. The motivation for developing Robot Scientists is to better understand the scientific method, and to make scientific research more efficient. The Robot Scientist ‘Adam’ was the first machine to autonomously discover scientific knowledge: it formed and experimentally confirmed novel hypotheses. Adam worked in the domain of yeast functional genomics. The Robot Scientist ‘Eve’ was originally developed to automate early-stage drug development, with specific application to neglected tropical disease such as malaria, African sleeping sickness, etc. More recently we have adapted Eve to work on yeast systems biology, and cancer. We are also teaching Eve to autonomously extract information from the scientific literature.

2:00 PM *GI01.04.02*
**Autonomous Experimentation Applied to Carbon Nanotube Synthesis**
Benji Maruyama1, Pavel Nikolaev2, Daylond Hooper3, Fred Webber4, Kevin Decker5, Jason Poleski1, Michael Krein1, Richard Barto5, Ahmad Islam5, Rahul Rao1 and Abigail Juhl1; 1Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2Materials and Manufacturing Directorate, Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States; 3US Inc., Dayton, Ohio, United States; 4InfoSext, Inc., Dayton, Ohio, United States; 5Lockheed Martin Corp., Cherry Hill, New Jersey, United States.

We have developed a first-of-its-kind Autonomous Research System, ARES, capable of designing, executing, and analyzing its own experiments autonomously using artificial intelligence (AI) and Machine Learning (ML). The closed loop, iterative method enables ARES to design new experiments based on prior results dynamically, after each experiment; a first for materials research.

We are applying this method to understand and control the synthesis of single wall carbon nanotubes, in this case optimizing growth rate in (7) - dimensional parameter space. We use automated in situ Raman spectroscopy characterization of growth rate for CVD synthesis of carbon nanotubes as a metric for a target objective used by our AI planner. We use a random forest learning approach which models experimental results, and a genetic algorithm planner to propose new experiments expected to achieve the targeted growth rate.
We expect ARES to be a disruptive advance in the near future, combining advances in robotics, AI, data sciences and operando methods to enable us to attack high dimensional research problems that were previously intractable by current research processes. We are applying the ARES method to multiple problems, including Additive Manufacturing and defect engineering in graphene. Human-robot research teams have to potential to redefine the research process and lead to a Moore’s Law for the speed of research.

2:30 PM GI01.04.03
Experimental Bayesian Optimization of a 3D Printed Mechanical Structure Aldair E. Gongora1, Bowen Xu1, Wyatt C. Perry1, Chika S. Okoye2, Kristofer Reyes3, Elise F. Morgan1 and Keith A. Brown1; 1Department of Mechanical Engineering, Boston University, Boston, Massachusetts, United States; 2Department of Materials Design and Innovation, University at Buffalo, Buffalo, New York, United States.

Additive manufacturing presents numerous possibilities for design due to the high level of control afforded by the 3D fabrication processes. However, each new design choice introduced by the flexibility of the processing represents a decision that could have important implications on performance. While structures can be optimized for many types of mechanical performance, improving failure properties is particularly challenging due to the stochastic nature of failure and the difficulty in reliably predicting the influence of the microstructure introduced by processing. Here, we explore the degree to which machine learning can guide physical experimentation to produce tough 3D-printed structures in as few experiments as possible. Specifically, we present an experimental optimization of a parametric structure to maximize specific toughness as a model figure of merit that is central to the realization of energy-absorbing structures. Utilizing Bayesian optimization with Gaussian process regression, the mechanical performance of each new design is predicted based on previous experiments in order to continuously predict the optimal design with all available data. Of particular importance, we study the influence of the decision policy, or the algorithm by which subsequent experiments are selected, on convergence to an optimum design. We investigate the effectiveness of policies such as pure exploration, expected improvement, maximum variance, and Bayesian D-optimality in optimizing specific toughness. These approaches are benchmarked against classical design of experiments. The application of these machine learning approaches to an experimental system forces the accommodation of real-world artifacts such as defects introduced through printing, variability between printers, and the stochastic nature of failure. In addition to aiding in the development of high-performance materials and structures, the lessons described will assist in the selection of decision policies for broader classes of experimental optimizations in a manner that facilitates the convergence of machine learning, physical experimentation, and design.

2:45 PM GI01.04.04
Machine Learning Based Monitoring of Advanced Manufacturing Brian Gieria1, Bo Li2, Albert Chu3, Philip DePond4, Gabe Guss2, Du Nguyen1, Congwang Ye1, William Smith1, Nikolai Dudukovic1, Sara McMains1 and Manyalibso Matthews1; 1Lawrence Livermore National Lab, Livermore, California, United States; 2Mechanical Engineering, University of California, Berkeley, Berkeley, California, United States.

As with most advanced manufacturing (AM) systems, analysis of AM sensor data currently occurs post-build, rendering process monitoring and rectification impossible. Supervised machine learning offers a route to convert sensor data into real-time assessments; however, this requires a wealth of labeled sensor data that traditionally is too time-consuming and/or expensive to assemble. In this work, we solve this critical issue in a variety of AM systems. We develop and implement machine learning (ML) algorithms for the purposes of automated quality assessment and, in some cases, rectification. We discuss ML-based algorithms capable of automated detection in a host of AM technologies such as Laser Powder Bed Fusion and Direct Ink Write and also microfluidic platforms that are used for feedstock production. The common thread within these systems is that routinely collected sensor data (e.g. high-speed video, pressure gauges, etc.) contains pertinent information about the state of the system that can be converted into actionable information in real-time via ML. Successful implementation of these machine learning algorithms will reduce time and cost during process by automating quality assessment and lead to process control.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

3:00 PM BREAK

3:30 PM GI01.04.05
Autonomous Integration of Materials Theory, Experiment and Computation—SARA R. Bruce van Dover1, John M. Gregoire2, Carla P. Gomes1, Bart Selman1, Christopher M. Woverton3 and Alex Zunger4; 1Cornell University, Ithaca, New York, United States; 2California Institute of Technology, Pasadena, California, United States; 3Northwestern University, Evanston, Illinois, United States; 4University of Colorado Boulder, Boulder, Colorado, United States.

Many new materials have been suggested, either by first principles theory or by heuristic inference, as having critical enabling properties for technologies such as Li-ion batteries, transparent conductors, and photochemical energy capture. Yet theory has not provided adequate guidance regarding the conditions, if any, under which they can be synthesized. Traditional synthesis of novel compounds often involves laborious and slow manual iterative exploration of composition and processing space. We are radically transforming the ability to identify and synthesize new materials using innovative AI-based strategies for reasoning and conducting science, including the representation, planning, optimization, and learning of materials knowledge. The logical structure of our approach, SARA (Scientific Autonomous Reasoning Agent), is based on a community of software agents that cooperatively generate hypotheses and autonomously test them through autonomous execution of the materials discovery/development process, and is enabled through concomitant development of robotic processing and characterization tools, on-the-fly DFT calculations, and AI-based algorithms. Our approach is further augmented with human insights so that the artificial intelligence leverages the human intelligence of expert scientists, creating an unprecedented platform for human-machine collaboration. SARA includes methods and methodologies for the rational design of functional materials and for discovering the requisite synthesis parameters for both stable and metastable materials.

4:00 PM GI01.04.06
Autonomous Research System for Biology (ARES-B)—A Machine Learning Approach to Optimizing Materials Synthesis Using Synthetic Biology Maria Torres1, Colleen Reynolds1, David Coar1, Jeffrey Stuart1, Michael Jewett2, Ashby Karim2 and Michael Krein1; 1Lockheed Martin, Cherry Hill, New Jersey, United States; 2Northwestern University, Evanston, Illinois, United States.

Synthetic biology is an emerging manufacturing method of materials and precursors, such as those typically derived from fossil fuels. However, controlling synthesis pathways to optimize product yield remains a significant challenge in process maturation and scale up. Current strategies rely on laboratory experimentation. Depending on the design of experiments, this can be time and resource intensive, and results are not guaranteed. A metabolic synthesis pathway is typically a multistep process with dozens of degrees of freedom, such as cofactor concentrations and homologue variants. This describes a
parameter space intractable to exhaustively explore through experiments. Machine learning provides a means to intelligently and efficiently explore this parameter space by building and optimizing models which describe the synthesis process and guide state-of-the-art cell-free experiments. We adapted principles from our previous work on the Autonomous REsearch System (ARES) in which an autonomous system iteratively performed experiments, analyzed results, and applied machine learning models to automatically design and execute a new set of experiments, drastically reducing the experimental time needed to optimize a chemical synthesis process. Here, we applied our approach to synthetic biology pathway modeling and optimization. We used two machine learning approaches – neural networks and parameter-fit ordinary differential equations (ODEs) – to build models of a 5-step metabolic process for butanol production. These models were used to inform a series of cell free experiments, resulting in a 3-fold improvement in butanol yield over prior trial-and-error experimentation. We found a trade between model interpretability and optimization ability: The ODEs required very little initial information and were interpretable, but fell short of the neural networks’ ability to suggest optimized conditions.

SESSION GI01.06: Machine Learning for Imaging, Characterization and Inverse Problems

8:30 AM GI01.06.01
Helium Ion Microscopy for Imaging and Quantifying Porosity at the Nanoscale
Alex Belianinov, Matthew J. Burch, Kyle T. Mahady, Holland Hysmith, Philip D. Rack and Olga Ovchinnikova; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Nanoporous materials play a key role as components in a vast number of applications from energy to drug delivery and to agriculture. However, a comprehensive analysis to analytically measure and quantify salient features e.g.: surface structure, pore shape, and size, remain limited, or prohibitively expensive. The most common approach is gas absorption, where volumetric gas absorption and desorption are measured. The gas absorption approach has a few fundamental drawbacks such as low sample throughput and a lack of direct surface visualization. In this work, we demonstrate Helium Ion Microscopy (HIM) for imaging and quantification of pores in industrially relevant SiO2 catalyst supports. We start with the fundamental principles of ion-sample interaction, and expand to experiment; where we observe and quantify pores on the surface of the catalyst support by using the HIM, and image data analytics. We contrast our experimental results to gas absorption and demonstrate full statistical agreement between two techniques. The principles behind the theoretical, experimental, and analytical framework presented herein offer an automated framework for visualization and quantification of pore structures in a wide variety of materials, and offer data processing solutions to automate these types of imaging workflows.

Thoughts on Automated Electron Microscopy
Mark Ruemmler1, 2; 1SIEMIS, Suzhou, China; 2CMPW, Zabzre, Poland.

The use of materials in society cannot be underestimated. Indeed, it is often said that our ability to use materials has developed civilizations throughout human history and this is even reflected in how we name historical ages, for example the stone age and the bronze age. As we have developed ever better scientific understanding so has our knowledge base on materials and ways to use them increased. We are now at an age where we are beginning to deal with materials in terms of their processing and properties at the atomic scale. At the same time there is an important drive to discover complex materials and be able to manipulate their properties with an ever greater efficiency. This is leading to an immense drive for instrument automation, data interpretation, and the development of new ways to do this both with existing and novel instrument and equipment. In our quest to achieve these goals, particularly at the atomic level, it is clear one of the more important techniques will be microscopy, with electron microscopy based techniques probably playing key roles. The automation and interpretation of data from electron microscopy is enormously challenging. That said, approaches toward these goals are being developed and are expected to grow rapidly in the next decades. In this presentation some of the advances in automation and data interpretation are presented. Numerous challenges in achieving automation, data interpretation, sample preparation and measurement are discussed. The importance of this for new materials discovery (viz. synthesis (including combinatorial materials science) and structure-property relationships at the atomic scale) are also discussed and early ideas and approaches, such as the development of ins situ/in operando electron microscopy are presented.

9:15 AM GI01.06.03
Real-Time Tomography with Interactive 3D Visualization Using tomviz
Robert Hovden1, Jonathan Schwartz2, Chris Harris3, Cory Quammen2, Shawn Waldon1, Yi Jiang1, Peter Ercius4 and Marcus Hanwell2; 1University of Michigan, Ann Arbor, Michigan, United States; 2Kitware Inc., Clifton Park, New York, United States; 3Argonne National Laboratory, Lemont, Illinois, United States; 4Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Three-dimensional (3D) characterization at the nano- and meso-scale using scanning / transmission electron microscope (S/TEM) is now possible[1,2] but high-throughput tomography still requires innovative tools for reconstruction and visualization of large datasets. Currently, the best tomographic reconstructions are obtained from algorithms that are slow and iterative and will run from hours to days depending upon the size of the data set and the algorithm(s) employed. Thus, it has been a longstanding desire to see a reconstruction and begin 3D analysis before it completes. Continuous feedback provides high-throughput and early diagnoses for 3D structure or opportunity to optimize experimental parameters for maximal reconstruction quality. Here we demonstrate interactive 3D visualization displayed in real-time as tomographic reconstructions proceed and as new data arrives using the open-source tool, tomviz. In the actual software, the 3D visualizations are dynamically updated throughout the computation. This means that scientists need not wait for a reconstruction to complete, or all data to be collected before beginning the interpretation of results. The iterative nature of tomographic methods
allows tomviz to show intermediate results with minimal impact on performance. This enables interactive 3D analysis of the current reconstruction state while the reconstruction proceeds on a separate thread. A robust graphical interface allows objects to be rendered as shaded contours or volumetric projections and these objects can be rotated, cropped, or sliced[3]. Experimental nanomaterial datasets were made public and used to validate live reconstruction[4]. Additionally, tomviz visualizes new data as it arrives. As aligned projections are provided from each new specimen tilt, the tomographic reconstruction quality improves in real-time. tomviz accomplishes this by monitoring data / directories for change, and upon arrival of new data, the data is imported and all associated 3D data visualizations are dynamically updated. If data processing routines are present in the pipeline—such as alignment, preprocessing, and reconstruction—all steps will automatically rerun. This capability opens radically new possibilities for developing high-throughput, real-time tomographic reconstruction algorithms. Ultimately, interactive real-time visualization will allow researchers to make early judgments to best answer scientific questions or guide experimental design.

tomviz is publicly available for download at www.tomviz.org

[5] tomviz is supported from DOE Office of Science contract DE-SC0011385.
Machine Learning Clustering Technique Applied to X-Ray Diffraction Patterns to Distinguish Alloy Substitutions

Rutchopon Hunkao1, Keishu Utimula3, Masao Yano3, Hiroyuki Kimoto3, Shogo Kawaguchi3, Sujiin Suwanna3, Kentaro Hongo3 and Ryo Maccione3; 1School of Information Science, JAIST, Nomi, Japan; 3Department of Physics, Mahidol University, Bangkok, Thailand; 3School of Materials Science, JAIST, Nomi, Japan; 3Research Center for Advanced Computing Infrastructure, JAIST, Nomi, Japan; 3Advanced Material Engineering Div., Toyota Motor Corporation, Toyota, Japan; 3FASRI, Sayo-gun, Japan.

SmFe12 is one of the candidate of the main phase in rare-earth permanent magnets[1]. The origin of intrinsic properties emerging at high temperature as well as that of the phase stability has not yet been clarified well. Introducing Tl and Zr to substitute Fe and Sm is found to improve the magnetic properties and the phase stability. To clarify the mechanism how the substitutions improve the properties, it is desired to identify substituted sites and its amount quantitatively, preferably with high throughput efficiency for accelerating the 'materials tuning'. Motivated by the above, we have developed a machine learning clustering technique to distinguish powder XRD patterns to get such microscopic identifications about the atomic substitutions.

Ab initio calculations are used to generate supervising references for the machine learning of XRD patterns: We prepared several possible model structures with substituents located on each different sites over a range of substitution fractions. Geometrical optimizations for each model give slight different structures each other. Then we generated many XRD patterns calculated from each structure. We found that the DTW (dynamic time wrapping) analysis can capture slight shifts in XRD peak positions corresponding to the differences of each relaxed structure, distinguishing the fractions and positions of substituents. We have established such a clustering technique using Ward's analysis on top of the DTW, being capable to sort out simulated XRD patterns based on the distinction.

The established technique can hence learn the correspondence between XRD peak shifts and microscopic structures with substitutions over many supervising simulated data. Since the ab initio simulation can also give several properties such as magnetization for each structure, the correspondence in the machine learning can further predict functional properties of materials when it is applied to the experimental XRD patterns, not only being capable to distinguish the atomic substitutions. The machine learning technique for XRD patterns developed here has therefore the wider range of applications not limited only on magnets, but further on those materials which properties are tuned by the atomic substitutions.

Deep Learning for Inverse Imaging Problems

Rama K. Vasudevan, Noumane Laaait, Ondrej Dyck, Maxim Ziatdinov, Stephen Jesse, Andrew Lupini, Junqi Yin, Mark Osley and Sergei V. Kalinin; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Inverse problems in imaging constitute some of the most interesting and challenging tasks, with examples ranging from tomographic reconstruction to protein structure determination. Here, we present an approach to tackling the inverse problem in imaging via large-scale forward modeling of many physically realizable examples, and then using these simulations to train deep neural networks to learn the inverse mapping. We show this method with two test cases: in the first, we introduce a deep convolutional neural network trained on simulated 2D diffraction patterns, to perform a classification task to sort each diffraction pattern into one of the five possible Bravais lattice types. The DCNN is tested on experimental imaging data from both scanning transmission electron microscopy and scanning tunneling microscopy, and is found to be robust, providing advantages over more traditional threshold-based methods and is largely insensitive to both scale and rotations of the lattice. By using Monte-Carlo dropout on the predictions, a confidence estimate is obtained for each symmetry classification.

In the second example, we train a 3D convolutional neural network on hundreds of gigabytes of simulated convergent beam electron diffraction patterns of the LaAlO3-SrTiO3 interface. The network is trained on simulated data to classify whether the interface is diffuse or stepped in nature and shows extremely high accuracy on a simulated validation set. The approach outlined here is general to any situation where forward simulations exist, but wherein the inverse is difficult to obtain using traditional means.

The work was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division. Research was conducted at the Center for Nanophase Materials Sciences, which also provided support and is a US DOE Office of Science User Facility. This research used resources of the Compute and Data Environment for Science (CADES) at the Oak Ridge National Laboratory, which is supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC05-00OR22725.

Accelerating Materials Development Through Rapid Analysis of Experimental Data Using Machine Learning Based Tools

Marcus Schwarting1, Caleb Phillips1, Andriy Zakutayevey2, Robert White2, Kristin Munch3, Magali Ferrandon2, Deborah Myers2 and John D. Perkins1; 1National Renewable Energy Laboratory, Golden, Colorado, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.

To effectively use high-throughput experiments (HTE) as envisioned in the Materials Genome Initiative (MGI) requires not only rapid experiments but also the ability to efficiently transform the resultant large sets into usable knowledge. To address this issue, we are developing machine learning based tools to address the specific challenge of rapid analysis of large amounts of x-ray diffraction (XRD) data including factoring and clustering analysis along with custom data visualizations. These capabilities will be demonstrated by application to both combinatorially grown Co-Zn-Ni-O thin film and bulk powdered Fe-N-C catalyst materials. The composition-gradient thin-film libraries were grown on glass substrates using off-axis co-sputtering and the powdered Fe-N-C materials were synthesized by pyrolysis of Fe substituted ZIFs. XRD patterns were measured using a commercial (Bruker D8 Discover diffractometer equipped with either a 2D detector (thin film libraries) or a point detector (bulk powder samples). The developed tools are built in Python and leverage the machine learning algorithms available in scikit-learn (scikit-learn.org). After testing a variety of algorithms, we are currently using Orthogonal Matching Pursuit (OMP) for factoring analysis and Spectral Clustering for clustering analysis. Reference XRD patterns for factoring are pulled from the ICSD for known materials as well as from MatDB (materials.nrel.gov) and the Materials Project (materialsproject.org) for unknown or unmeasured materials. Experimental data can be pulled from HTEM-DB (htem.nrel.gov), a recently-launched public-facing database of experimental synthesis and property data for inorganic thin film materials with more than 50,000 entries. Select data visualization and machine learning based tools have been implemented in unmix_xrd, our custom Python package which combines the analysis and visualization into simple single line command calls to facilitate use. For deployment, we are testing locally hosted and cloud hosted Jupiter notebooks with the latter aimed at creating free standing analysis tools intended for deployment on the Energy Materials Network (EMN) such as via the Electr0CAT database (databhub.electrocat.org). In addition, this analytics package can be run from within program capable of issuing a system command which we will demonstrate using Igor Pro, a commercial analysis program widely used at NREL. The overall result is a scientist-friendly extensible analysis environment with project specific machine learning analysis and
In the traditional materials optimization paradigm, a material system is characterized by forming many different samples across different compositions and measuring their properties as a function of e.g. temperature or pressure to produce a phase diagram. As such, each measurement represents a single point in chemical space, and spanning the phase diagram requires many samples and measurements which are time-consuming and expensive. At the same time, small fluctuations in the samples are considered a hindrance and limiting factor to the interpretation of the results. Here, we present an alternative approach that instead exploits this fact, leveraging statistical physics to take atomic observations of structural and chemical fluctuations to map them into generative lattice models that have predictive power. We use a newly developed statistical distance framework to perform model optimization based on imaging data, and then use the model to produce configurations for a range of compositions and temperatures. We apply the method to understand segregation in FeSexTe1-x single crystal, attempting to identify the segregation tendency of the chalcogen atom, as well as the divalent cation segregation in a manganite thin film. The generative model produces configurations that well approximate those observed, and further are run for different temperatures and compositions. A variational autoencoder is then applied on the simulated configurations to map the observations to a single latent parameter, allowing easy visualization of any anomalies in the phase diagram. In this way, a measurement of a single point in chemical space is turned into a prediction across a finite range of chemical space. This method is general and can be used to add to the current materials design paradigms, providing more information on microscopic driving forces, and reducing the need to finely sample the chemical space.

The work was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division (R. K. V., S. V. K., L.V). Research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

Database-Driven Materials-Selection Framework for Semiconductor Heterojunction Design Ethan Shapera and Andre Schleife; University of Illinois at Urbana-Champ, Urbana, Illinois, United States.

At the interface of two semiconductors, where bulk band structures merge into each other, an electronic transition region forms, with band-edge discontinuities that are confined to not more than a few atomic layers near the interface. These discontinuities, also known as valence- and conduction-band offsets, naturally occur at the interface of materials with different band gaps. While the sign of an interface as a barrier or conductor for electrons or holes, their magnitudes determine how good of a barrier/conductor the interface is. Such heterojunctions are at the heart of many modern semiconductor devices with tremendous societal impact: Light-emitting diodes shape the future of energy-efficient lighting, solar cells are promising for renewable energy, and photo-electrochemistry seeks to optimize efficiency of the water-splitting reaction.

Unfortunately, design of heterojunctions, e.g. to find optimal electron- and hole-transport layers for new active-component materials, is difficult due to the limited number of materials for which band alignment is known and the experimental as well as computational difficulties associated with obtaining this data. At the same time, the dependence of band alignment on intrinsic properties of the involved materials turns the design of heterojunctions with specific alignment into an interesting materials-design or materials-selection optimization problem. In order to tackle this problem, we show that band alignment based on branch-point energies is a good and efficient approximation that can be obtained exclusively using data from existing electronic-structure databases. To this end, we shows that errors associated with this approach are comparable to those of expensive first-principles computational techniques as well as experiment.

We then incorporate branch-point energy alignment into a framework that is capable of rapidly screening existing online databases to design semiconductor heterojunctions. We showcase our technique for different prototype cases, including successful predictions of electron- and hole transport layers for CdSe- and InP-based LEDs as well as for novel CH3NH3PbI3- and nanoparticle PbS-based solar absorbers. From our results we show that our framework addresses the challenge of accomplishing fast materials selection for heterostructure design by tying together first-principles calculations and existing online materials databases. We show that it can be used to directly design desired semiconductor heterostructures, or, at least, to reduce the vast candidate search space.

GI01.05.02

The study of gas adsorption in microporous solids is vitally important for addressing the crises facing modern society including climate change (carbon dioxide capture) and energy production (hydrogen storage). Whilst databases of possible materials[1] and software for performing Grand Canonical Monte Carlo (GCMC) simulation of these[2] have been created, to date there is no framework for performing the fully autonomous computational screening of these materials.

In this contribution we present a freely available software package, GCMCWorkflow[3], which allows fully autonomous computational modeling of materials in a reliable, repeatable and reproducible way. The package is built upon the Fireworks[4] package and acts as a controller of existing GCMC tools, in this case Raspa[5].

Building upon previous work into the quantification of uncertainty of these simulations and what constitutes “enough” sampling[6], the package is able to adaptively start more simulations as required to achieve the defined sampling. Other features such as restarting simulations after crashes and the massively parallel scale enabled by Fireworks allows GCMCWorkflow to make performing large scale screening on high performance computing clusters far less
user intensive.

Finally we show how the abstraction layer this automation provides allows multiple GCMC simulations to be programmed into larger machine learning pipelines. In the first example we show how genetic algorithms can be used to derive force field parameters in a top down approach to match data gathered from experiments. In another example, we show how we can search for adsorption capacities of materials where the exploration of sampling space is automated through data-driven algorithms.

The huge demand for new materials, rapid change in technology, and limitation associated with long-term and costly experiments encouraged the scientific community to predict material properties using various scientific simulation tools. In order to discover new materials, simulation tools such as density functional theories, force field modeling, finite difference time domain methods, and other ab-initio methods are available to predict the band-structures, atomic arrangement, and other physical properties. Undoubtedly these methods have been used in many aspects, however, most of these methods are highly computationally expensive and do not much incorporate inputs from previous outcomes and past results. In contrast, a relatively new method, machine learning, can also be used to predict the performance of material and can be used as a screening tool prior to DFT simulations. In this piece of research, data have been selected from the database and literature that are divided into test sets, cross-validation tests, and training sets. The mathematical models have been made using standard machine learning tools such as logistic regression, support vector machine, and artificial neural network. Using these models, band gap, electronic properties, and crystal structures can be predicted and accuracy can also be measured by performing actual DFT calculations for some of them. Note that machine learning outcomes depend mainly on the size of the training set, hence, performance graphs will also be presented for selected results.

Meinig School of Biomedical Engineering, Cornell University, Ithaca, New York, United States; *Current Affiliation: Elucida Oncology, New York, New York, United States.

Artificial intelligence (AI) is beginning to show significant potential for accelerating research in materials science and engineering. In particular, single-particle three-dimensional (3D) reconstruction of cryo-electron microscopy (cryo-EM) images using machine learning computer algorithms has recently emerged as a powerful tool in structural biology for revealing high-resolution information of biological structures, including virus, protein, and DNA assemblies. However, to the best of our knowledge such AI-based approaches have not yet been successfully applied to synthetic materials discovery. In this contribution, we describe how such machine learning approaches resulted in the discovery of an ultrasmall (~10 nm diameter) dodecahedral silica nanocage, or ‘silicage’ [1].

In the study, tens of thousands of single-particle cryo-EM images were collected on early formation stages of surfactant self-assembly directed silica nanostuctures. However, the well-defined structures could not be identified from regular TEM and cryo-EM observations. In contrast, feeding the cryo-EM images into machine learning algorithms for single-particle 3D reconstruction revealed a previously unidentified dodecahedral silica cage. The dodecahedron is the highest symmetry structure of the five Platonic solids known since antiquity and extensively studied by the ancient Greeks. Details of the reconstruction provided insights into possible formation mechanism of these cages around self-assembled surfactant micelles. Cage structures were not limited to silica, but were also observed from other materials including metals and transition metal oxides. Such materials may find a plethora of applications in areas including catalysis and nanomedicine. This discovery, facilitated by artificial intelligence, not only provides novel insights into the fundamental understanding of molecular self-assembly, but also paves the way for the search of related structures with different symmetry and from different materials.

Software Tools, Methods and Applications of Machine Learning in Functional Materials Design Anubhav Jain; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

In this talk, I will describe our group’s efforts to build a general framework for performing data mining on materials properties based on structure and composition. I will introduce matminer (https://hackingmaterials.github.io/matminer/), an open-source code capable of extracting materials data, generating thousands of crystal structure and compositional descriptors, and quickly reproducing and extending existing machine learning studies. I will demonstrate
how new structural features implemented in matminer based on local environment can be used for machine learning and classification. I will also describe our group’s effort to create a “black-box” machine learning model that can be applied to any property and that can be used as a benchmark comparison for machine learning efforts. Finally, I will describe multiple applications, including the prediction of electronic properties, bulk metallic glass behavior, and an effort to learn the properties of materials from unstructured text.

Data Analytics for Mapping of Catalytic Performance Form High Throughput Cyclic Voltammetry Experiments Kiran Vaddi, Surya V. Devaguptapu, Tianmu Zhang, Xiaozhou Shen, Scott Broderick, E. Bruce Pitman, Fei Yao, Olga Wodo and Krishna Rajan; Material Design and Innovation, University at Buffalo, The State University of New York, Buffalo, New York, United States.

The high throughput exploration of materials space has been recognized as a new paradigm in materials design and discovery. However, typical high throughput exploration methods deliver high dimensional datasets that pose the challenge of extracting the key features and trends that could guide the discovery process. To address this challenge, we develop data analytics tools to extract irreducible representation of the high throughput exploration data.

We develop computational tools to perform feature extraction from high throughput electro-chemistry experiments. We leverage non-linear dimensionality reduction techniques to project a high dimensional set of cyclic voltammetry (CV) experiments into a lower dimensional space. The main advantage of our approach is the mathematically rigorous extraction of the inherent dimensionality of a given data set. This is in contrast to the traditional Engineering Figure of Merit used to interpret CV curves. To demonstrate the performance of our approach, we analyze CV curves for a compositional library of perovskites devices subjected to a series of various electrochemical tests. Each device’s current response to cyclic voltammetry test is recorded over several time points (considered as dimensions from here on). In all these cases, we discovered the inherent dimensionality to be as low as 3 (comparing to input 4200 dimensions) with over 90% variance explained. Moreover, we observed a strong compositional dependency of the current responses. Finally, we unraveled the dominant structure hidden in the data as belonging to two types of manifolds regardless of the noise present in the data.

Our method has capability to inform the iterative design process of linking theory, modeling, and experiments for improvement and acceleration of materials design.

Automated Bayesian Optimization of the CANDLE Implicit Solvation Model Yuxi Chen, Henry C. Herbol and Paullette Clancy; 1Chemical Engineering, Cornell University, Ithaca, New York, United States; 2Materials Science and Engineering, Cornell University, Ithaca, New York, United States.

The creation of hybrid organic-inorganic perovskite thin films is frequently made in solution to promote energy-inexpensive sustainable processing. Unfortunately, the inclusion of solvent molecules greatly increases the computational expense during simulations of the solubilization and subsequent crystallization of said thin films. Implicit solvation models represent a solvent as a continuous medium instead of individual atomically “explicit” solvent molecules, and are commonly used in order to allow for larger-scale studies of solvent-solute interactions in DFT. The Joint Density Functional Theory (JDFTx) is a Density Functional Theory (DFT) software written by Prof. Tomás Arias (Physics, Cornell). JDFTx specializes in its implementation of solvation models, such as the charge-asymmetric nonlocally-determined local-electric solvation model (CANDLE), which has been shown to be particularly efficient and accurate [R. Sundararaman et al., 2014].

Despite the efficiency and accuracy of the model, the solvent parametrization process is tedious. We are working to apply an automated Bayesian Optimization algorithm towards parametrization of CANDLE Models on other organic solvents. This novel approach, as applied to molecular simulations, will make the parametrization process more readily accessible to the scientific community at large. Bayesian Optimization searches for the best combination of the parameter set to maximize an objective function, which is set to be the mean absolute error (MAE) between the experimental solvation energy and the calculated solvation energy of a set of solute molecules. To allow for robustness, solute molecules studied include neutral, anionic, and cationic species.

Semiconducting Materials from Analogy and Chemical Theory (SMACT) Daniel W. Davies, Keith Butler, Adam J. Jackson, Jonathan Skelton and Aron Walsh; 1University of Bath, Bath, United Kingdom; 2ISIS Facility, Oxford, United Kingdom; 3Chemistry, University College London, London, United Kingdom; 4Materials, Imperial College London, London, United Kingdom.

We present an open-source code SMOCT [1] to perform rapid screening of known and hypothetical materials. It combines elemental descriptors and chemical heuristics to navigate large numbers of compounds, which can be fed into machine learning procedures or other materials design workflows.

Forming a four-component compound from the first 103 elements of the periodic table results in more than $10^{12}$ combinations. Such a materials space is intractable to high-throughput experiment or first-principles computation. We introduce a framework to address this problem and quantify how many materials can exist. We apply principles of valency and electronegativity to filter chemically implausible compositions, which reduces the inorganic quaternary space to $10^{10}$ combinations [2]. We demonstrate that estimates of bandgaps and absolute electron energies can be made simply based on the chemical composition and apply this to search for new semiconducting materials to support the photoelectrochemical splitting of water [3].

The applicability to crystal structure prediction by analogy with known compounds is shown, including exploration of the phase space for ternary combinations that form a perovskite lattice. Computer screening reproduces known perovskite materials and predicts the feasibility of thousands more. Due to the simplicity of the approach, large-scale searches can be performed on a single workstation. For example, we have been able to assign likely crystal structures to all hypothetical quaternary oxide compositions produced by SMOCT, constituting a database of over 2 million compounds. The stability and properties of these compounds are then assessed methodically using high-throughput workflows for first-principles calculations.

Predicting the Glass Forming Ability of Bulk Metallic Glasses Using Random Forests Vanessa Nilsen, Michael Hibbard, Logan Ward and Dane Morgan; 1University of Wisconsin - Madison, Madison, Wisconsin, United States; 2Computation Institute, The University of Chicago, Chicago, Illinois, United States.
Predicting the glass forming ability of metallic alloys is an active area of research due to the many existing and potential uses of metallic glasses. Many descriptors accounting for the thermodynamics and kinetics of the vitrification process have been proposed to quantify the likelihood of glass formation for an alloy. A particularly widely used class of descriptors involve simple functions of the glass transition temperature ($T_g$), the liquidus temperature ($T_l$), and the crystallization temperature ($T_c$). The descriptors we focus on in this work include $Tr_g = T_g/T_l$, $\gamma = T_c/(T_g + T_l)$, and $\omega = T_g/T_c - 2T_g/(T_g + T_l)$. It is of interest to predict these descriptors quickly for new alloy systems. We note that these transition temperatures are also of interest in their own right, separate from their ability to predict glass forming ability, as they control important design properties of alloys. Accurately predicting these transition temperatures could also prevent the need to first make a glass to calculate the value of any of the descriptors. In this work we have used a random forest machine learning method to model these descriptors as a function of simple elemental properties. We used two approaches to model the value of the glass forming descriptors. First, we modeled $Tr_g$, $\gamma$, and $\omega$ directly. Second, we modeled the transition temperatures and used the resulting predictions to calculate the glass forming descriptors. Interestingly, the latter approach was significantly more accurate. In addition to predicting the glass forming descriptors, we assessed the applicability of the model in various compositional domains by examining the error and uncertainty on predictions of alloys with varying degrees of representation in the training data set.

GI01.05.10
Extending Bayesian Inference to Infer Thermal Transport Characteristics in Thermoelastic Materials

We report on a single-step experimental diagnostic tool, which applies Bayesian inference to infer electronic and thermal transport characteristics of thermoelastic materials from simple power-load curve data. By using Boltzmann transport equation as the forward model and by feeding experimental data from our in-house built single-leg thermoelastic measurement setup, our tool is able to extract intrinsic thermoelastic properties. Employing only three experimental input parameters (base temperature, temperature across the device - $\Delta T$, and external load resistance) and the output power from the thermoelastic setup as constraint parameters, we are able to extract the electronic transport parameters of thermoelastic material. In addition to electronic material descriptors, a good thermoelastic behaves like an ‘electron-crystal-phonon-glass’, where optimally tuned electronic transport has to be coupled with reduced thermal conductivity. Measurement of thermal conductivity is typically an independent experiment, which requires careful domain expertise and detailed analysis. In this work, we extend our work to inferring thermal conductivity by replacing the $\Delta T$ by heat current as the input, incorporated into a Bayesian Inference algorithm. This is done by taking into account both the radiative and conductive heat loss using the Stefan-Boltzmann law in the guiding forward model. Remarkably, we are able to also extract the heat loss which serves as a valuable guide for further experimental optimization. Our Machine learning based technique allows, from a single step experiment, to provide all transport properties of the thermoelastic material of interest.

A Data Driven Analysis of Volcano Plots and Prediction of New Binary Catalysts

Aparajita Dasgupta, Yingjie Gao, Thaicia Stona de Almeida, Scott Broderick, E. Bruce Pitman and Krishna Rajan, Material Design and Innovation, University at Buffalo, The State University of New York, Buffalo, New York, United States.

In this study, we describe a computational approach where we ingrain the underlying theoretical constructs behind these and subsequently use the underlying physical descriptors to expand and extend the database of known catalytic reactions. To this end, we use spectral clustering methods to identify key physical regimes underlying volcano plots by using the volcano plot for ammonia synthesis rate as a function of nitrogen adsorption energy as our case study. The application of dimensionality reduction techniques and graph networks to these catalytic systems is illustrated by applying to elemental and binary transition metal alloys to predict the positions of these systems on volcano plots.

Pycroscopy—A Community-Driven Approach for Analyzing and Storing Materials Imaging Data

Suhas Somnath, Christopher R. Smith, Rama K. Vasudevan and Stephen Jesse, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Materials science is undergoing profound changes, driven by continual improvements to instrumentation that have resulted in an explosion in the data volume, dimensionality, complexity, and variety, in addition to increased accessibility to high-performance computing (HPC) resources, and more sophisticated computer algorithms. These changes are especially prominent in the functional imaging of materials. However, the current software typically do not provide access to advanced or user-defined data analysis routines, and store measurement data in proprietary file formats. These proprietary software and file formats not only impede data analysis but also hinder continued research and instrument development, especially in the era of “big data.” Therefore, moving to the forefront of data-intensive materials research requires general and unified data curation and analysis platforms that are HPC-ready and open source.

We have developed a free and open-source python package called Pycroscopy for analyzing, visualizing and storing data. Pycroscopy is freely available via popular software repositories, and therefore lifts any financial burden for interrogating data. Pycroscopy describes data in an instrument-agnostic structure that allows it to represent data of any size, dimensionality, or complexity acquired on a regular grid of positions or random positions as in compressed sensing. This data model is stored in open hierarchical data format files (HDF5) that can be interrogated using any programming language, scale well from kilobyte to terabyte sized datasets, and can readily be used in HPC environments unlike proprietary data formats. As a consequence, Pycroscopy-formatted data files are curation-ready and therefore both meet the guidelines for data sharing issued to federally funded agencies and satisfy the implementation of digital data management as outlined by the United States Department of Energy. The generalized data format allows data processing and analysis algorithms to be generalized in turn allowing a single version of the algorithm to be applied to data collected from instruments from different brands or even modalities. The simple structure and comprehensive documentation in pycroscopy enable even novice programmers to easily translate physical or chemical problems into computational problems. Unlike many other open-source packages that focus on analytical or processing routines specific to an instrument, the general definition of the Pycroscopy data format can be readily adopted for different microscopy techniques. Furthermore, the generality of Pycroscopy provides a natural step towards a vast and growing library of community-driven data processing and analysis routines that far exceed those provided by instrument manufacturers and are desperately needed in the age of big data. This research was conducted at the Center for Nanophase Materials Sciences, which is a US DOE Office of Science User Facility.

GI01.05.13
Theoretical Classification for Softmagnetic Compounds Applying Regression-Based Model Selection

Masakuni Okamoto, 1 Research & Development Group, Hitachi Ltd., Hatoyama, Japan; 2Department of Data Science, Yokohama City University, Yokohama, Japan.

Materials science is undergoing profound changes, driven by continual improvements to instrumentation that have resulted in an explosion in the data volume, dimensionality, complexity, and variety, in addition to increased accessibility to high-performance computing (HPC) resources, and more sophisticated computer algorithms. These changes are especially prominent in the functional imaging of materials. However, the current software typically do not provide access to advanced or user-defined data analysis routines, and store measurement data in proprietary file formats. These proprietary software and file formats not only impede data analysis but also hinder continued research and instrument development, especially in the era of “big data.” Therefore, moving to the forefront of data-intensive materials research requires general and unified data curation and analysis platforms that are HPC-ready and open source.

We have developed a free and open-source python package called Pycroscopy for analyzing, visualizing and storing data. Pycroscopy is freely available via popular software repositories, and therefore lifts any financial burden for interrogating data. Pycroscopy describes data in an instrument-agnostic structure that allows it to represent data of any size, dimensionality, or complexity acquired on a regular grid of positions or random positions as in compressed sensing. This data model is stored in open hierarchical data format files (HDF5) that can be interrogated using any programming language, scale well from kilobyte to terabyte sized datasets, and can readily be used in HPC environments unlike proprietary data formats. Unlike many other open-source packages that focus on analytical or processing routines specific to an instrument, the general definition of the Pycroscopy data format can be readily adopted for different microscopy techniques. Furthermore, the generality of Pycroscopy provides a natural step towards a vast and growing library of community-driven data processing and analysis routines that far exceed those provided by instrument manufacturers and are desperately needed in the age of big data. This research was conducted at the Center for Nanophase Materials Sciences, which is a US DOE Office of Science User Facility.
In order to improve the magnetic properties of the compounds forming the main phase of the soft magnetic materials, we study the magnetization ($M_H$) and the magnetostriction constant ($\lambda_{001}$) of ternary alloy compounds consisting of 3d transition-metal elements by using the first principles calculation and the machine learning technique. First we prepare totally 1393 training data using first-principles calculation for bcc/fcc-(Fe,Co,Ni)-based ternary compounds. We obtain 36 promising compounds after manual screening of 1393 compounds under several conditions such as $|\lambda_{001}| > 2 \times 10^{-5}$. We expect magnetic permeability ($\mu$) of these compounds is large due to a correlation between $\mu$ and $\lambda_{001}$. Next we classify the calculated 1393 data by using the machine learning technique. We use new descriptors based on the Voronoi-polygons, in addition to the common descriptors for materials informatics, such as lattice constants, ionization energy, atomic angular momentum $L$, $S$, $J$. Nonlinear regression with a Gaussian kernel and sparse modelling accurately reproduces the values $M$, of 1393 compounds. The relevant descriptors for prediction of $M$, are $L$, $S$, $J$ and Voronoi volumes. On the other hand, prediction of $\lambda_{001}$ is poor at present, some new descriptors may be necessary.

We demonstrate how the first-principles calculation and the regression-based model selection technique can be utilized for classifying new materials.

GI01.05.14 Predicting the Charge Density of Organic Molecules and Polymers Using Deep Learning Deepak Karnal, Anand Chandrasekaran and Rampi Ramprasad, Georgia Institute of Technology, Atlanta, Georgia, United States.

Over the past few decades, the Kohn-Sham scheme of density functional theory (KS-DFT) has become the customary method to probe solid-state properties of materials. Despite its preeminence, the computational cost of this methodology renders it intractable for large-scale calculations involving thousands/millions of atoms. The simulation of mesoscale properties of polymers is one such example where this limitation is most apparent. Here we propose a method to accurately predict charge densities of organic systems (both molecules and polymers) by learning from pre-calculated examples of smaller systems. We start with creating a database of organic compounds which cover a wide range of configurational and bonding environments. Further, we introduce a novel fingerprinting scheme which maps the charge density to the local atomic environment using deep neural networks. The model thus obtained is systematically improved (both in terms of accuracy and transferability) by selectively training on poorly predicted local environments encountered in new configurations. Following the proposed methodology, we develop a robust model that can rapidly predict the charge density of large organic systems. This charge density can then be used as input to orbital free density functional theory scheme to swiftly access a broad range of materials properties, thus bypassing the need to explicitly solve the Kohn-Sham equation.

GI01.05.15 Accelerated Informatics Base Design of Multi-Component Systems Xiaozhou Shen, Tianmu Zhang, Scott Broderick, E. Bruce Pitman and Krishna Rajan, Material Design and Innovation, University at Buffalo, The State University of New York, Buffalo, New York, United States.

We introduce an integrated computational chemistry/ informatics approach to accelerate the design and discovery of new complex materials. Our approach involves coupling topological data (TDA) analysis classification methods with Hirshfeld Surface Analysis (HSA). 3-dimensional Hirshfeld surfaces, encode both chemical bonding and molecular geometry information; while TDA captures the “shape” of data in a multiscale manner to probe for hidden correlations between crystallographic structure and electronic structures. When applied collectively, we show how new classifications and insights into crystal chemistry can be revealed.

GI01.05.16 Fast Evaluation of Microstructure-Property Relation in Duplex Alloys Using SEM Images Thantip S. Krasienapibal, Yasuhiro Shirasaki, Momoyo Enyama, Akiko Kagatsume, Minseok Park and Sayaka Tanimoto, Research and Development Group, Hitachi Ltd., Tokyo, Japan.

Recently, fast material development and design is highly in-demand due to the needs of high performance materials. Microstructure-property relation, a key in material development, has long been investigated qualitatively. For example, controlling crystal structure and crystal size can manipulate material strength and anti-corrosion properties in alloys. To achieve highly-efficient experimental planning such as process tuning and controlling trade-off of multiple properties, the quantitative and large volume of datasets of microstructure-property relation is required. However, a method that accurately and automatically provide microstructure features in a short time is still a challenge.

For alloys, the microstructure i.e. crystal phase and orientation, is usually evaluated by electron back-scattered diffraction (EBSD) measurement [1]. The measurement needs highly-skilled technicians and long time limiting the automation for lots of samples. Backscattered electron (BSE) images acquired from scanning electron microscope (SEM) also provide crystal information. Using Z-contrast in BSE images, crystal phase information can be simply obtained due to different average atomic density [2]. In comparison to EBSD, using BSE images is promising since it can be acquired within few minutes and easy to operate. Hence, an approach to realize microstructure-property using BSE images should be considered.

In this research, we propose a method to utilize microstructure features in alloy from BSE images. By applying machine learning i.e. DNN-based segmentation, microstructure features, such as the amount of each phase present are extracted and are used for evaluation of microstructure-property relation. We evaluated the relation of microstructure and mechanical properties in Cr-duplex alloy. In addition, we study the detail of preparation of training data for the DNN-based segmentation under different measurement conditions of BSE images. The result suggested that by applying DNN-based segmentation on BSE images of Cr-duplex alloy, accurate phase distinction was performed with 90% accuracy in average resulting in reliable extraction of microstructure features i.e. the amount of each phase. The extracted amount of each phase is well-agreed with the result of EBSD measurement. The relation of the microstructure features and mechanical properties such as Vickers hardness, abrasion loss, and 0.2% yield strength of Cr-based duplex alloy was evaluated using regression model. Using the relation, prediction of the mechanical properties was performed and the error was less than 10%. From these results, we have demonstrated a method to utilize microstructure features from BSE images leading to fast and easy evaluation of microstructure-property relation in duplex alloy.

GI01.05.17 Elastic Strain Engineering Reaches Six Dimensions via Machine Learning Zhe Shi1, Evgeni Tsymbalov2, Alexander Shapecree2 and Ju Li3; 1Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Center for Computational and Data-Intensive Science and Engineering, Skolkovo Institute of Science and Technology, Moscow, Russian Federation; 3Nuclear Science Engineering and Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The controllable incorporation of strain on materials merits unfold scientific and technological potential, yet poses a challenge of exploring the vast six-
dimensional space of admissible elastic strains. Here we demonstrate that systematic machine learning can make the problem of representing electronic structure as a function of six-dimensional strain computationally tractable. Specifically, we develop a number of general methods for surrogate modeling of elastic strain engineering which, relying on a limited amount of data from ab initio calculations, can be used to fit the required properties with sufficient accuracy. In particular, an artificial neural network predicts the band structure within the accuracy of 19 meV in case of three-dimensional strain.

**Oxygen Removal from Ce₀.75Zr₀.25O₂ Solid Solution Under Reducing Condition Using Genetic Algorithm**

Ki-Yung Kim¹, Yurie Kim², Jason Kim³, Dong-Gang Shin¹, Jun-Yeong Jo¹ and Yeong-Cheol Kim¹; ¹School of Energy Materials and Chemical Engineering, KoreaTech, Cheonan, Korea (the Republic of); ²Department of Creative IT Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Mean field approach has been employed to consider random distribution of atoms in solid solutions [1]. The mean field approach, however, shows averaged characteristics of the solid solutions, and, therefore, cannot represent energetically favorable solid solutions. We studied Ce₀.75Zr₀.25O₂ solid solutions using genetic algorithm and density functional theory (DFT) [2]. Initial population, fitness function, selection, crossover, and mutation were varied in genetic algorithm to find an energetically favorable solid solution. In this study, we employed lattice dynamics to increase the calculation speed and to consider temperature effect. The increased calculation speed also allowed us to consider bigger systems. The bond strengths of the oxygen atoms in the favorable solid solution structure should vary because each oxygen atom is surrounded by Ce and/or Zr atoms differently; the oxygen atom with weak bond strength would be removed first under reducing conditions. We employed genetic algorithm again to find easily removable oxygen atoms in the solid solution under reducing conditions.

**Machine Learning Approach to Discover the Correlation Between Core-Loss Spectra and Materials Information via Clustering and Decision Trees**

Shin Kiyohara and Teruyasu Mizoguchi; University of Tokyo, Tokyo, Japan.

Spectroscopy is one of the most promising techniques to reveal atomic and electronic structures of material inside and surface. Among a variety of spectroscopy, core-loss spectroscopy using electron (ELNES) and X-ray (XANES) has nano- or sub nano-scaled spatial resolution and nano- or femto-scaled temporal resolution, enabling to analyze lattice defects and chemical reaction. However, interpreting ELNES/XANES spectra is not straightforward, and therefore comparing experimental spectra with those in databases, namely, “experimental fingerprint”, has been generally used. While such a large database has been constructed, we often come across an unknown spectrum which isn’t contained by the database. To overcome the infeasibility of interpreting an unknown spectrum, theoretical calculation must be effective. Devoting a lot of effort enabled to calculate ELNES/XANES spectra of most of elements and atomic configurations, whereas calculating just single spectrum requires much computation time. Since the spatial and temporal resolutions of ELNES/XANES can generate a thousand of spectra in an experiment, such one by one “theoretical fingerprint” is impracticable. In that situation, utilizing the correlations between the spectra and atomic information discovered from the database can be an alternative method.

Here, we developed a new interpretation approach based on machine learning which can deal with a big data and be implemented without the theoretical calculation. First, a spectra database was constructed by the theoretical calculation. Then, hierarchical clustering was performed on the database, resulting in categorizing similar spectra into clusters. Spectral similarity was measured by cosine distance. Cutting the hierarchical tree at an arbitrary threshold makes some clusters of the spectra. We successively lowered the cutting threshold to each branch point, resulting in making two clusters at every branch point. At those branch points, we repeatedly implemented decision tree analysis considering the newly generated two clusters of the spectra as the training label and their structure information as the descriptors.

The queries of the constructed decision trees can provide the best (most characteristic) features for distinguishing each of the clusters. These features are also believed to be physically important, and detailed comparison of the two types of spectra in the clusters can endow the origins of the differences between these two types of spectra.

We applied this approach to approximately a lot of O-K edge ELNES spectra of SiO₂ polymorphs. The results will be discussed in my presentation.

**Analytic Continuation via “Domain-Knowledge Free” Machine Learning**

Hongkee Yoon, Jae-Hoon Sim and Myung Joon Han; KAIST, Daejeon, Korea (the Republic of).

We present a machine-learning approach to a long-standing issue in quantum many-body physics, namely, analytic continuation. This notorious ill-conditioned problem of obtaining spectral function from imaginary time Green’s function has been a focus of new method developments for past decades including many numerical approaches; such as maximum entropy method [1,2], stochastic method [3], Padé approximation [4]. Here we demonstrate the usefulness of modern machine-learning techniques including convolutional neural networks and the variants of stochastic gradient descent optimizer. Machine-learning continuation kernel is successfully realized without any ‘physical domain knowledge’ and the outstanding performance is achieved for both insulating and metallic band structure [5]. Unlike other methods, our method is additional parameter free fully automatic approach with no further human intervention. Our machine-learning-based approach not only provides the more accurate spectrum than the conventional methods in terms of peak positions and heights but is also more robust against the noise which is the required key feature for any continuation technique to be successful. Furthermore, the ML-based kernel is 10³-10⁴ faster than conventional analytic continuation algorithms and more robust to noise from Green’s function. Our approach to tackling ill-posed problems by statistical data-based ML shows the applicability of ML in other ill-posed physical problems.

**First-Principles Theory Based Machine Learning Force Fields for 2D Materials**

Yang Yang¹,², Hongxiang Zong², Hua Wang¹, Xiandong
Molecular dynamics simulation is a powerful tool to understand the underlying physics of dynamic behavior of materials. However, its application is greatly limited by the availability of accurate force fields. Here we demonstrate machine learning as a strong tool to combine the accuracy of first-principles density functional theory and low-cost MD simulations. By learning the database generated from density functional theory calculations, we are able to generate accurate and effective force fields. We will show a few interesting examples of our method for elemental materials and 2D materials where the generated force fields can capture both energetic and structural properties.

**Machine Learning Induction of Parameters in Numerical Models of Capacity-Voltage Curve in Lithium-Ion Batteries**

Takuya Hiramoto, Masahiro Soeno, Misato Nakamura, Takashi Kusachi, and Hiromitsu Takaba; Graduate School of Applied Chemistry and Chemical Engineering, Kogakuin University, Tokyo, Japan; School of Advanced Engineering, Kogakuin University, Tokyo, Japan.

Numerical model of battery performance is indispensable for developing and optimizing battery materials and structures. Since Newman-model built one-dimensional model based on electrochemical reactions and ion transport, a numerical simulation to evaluate a charge/discharge characteristics as well as a capacity-voltage curve of lithium ion batteries have been widely applied in the field of battery research. It is difficult to know, however, all needed parameters in the model only from the experiments. Moreover, the induction of unknown parameters mostly depends on the experience of expert researchers. We have studied a numerical model for describing a charge/discharge characteristics of lithium air battery where the precipitation of discharged compound, lithium peroxide, on the surface of carbon is modeled in which the deposition rate and distribution on the carbon surface are considered as the parameters [1]. There are more than 20 parameters in this numerical model. It would take a lot of time to obtain all of them only from the experiments. In this study, we conducted the parameters needed for the numerical model for describing the charge and discharge or capacity voltage curves of lithium ion and lithium air batteries using a machine-learning. Used learning method is the neural network (NN) that shows remarkable progress in the field machine learning. NN has a layered structure, and between layers are formed by multiply-add operation with a weighting factor. In this research, NN learning is carried out to induce parameters used in the numerical model. Training-data (capacity-voltage or discharge-capacity curves) are generated by employing the numerical model calculation with various different input parameters. For instance, we constructed a deduction model using 24 charge using NN and discharge curves as a training set and confirmed the reasonable accuracy. In addition, we also check the accuracy for the induction of multiple parameters such as the reaction rate and temperature, etc. The accuracy of induction tends to depend on the number of kind of unknown parameters, the accuracy and their dependency on the detailed algorithm of NN will be presented and discussed. Consequently, machine learning is useful tool for quickly determination of unknown parameters in the numerical model that are sometimes difficult to measure directly.

**Bayesian Inference Enabled Experimental Determination of Materials and Transport Descriptors in ThermoElectric**

D V M. Repaka, Ady Suwardi, Zekun Ren, Tonyo Buonassisi, and Kedar Hippalgaonkar; IMRE A-STAR, Singapore, Singapore; Singapore-MIT Alliance for Research and Technology, Singapore, Singapore; Massachusetts Institute of Technology, Cambridge, Boston, Massachusetts, United States.

ThermoElectric, which can convert heat into electrical power based on the Seebeck effect and vice-versa based on the Peltier effect can be a very useful alternative source of both electrical and thermal power. So far, machine learning approaches have only been used to predict promising new thermoelectric compositions from density functional theory calculations, building upon open-source databases towards the discovery of high performance materials. Further, high-throughput materials screening approaches are still rudimentary, limited by the lack of universally defined material and thermoelectric transport descriptors. Finally, rapid and accurate materials characterization that can directly measure these descriptors are arduous (for example, method of four coefficients) or do not exist. Our work discloses a rapid and accurate way to determine the material and transport descriptors of thermoelectric performance by feeding simple single-leg power/load experimental data to a Bayesian machine learning algorithm using Boltzmann transport theory. The accurate generalized forward model we have developed allows the use of Bayesian inference demonstrating its utility as an ideal machine-learning (ML) tool for material diagnostics. Employing only two input parameters (temperature gradient and external load resistance) and the observed power output, the Bayesian inference algorithm is able to extract thermoelectric parameters ranging from material-layer properties (Seebeck coefficient, electrical resistivity) to transport-layer characteristics (energy-dependent scattering parameter, band gap offset, etc.) as well as extrinsic contributions such as parasitic contact resistance. In addition, systematic error from measurement can also be identified and corrected. This is made possible since we have devised an experimental setup developed in-house that can generate temperature-dependent data for ML-enabled characterization. Hence, we are able to predict band and transport descriptors that can be measured directly using experiments for the first time. While these reveal the complex dynamics of scattering in thermoElectric materials, we envision that they will also provide universal screening criteria for high performance thermoelectrics in the near future.

**Accelerating Molecular Dynamics with On-the-Fly Machine Learning**

Jonathan Vandermause, Steven Torrisi, Simon Batzner, Alexie Kolpak, and Boris Koziynsky; Harvard University, Cambridge, Massachusetts, United States; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Ab initio molecular dynamics (MD) is a powerful tool for accurately probing the dynamics of molecules and solids, but it is limited to system sizes on the order of 1000 atoms and times scales on the order of 10 ps. We present a scheme for rapidly training a machine learning (ML) model of the interatomic force field that approaches the accuracy of ab initio force calculations but can be applied to larger systems over longer time scales. Gaussian Process (GP) models are trained “on-the-fly”, with density-functional theory (DFT) calculations of the atomic forces performed whenever the model encounters atomic configurations sufficiently far outside of the training set. This active learning scheme includes a principled means of deciding when to run additional DFT calculations, accelerating the model's exploration of parameter space while reducing the time spent training the model. Furthermore, we demonstrate that additional ML models can be trained in parallel to predict other quantities of interest, including the ground state energy and charge density, making it possible to efficiently capture with ML the wealth of information provided by full DFT calculations. We demonstrate the flexibility of our approach by testing it on a range of single- and multi-component molecular and solid-state systems, including benzene, silicon, and silicon carbide.

**Prediction of Repeat Unit of Optimal Polymer by Bayesian Optimization**

Tokuya Minami, Masaki Kawata, Toshio Fujita, Katsumi Murofushi, Hiroshi Uchida, Kazuhiro Omori, Yoshishige Okuno; Showa Denko K. K., Tokyo, Japan; National Institute of Advanced Industrial Science and Technology, Ibaraki, Japan; Research Association of High-Throughput Design and Development for Advanced Functional Materials, Tokyo, Japan.

In recent years, an inverse analysis that can predict materials with desired physical properties has attracted attention as a method that enables rapid design of materials [1].
Bayesian optimization is one of the approaches which efficiently design optimal materials [2]. For examples, numerous successful studies have been reported on Bayesian optimization in inorganic material design [3] and automatic laboratory robots [4]. However, although it is important for industries, there are only a few reports on Bayesian optimization in polymer design. In this study, to confirm the effectiveness of Bayesian optimization for polymer design, we performed the case study on the prediction of repeat unit of polymer with optimal glass transition temperature. To evaluate the number of trial and error for achieving optimal physical properties, a trial and error test was conducted using a known data set. Here, the prediction model was constructed by a part of prepared dataset, and the optimal polymer was explored for the rest dataset. The prediction model was made from the features of structural formulas [5] and the glass transition temperatures of polymers, by using Gaussian process regression. As the result, we found that the Bayesian optimization could significantly reduce the number of trial and error in the prediction of repeat unit of polymer, compared to the random search.

Feature-Based Data Analysis Methods in Alloy Systems
Zhiting Guo1, Tao Xu1, Hongqing Hu1, Gaofeng Zhou1, Shengzhou Li1, Xin Wang1, Dongbo Dai1, Xiao Wei1, Huiran Zhang1 and Guangxi Ding1; 1School of Computer Engineering and Science, Shanghai University, Shanghai, China; 2Materials Genome Institute, Shanghai University, Shanghai, China.

This paper proposes a dynamic model, which is built by machine learning methods, used for predicting the property in metal alloy systems. The model is trained by adding features of 64 sets of the data. It is found that the process of phase transformation is related with its properties and can accurately predict the property like solid solution ability. The result of the experiment shows that if the optimal features are chosen, the model has a better predicting performance than traditional methods using all the features.

Realizing Real-Time Crystallographic and Materials-Based Analysis Using Deep Learning Tools
Jeffery A. Aguiar1, 3, Matthew Gong2, 1 and Tolga Tasdizen2; 1Nuclear Materials Department, Idaho National Laboratory, Idaho Falls, Idaho, United States; 2Scientific Computing and Imaging Institute, The University of Utah, Salt lake city, Utah, United States; 3Materials Science and Engineering Department, The University of Utah, Salt Lake City, Utah, United States.

Extending from the micron to the atomic scale transmission electron microscopy is a powerful research tool for structural and chemical analysis for materials research. The breadth of data collected simultaneously in the latest generation of scanning transmission electron microscopes presents challenges and opportunities for advancements in microscopy, multi-modal data analytics, image-based forensics, and materials research. Recent advancements in deep learning have made it possible to analyze these massive data sets and perform complex imaging tasks. However, deep learning and augmented analysis have not yet disrupted the microscopy and microanalysis community like they have the computer vision community. Breakthroughs in automating and augmenting microscopy data collection and analysis could more than halve research cycle times in fields that rely on microscopy including materials and biological research.

The goal of recent technological developments and research is to create a suite of tools to expand the real-time analytic capabilities of microscopy as well as post-hoc analysis for diffraction-based tools. By applying cutting edge deep learning, computer vision, and signal processing techniques, our team aims to make real-time event tracking and automation of imaging, diffraction, and spectroscopy acquisition a reality in the future. This suite of computational tools and analytical packages is being developed in collaboration with commercial partners, national laboratories, and universities/academia. The software has now been publicly released and designed to draw from standard materials libraries including the Materials Project database and the Open Crystallography database, but also can be further enhanced by research and experimental data from the greater materials community.

In this late breaking poster, we will present our developments and look to the community to further evaluate our emerging real-time augmented feedback framework for materials prediction. This includes pending developments that utilize hybridized first principal and deep learning models for augmented analysis of material properties, spectroscopy, and diffraction patterns. We further look forward to discussing the growing potential of automating data collection from materials-centric data feeds for real-time event tracking and potentially prediction.

GI01.05.29
Application of Deep Learning Methods to the Analysis of Mass Spectra in Atom Probe Tomography
Arpan Mukherjee, Scott Broderick and Krishna Rajan; Materials Design and Innovation, University at Buffalo, The State University of New York, Buffalo, New York, United States.

We present the use of deep learning methods to develop automated methods for the deconvolution of time of flight spectra in atom probe tomography. This work describes the nature of the algorithms underlying the deep learning methods. This new automated process of labeling of atoms replaces the manual process of ranging and shows high accuracy.

GI01.05.30
Statistical Learning and Prediction of Electronic Transport in Multilayered Non-Ideal Semiconductor Architectures
Sanhmitra Neogi and Artem K. Pimachev; University of Colorado Boulder, Boulder, Colorado, United States.

Computing components are being aggressively inserted into electronic, optical, sensing, robotic, bio-system or energy transport devices, to perform multitudes of data-centric operations at high rates. Modern fabrication techniques have reached the sizes of quantum confinement regime, therefore making it possible to model electronic properties of device components with first principle calculations. The contact interfaces between these components dictate the device performance, especially as the device dimension approaches nanoscale. These interfaces are often marked by point defects, dislocations and additional strains due to lattice mismatch between the components. Ab initio methods become expensive and infeasible to predict electronic properties of integrated architectures with such a great number of compositional and configurational degrees of freedom. In recent years, there has been a large effort in the materials science community to employ data driven methods to accelerate materials discovery or to develop new understanding of materials behavior. However, the number of efforts, employing first-principle based data-driven methods to predict device performance incorporating processing variability, is almost non-existent.

In this study, we employ machine learning (ML) algorithms to predict electronic structure and transport properties of non-ideally fabricated multilayered thin film Si/Ge nanostructures. The ML model is trained on inexpensive ~200 DFT calculations of Si/SiGe alloys: the training data set is populated exploiting the relationship between geometrical features or local atomic environments in these systems and their electronic structure properties. The predictor variables are obtained with Voronoi tessellation approach and the response variables are calculated with the decision tree regression algorithm. [1] This approach has successfully predicted formation energies to expedite materials discovery, [2] Our ML model trained on random alloys, has shown remarkable ability to predict electronic band structures and Onsager electronic transport coefficients of large non-ideal thin film Si/Ge superlattices. We show the predictive power of our model by comparing the predicted band structures learned from small 16-atom alloy unitcells with the electronic states of large Si/Ge superlattices unfolded to 4x4 monolayer superlattice Brillouin zones [3]. The ML framework has been especially effective in capturing crucial trends in electronic properties for a range of multilayered structures. Our ML framework will facilitate the development of inverse design approach to engineer interface profiles of integrated semiconductor architectures, to accomplish desired device performance and functionalities.

G01.05.31
Machine Learning for Perovskite Solar Cells
John M. Howard and Marina S. Leite; University of Maryland, College Park, Maryland, United States.

Perovskite solar cells have recently reached power conversion efficiency > 22%, representing a promising option for high-performance and low-cost photovoltaic (PV) devices [1]. Yet, their performance is dynamic, varying as a function of time under intrinsic (bias, temperature, and light) and extrinsic (water and oxygen) parameters [2,3]. Because the influence of each stressor on device response depends on the perovskite chemical composition (>9000 options with potential application in PV) and on the order of exposure and the value range of each parameter, an extremely large number of possible combinations is expected. Therefore, we propose a machine learning (ML) paradigm based on an artificial neural network (ANN) to determine the optimal conditions for the perovskites operation, including their ‘reap’, ‘rest’ and ‘recovery’ phases [3]. ‘Reap’ is required for harvesting energy (PV device operation), while both ‘rest’ and ‘recovery’ stages are needed for assuring that the changes in the optical and electrical responses are reversible, preventing material/device degradation and maximizing long-term performance [4]. The successful implementation of the ANN routine for ultimate unsupervised learning relies on our suggested ‘knowledge-shared’ tactic, where researchers from academia, national laboratories and companies will gather positive and negative experimental results in a shared data repository. We highlight that while most ML efforts applied to perovskites focus on screening thermodynamically stable options, our artificial intelligence approach targets the dynamic response of this promising class of material, never exploited before. Our ML strategy will accelerate monitoring and controlling of device performance recovery, paving the way for the fast development of stable perovskites and its commercialization.

Coordination environments (e.g., tetrahedra and octahedra) are powerful descriptors of the structure of a solid. An automatic and robust detection of these environment is an important step towards the data mining of the large databases (experimental or theoretical) currently available to materials scientists. In this work, we present a tool to automatically determine coordination environments in a given structure. The identification is performed based on the sole consideration of the geometrical knowledge of the structure. Distortions are taken into account and we allow the description of an environment as a mixture of several environments. After outlining our algorithm, we will illustrate the approach by presenting a statistical analysis of coordination environments for all oxides from the Inorganic Crystal Structure database (ICSD). We will discuss the implication of our study and how this tool can be used to accelerate the materials design process.

2:15 PM GI01.07.03 Materials Discovery for Thermal Energy Storage—A High Throughput Computational and Machine Learning Approach Steven G. Kiyabu, Alaudin Ahmed, Jeffrey S. Lowe and Donald Siegel; University of Michigan, Ann Arbor, Michigan, United States.

Salt hydration reactions show great promise for thermal energy storage (TES) due to their high energy densities, cost effectiveness, and potential for reversible operation at moderate temperatures. While a number of salt hydrate compositions have been investigated previously for TES, many have yet to be explored. The goal of this work is to identify hypothetical salt hydrate structures that are thermodynamically stable and can out-perform known materials. All 25 distinct crystal structures of the form M\textsuperscript{n+}\textsubscript{m}nH\textsubscript{2}O (where M\textsuperscript{n+} is a metal cation, X\textsuperscript{2} is a halide, and n \geq 6) found in the Inorganic Crystal Structure Database were used as structural templates. A total of 1,824 hydrate structures were generated from systematic cation and anion substitution and were characterized by Density Functional Theory calculations according to their energy densities and operating temperature range. A variety of classification and regression machine learning (ML) algorithms were trained on the data to predict stability as well as TES performance. Thousands of mathematical combinations of the basic ionic and structural properties were generated and the most promising features were selected from this list to be used in the ML algorithms. In addition to identifying new, promising materials for TES, our study identified which features are relevant to TES performance as well as predictive models that can be used to further accelerate our screening of hypothetical salt hydrate structures for TES.

2:30 PM BREAK

3:30 PM *GI01.07.04 Accelerated Search for Materials with Targeted Properties Turab Lookman; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Finding new materials with targeted properties with as few experiments as possible has been a goal of the materials genome initiative. The enormous complexity due to the interplay of structural, chemical and microstructural degrees of freedom in materials makes the rational design of new materials rather difficult. Machine learning and optimization, used in industry for solving complex problems, are increasingly being adapted for the design of new materials by learning from past data and making smart decisions about what the test next. However, the number of well characterized samples available as sources of data to learn from is often relatively small. I will review how we have utilized Bayesian Global Optimization to iteratively guide experiments to discover new alloys and ceramics.

4:00 PM GI01.07.05 Accelerated Search for Ultra-Incompressible, Superhard Materials Through Machine Learning Aria Mansouri Tehrani and Jakoah Brgoch; University of Houston, Houston, Texas, United States.

In the search for materials with exceptional mechanical properties, we have developed a machine-learning model to predict the elastic moduli of inorganic materials, which act as a proxy for hardness. Materials project database of elastic moduli has been used as the training set and the machine learning model is developed using support vector regression method implementing 150 compositional and structural variables. Further, a genetic algorithm-based variable selection is performed using partial least square regression method resulting in a cross-validated root mean square error (RMSE) of 17.2 GPa and 16.5 GPa for bulk and shear modulus. Subsequently, 118,287 compounds from crystalline databases are screened regardless of their chemical composition and atomic disorder for compounds with high bulk and shear moduli having potential for superhardness. We then identified compounds of two interest, a ternary rhenium tungsten carbide and a quaternary molybdenum tungsten borocarbide for experimental investigation. These materials were synthesized using arc melting and characterized with high-pressure diamond anvil cell measurements to confirm the machine learning predictions with <10% error. Vickers hardness measurements revealed the extremely high hardness nature of these compounds making these the hardest transition metal carbide and borocarbide reported. The successful identification of these superhard materials using state-of-art machine learning and materials screening techniques emphasizes the effectiveness of these methods in materials discovery and development.

4:15 PM GI01.07.06 Machine Learning for Searching the Stable Structure of Crystal Interface Teruyasu Mizoguchi and Shin Kiyohara; The University of Tokyo, Tokyo, Japan.

Interfaces are a lattice defect inside materials, and influence the overall material properties. For instance, interfaces in polycrystalline materials, i.e., grain boundaries (GB), determine ion transportation properties and high-temperature mechanical properties. The fact that interfaces have different properties from the bulk is a consequence of the fact that they have different atomic configurations from that inside the bulk. Thus, for a comprehensive understanding of the interface properties, determination of the atomic structure of the interface is crucial. However, extensive calculations are necessary to determine even one interface structure because of the geometrical freedom of the interface. The number of atomic configurations to be considered often reaches 10,000 in even the simplified coincidence site lattice grain boundary, namely Σ grain boundaries. To accelerate interface structure searching, very efficient methods based on machine learning techniques, including virtual screening and Bayesian optimization have been proposed by the present authors.

We applied the virtual screening method to [001] symmetric tilt GB of Cu. The predictor was constructed using two Σ5 and two Σ17 GBs, and totally 83 descriptors related to the geometrical data, such as bond length and atom density, were used. The constructed predictor successfully determined other 12 GBs of Cu, Σ13 ~ Σ125 [1].

In addition to the virtual screening, we have developed an alternative and powerful method with the aid of a geostatistics approach called kriging[2]. Kriging is an effective interpolation method based on a Bayesian optimization and Gaussian process governed by prior covariance. The kriging method has been applied and demonstrated to determine the grain boundaries of fcc-Cu, bcc-Fe, MgO, rutile-TiO2, and CeO2 GBs [3-4].

The details of those studies will be shown in my presentation.

Fast charging protocols for lithium-ion batteries are critical for widespread adaptation of electric vehicles. However, a limited understanding of battery degradation modes during fast charging and the large manufacturing variability of commercial lithium-ion batteries are major challenges to the development of high-performance fast charging protocols. In this work, we optimize a three-step charging protocol for commercial 18650 lithium-ion batteries that achieves 80% state of charge in ten minutes. We employ two key elements to reduce the optimization cost: early prediction of failure, which uses cycling data from the first 100 cycles to predict cycle lives that reach up to 1200 cycles, and adaptive Bayesian optimal experimental design, which significantly reduces the number of experiments required. We identify promising fast charging protocols with identical charging times but lifetimes that exceed the baseline charging protocol out of a candidate pool of nearly 180 protocols. This method can be extended to accelerate development of other tasks in battery manufacturing and deployment, such as formation cycling and state-of-health estimation.

SESSION GI01.08: Machine Learning Enhanced Computational Materials
Session Chairs: Keith A. Brown and Patrick Riley
Thursday Morning, November 29, 2018
Hynes, Level 1, Room 110

8:00 AM *GI01.08.01

The advent of innovative molecular modeling algorithms, optimization strategies, and machine learning techniques is ushering in a new era of materials science and engineering in which computational tools are routinely used to probe, design, and interrogate matter and functional materials systems. In this presentation I will illustrate some of these ideas in the context of a variety of examples taken from chemical engineering, physics, biology and materials science. In the first, I will discuss the simultaneous interpretation of scattering data from multiple sources by relying on molecular models. In the second I will present models of biological systems that use machine learning to integrate experimental and computational information form a wide range of sources, and to discover collective variables that can be used to enhance sampling. In a third demonstration, I will explain how machine learning can by itself be used to improve and accelerate enhanced sampling algorithms. In a fourth example, I will discuss how evolutionary optimization and machine learning can be used to create new mechanical metamaterials, and to predict electronic transport in organic conductors.
Emerging machine learning (ML)-based atomic force fields provide a powerful tool to accurately model a variety of large-scale (length-scale > nm and time-scale > ns) physical and chemical processes, which remain outside the realm of quantum mechanical methods—such as density functional theory (DFT)—owing to their computational cost [1,3,4]. In the past, we proposed one such approach to construct a ML-based force field, where only the vectorial force on an atom is “learned” directly from its atomic environment [1]. The capability and transferability of this approach was demonstrated by accurately reproducing the structural, mechanical, transport and vibrational properties of elemental Al [1,2], and correctly modeling atomic forces for diverse elemental solids such as Cu, Ti, W, Si and C [5]. In this contribution, we showcase the true power of such ML-based force fields, the capability to systematically improve by actively learning from “failed” cases. The general strategy is based on the idea of repeated augmentation of poorly predicted configurations to the reference dataset, and re-training the model in a cyclic manner. Such a pathway for the iterative improvement of these force fields is straightforward, efficient, and universal. Here, we demonstrate this approach for Cu, Al and Pt using actively trained ML-based force fields that capture an array of phenomena such as surface diffusion mechanisms, stacking fault energies, divacancy behaviors and screw dislocation core structure. We conclude that this simple strategy can be adopted to construct targeted, application-specific ML force fields, extending our ability to capture materials phenomena which lie beyond the current reach of classical and/or quantum mechanical methods.

The scale of typical polymer molecular dynamics (MD) simulation usually involves at least several thousand atoms, which is necessary because the motion and dynamics of polymer chains strongly depends on the length of the polymer chains. This in turn makes it impossible to use ab-initio MD on systems which are representative of real polymer system, making it necessary to fit ab-initio data from separate fragments of organic functional groups in gas phase to classical force field with complex functional forms (such as the OPLS force field, for example). These functional forms typically do not describe chemical reactions due to its definition of explicit unbreakable atomic bonds. In addition, they do not accurately describe ionic interactions and other properties which involve electronic polarizability and charge transfer of atoms which only shows up under quantum mechanics in real bulk atomic systems.

In this work, we develop a multi-element neural network force field fitting procedure suitable for simulating randomly large bulk atomic systems such as polymers. We show that atomic snapshots under a certain radius of the central atom contains sufficient information to describe quantum mechanical atomic force accurately. Consequently, small atomic cluster snapshots can be simulated within quantum mechanical simulations in reasonable time scale to generate the training set (in the order of several tens of thousands of small atomic snapshots). Force vector projection on internal structural axes in combination with Behler-Parrinello style fingerprinting scheme enables direct training of atomic force vectors of individual atom elements, as opposed to training on the aggregate scalar energy of the entire ab-initio ensemble in the original Behler-Parrinello scheme. The neural network force field fitting algorithm will be presented, as well as accuracy results for polyethylene oxide (PEO) polymer typically used in Lithium battery polymer electrolytes.

The evaluation of atomic forces and total energy is a key challenge for large-scale atomistic simulations of materials. Ab-initio molecular dynamics (AIMD) is a successful approach but it becomes computationally too expensive for large systems. In this work, we demonstrate a direct and local Deep Learning (DL) model for atomic forces. We demonstrate this model for bulk aluminum, silicon and sodium and show that the model errors are comparable to other state of the art algorithms. Our model allows the calculation of forces in large cells using a training data that we built from smaller cells that were calculated with Density Functional Theory (DFT). In addition, we examine the question of temperature transferability of the mode and show that we can train the model with data that was produced at a high temperature and then test it on data that was produced at lower temperatures. Finally, we show that the physical properties of the system (e.g. number of nearest neighbors) is manifested in the model convergence with respect to some of its parameters.
Molecular crystals are bound by dispersion interactions, whose weak nature produces potential energy landscapes with many local minima. Hence, molecular crystals often exhibit polymorphism, whereby the same molecule crystalizes in several structures. Polymorphs may exhibit markedly different physical and chemical properties. Crystal structure prediction is challenging due to the high accuracy required for the small energy differences between polymorphs and the high dimensionality of the configuration space. We present the genetic algorithm (GA) code, GAtor [J. Chem. Theory Comput., 14, 2246 (2018)], and its associated structure generation package, Genarris [J. Chem. Phys., 148, 241701 (2018)]. Both rely on dispersion-inclusive density functional theory (DFT) for geometry relaxations and energy evaluations.

Genarris generates random structures with physical constraints and uses a Harris approximation to construct the electron density of a molecular crystal by superposition of single molecule densities. The DFT energy is then evaluated for the Harris density without performing a self-consistent cycle, enabling fast screening of initial structures with an unbiased first-principles approach. Genarris creates a maximally diverse initial pool of structures by using machine learning for clustering based on structural similarity with respect to a relative coordinate descriptor (RCD) designed for molecular crystals. GAs rely on the evolutionary principle of survival of the fittest to perform global optimization. GAtor offers a variety of crossover and mutation operators, designed for molecular crystals, to create offspring by combining/modifying the structural genes of parent structures. GAtor achieves massive parallelization by spawning several GA replicas that run in parallel and read/write to a common pool of structures. GAtor performs evolutionary niching [Faraday Discussions, DOI: 10.1039/C8FD00067K (2018)] by using machine learning for dynamic clustering on the fly. A cluster-based fitness function is then used to steer the GA to under-sampled low-energy regions of the potential energy landscape. This helps overcome initial pool biases and selection biases.

Transition metal dichalcogenide (TMD) are novel nanomaterials that can behave like conductors, semiconductors, or insulators depending on the type of transition metal used. With a thickness as small as 3 atoms and size dependent properties, TMDs have a great potential in applications such as flexible and wearable electronics. Despite the early discovery of TMDs and their synthesis via vapor deposition, fundamental understanding on their growth mechanisms remains largely unknown, which hindered the preparation of these materials on a larger scale. Molecular simulations can be used to address this problem, but the lack of accurate interatomic potentials and the large effort required to develop them presents a major barrier. Here, we demonstrate the use of a machine learning based framework in the development of a reactive force field model for tungsten diselenide. Our data-driven procedure led to a model that accurately captures various properties, including structures, dynamical stability, phonon, and various energetics, which is obtained without the need to rely heavily on human intuitions or lengthy development time. With the model, we perform molecular dynamics simulations to investigate the growth of 2D tungsten diselenide under different vapor deposition conditions as well as to study their mechanical properties.

DNA-stabilized silver clusters (Ag-DNAs) are composed of ~10-30 silver atoms wrapped in short strands of DNA [1]. Ag-DNAs can be highly fluorescent and are finding use for chemical sensing and DNA detection [2]. The nucleobase sequence that stabilizes a cluster controls silver cluster size, leading to well-known yet little-understood sequence-tuned Ag-DNA fluorescence colors. The large space of possible stabilizing sequences challenges the understanding of how sequence selects Ag-DNA properties, limiting the design of new applications for Ag-DNA. Are there subsequences, akin to genes, that are important for stabilization of products with desired properties? Can these subsequences be used for predictive Ag-DNA design? To answer these questions, we develop a closed-loop framework combining machine learning and experimentation. We determine the fluorescence spectra
of Ag-DNAs stabilized by over 1000 distinct DNA oligomers of fixed length using high-throughput synthesis and fluorimetry. Then, we mine for DNA subsequences, or motifs, that are discriminative of fluorescence brightness and color. As a result, each DNA template is represented by a feature vector encoding the inclusion/exclusion of discriminative motifs. We train classification models based on the above training data and further employ those to generate and screen new sequences, improving both fluorescence brightness [3] and the selectivity for a desired Ag-DNA color [4]. Our methodology improves color selectivity by 330% for Ag-DNAs with peak emission beyond 660 nm. The discovered motifs also provide physical insights into how DNA sequence controls silver cluster size and color. This data-driven design approach for color of DNA-stabilized silver clusters demonstrates the potential of machine learning and data mining to increase precision and efficiency of nanomaterials design.

In our ongoing work, we extend these methods to varying-length templates and Ag-DNAs emissive at unobserved wavelengths. Are the motifs detected in a training set of fixed-length DNA template predictive when templating with DNAs of different length? Furthermore, is it possible to employ our data-driven framework to predict and design for unobserved Ag-DNA colors in the near-infrared? Strong evidence for the utility of motifs in the above tasks will support the hypothesis of “motifs serving as genes” for Ag-DNAs and further direct the study of these important materials.

11:30 AM GI01.08.12
Data Generated Formula for Creep and Stress Relaxation Sheng Sun and Tong-Yi Zhang; Materials Genome Institute, Shanghai University, Shanghai, China.

Analytic formula is the best and ideal means in the clear description of time-, stress-, and temperature-dependent deformation behavior and in the understanding of the deformation mechanism. To have such a formula for creep and stress relaxation, multi-temperature creep, stress-relaxation, and indentation creep tests were conducted on nanograined copper and nanotwinned copper under various loading levels to generate sufficiently large number of data, which allows one to develop an analytic formula of plastic strain rate versus temperature and stress (or hardness in indentation creep) by using symbolic regression with domain knowledge. The analytic formula explicitly involves the athermal stress (or hardness) exponent, activation energy, and activation volume, which values are determined reliably from the experimental data from the multi-temperature tests.

Promise and Perils of Machine Learning in the Sciences Patrick F. Riley; Google Research, Google, Mountain View, California, United States.

All around we see excitement about machine learning to make a meaningful change in a variety of scientific disciplines. Sometimes lost in this discussion is a clear understanding and discussion of the risks, expected utility, and proper application of these powerful techniques. Through vignettes of real applications of machine learning to scientific problems by the Google Accelerated Science group, this talk will illustrate important lessons for scientists who want to make machine learning part of their toolkit.

2:00 PM GI01.09.02
Automatic Classification of Hypothetical Zeolites with Unsupervised Machine Learning Daniel Schwalbe-Koda and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Zeolites are inorganic nanoporous materials with wide industrial applications for their catalytic, adsorbent and ion-exchange properties. Because of their broad applications, selectivity, robustness and cost-effectiveness, intense basic and applied research is devoted to the discovery new zeolitic materials. Whereas hundreds of thousands of hypothetical zeolite-like frameworks are theoretically possible, only ~235 different known geometries have been synthesized to date [1]. The virtual space of possible zeolites has been explored by algorithmic generation and later filtered by physics-based simulations of thermodynamic driving force [2]. Several hand-made criteria based on geometrical or thermodynamic analysis have been proposed to differentiate synthetically accessible zeolites, but the underlying aspects that define zeolite feasibility remain unknown.

Aiming to accelerate the discovery and design of realizable zeolites, we have applied unsupervised machine learning methods to explore the topological and geometrical degrees of freedom responsible for the synthetic accessibility of zeolitic frameworks. Similar deep learning models have been successfully applied to map molecules onto a continuous space [3]. A generative model comprised of a Wasserstein autoencoder [4] was coupled to graph convolutional neural networks customized for crystalline solids [5]. Using a large dataset of hypothetical zeolites, the model was trained to reconstruct the original unit cells from a low dimensional representation. Going through this information bottleneck allows to automatically identify the key collective variables that describe zeolitic frameworks. In addition, the model was jointly trained to predict physics-based labels in a semisupervised fashion using existing simulations, thus contributing to create a smooth and robust latent representation. In a last step, hypothetical and known feasible zeolites were projected onto the latent space. By exploring common patterns, the deep learning toolset allows to single out hypothetical zeolite frameworks that are likely to be feasible.

Emerging machine learning (ML) based methods provide powerful tools to extract structure-property relations from the ever-growing materials simulation and experimental databases. However, most existing ML methods depend on feature vectors to represent different materials, which are limited to specific material groups and some computationally expensive features. In this talk, we present a crystal graph convolutional neural networks (CGCNN) framework [1] that represents an arbitrary periodic structure with an arbitrary number and type of atoms in a unit cell. We achieve state-of-the-art prediction performance for 8 different material properties using only the crystal structure information. We also extract materials design knowledge from the neural networks which can help accelerate the screening of materials. Finally, we show several examples of how the method can be applied to the design of Li metal battery electrolytes [2] and other material systems.

2:30 PM GI01.09.04
Deep Transfer Learning for Active Optimization of Functional Materials Properties in the Data-Limited Regime Brian DeCost and Gilad Kusne; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The recent development of learned representations for molecules and crystals via variants of graph convolutional neural networks (GCNs) has enabled significant improvements in the performance of data-driven models of chemical and physical properties of materials. This class of neural networks learns complex hierarchical representations of molecules and crystals using only a small number of elemental properties and the topology of the molecule or crystal. The representations learned by GCNs are built up by sequentially performing graph convolutions (i.e. local weighted sums) over the bonding network, where the graph convolution weights are optimized by stochastic gradient descent via backpropagation. We explore a deep transfer learning approach to leverage this representational power in solid state systems for which available data is limited and especially where additional data is expensive to acquire. In this proof of concept study, we hold out entire classes of functional materials (e.g. perovskite photovoltaic candidates, Heusler and Heusler-related compounds) during the GCN training process, using large density functional theory (DFT) calculation datasets for both training and active learning test sets. We then perform de novo active learning using GCN-derived features to optimize the relevant functional materials properties for each held out materials system. We compare the computational efficiency of the active learning process using GCN features to that using competitive engineered features, such as the Magpie feature set. Future efforts will focus on directly driving experimental efforts and DFT calculations using this deep transfer learning strategy.

Applying Deep Learning to Proteins and Small Molecules Lucy Colwell; Department of Chemistry, University of Cambridge, Cambridge, United Kingdom.

The evolutionary trajectory of a protein through sequence space is constrained by its function. Collections of sequence homologs record the outcomes of millions of evolutionary experiments in which the protein evolves according to these constraints. The explosive growth in the number of available protein sequences raises the possibility of using machine learning and artificial intelligence to exploit the natural variation present in homologous protein sequences to infer these constraints and thus identify sequences with different protein phenotypes.

Because in many cases phenotypic changes are controlled by more than one amino acid, the mutations that separate one phenotype from another may not be independent, requiring us to understand the higher order structure of the data. We show that models learned from data are capable of predicting key aspects of protein function. These include (i) the inference of residue pair interactions that are accurate enough to predict all atom 3D structural models; and predictions of (ii) binding interactions between different proteins and (iii) binding between protein receptors and their target ligands. Finally, I will discuss current efforts to search the space of possible sequences for those that correspond to proteins with specific functional properties that exploit recent advances in deep learning.

3:45 PM GI01.09.06
Design of Bioinspired Hierarchical Systems Using Machine Learning, Additive Manufacturing and Experiment Grace Gu, Chun-Teh Chen, Deon Richmond and Markus Buehler; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Developments in the materials science community are tending more and more to a materials-by-design approach, no longer accepting the status quo with the insight that we can tailor-make materials with desired properties for specific applications. Biological materials, such as bone, wood, and seashells, have multifunctional properties that often surpass that of their synthetic counterparts. Composed of a limited set of building blocks, nature intelligently organizes these building blocks into hierarchical architectures, allowing them to overcome the limitations of their constituents while combining their best attributes. These complex architectures pose a challenge for traditional manufacturing techniques due to their multi-material construction, hierarchy, and potential voids. Additive manufacturing is a new tool that can overcome these limitations. In this work, we use convolutional neural networks (CNN) to cast the natural process of evolution into a computational framework to study bioinspired hierarchical structures. With an integrated approach of simulation, machine learning, additive manufacturing, and experimental testing, we investigate the optimal microstructural patterns that lead to tougher and stronger materials. In the future, this bioinspired machine learning approach will enable materials-by-design of complex architectures to tackle demanding engineering challenges.
Deep Learning Bandgaps of Topologically Doped Graphene

Yuan Dong, Chuhan Wu, Chi Zhang, Jianlin Cheng and Jian Lin; University of Missouri-Columbia, Columbia, Missouri, United States.

Manipulation of physical and chemical properties of materials via precise doping has afforded an extensive range of tunable phenomena to explore. Recent advance shows that in the atomic and nano scales topological states of dopants play crucial roles in determining their properties. However, such determination is largely unknown due to the incredible size of topological states, which makes it almost impractical to search by experiments or ab initio calculations. Here, we present a case study of using deep learning algorithms to predict bandgaps of boron-nitrogen pair doped graphene with random dopant topologies. In the study, the bandgaps are calculated by the accurate first-principle calculations, and together with the structure information they are fed as datasets to train three types of convolutional neuron networks (CNNs), including VGG16 convolutional network (VCN), residual convolutional network (RCN), and concatenate convolutional network (CCN). All of these CNNs afford good prediction accuracy, outperforming non-convolutional support vector machine (SVM). We further perform the transfer learning by leveraging data generated from smaller systems to improve the prediction for large supercell systems. The success of this work provides a cornerstone for future investigation of topological doping in graphene and other 2D materials beyond graphene. Furthermore, it will stimulate widespread interests in applying materials property data into actionable knowledge, and more recently it has been used to assist in experiment design. In this talk we present the next step in machine learning for materials research - autonomous materials research systems. We first demonstrate autonomous measurement systems for phase mapping, followed by a discussion of ongoing work in building fully autonomous systems. For the autonomous measurement systems, machine learning

SESSION GI01.10: Autonomous Research II

8:30 AM *GI01.10.01
Autonomous Materials Research Systems—Phase Mapping Gilad Kusne1, 2, Brian DeCost1, Jason Hattrick-Simpers1 and Ichiro Takeuchi2; 1National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2University of Maryland, College Park, Maryland, United States.

The last few decades have seen significant advancements in materials research tools, allowing researchers to rapidly synthesize and characterize large numbers of samples - a major step toward high-throughput materials discovery. Machine learning has been tasked to aid in converting the collected materials property data into actionable knowledge, and more recently it has been used to assist in experiment design. In this talk we present the next step in machine learning for materials research - autonomous materials research systems. We first demonstrate autonomous measurement systems for phase mapping, followed by a discussion of ongoing work in building fully autonomous systems. For the autonomous measurement systems, machine learning
controls X-ray diffraction measurement equipment both in the lab and at the beamline to identify phase maps from composition spreads with a minimum number of measurements. The algorithm also capitalizes on prior knowledge in the form of physics theory and external databases, both theory-based and experiment-based, to more rapidly hone in on the optimal results. Materials of interest include Fe-Ga-Pd, TiO2-StrO2-ZnO, and Mn-Ni-Gic.

9:00 AM GI01.10.02 Streaming Data Analysis Software Taking Us Towards Autonomous Experimentation—SHED and Streamz
Christopher J. Wright1, Jason Hattrick-Simpers2 and Simon J. Billinge3, 4; 1Columbia University, New York, New York, United States; 2Materiel Energy and Sustainable Development Group, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 3Condensed Matter Physics & Materials Science, Brookhaven National Laboratory, Upton, New York, United States.

Autonomous experiments have three major parts, data acquisition, data analysis, and feedback. While all three are crucial to performing the experiment, the data analysis portion may be the most challenging. The data analysis must take raw data, produce meaningful quantities of interest, and translate them into actionable experimental parameters. Importantly all of this must be done live. In this talk I will discuss our approach to streaming data analysis for x-ray total scattering measurements, using analysis pipelining programs we have written, streamz and SHED. Streamz and SHED provide a simple, powerful, and easy to use way to build streaming data processing protocols in python. The SHED system also provides seamless data provenance with minimal user input. Finally we'll discuss the application of these pipelines to kriging driven autonomous experimentation for discovering novel glass forming alloys via atomic pair distribution function analysis.

9:15 AM *GI01.10.03 Industrial Waste Gas Mixture as a Feedstock in Efficient Carbon Nanotube Growth—Using an Autonomous Research System to Probe Growth Kinetics and Mechanisms
Brian Everhart1, Pavel Nikolaev2, 3, Rahul Rao2, 3, Benji Maruyama2 and Placidus B. Amama1; 1Tim Taylor Department of Chemical Engineering, Kansas State University, Manhattan, Kansas, United States; 2Materials and Manufacturing Directorate, Air Force Research Laboratory, WPAFB, Ohio, United States; 3UES Inc., Dayton, Ohio, United States.

Fischer–Tropsch synthesis (FTS) is an environmentally friendly process used in industry for the conversion of syngas (CO and H2) – usually obtained from low-value biomass, natural gas, and coal – to high-value hydrocarbon liquid fuels over transition metal catalysts (typically Fe or Co). The gaseous product mixture (FTS-GP) usually consists of C1-C4 hydrocarbons and unconverted CO and H2, which we use as a feedstock for the chemical vapor deposition (CVD) growth of carbon nanotubes (CNTs). A comparison of the growth curve of FTS-GP CVD using an Fe catalyst with other conventional CVD processes for CNT forest growth, reveals growth behavior (in terms of catalyst lifetime and growth rate) superior to existing CVD approaches. The objective of this study is to develop the fundamental understanding required to couple catalytic CVD for CNT growth to the waste-gas stream of FTS (FTS-GP) for scalable, continuous, and controlled growth of CNT arrays. Due to the breadth of parameters that affect CVD growth of CNTs, rapid experimentation is necessary for effective growth condition optimization and detailed understanding of the role of FTS-GP. Here we employ an autonomous research system (ARES), equipped with in situ Raman spectroscopy, to probe the growth kinetics of CNTs and elucidate the secret role of FTS-GP in enhancing catalyst lifetime and growth efficiency. ARES allows for both rapid, automated experimentation as well as autonomous growth, in which the system self-generates experiments to maximize growth rate based on previous results. Our study reveals the dependence of growth temperature, catalyst properties, feedstock composition, and partial pressure of FTS-GP on activity and lifetime of catalysts. As examples, the optimal growth temperature and FTS-GP partial pressure for CNT growth on an Fe catalyst were determined to be approximately 850 °C and 20 Torr, respectively. We have also studied the effects of continual water generation on the surface of a catalyst, and its capability of enhancing growth by prolonging catalyst lifetimes. This study is expected to illuminate the complex interdependence of catalysts and carbon feedstock and facilitate rational design of catalysts and growth recipes for efficient and controlled CNT growth.

9:45 AM GI01.10.04 The Odds of Synthesis—Predictions from Network Analysis and Phase Diagrams
Muratathan Avkoli; Toyota Research Institute, Los Alisos, California, United States.

Synthesis of new materials is a complex, multi-faceted process driven not only by thermodynamics or kinetics but also by the availability of precursors and techniques, expertise, intuition and many other circumstantial factors. With this complexity, predictive synthesis is emerging as the new grand challenge in materials discovery. In this talk, we will present a tractable information approach to predicting the likelihood of successful experimental synthesis of hypothetical materials, such as those identified via high-throughput (HT) density functional theory (DFT), prototype searches or various other modeling techniques. The method combines network interpretation of the free energy-composition space obtained from HT-DFT, i.e. the convex-hull, and the discovery timeline of materials extracted from publications, to build accurate machine-learning models that forecast probability of successful synthesis in the laboratory. *This work was done in collaboration with Santosh Suram, Patrick Herring, Linda Hung, Vinay Hegde, Jens Hummelsheim and Chris Wolverton.

10:30 AM *GI01.10.05 Cold Spray from Coatings to Additive Manufacturing
Leonardo Ajdehazian; GE Global Research, US, Niskayuna, New York, United States.

This work describes the fundamentals of cold spray and explore its use beyond just a coating process. The use of cold spray as an additive technology shows promising due to the unique solid-state characteristics of the process and the low thermal input to the material. This enable us to produce microstructures that are not possible with traditional manufacturing techniques, and properties that can exceed current commercially available alloys with the same chemistry. Nevertheless, to transform a coatings process into a 3D additive modality, a significant effort must be placed on how to design and build complex shapes using cold spray. The implementation of machine learning techniques to produce complex geometries using cold spray, and its advantages over other approaches, will also be discussed.

11:00 AM GI01.10.06 A Bayesian Framework for Selection, Calibration and Uncertainty Quantification of Thermodynamic Property Models
Noah H. Paulson, Elise Jennings and Marius Stan; Argonne National Laboratory, Chicago, Illinois, United States.

Thermodynamic property models form the basis of numerous technologically important applications including the calculation of equilibrium phase diagrams and the simulation of microstructure evolution. Traditionally, the selection of models, weighting of data and removal of outliers are informed by the intuition of the researcher. Furthermore, model calibration is deterministic, rarely resulting in uncertainty intervals for the model predictions. In this work, we present a framework for the selection, calibration and uncertainty quantification (UQ) of thermodynamic property models. Enabled by recent developments in the field of machine learning and Bayesian inference, we present a methodology for applying a Bayesian framework to the above problems. The method combines network interpretation of the free energy-composition space obtained from high-throughput density functional theory (DFT), prototype searches or various other modeling techniques. The method combines network interpretation of the free energy-composition space obtained from high-throughput density functional theory (DFT), prototype searches or various other modeling techniques.
On Converting Material Phase Dynamic Transformation Problem into Material Video Frame Variation Problem

2:15 PM

advances in numerical sampling algorithms, we employ fully Bayesian methods to address each of these tasks in addition to common issues seen in thermodynamic data including outliers, inaccurately reported or missing error bars and systematic errors. In addition, the framework enforces consistency between the thermodynamic quantities while optimally leveraging data from all available sources. The framework is demonstrated through the construction of thermodynamic property models for the alpha, beta and liquid phases of Hafnium metal for specific heat, enthalpy, entropy and Gibbs free energy.

Learning UV-Vis Spectroscopy from Images on the World's Largest Experimental Materials Database Helge S. Stein, Dan Guevarra, Paul Newhouse, Edwin Soedarmadji and John M. Gregoire; Joint Center for Artificial Photosynthesis, California Institute of Technology, Pasadena, California, United States.

UV-Vis spectroscopy is the first step in assessing light absorbers for solar fuels generation, but the community lacks sufficiently large experimental datasets and predictive models for experimental optical properties. Based on the largest and most diverse experimental materials science dataset of 180,902 distinct materials, including 45 elements, and more than 80,000 unique quinary oxide and 67,000 unique quaternary oxide compositions we trained different deep neural nets that enable us to predict complete UV-Vis absorption spectra from a materials sample image. The models learn how to spectrally hyperscale from a low energy but high spatial resolution input. Extracting direct bandgaps from predicted spectra yields an accuracy of bandgap prediction of 0.2 eV RMSE, which is well within the uncertainty of traditional extraction of bandgaps. Building upon these models we will present a one million experimental materials sample image dataset with complete data lineage and UV-Vis characterization. We will discuss methods and challenges in predicting optical properties from composition featurizers and chart pathways to autonomous experiment planning using state of the art visualization tools.

2:00 PM GI01.11.03
Material Image Segmentation with Machine Learning Method and Complex Network Method Chuabin Lai, Leilei Song, Yueying Han, Qian Li and Hui Gu; Shanghai University, Shanghai, China.

The study of the relationship among the manufacturing process, the structure and the property of materials can help to develop the new materials. Material images contain the microstructures of materials, therefore, the quantitative analysis for material images is the important means to study the characteristics of material structures. Generally, the quantitative analysis for material microstructures is based on the exact segmentation of the materials images.

However, most material microstructures are shown with various shapes and complex textures in images, and they seriously hinder the exact segmentation of the component elements. In this research, machine learning method and complex networks method are adopted to the challenge of automatic material image segmentation. Two segmentation tasks are completed: one, images of titanium alloy are segmented based on pixel-level classification through feature extraction and machine learning algorithm; the other, ceramic images are segmented with complex networks theory. In the first task, texture and shape features near each pixel in titanium alloy image are calculated, such as Gabor filters, Hu moments and GLCM (Gray-Level Co-occurrence Matrix) etc. Feature vector for the pixel may be obtained by arraying these features. Then, classification is performed with the random forest model. Once each pixel is classified, the image segmentation is also completed. In the second task, a complex network structure is built for the ceramic image, by using K-mean algorithm and gridding method. Then, a clustering algorithm of complex network is used to obtain network connection area. Finally, the clustered network structure is mapped back to the image and getting the contours among the component elements.

The experimental results demonstrate that these methods can accurately segment materials images. The segmentation methods can provide the data foundation for further quantitative analysis of the materials microstructures.

3:00 PM GI01.11.05

Recent development of nickel superalloys for additive manufacturing has shown to be challenging due to the susceptibility to micro cracking in as build microstructure. Significant effort has gone into optimizing build parameters for these hard to process alloys. A new protocol was developed by leveraging machine learning algorithm to accelerated the development cycles. In this paper, example of the use of machine learning method to guide parameter development for hard to weld alloys will be presented.

3:15 PM GI01.11.06
Development of a Machine Learning-Based Approach for Diffusion Studies in Crystals—Application to Diffusion in III-V Semiconductors Mardochee Reveil1 and Paulette Clancy1; 1Cornell University, Ithaca, New York, United States; 2Corning Incorporated, Corning, New York, United States.
Recent developments in machine learning have created unprecedented opportunities for incorporation of artificial intelligence techniques in scientific research in a variety of fields including medicine, astronomy, robotics, etc. Application of such advanced techniques in molecular design of materials is still in its infancy and, indeed, lags behind the fields mentioned above. Here, we explore and develop a novel approach whereby recent advances in machine learning techniques are used to study diffusion in crystals, which is critically important for the semiconductor industries. We show that this method offers a viable alternative to traditional techniques used to quantitatively (i.e., gain mechanistic insights) and qualitatively uncover how different species diffuse in a crystal lattice. We explain how this method can be applied to the study of defect diffusion in III-V semiconductors. III-V materials, like GaAs or InGaAs, are promising classes of materials for use in next-generation computing devices for their combination of high performance and better heat management characteristics. But the combinatorial nature of this design space makes it challenging to efficiently explore potential candidates. By providing enhanced screening capabilities, this new approach represents a significant step in the right direction for faster design of next-generation materials. Finally, we explain why Machine Learning could be a powerful tool to help tackle other traditional chemical engineering problems.

3:30 PM GI01.11.07
Combined Data-Driven Identification and Physically-Based Understanding to Materials Development—Building a Solid Process-Structure-Property Link in Ga-Doped ZnO Films Yuyun Chen and Feng Huang; Ningbo Institute of Materials Technology and Engineering, Ningbo, China.

Building a solid process-structure-property link to improve electrical properties effectively is difficult, especially in the vapor-deposited functional films with hierarchical structures. Here, we have introduced a semi-empirical method combined top-down data-driven identification and bottom-up physically-based understanding to build such a link for the magnetron sputtered Ga-doped ZnO (GZO) films. Artificial neural network (ANN) was utilized to identify the most correlative inverse structure-property and process-structure relationships. Moreover, a physically-based understanding of ANN results was to examine the rationality of the identified inverse relationships and capture the dominant mechanism for further materials design. It has been demonstrated that this combined method can identify the feasible process space to tailor the structures at a "correct length scale" and thus significantly improve the conductivity of our GZO films. Our semi-empirical method is probably valid for effective enhancement in physical properties of other vapor-deposited thin films.

3:45 PM GI01.11.08
Exploring Large Scale ToF-SIMS Data Matrices Using Artificial Neural Networks—Polymers and Biointerfaces Paul Pigram1, Robert Madiona1, Nicholas Welch2, David Winkle3,2,3 and Benjamin Muir2; 1La Trobe University, Melbourne, Victoria, Australia; 2CSIRO Manufacturing, Melbourne, Victoria, Australia; 3Monash University, Melbourne, Victoria, Australia.

Time-of-flight secondary ion mass spectrometry (ToF-SIMS) is continuously advancing. The data sets now being generated are growing dramatically in complexity and size. More sophisticated data analytical tools are required urgently for the efficient and effective analysis of these large, rich data sets. Standard approaches to multivariate analysis are being customised to decrease the human and computational resources required and provide a user-friendly identification of trends and features in large ToF-SIMS data sets. We demonstrate the generation of very large ToF-SIMS data matrices using mass segmentation of spectral data in the range 0 – 500 m/z in intervals ranging from 0.01 m/z to 1 m/z. No peaks are selected and no peak overlaps are resolved. Sets of spectra are calibrated and normalized then segmented and assembled into data matrices. Manual processing is greatly reduced and the segmentation process is universal, avoiding the need to tailor or refine peak lists for difficult sample types or variants. ToF-SIMS data for standard polymers (PET, PTFE, PMMA and LDPE) and for a group of polyamides are used to demonstrate the efficacy of this approach. The polymer types of differing composition are discriminated to a moderate extent using PCA. PCA fails for polymers of similar composition and for data sets incorporating significant random variance.

In contrast, artificial neural networks, in the form of self-organising maps (SOMs) deliver an excellent outcome in classifying and clustering different and similar polymer types and for spectra from a single polymer type generated using different primary ions. This method offers great promise for the investigation of more complex bio-oriented systems.

We compare the analysis of large scale mass segmented matrices with those formed using conventional selection of ToF-SIMS peak lists. SOMs are used to cluster and discriminate antibody fragments bound at surfaces and to demonstrate antibody orientation in optimised ELISA format assays.

4:00 PM GI01.11.09
Machine Learning with Force-Field-Inspired Descriptors for Materials—Fast Screening and Mapping Energy Landscape Kamal Choudhary; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

We present a complete set of chemo-structural descriptors to significantly extend the applicability of machine learning (ML) in material screening and mapping the energy landscape for multicomponent systems. These descriptors allow differentiation between structural prototypes, which is not possible using the commonly used chemical-only descriptors. Specifically, we demonstrate that the combination of pairwise radial, nearest-neighbor, bond-angle, dihedral-angle, and core-charge distributions plays an important role in predicting formation energies, band gaps, static refractive indices, magnetic properties, and modulus of elasticity for three-dimensional materials as well as exfoliation energies of two-dimensional (2D)-layered materials. The training data consist of 24549 bulk and 616 monolayer materials taken from the JARVIS-DFT database. We obtained very accurate ML models using a gradient-boosting algorithm. Then we use the trained models to discover exfoliable 2D-layered materials satisfying specific property requirements. Additionally, we integrate our formation-energy ML model with a genetic algorithm for structure search to verify if the ML model reproduces the density-functional-theory convex hull. This verification establishes a more stringent evaluation metric for the ML model than what is commonly used in data sciences. Our learned model is publicly available on the JARVIS-ML website (https://www.ctcms.nist.gov/jarvisml), property predictions of generalized materials.

4:15 PM GI01.11.10
Crystal Site Feature Embedding Enables Deep Image Recognition Based Exploration of Chemical Spaces Exceeding One Billion Compounds Mikhail Askerka1, Kevin Ryczko2, Oleksandr Voznyy1, Kyle Mills2, Isaac Tamblyn3, 2 and Edward H. Sargent1; 1University of Toronto, Toronto, Ontario, Canada; 2University of Ottawa, Ottawa, Ontario, Canada; 3National Research Council, Ottawa, Ontario, Canada.

Recent years have seen rapid advancements in artificial intelligence, with computer vision methods achieving >96% accuracy on image classification problems. Mapping materials science problems onto computational frameworks that can leverage advances in image recognition could accelerate the discovery of new materials for applications ranging from energy storage to efficient photon capture. Here we translate the
problem of ordering atoms in crystals into an image recognition problem. In Crystal Site Feature Embedding (CSFE), we partition the crystalline lattice into sites according to their spatial arrangement and map it onto a 4D feature vector. This volumetric vector is analogous to a 3D color image, where the first three dimensions reflect the sites’ arrangement, and the fourth dimension corresponds to the sites’ physical properties. We show that this new compact, position-agnostic representation carries sufficient physical insight to machine learn materials properties predicted by complex and time-consuming electronic structure methods such as Density Functional Theory (DFT). Only by using CSFE to leverage image recognition techniques such as Convolutional and Extensive Deep Neural Networks, do we achieve an impressively low mean absolute test error of 3.5 meV/atom on DFT total energies and 0.07 eV on DFT bandgaps of mixed halide perovskites. This enables us to capture nontrivial property trends, such as the U-shape of the bandgap of MAPbSn(1-x)I3 even though the learned algorithm was not explicitly trained in any of the intermediate compositions that make up this nonmonotonic bandgap vs. composition behavior. The method provides an unprecedented >10¹⁰ times acceleration factor compared to DFT alone. Additionally, we use CSFE to explore chemical spaces beyond those used for training, taking advantage of Brillouin zone folding and nature of deep image recognition methods.

4:30 PM GI01.11.11
Data-Driven Equation Discovery—Peak Current of Cyclic Voltammetry Simulations Sheng Sun and Tong-Yi Zhang; Materials Genome Institute, Shanghai University, Shanghai, China.

Cyclic voltammetry test is popular in electrochemical field to study the redox reaction kinetics at the electrode/electrolyte interface. Cyclic voltammogram (CV) can be plotted showing the current as a function of periodic linear swept potential. The current peak ($I_p$) in a CV under different experiment setup and reaction condition is a significant indicator of the underneath reaction kinetics. However, the explicit expression of $I_p$ cannot be derived theoretically. Here, we demonstrate the success of data-driven model discovery by using symbolic regression (SyR) combining with sparse regression (SpR) for $I_p$. At first, SyR and SpR were shown to be able to produce exactly the widely used expressions of $I_p$ as a function of diffusion constant, potential scan rate, reaction constant and initial concentration of the oxide for reversible and irreversible reactions. Then, a very accurate expression of $I_p$ across all reaction regions, including reversible, quasi-reversible and irreversible reactions, was obtained by SyR, when a few expert knowledge was introduced. This preliminary work indicates that SyR should be a powerful tool to find expressions of $I_p$ for more complex reactions with other influence factors, such as stress field and electrode shape.

8:30 AM *GI02.01.01
Unleashing your Inner Maker Daniela Rus; EECS, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The digitization of practically everything coupled with the mobile Internet, the automation of knowledge work, and advanced robotics promises a future with democratized use of machines and wide-spread use of robots and customization. While the last 60 years have defined the field of industrial robots, and empowered hard bodied robots to execute complex assembly tasks in constrained industrial settings, the next 60 years will be ushering in our time with Pervasive robots that come in a diversity of forms and materials, helping people with physical tasks. However, pervasive use of robots remains a hard problem. How can we accelerate the creation of robots customized to specific tasks? Where are the gaps that we need to address in order to advance toward a future where robots are common in the world and they help reliably with physical tasks? In this talk I will discuss recent developments toward pervasive robots the role of computation in (1) on demand creation of robots, (2) making robots more capable of reasoning in the world, and (3) making more intuitive interfaces between robots and people.

9:00 AM *GI02.01.02
Developments in materials promise to help improve the skin and muscle of robots and protheses - in both hard and soft machines. Here the potential of supercoiled polymer fibres is explored as a 'muscle'. Elastomer and gel-based sensors are proposed as the 'skin' that can actively or passively detect pressure, stretch, bend, proximity and - possibly - shear.

Coiled nylon and polyethylene actuators make use of anisotropies in thermal expansion coefficients in order to generate strains that are similar to or larger than those of muscle. They can operate under much larger loading conditions. Low cost and ready availability makes these interesting for robotics. Challenges are speed, efficiency and shape memory effects. In comparing requirements of various robotic actuators with the specifications of this artificial muscle, some application areas are identified, along with a path for further materials and device development.

In order for robots and prosthetic limbs to be dexterous, sensation is essential. Thin sheets of eactomers can be combined with gels and other conducting materials to simultaneously sense multiple inputs. One approach uses capacitive sensing, similar to that on a touch screen - but in a stretchable format. Some challenges include distinguishing between the touch of a finger, the stretch or bend of the sensor, and forces - normal or shear. Early work shows an ability to discriminate between these modes, while detecting finger proximity within about 1 cm, and very light touch. Another sensor type, which is loosely dubbed piezoionic, makes use of the voltages and currents generated by differences in ion mobilities produced by the deformation of ionically conductive materials. These can be slow, but sensitivity is similar to piezoelectrics. Fast response is obtained by ionic double layer sensors, where changes in contact area between gels and metals lead to 0.5 V amplitude responses with no input electrical energy. Combining these two modes of sensing could provide a mix of fast and slow 'receptors' that require no electrical power input to run.

Looking ahead, how do we integrate actuators and sensors into complex robots - or even make the electrical & mechanical connections between soft and hard materials? And will we need to replace or regenerate materials? Muscle can undergo billions of cycles- while artificial muscle reaches 1/10th that at its very best. Successful approaches will need to combine materials, processing, design, manufacturing and cycle life considerations.

9:30 AM *GI02.01.03 Reprogrammable Shape-Memory Polymer Actuators for Robotics Andreas Lendlein1, 2; 1Institute of Biomaterial Science, Helmholtz-Zentrum Geestacht GmbH, Teltow, Germany; 2Institute of Chemistry, University of Potsdam, Potsdam, Germany.

The classical shape-memory effect in polymers has so far been limited to its one way character, one time shape change. This limitation was overcome with the realization of shape-memory polymer actuators, which can repetitively change their shape under stress-free conditions [1]. A conceptual novelty in this soft actuator class is the re-programmability of the shape changing geometry and the switching temperature. The reversible actuation can occur many times upon heating and cooling within a suitable temperature interval. Besides the geometry of movement, the switching temperature could be made programmable in temperature-memory polymer actuators [2]. Interestingly, semi-interpenetrating polymer networks, obtained by incomplete crosslinking, additionally exhibited a pronounced self-heating capability [3].

With the availability of such shape-memory polymer actuators (SMPA) being able to bend, twist or contract fully reversibly upon cyclic temperature changes, the next generation of reprogrammable, adapting robots seems to be approachable [4]. A prospect, of what can be achieved, is given by a demonstration of a twisted, non-continuously responding SMPA, which reversibly turns an arrow sign between three different positions in the hand of a manikin [5].

10:00 AM BREAK

10:30 AM *GI02.01.04 HASEL Artificial Muscles—Versatile High-Performance Actuators for Next-Generation Robotics Christoph Keplinger; University of Colorado-Boulder, Boulder, Colorado, United States.

Actuators are key components of robotic systems. Robots today predominantly rely on rigid components and electric motors based on metal and magnets. The limited choice of materials and actuators restrains the capabilities of robots, which are heavy, complicated, expensive, often unsafe near humans, and ill-suited for unpredictable environments. Nature, in contrast, makes extensive use of soft materials and has produced living systems that drastically outperform robots in terms of agility, dexterity, and adaptability. Biological muscle is a masterpiece of evolution, featuring astonishing all-around actuation performance, the ability to self-heal after damage, and seamless integration with sensing in a soft matter based system. Advances in materials science and actuation mechanism are necessary to overcome limitations of traditional robotic hardware and enable a new generation of bio-inspired robots which replicate the vast capabilities of biological systems.

This talk gives an overview of a new class of self-sensing, high-performance artificial muscles, termed Hydraulically Amplified Self-healing Electrostatic (HASEL) transducers. HASEL actuators are electrically driven and harness a mechanism that couples electrostatic and hydraulic forces to achieve a wide variety of actuation modes. Several different designs and fabrication strategies, as well as prototypical applications are introduced. Using only off-the-shelf materials, current designs of HASEL are capable of exceeding actuation stress of 0.3 MPa, linear strain of 100%, specific power of 800W/kg, full-cycle electromechanical efficiency of 30% and bandwidth of 50Hz. All these metrics match or exceed the performance of biological muscle. Additionally, HASEL actuators can repeatedly and autonomously self-heal after electric breakdown, thereby enabling lifetimes of a few million cycles at muscle-like levels of strain. Further, this talk introduces a facile fabrication technique that uses an inexpensive CNC heat sealing device to rapidly prototype HASELs. New designs of HASEL incorporate mechanisms to greatly reduce operating voltages, enabling the use of lightweight and portable electronics packages to drive untethered soft robotic devices powered by HASELs. Finally, a model of linearly contracting Peano-HASEL actuators predicts the behavior and scaling laws of these actuators, laying out a roadmap towards future HASEL actuators with drastically improved performance. These results highlight opportunities for the materials science community to further develop HASEL artificial muscles for wide use in next-generation robotic devices.

11:00 AM GI02.01.05 Rapid Prototyping of HASEL Actuators for Versatile and High-Speed Artificial Muscles Shane K. Mitchell1; Xingruo Wang1, 2; Eric Acome, Trent Martin1; Khoo Ly1; Nicholas A. Kellaris1, 3 and Christoph Keplinger1, 4; 1Mechanical Engineering, University of Colorado Boulder, Boulder, Colorado, United States; 2Tongji University, Shanghai, China; 3Electrical, Computer & Energy Engineering, University of Colorado Boulder, Boulder, Colorado, United States; 4Materials Science and Engineering, University of Colorado Boulder, Boulder, Colorado, United States.
Soft robots with outstanding agility and dexterity require versatile and high-speed artificial muscles. Recently developed hydraulically amplified self-healing electrostatic (HASEL) actuators open new opportunities to create high-performance muscle mimetic actuators that are electrically driven, energy efficient, and capable of self-sensing their deformation. Initial prototypes of HASELs utilized fabrication techniques not easily modified to iterate designs and required bulky high voltage driving electronics. Here, we describe a facile fabrication technique that uses an inexpensive CNC heat sealing device to rapidly prototype complex designs of HASEL actuators using only off-the-shelf materials. We fabricate HASELs which feature linear and out-of-plane deformations and harness electrostatic zipper mechanisms to reduce operating voltages, thereby allowing us to demonstrate a lightweight and portable electronics package for untethered operation of these soft robotic devices. We show designs of HASEL which features linear strains up to 118 %, strain rates of 13,000 %/s, and power densities greater than 800 W/kg. These metrics enable actuators that are fast and powerful enough to jump, while rapid design iteration allows us to create continuum actuators with three-dimensional mobility. We further prototype designs for HASEL actuators to create bio-inspired curling actuators which mimic the high-speed strike of a scorpion tail. We show that these curling actuators can also operate as multifunctional grippers and shape-morphing structures. This presentation will highlight opportunities to further develop HASEL actuators tailored towards a variety of applications in robotics.

11:15 AM GI02.01.06
Dielectric Elastomer Actuators as Soft, Energy Dense, Artificial Muscles
Mihai Duduta, Ehsan Hajesmaili, Huichan Zhao, Robert Wood and David Clarke; Harvard University, Cambridge, Massachusetts, United States.

Soft robots require a new set of technologies aimed at operating in natural environments, including near, or inside the human body. To move within and interact with their environment, soft robots require artificial muscles to actuate movement. These artificial muscles need to be as strong, fast, and robust as their natural counterparts. Dielectric elastomer actuators (DEAs) constitute a highly promising class of materials, but typically exhibit low output forces and low energy densities, when used without rigid supports. Here we report a soft composite material made of strain stiffening elastomers and carbon nanotube electrodes, which actuates under an applied electric field and demonstrates a peak energy density of 19.8 J/kg. The result is close to the upper limit for natural muscle (40 J/kg) making these DEAs the highest performance electrical driven artificial muscles. To obtain high forces and displacements, we used low density, ultra-thin carbon nanotube electrodes which can sustain applied electric fields upwards of 100 V/micron, without suffering from dielectric breakdown. The fabrication process described herein is fast, scalable, and uses relatively low cost components and equipment. Potential future applications include biomedical uses, such as prosthetics, surgical robots, and wearable devices, as well as more capable soft robots capable of locomotion and manipulation in natural or human-centric environments.

11:30 AM GI02.01.07
Hybrid Soft Dielectric Elastomer Robots Exploiting Pneumatics to Generate Large Actuation
Ernst-Friedrich M. Henke1,2,3, Sascha Pfeil1,3 and Andreas Richter1; 1Solid State Electronics Lab, TU Dresden, Dresden, Germany; 2Auckland Bioengineering Institute, The University of Auckland, Auckland, New Zealand; 3Institute of Semiconductors and Microsystems, TU Dresden, Dresden, Germany.

Multifunctional Dielectric Elastomer (DE) devices are well established as actuators, sensors and energy harvesters. Since the invention of the DE Switch (DES), a piezoresistive electrode that can directly switch charge on and off, it became possible to expand the wide functionality of dielectric elastomer structures even more.

It is possible to couple arrays of actuator/switch units so that they switch charge between themselves on and off. One can then build DE devices that operate as self-controlled oscillators. With an oscillator one can produce a periodic signal that controls a soft DE robot. Now one has a DE device with its own DE nervous system.

We have demonstrated a variety of components for autonomous soft robots without conventional electronics. The combination of digital logic structures for basic signal processing, data storage in dielectric elastomer flip-flops and digital and analogue clocks with adjustable frequencies, made of dielectric elastomer oscillators (DEOs), puts us in the position to design self-controlled and electronics-free robotic structures.

The last remaining stiff structures in DE robotic structures were stiff PMMA frames to maintain necessary pre-strains to enable sufficient actuation of dielectric elastomer actuators (DEAs). Here we present a design and production technology for a first robotic structure consisting only of soft silicones and carbon black. We present different promising designs for entirely soft DE-driven robots.

We present the design of the hybrid, soft DE robots exploiting pneumatics for pre-stretching their muscles. It combines the advantages of pneumatic pre-stretching DE membranes with the electronic control of DE muscles. This approach reduces the complexity of the necessary pneumatic control system needed for driving the robot, it only needs a constant internal pressure. We present a circular crawling robot that is designed in such a way that an internal pneumatic pressure only leads to an elongation in longitudinal direction, but not in radial direction. This design prevents an inflation of the DE muscles, and, thus keeps the diameter of the structure constant. The actuation is generated by pulsing electric signals applied to the robot’s muscles. The elongation of the individual muscle segments is then transformed into an actuation by directional friction structures. We present the design of the robot an analytical and a FEA model and the first experimental results.

11:45 AM GI02.01.08
Brilliantly Structured Light-Weight Twisted-Coiled Fiber Actuators Using Polymer Threads and Twisted Dry Spun Carbon Nanotube Yarns
Brilliantly Structured Light-Weight Twisted-Coiled Fiber Actuators Using Polymer Threads and Twisted Dry Spun Carbon Nanotube Yarns
Yasuhiko Hasyashi1,2, Takayuki Yoshiyama1, Hirota Inoue1, Masaki Hada1,2, Daiki Chujo1, Yoshitaka Saito1, Kaito Paneer Selvam1, Wataru Takarada1 and Hideoshi Matsumoto1; 1Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan; 2Institute of Innovative Research, Tokyo Institute of Technology, Tokyo, Japan; 3Department of Materials Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan.

Fiber actuators have attracted considerable attention as they are not only lightweight but also can generate a large strain, they realize human mimetic motions that are strongly demanded in the field of soft robotics. One of the crucial challenges presented by self-contained electrically heated carbon cloth-shaped fiber actuators resides in their thermal absorption and contraction units. So far, coil-shaped polymer actuators wrapped with copper wire or silver paste as heating sources were reported. However, the use of metals increases the weight of the fiber actuators and effect their flexibility. Also, the difference in the thermal expansion coefficients between the polymer thread and accompanying metal frame may degrade the performance of actuation motions.

Fiber actuators and shape-morphing structures. This presentation will highlight opportunities to further develop HASEL actuators tailored towards a variety of applications in robotics.

Hear, three types of coil-shaped polymer fiber actuators were fabricated from polyethylene terephthalate (PET) threads as actuators and high thermal conducting twisted dry spun carbon nanotube (CNT) yarns as heating wires. We analyzed the thermal absorb desorb effects on their performance concerning their mechanical force.

The diameter of a PET fiber was approximately 20 μm. The lengths of PET threads and CNT yarns were 15 cm. The “MultiF-A” is composed of the PET threads and CNT yarns homogeneously. These fibers contain randomly in their cross section profile and they were rotated until it changes to coil-shaped structure. The “MultiF-B” is composed of few fine coil-shaped threads. At first, two CNT yarns and four PET threads are bundled and rotated. And then, a
certain number of fine coil-shaped PET/CNT fibers are bundled. The "MonoF" is fabricated from a bundle of PET threads and a bundle of CNT yarns, similar to the reported fiber actuator made from one polymer fiber and one heating wire.

The applied electric power to CNT yarns was maintained constant at 50 mW (5 mW per CNT yarn). The mechanical force linearly increases as the number of PET threads are increased in all types of fiber actuators. The mechanical force generated in MultiF-A and -B is 1.6 times higher than that generated in the MonoF. The responsivities (heating and cooling processes) of the fiber actuator strongly depends on the time constant of the deformation of PET threads, and therefore the response behaviors of the three types of fiber actuators are identical. The amount of displacement of MultiF-A and -B is 1.4–1.8 times higher than the MonoF at 50 mW. This is in good agreement with the result obtained by the measurements of mechanical force.

A more in-depth analysis of the thermal effects on the fiber actuator was performed by constructing a model including both MultiF-A and MonoF. The MultiF-A is homogeneously thermalized with the input energy, however, the MonoF shows inhomogeneous thermal distribution.

Based on our results, homogenous thermal distribution in the fiber actuators realized by brilliant structure is key factor for the highest actuation performance.

SESSION GI02.02: Responsive Materials
Session Chair: Peer Fischer
Monday Afternoon, November 26, 2018
Hynes, Level 1, Room 111

1:30 PM *GI02.02.01
Materials for Next Generation Robotics Soft Materials and Soft Robotics for Future Robot Abilities and Applications Cecilia Laschi and Matteo Cianchetti; The BioRobotics Institute, Scuola Superiore Sant’Anna, Pisa, Pisa, Italy.

Though a young discipline, robotics progressed rapidly and pervaded our lives more than we perceive, becoming a tool we cannot do without in manufacturing. Futuristic scenarios have been proposing robots in daily life of citizens and professionals for decades, creating expectations that have not yet been matched. What is the real status of development of robotics today and what are the realistic scenarios that robotics technologies enable today? What are the abilities that robots still miss to match expectations for extensive application and healthier and safer human life?

Largely inspired by the observation of the role of soft tissues in living organisms, the use of soft matter for building robots is recognized as one of the current challenges for pushing the boundaries of robotics technologies and building robotic systems for service tasks in natural environments. The study of living organisms sheds light on principles that can be fruitfully adopted to develop additional robot abilities or to facilitate more efficient accomplishment of tasks, because living organisms exploit soft tissues and compliant structures to move effectively in complex natural environments. The compliance and the elasticity of soft body parts, and especially a tunable stiffness, allow purposive reactions to interaction forces. So-called Soft Robotics is the use of soft materials or deformable structures in robotics. The wide spreading of soft robotics research worldwide has brought significant achievements in terms of principles, models, technologies and prototypes.

The main characteristic of compliance makes soft robotics technologies particularly well suited for biomedical applications, where robots have to interact effectively and safely with a patient. Soft robots are well suited when used in direct contact with a patient, like in surgery in rehabilitation and assistance. A soft manipulator can move safely inside the human body and act as an endoscope or change its stiffness to perform surgical procedures. A soft arm can help elderly people in bathing activities by becoming a robotic shower, able to approach and interact safely yet effectively with the user. In addition to this, soft robotics technologies are useful for building simulators of body parts, for medical studies and training, like the vocal cords or the minute lungs of pre-term babies. Explorations are also a terrific field of applications for soft robots, that can reach remote inaccessible areas, including and especially underwater. Advances in soft materials, smart materials and energy harvest represent today the main line of robotics progress.

2:00 PM GI02.02.02
Multi-Responsive Tactile Hydrogels as Soft Robotic Materials Xinmin He, Yixuan Xu, Yusen Zhao and Mo Sun; University of California, Los Angeles, Los Angeles, California, United States.

Stimuli-response hydrogels have found tremendous applications as adaptive lenses, artificial muscles, vehicles for drug deliveries, scaffolds or matrices for tissue engineering, as well as sensors and actuators for soft robots and soft machines. Here we report a tough, conductive, multi-responsive hydrogel, which is designed and synthesized by one-step polymerization with double network made of conductive polymer and chemically nano-crosslinked hydrogels. This hydrogel possesses a highly mechano-electrically sensitive that can change shape rapidly at large ratios upon local sensing of the approaching of an arbitrary object in contact with the hydrogel. This smart hydrogel can change its volume in response to subtle mechanical force and electric signals like the neural commands and acute tactility of octopus or human skin when it is in contact with an object. This presents a novel capability of force-induced shape changing, achieved through the force-electro-mechanical energy transduction within the gel material. Overall, the important novel characteristic of this force-sensitive tactile hydrogel is the capability of detecting the geometry or rigidity of the environment and adaptively changing its own shape to adapt to the shape of the environment. For example, such gel can behave as a fully automatic gripper without external control, which can grasp an object in arbitrary shape that is poking the gel. Additionally, this hydrogel is highly strong mechanically. Unlike previously developed pneumatic or hydraulic soft robotic arms and manipulators, our tactile hydrogel-based robotic materials will be self-contained and capable of continuous "sense-diagnose-response" to perform adaptive configuration changes without incurring damage.

2:15 PM GI02.02.03
Fabric Reinforced Hydrogel/Elastomer Composites for Stimuli-Responsive Actuators Daniel R. King1, 2, Amber M. Hubbard1, Wei Cui1, Yiwan Huang1, Michael Dickey2, Jan Gretzer1, 2 and Jian Ping Gong1, 2; 1Faculty of Advanced Life Science, Hokkaido University, Sapporo, Japan; 2Global Station for Soft Matter Research, Sapporo, Japan; 3Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States; 4Graduate School of Life Science, Hokkaido University, Sapporo, Japan.

Hydrogels are useful in biomaterials applications, but often lack the robust mechanical properties seen in nature. Natural materials rarely consist of discrete independent materials, rather utilizing composite structures to achieve significant mechanical properties. Here, we report the use of fabrics as a reinforcing phase within hydrogel matrices. The use of fabric results in many preferential properties. During tearing, we observe a synergistic increase in fracture strength due to a dramatically enlarged process zone in the composite structure. Furthermore, the hydrogel composites possess high stiffness in plane, while
Advantageous in these scenarios if the robot is padded. This led to our exploration of stretchable tactile sensing skins, which can accommodate the large energy harvesters and actuator devices. New azo liquid crystal materials and polymers to optimize this effect will be presented, and some simple mechanically to permit visible light to be converted directly to mechanical work. Reversible changes in surface energy are also inducible as a result, for a variety of reversible surface energy switching applications via light. Irradiation with light in the solar spectrum at sun-like intensities will be shown to lead to a measurable reversible photo-expansion of these coatings, of up to a few %, allowing the materials to function as photo-mechanical switches or light energy harvesters and actuator devices. New azo liquid crystal materials and polymers to optimize this effect will be presented, and some simple macroscopic devices will be demonstrated that take mechanical advantage of this effect for larger scale motion driven by sunlight.

The mechanism for this effect will be discussed from studies using ellipsometry, light-bending of AFM cantilevers, high-pressure raman spectroscopy, and neutron reflectometry. In particular, recent materials prepared from pseudostilbene-type azo molecules exhibit unusually fast, and reversible photomechanical motion under visible-light irradiation, with the extremely rapid switching using just one wavelength of light by shortening the lifetime of the ciss-form. This results in a bending motion in the microsecond regime. The influence of density, thickness, and molecular orientation on optimization of the photomechanical effect will be discussed. Lastly, some simple soft-robotic proof-of-principle devices will be presented, that upon visible irradiation, can bend and wiggle; crawl, walk, and roll.

3:00 PM BREAK

SESSION GI02.03: Robots
Session Chair: Rebecca Kramer-Bottiglio
Monday Afternoon, November 26, 2018
Hynes, Level 1, Room 111

3:30 PM *GI02.03.01
Bio-Inspired Tactile Sensing Skins for Robots Elisabeth Smela, Ying Chen, Miao Yu and Hugh Bruck; Department of Mechanical Engineering, University of Maryland, College Park, Maryland, United States.

Robots working in unstructured situations, particularly around humans, need to detect the occurrence and location of physical contacts with objects or people, not only for safety but also to enable touch-based communication. Care-giving and factory floor environments are two examples. It is also advantageous in these scenarios if the robot is padded. This led to our exploration of stretchable tactile sensing skins, which can accommodate the large deformations experienced during contact and which can be produced at whole-body scales. In fact, the response of piezoresistive strain sensors is amplified by localized deformation in the foam. The advantages of soft materials are, however, tempered by their concomitant time and history-dependent mechanical responses. The behavior of the foam, in particular, can dominate the response from the sensor. The readings from the skin may be useful nonetheless because a robot may only need to determine the nature, magnitude, and location of contacts rather than exact force values for operational success. The use of multilayered or geometrically restricted architectures can aid the interpretation of data obtained during contact, as can the use of techniques such as electrical impedance tomography (EIT) for distributed sensing, particularly for interpreting human touches such as multi-point finger...
presses and sliding. For example, while information from a single sensing layer on foam can reasonably distinguish forces applied by a machine, two stretchable sensing skin mimics with two foam layers are superior for interpreting highly variable human touch. Use of multiple layers also permits higher sensitivity readings at low force coupled with an extended high force range. To move forward in this effort, it is critical to address integration issues, particularly the formation of good electromechanical connections between the soft materials and the rest of the platform. Another challenge is improving the stability and robustness of the soft sensors.

4:00 PM GI02.03.02
Towards Damage Resilient Soft-Matter Robotics and Electronics
Eric Markvicka1, Michael D. Bartlett2, Xiaolan Huang1, Ravi Tutika3 and Carmel Majidi1; 1Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 2Iowa State University of Science and Technology, Ames, Iowa, United States.

Emerging applications in soft robotics, human-machine interaction, and wearable robotics will increasingly rely on new soft-matter technologies that are considered inherently safe as they are primarily composed of intrinsically soft materials—elastomers, gels, and fluids. These materials provide a method for creating soft-matter counterparts to traditionally rigid devices that exhibit the mechanical compliance of natural, biological systems. However, these soft-mimics are increasingly susceptible (as compared to their rigid counterparts) to varying forms of mechanical damage such as cutting, tearing, or puncture. These can result in operational failure. Here, a new material architecture will be presented for creating soft and highly deformable circuit interconnects. The traces are electromechanically stable under typical loading conditions, and exhibit uncompromising resilience to mechanical damage—cutting, tearing, or puncture. The material is composed of micron-scale droplets suspended in a soft elastomer, when damaged, the droplets rupture to form new connections with neighbors and re-route electrical signals without interruption. Since self-healing occurs spontaneously, these materials do not require manual repair or external heat. We demonstrate this unprecedented electrical robustness using a self-healing soft robotic quadrapod that continues to function after significant damage. We will also present a recently developed method for actively sensing and localizing damage (compression, cutting, and puncture) within a thin elastomer film. When coupled with processing, actuation, and communication, this soft and highly deformable composite presents new opportunities to identify and respond to mechanical damage in soft-matter robotic systems.

4:15 PM GI02.03.03
Biodegradable Soft Robots with Electronic Skins
Florian Hartmann, Melanie Baumgartner, Michael Drack, David Preninger, Stephan Demchysyn, Robert Gerstmayr, Daniela Wirthl, Lukas Lehner, Siegfried Bauer and Martin Kaltenbrunner; Johannes Kepler University, Linz, Austria.

Cephalopods, caterpillars and other soft creatures inspired a broad spectrum of bio-mimetic actuators -- enhanced with perceptive electronic skins -- capable of sensing and adapting to their complex erratic environments. Yet, they are missing a feature of nature’s designs: biodegradability. Soft robots that degrade at the end of their life cycle reduce electronic waste and are paramount for a sustainable future. At the same time, medical (robotic) technologies have to address hygiene requirements. We therefore develop biodegradable hydrogels for single-use wearable electronics and transient soft robots that are reversibly stretchable, are able to heal and are resistant to dehydration. Soft machines and robots -- built from hydrogels with tuned mechanical properties - are designed to be operated in ambient conditions and degrade after use. An equally compostable electronic skin provides our soft actuators tactile feedback and temperature sensing, directly processed with a recyclable on-board computation unit. Besides progressing stand-alone soft machines, our advances in the synthesis of biodegradable hydrogels bring bionic soft robots a step closer to nature.

4:30 PM GI02.03.04
Electronic Epidermis That Activates Soft Robots Wirelessly
Junghwan Byun1,2, Yoontaek Lee1,3, Jaeyoung Yoon1,3, Yongtaek Hong1,3 and Kyu-Jin Cho1,2; 1Seoul National University, Seoul, Korea (the Republic of); 2Soft Robotics Research Center, Seoul, Korea (the Republic of); 3Inter-university Semiconductor Research Center, Seoul, Korea (the Republic of).

A recent stream of research on robotics, called “Soft Robotics”, aims for designing softness into each robot part on the basis of soft materials and body architectures. Reducing rigid boundaries of robots greatly improves robotic compliance to dynamic, unstructured environments in terms of adaptiveness. In this regard, several studies have reported fabrication and integration methodologies for soft body architectures in which soft actuators or actuating frames are integrated into a soft body frame. Despite the body’s softness, however, existing models mostly carry inherent hardness and bulkiness in their driving parts, such as pressure-regulating components and rigid circuit boards. This compliance gap can frequently interfere with the robot motion and makes soft robotic design dependent on rigid assembly of each robot component. In this work, we report a class of electronic systems that can be softly and reversibly integrated as a “robotic epidermis” into soft robot frames and then can activate (and control) them wirelessly. The proposed electronic epidermis (e-epidermis) is soft (~30% stretchable), thin (~1 mm), lightweight (~1 g), and involves driving capability on the basis of controlled Joule heating. The electronic functionality with skin-like mechanical property is designed by stretchable hybrid electronics (SHE) layouts. A large number of surface mountable devices (SMDs) are directly assembled onto a soft substrate and bridged by inkjet-printed stretchable interconnection networks (silver thin films with wrinkled geometry) to achieve adequate circuit architectures for wireless robot control. In particular, the size of the assembled SMDs is regulated (≤1.5×1.5×0.6 mm²) for the e-epidermis to share the large local bending curvature which can be the deformation profile of soft robots. The resulting e-epidermis can not only mechanically conform to dynamic surfaces like soft robot frames but also activate soft actuators through controlled current driving. Benefits of this design enable compact integration of fully soft robots. We demonstrate a thin (total thickness: 2 mm), compact, soft robotic hand whose body dimension in itself cannot possibly equip any other types of conventional driving systems. This fully soft robot can be actuated and mechanically deformed in ways not previously possible: a body architecture and embedded e-epidermis can equally share the sequential deformation profiles. Furthermore, this e-epidermis concept provides universality for robotic actuation based on reversible assembly.

This work was supported by the National Research Foundation of Korea (NRF) Grant funded by the Korean Government (MSIP) (No. NRF-2016R1A5A1938472).

4:45 PM GI02.03.05
Self-Healable Stretchable Light Sources
Benjamin C. Tee1,2, Yu Jun Tan1 and Hareesh Godabai1; 1Materials Science and Engineering, National University of Singapore, Singapore, Singapore; 2Biomedical Institute for Global Health Research and Technology, National University of Singapore, Singapore, Singapore; 3Institute of Materials Research and Engineering (IMRE), Agency for Science Technology and Research, Singapore, Singapore.

Most human-machine interfaces rely on some form of visible light sources such as light emitting displays. In flexible and stretchable electronics, exciting progress has been made via the use of strain robust electronic devices for advanced soft robotics1, wearable biomedical devices2 and flexible touch interfaces3. On the other hand, self-healing and self-repairable materials and devices are gaining tremendous interest due to the possibility of reducing technological waste4,5. Hence, it is useful to investigate stretchable light sources that could have self-repair functions for such applications. In this talk, I will describe a stretchable and self-healable electroluminescent (EL) material that can stretch elastically. The material processing is facile, and the devices
can withstand multiple mechanically inflicted ‘wounds’ and recover functionality. Such materials can be integrated into devices for emerging wearable soft robotics and human-machine interactions.

**Navigable Soft Robotic Microcatheter for Endovascular Treatment of Cerebral Aneurysms**

*James Friend*; University of California, San Diego, La Jolla, California, United States.

We report a unique solution of an unmet clinical need in vascular microsurgery using a combination of novel 10-100-µm scale soft polymer cast-and-print fabrication techniques, simple microhydraulics, hyperelastic media with tailored nonlinear elasticity properties, and carefully designed, complex cross-sectioned microstructures. The third most common cause of death in the United States, strokes present a tremendous sociological and economic burden. While rapid, minimally invasive surgical intervention is sometimes beneficial, the crude tools available today are completely inadequate. We focus upon the most serious problem in stroke intervention: intracranial aneurysms. Nearly one-fourth of neurointerventions fail due to the difficulty in navigating the microcatheter to the aneurysm location through tortuous vasculature and in orienting the microcatheter tip in the aneurysm dome to an optimal position for coil deployment to close off the aneurysm.

Our approach produces a completely steerable microcatheter at the small (~100 µm) scales necessary for endovascular neurosurgery via direct hydraulic microactuation and a hand controller simple enough for a neurointerventionist to use. With data from ex-vivo and in-vivo animal trials, we show the technology quantifiably produces better outcomes, fewer mistakes, speeds treatment, and enables greater treatment capabilities than current state-of-the-art devices. Our ex-vivo testing furthermore employs new MRI-to-in-silico models printed from anonymized angiograms of patients with aneurysms. The models include accurate blood flow and neurovascular elasticity, and such minor but important details as the surgical bed and the extended vasculature from the groin through the aorta, heart and chest to the neurovasculature. Beyond the neurovasculature and steering, ideas on the next generation of facile, distal microactuation for biopsy, suturing, drug delivery, and many other applications via our technology will be proffered to result in improved patient outcomes and reduced healthcare costs for all.

**8:30 AM *GI02.04.02**

**Photoalignment Control and Mechanical Analysis of Polymer Films for Soft Robotics**

*Atsushi Shishido*; Tokyo Institute of Technology, Yokohama, Japan.

Macroscopic alignment control of liquid crystal (LC) films is key to the development of next-generation high-performance soft robot materials. Current methods achieve such large-area alignment of LCs, having intrinsic structural ordering over various length scales from nanometer to micrometer, by applying uniform external fields along one direction, such as mechanical stress, surface rubbing treatment, and electromagnetic or light fields. Among these more advanced 2D techniques, light-driven alignment control (photoalignment) might provide the greatest potential for fine control over molecular orientation, because of its remote and precise influence, and suitability for micro- or nanofabrication, which can enable many applications that require more complex alignment patterns. With conventional photoalignment methods, one typically irradiates an LC film containing added photoreactive molecules with spatiotemporally uniform polarized light. We report here a new concept of scanning wave photopolymerization (SWaP) using spatiotemporal scanning of UV light to start photopolymerization and create a mass flow in the film, which results in LC alignment coincident with the incident UV light patterns. Furthermore, we introduce mechanical analysis of such flexible polymer films to quantitatively understand a new mechanics for soft robotics.

**Self-Growing Adaptable Soft Robots**

*Barbara Mazzolai*, Ali Sadeghi, Emanuela Del Dottore and Alessio Mondini; Istituto Italiano di Tecnologia, PONENTE, Italy.

Growth is a very interesting feature of living beings that can inspire a generation of robots endowed with new and unprecedented abilities of movement. Growth involves the cellular activity of both animals and plants, yet the evolution of organisms in these two kingdoms is completely different. Animals grow until maturity, while plants grow indefinitely, mostly for their entire life. Animal growth is also known as “determinate” growth, since trajectory and asymptotic size are usually genetically defined and environmental influence has a limited impact. Plant growth, on the other hand, is “indeterminate”, since it extends throughout life. Growth allows a strong adaptation of body morphology to environmental conditions, also called plasticity, which characterizes the plant kingdom. Differently from animals, plants grow to move, in search for nutrients and light and for protection from harmful agents. Noteworthy,
plants represent an alternative model of movement in robotics, which is not animal-like and muscle-based.

For the first time in robotics, we proposed a growing robot inspired by movements and behaviors of plant roots. The robot is able to create in real-time its own body structure exploiting a 3D printer-like system integrated in its tip for the deposition of a thermoplastic material, thus imitating the indeterminate axial growth and bending root abilities.

Passive and active movements in plants can also be exploited for developing multifunctional materials and energy-efficient actuators based on osmosis. Starting from the investigation of nutrient uptake phenomena, movements and communication strategies adopted by plant roots, we developed uptake–kinetics feedback control and self-organization ability for exploitation tasks. Based on these plants’ features, we can generate new, unexplored abilities in bioinspired robots, which can better adapt to external, unstructured environments, move purposively, effectively and efficiently.

9:30 AM GI02.04.04
Polymer Hydrogels for Artificial Transpiration in Biomimetic Plant Robots

Doruk S. Cezan1, Hasan T. Baytekin2 and Bilge Baytekin1, 2; 1Chemistry Department, Bilkent University, Ankara, Turkey; 2 National Nanotechnology Research Center (UNAM), Bilkent University, Ankara, Turkey.

Bio-inspired materials – using the strategies of nature to design materials – has many implications in fields extending from energy to medicine to robotics. In robotics, biological systems have been a great inspiration source owing to their fascinating abilities developed in the course of evolution. Plants, in particular, have interesting abilities like adaptability, sensing, self-regulation, self-healing, and unique surfaces structures that have great possibilities to feed ideas for new materials production. Especially interesting are heliotropism (solar tracking of plants), and nyctinasty (opening and closing leaves) in plants, used for achieving high-energy efficiency in photosynthesis. Previously, using shape memory alloys or liquid crystal structures, it was shown that plant robots, too, can possess these features but none of these robots were truly biomimetic. In this study, we demonstrate biomimetic robot plants, which display heliotropism and nyctinasty by artificial transpiration (water transport in plants) – the exact strategy used in nature. Several thermo-responsive hydrogels (PNIPAM, PDEAAM, and PNVCL) were used on a cellulose plant body to achieve the targeted biomimicry. The systems are assessed for the transpiration efficiency, actuation speed and its relevance to the sensory motion, as well as for their heliotropic efficiencies. The bioinspired approach used in this study for the plant robots and structures designed by using them could be of interest for autonomous soft robotic systems in which the motion solely controlled by materials.

9:45 AM GI02.04.05
Memory and Learning in Biomolecular Soft Matter for Low-Power Brain-Like Computing

Joseph S. Najem1, 2, Md Sakib Hasan1, Ryan Weiss1, Catherine Schuman2, Alex Belianinov2, Graham Taylor1, 2, Garrett Rose1, Stephen A. Sarles1 and Charles P. Collier2; 1The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The capacity of robots to learn, operate autonomously, and support other cognitive tasks independently and in complex and dynamic environments will require approaches to computation that are inherently brain-like. Neuroromorph computing systems co-locate information processing and memory at levels approaching the density, complexity, and energy efficiency of the brain needed for the next generation of robotics. Reproducing these features using traditional electronic circuit elements is virtually impossible, requiring the design and fabrication of new hardware elements that can adapt to incoming signals and remember processed information. We refer to these elements as mem-elements (short for memory elements), which are passive, two-terminal devices whose resistance, capacitance, or inductance remembers the past electrical activity of the device. These elements should be scalable, biomimetic, and preferably ionic to achieve energy consumption levels approaching those in the brain. Here we describe two-terminal, biomolecular memcapacitors and memristors, consisting of highly insulating 5 nm-thick lipid bilayers assembled between two water droplets in oil. These devices exhibit memcapacitance that is nonlinearly dependent on the applied voltage, and hysteresis in the charge due to reversible changes in the area and thickness of the bilayer membrane in response to voltage. This is the first demonstration of a memcapacitor in which capacitive memory results from geometrical changes in a lipid bilayer membrane. We also show that the incorporation of voltage-activated alamethicin peptides in these devices results in variable ionic conductance across the membrane and memristive behavior.

We discuss how these devices exhibit learning through synaptic plasticity, and how to implement them in online learning applications. These results serve as a foundation for a new class of low-cost, low-power, soft mem-elements based on lipid interfaces and other biomolecules for applications in neuromorphic computing which could have major implications on the robotics field.

10:00 AM BREAK

SESSION GI02.05: Electronics, Memory and Perception

Session Chair: Peer Fischer
Tuesday Morning, November 27, 2018
Hynes, Level 1, Room 111

10:30 AM *GI02.05.01
The Mechanical Side of AI
Robert Wood; Wyss Institute for Biologically Inspired Engineering and John A Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

Artificial Intelligence typically focuses on perception, learning, and control methods to enable autonomous robots to make and act on decisions in real environments. On the contrary, our research is focused on the design, mechanics, materials, and manufacturing of novel robot platforms that make the perception, control, or action easier or more robust for natural, unstructured, and often unpredictable environments. Key principles in this pursuit include bioinspired designs, smart materials for novel sensors and actuators, and the development of multi-scale, multi-material manufacturing methods. This talk will illustrate this philosophy by highlighting the creation of several classes of soft-bodied robots.

11:00 AM GI02.05.02
3D-Printable Shape-Morphing Architectures via Programmable Stress
Quanduan Han and Victor Ugaz; Texas A&M University, College Station, Texas, United States.

Significant advancements in soft robotics have been achieved through the use of polymeric materials that actively respond to external stimuli via shape memory or physico-chemical interactions with their surroundings. And recent excitement has been generated by application of these responsive properties to produce shape-shifting 2D structures capable of morphing into complex 3D topologies. But manufacturing these active components generally requires
specialized chemical formulations and sophisticated multi-material patterning capabilities that are not widely available outside research laboratory settings, significantly limiting their impact. Here we show how this barrier can be overcome by using 3D printing to embed prescribed internal stresses within a planar2D substrate. These stresses are controllably released in response to an external trigger, deforming the material into a desired 3D shape.

We apply this capability to construct active components relevant to soft robotics in three ways. First, we produce a library of building blocks embedding programmed internal stresses that can be assembled to enable 3D deformation with controllable local curvature. We then show how these elements can be combined to spatially distribute strain across multiple length scales, replicating hierarchical structures found in living systems. Finally, we apply these design principles to produce a self-assembled metal/air battery capable of functioning either as a stand-alone power source or as part of a self-powered electrochromic glucose sensor for use as a diagnostic tool in resource-limited settings. Notably, all of these components can be manufactured using standard 3D printers and materials, significantly broadening access to soft robotics technology.

11:15 AM GI02.05.03 Actively Perceiving and Responsive Soft Robots Enabled by Self-Powered, Highly Extensible, and Highly Sensitive Triboelectric Proximity- and Pressure-Sensing Skins Ying-Chih Lai¹ and Zhong Lin Wang‡; ¹Materials Science and Engineering, National Chung Hsing University, Taichung City, Taiwan; ²Georgia Institute of Technology, Atlanta, Georgia, United States.

We will propose the first demonstrations of using triboelectric effect to realize various actively sensing and responsive capabilities in soft robots. Robots that can move, feel, and respond like organisms will bring revolutionary impact to today’s technologies. Soft robots with organism-like bodies have shown great potential in vast robot-human and robot-environment applications. Developing skin-like sensory devices allows them to naturally sense and interact with environment. It would be better if the capabilities to sense can be active like real skin. However, challenges in complicated structures, incompatible moduli, poor stretchability and sensitivity, large driving-voltage, and power dissipation hinder applicability of conventional technologies.

Here, for the first time, various actively perceivable and responsive soft robots are enabled by using self-powered active triboelectric robotic skins that simultaneously possess excellent stretchability and excellent sensitivity in low-pressure regime. The robots’ skins can actively sense proximity, contact, and pressure to external stimuli via self-generating electricity. The driving-energy of its sensing ability comes from natural triboelectrification effect. Various kinds of perceiving soft robots will be demonstrated to use triboelectric effect to complete different actively sensing and responding tasks. For a conscious gripper, it can actively be aware of different actions in moving an object including approaching, grabbing, lifting, lowering, and even the accident of dropping off the objects. A perceivable robot-finger can check a baby’s diaper condition. A conscious robotic crawler enable to perceive its muscle motions during undulating gaits and detect very subtle human physiological signals, showing their potential in palpation. Such robots with large-area skins have been demonstrated for actively multiplexing sensing uses. Moreover, the actively responding signals can directly drive optoelectronic components for intuitive communication and be further processed for more sophisticated uses such as answering with sound, light, phrases, and so on. We believe the presented robotic skins that are self-powered, highly-sensitive, highly-stretchable can meet applications where soft interfaces are needed. And, the first achievements in the actively perceiving and responsive soft robots can push the boundaries of artificial intelligences, soft robotics, as well as their vast related applications.

11:30 AM GI02.05.04 Enhanced Material Stiffness Change Using Low-Melting-Point Metallic Alloy Particle Additives Trevor L. Buckner¹, Rebecca Kramer-Bottiglio¹, Michelle C. Yuen² and Sangyup Kim¹; ¹Yale University, East Hartford, Connecticut, United States; ²Purdue University, West Lafayette, Indiana, United States.

Soft robots made from flexible and conformable materials face a major challenge resisting structural collapse or properly transferring forces when interacting with external loads. Without a permanent rigid support structure, soft robot design often turns to variable stiffness techniques that allow a robot to selectively generate rigid bones or soft joints as needed, thereby retaining the desirable properties of a soft robotic system while adding the ability to adapt to external obstacles and tasks as required. Many such solutions utilize stiffness-changing materials that soften or undergo a phase change with increasing temperature. In this talk we present a method of enhancing the range of stiffness change in these materials by introducing low-melting-point metallic alloy particles as an additive into the host material, specifically Field’s metal embedded in an epoxy matrix. This method can drastically increase the stiffness of the rigid state, enhance the stiffness change of the host material phase transition due to particle jamming effects, and further decrease the final stiffness of the softened state by taking advantage of the solid-to-liquid transition of the particle inclusions. We will present a facile method for fabricating low-melting-point metal particles which improves upon existing techniques by scaling up batch size while maintaining control of particle size distribution. These particles will then be demonstrated as an additive in a conductive thermoset epoxy composite to enhance the stiffness change of that material. The effects of this additive on thermal and electrical material properties will also be presented. Finally, we will demonstrate the application of this variable stiffness material towards a soft robotic platform that can be continuously varied between compliant and load-bearing states.

11:45 AM GI02.05.05 Lightweight Multifunctional Structures for Next-Generation Robotics Monica Jung de Andrade; The University of Texas at Dallas, Richardson, Texas, United States.

Flexible, lightweight, multifunctional structures have a significant impact towards morphing technologies. In this work, we discuss some of the main techniques to fabricate fiber-like materials towards robotics. For instance, both infiltration and conformal deposition routes demonstrated the versatility of nanostructured nanotube based nanocomposites towards yarn-like actuators and flexible woven energy harvester. We demonstrated our silent, flexible, and tunable and scalable actuators can perform over thousands of cycles with negligible hysteresis. Finally, we demonstrated that fiber-like actuators have great potential towards lightweight and inexpensive orthotics, prosthetics and other tensegrity structures.
Variable Elasticity Silicone—Multifunctional Elastomeric Systems Enabled by Modulus Switching

Michelle C. Yuan1, 2, Trevor L. Buckner2 and Rebecca Kramer-Bottiglio1; 1Purdue University, West Lafayette, Indiana, United States; 2Yale University, New Haven, Connecticut, United States.

Composite materials are greater than the sum of their parts—constituent materials work symbiotically to enhance the overall functionality of the composite. In this work, we create a new kind of silicone elastomer composite that can vary in its modulus of elasticity on demand. Our composite is made by embedding low melting point alloy (Field’s Metal - FM) particles in a silicone elastomer matrix creating Field’s Metal Silicone (FMSi). By applying heat to transition the FM particles between solid and liquid states, the composite can embody two different moduli of elasticity on-demand. In all cases, the composite remains “soft”—with a very low modulus (<10MPa)—but by changing its modulus, the silicone can fulfill different functions. Furthermore, by melting the FM particles, straining the bulk composite and then chilling the system, the shape of the deformed inclusions is fixed, holding the composite in a stretched state and adding anisotropy to the elastic modulus of the composite. This form of variable stiffness, (i.e. variable elasticity) has yet to be shown as a functional quasi-homogeneous material, rather than a functional system constructed of discrete materials. We will present the fabrication of the FM particles and the composite; characterization of the FMSi over a range of particle loading fractions, temperatures, and deformations; and finally applications of the FMSi composite material in soft robotics.

A Stretchable Ionic Diode from Interpenetrating Polyelectrolyte Hydrogels

Hae-Ryung Lee and Jeong-Yun Sun; Seoul National University, Seoul, Korea (the Republic of).

As the demand for soft and flexible devices steadily increases, the ionic applications demonstrated with gel materials have come under the spotlight. Here, stretchable ionic diodes (SIDs) made from polyelectrolyte hydrogels are introduced. Polyelectrolyte hydrogels were mechanically modified by methacrylated polysaccharides, forming interpenetrating networks (IPN) while preserving the ion-selectivity of poly(sulfopropyl acrylate) potassium salt (PSPA) and poly[(acrylamidopropyl)trimethylammonium chloride] (PDMAPAA-Q). Then, SIDs composed of interpenetrating polyelectrolyte gels were fabricated in VHB® substrates engraved by a laser. The SIDs showed rectifying behaviours under a maximum stretch of 3 and preserved their rectifications over hundreds of cycles. A wearable ionic circuit with LEDs operating during finger movements was also demonstrated as a corollary application of SIDs.

3D Printing of Liquid Crystal Elastomeric Actuators with Spatially Programmed Nematic Order

Arda Kotikian1, Ryan L. Truby1, John W. Boley4, Timothy J. White2 and Jennifer Lewis5; 1Harvard University, Cambridge, Massachusetts, United States; 2Yale University, New Haven, Connecticut, United States.

Applications ranging from soft robotics to deployable devices would benefit from shape-morphing architectures that exhibit reversible, programmable actuation. Liquid crystal elastomers (LCEs) are of particular interest due to their intrinsic contractility, large deformations and high energy density. Here, we present a 3D printing method that enables one to pattern LCE inks with programmed director alignment in arbitrary form factors for use as artificial muscles. Specifically, we use high operating temperature direct ink writing (HOT-DIW) to align their mesogen domains along the direction of the print path. We then characterize their order parameter, actuation strain, and specific work. Using this process, we create shape-morphing LCE actuator (LCEA) architectures that undergo reversible planar-to-3D and 3D-to-3D transformations on demand as well as 3D LCEAs (~1 mm thick) capable of lifting 233% more weight than other LCE actuators reported to date.

Zwitterions with Distinctive Stimuli-Responsive Behaviors to Construct Deformable Sensory Systems in Soft Robots

Zhouyue Lei1 and Peiyi Wu1, 2; 1Department of Macromolecular Science, Fudan University, Shanghai, China; 2Chemistry, Chemical Engineering and Biotechnology, Donghua University, Shanghai, China.

With growing interests in the fields of soft robots, it is crucial yet rather challenging to construct deformable sensory systems with customizable functionalities and human tissue-compatible mechanical properties. Herein, we design a type of zwitterions combining distinctive stimuli-responsive behaviors, i.e., both UCST (Upper Critical Solution Temperature) and LCST (Lower Critical Solution Temperature) by simply manipulating nano-level molecular dynamic interactions. It also integrates ultra-stretchability, high strength, impressive toughness, fatigue resistance, self-healability (at room temperature within 12 h) and facile processability (3D printing et al.), along with ionic conductivity for information transport. This material provides intelligent skins for soft robots and shows many advantages such as multiple sensations, tunable sensitivity, distinct visual effect (UCST and LCST) and adaptable mechanical properties. We believe this presentation is inspiring for the regulation of mechanical properties and stimuli-responsive behaviors in soft robots and we will also discuss the material design of artificial neuromuscular systems from the prospective of molecular dynamic interactions.
Liquid Metals for Soft Robotics

Michael Dickey; North Carolina State University, Raleigh, North Carolina, United States.

This talk will discuss recent progress in utilizing liquid metals as conductors for stretchable, soft, and reconfigurable components for soft robotics. Alloys of gallium are noted for their low viscosity, low toxicity, and near-zero vapor pressure. Despite the large surface tension of the metal, it can be patterned into non-spherical 2D and 3D shapes due to the presence of an ultra-thin oxide skin that forms on its surface. Because it is a liquid, the metal is extremely soft and flows in response to stress to retain electrical continuity under extreme deformation. By embedding the metal into elastomeric or gel substrates, it is possible to form soft, flexible, and conformal electrical components, stretchable antennas, and ultra-stretchable wires that maintain metallic conductivity up to ~800% strain. Thus, these materials are well-suited for soft robotics because they decouple electrical conductivity and mechanical properties. In addition to introducing the advantages of these materials for soft robotics, this talk will focus on recent work to utilize liquid metal for (1) soft energy harvesting that converts mechanical motion to electrical energy, (2) tough energy absorbing materials, and (3) color changing materials for camouflage, strain sensing, and materials logic. These advances have implications for soft machines and robots that have ultra-soft mechanical properties.

Jet Based Electrochemical 3D Printing for Micromechanical Systems Realization

Marco Stefancich1, Harry Apostoleris2,3, Matteo Chiesa2,3 and Wael Othman1; 1Dubai Electricity and Water Authority, Dubai, United Arab Emirates; 2Khalifa University of Science, Technology and Research, Abu Dhabi, United Arab Emirates; 3Fluid Metal 3D, Skien, Norway.

While laser based metal 3D printing is having a strong impact on the manufacturing sector, the lack of a low cost approach for this class of materials limits its further diffusion due to the high investment cost of the printer and the adjoining post-treatment equipment. The realization of small scale mechanical systems, to enable next generation robotics, calls for different approaches capable of operating in the 10 to 1000 microns scale. Multiple approaches are currently being proposed, among which we identify direct metal 3D printing by jet assisted localized electrochemical deposition as a particularly promising one. In its simplest form this approach is based on the use of a high speed electrolyte jet impacting on the intended deposition surface where a current, flowing through the jet, leads to the reduction of the metal ions to solid metal at the jet impact point. The specific hydrodynamic properties of the jet ensure that the reduction is highly localized, potentially down to the microns scale, and its limited solely by the jet diameter. The deposition rate, moreover, largely exceeds those of conventional electrodeposition processes. This approach allows metal deposition at room temperature without the need for controlled atmosphere and employing common water based electrolytic solutions with the use of simple hardware in a well understood process. Due to the properties of the process, the deposition is also not limited to conductive substrates but can be extended to plastics without any pre-treatment as long as sufficient metal-plastic adhesion is achieved. Here we discuss the fundamental physics and chemistry underlying the process and present the most current results on 3 dimensional structures in the mm scale realized in copper and nickel on conductive and non-conductive substrates. Deposition rates of several microns/second are demonstrated and complex structures like micro-gears and free standing spindles are realized without the need for supporting structures.

This approach can be applied to the realization of complex mechanical micro devices to be used as platform for mm scale robotics systems.

Programmable Elasticity of Soft Materials Overcomes the Gauge Limit of Capacitive-Type Strain Sensor

Young-Joo Lee, Seung-Min Lim, Jeong-Ho Lee, Sung-gyu Kang, Heung Nam Han, Jeong-Yun Sun, In-suk Choi and Young-chang Joo; Seoul National University, Seoul, Korea (the Republic of).

Soft and smart materials have been highlighted for providing intelligence to devices, i.e., soft robots, stretchable electronics, self-healing materials, camouflaging materials and so on. In this presentation, we will introduce a new soft material named ‘auxetic elastomer’, having unique elastic properties beyond the theoretical limit, by incorporating an auxetic frame within soft materials. Auxetic is known to be an open cell structure that can show negative Poisson’s ratio. The elastic property of our auxetic elastomer can be predictively modulated by considering the auxetic geometry design and proper material selection. The experimental and simulation results proved that our continuum-solid auxetic elastomers can be designed to have negative in-plane and high positive out-of-plane Poisson’s ratios, that cannot be achieved by conventional elastomers. Incorporating the mechanical characteristics of the auxetic elastomer, we successfully overcome the electrical performance limit of a capacitive-type stretchable strain sensor in terms of sensitivity. Our sensor can show a gauge factor improved by 3.2-fold even maintaining the linear response. The sensor can be stretched up to 100 %, and show great cyclic durability. Our research has an originality in mechanical metamaterial research because it provides mechano-electric developments beyond conventional structural applications.

3D Fabrication of Fully Metallic Magnetic Microrobots

Carlos C. Alcantara, Sangwon Kim, Bumjin Jang, Prakash Thakolkaran, Bradley Nelson and Salvador Pané; ETH Zurich, Zurich, Switzerland.

Small-scale robots have been proposed for a variety of medical applications, such as minimally invasive surgery, drug delivery, biopsy and diagnosis1. To transfer micro- and nanorobotics technologies to real clinical applications, approaches enabling the batch fabrication of micro- and nanoswimmers with biocompatible and biodegradable characteristics are necessary. Here, we present a process to manufacture arrays of fully metallic iron-based microrobots with complex features such as helices, double helices and spherical microscaffolds. The devices are fabricated by means of template-assisted electrodeposition (TAE) in 3D printed molds. The molds are obtained by two-photon polymerization (2PP). Compared to previous works with TAE and 2PP, our method is not restricted to the use of transparent conductive oxides (TCO) such as indium-tin-oxide2-4. While this substrate has been widely used in 3D printed molds. The molds are obtained by two-photon polymerization (2PP). Compared to previous works with TAE and 2PP, our method is not restricted to the use of transparent conductive oxides (TCO) such as indium-tin-oxide2-4. 3D Fabrication of Fully Metallic Magnetic Microrobots

Carlos C. Alcantara, Sangwon Kim, Bumjin Jang, Prakash Thakolkaran, Bradley Nelson and Salvador Pané; ETH Zurich, Zurich, Switzerland.

Small-scale robots have been proposed for a variety of medical applications, such as minimally invasive surgery, drug delivery, biopsy and diagnosis1. To transfer micro- and nanorobotics technologies to real clinical applications, approaches enabling the batch fabrication of micro- and nanoswimmers with biocompatible and biodegradable characteristics are necessary. Here, we present a process to manufacture arrays of fully metallic iron-based microrobots with complex features such as helices, double helices and spherical microscaffolds. The devices are fabricated by means of template-assisted electrodeposition (TAE) in 3D printed molds. The molds are obtained by two-photon polymerization (2PP). Compared to previous works with TAE and 2PP, our method is not restricted to the use of transparent conductive oxides (TCO) such as indium-tin-oxide2-4. While this substrate has been widely used for
terms of locomotion with weak rotating magnetic fields (<10mT) and in different fluids. Iron microhelices can perform corkscrew motion, while spherical microscaffolds can roll on surfaces. Interestingly, our microrobots exhibit a relatively high maximum forward velocity \((v_{max})\) of approximately 500 \(\mu m/s\) when manipulated in isopropyl alcohol. In silicone oil, the spherical rollers and the helices exhibit \(v_{max}\) values of 25 \(\mu m/s\) and 42 \(\mu m/s\), respectively. Additionally, we demonstrate that the iron microhelices can swim against gravity and in three dimensions. Finally, preliminary degradation tests in simulated gastric acid at pH 1.7 show partial degradation of the helical structures.

3D Printed Biodegradable Microrobots for Theranostic Delivery Hakan Ceylan, Ceren Yasa and Metin Sitti; Max Planck Institute for Intelligent Systems, Stuttgart, Germany.

Untethered micron-scale mobile robots can leverage minimally invasive technologies by navigating and performing in hard-to-reach, confined and delicate inner body sites. Such a complex task requires integrated design and engineering strategies, where materials, powering, control, medical functionality and degradability need to be considered altogether. The present study reports a magnetically mobilized, locally responsive and biodegradable microrobotic swimmer for medical cargo delivery and release tasks. We design double-helical, hydrogel-based microswimmers, of 20 \(\mu m\) length, 3D-printed with complex geometrical and compositional features. At normal physiological concentrations, matrix metalloproteinase-2 enzyme can entirely degrade the microswimmer body in 118 h to solubilized non-toxic products. The amount of enzyme around the microswimmers tailors the release kinetics of the drug payload, and the drug bioaccessibility is eventually attained in full from the collapsed network of the microswimmers. Antibody-tagged iron oxide nanoparticles released from the degraded microswimmers serve for targeted labeling of SKBR3 breast cancer cells to realize the potential of medical payload, and the drug bioaccessibility is eventually attained in full from the collapsed network of the microswimmers. Antibody-tagged iron oxide nanoparticles released from the degraded microswimmers serve for targeted labeling of SKBR3 breast cancer cells to realize the potential of medical imaging of local tissue sites following the therapeutic intervention. These results represent a leap forward toward clinical medical microrobots that are capable of sensing, responding to the local pathological information, and performing specific therapeutic and diagnostic tasks as orderly executed operations using their smart composite material architectures.

GI02.08.01
Graphene-Based Fiber for Artificial Muscle Hyunsoo Kim, Ji Hwan Moon and Seon Jeong Kim; Hanyang Univ, Seoul, Korea (the Republic of).

Artificial muscles are actively researched using various materials such as a polymer, carbon nanotube, and graphene for application to soft robotics or replacing motors. Especially, graphene-based actuators are attracted because of low cost and mass producibility. However, previous graphene oxide (GO)-based actuators demonstrated torsional and bending actuations. Her, we developed a torsional and tensile actuating GO-based fiber for expansion of the application to various fields such as an artificial muscle, soft robotics, and indicators. The GO-based fiber was produced by wet-spinning technique with Nylon coagulation bath. This GO-based tensile actuator actuates reversible contraction and elongation without hysteresis by control the twisting direction of mandrel coils of GO-based fiber. Moreover, the GO-based actuator demonstrates lift load over 100 times heavier than itself, stable actuation and able to withstand high temperature over the melting point of the polymer. This novel kind of GO-based actuator, which has multi-directional actuation, have potential for a wide range of applications such as artificial muscles, robotics, and temperature sensing.

GI02.08.02
Algorithmic Stacking for Hyperform and Pluripotent Transformable Materials Yuki Lee1, Young-chang Joo1, Jyh-ming Lien2 and In-suk Chei1; 1Seoul National University, Seoul, Korea (the Republic of); 2George Mason University, Fairfax, Virginia, United States.

Origami and kirigami, an art of paper folding, cutting, and transforming into a specific sculpture, are one of the innovative strategy for hyperform materials, which means scale-changeable materials from small to extremely large scale. In this study, we propose a novel algorithmic kirigami method that provides super compaction of an arbitrary 3-D shape, called “algorithmic stacking”. This super compacted structure can be manufactured in a workspace that is significantly smaller than the provided 3-D shape, by making the product a compacted state and converting it to the original 3-D shape. For example, even a product larger than 3D printer can be printed and used by the 3D printer. In addition, we have shown that the proposed stackable structures have high pluriplasticity and can transform into multiple 3-D target shapes. Our study includes voxelization for creating meshes, solutions for finding Hamiltonian path, mesh stripification, hinge design between adjacent meshes, and its application. Algorithmic stacking can give the solution for manufacturing products or devices in a limited workspace, make packing and transportation easier for a deployable application, and be a universal platform for pluripotent 3-D transformable structures.

Helical Nanomotors as Intracellular Probes Malay Pal1, Neha Somalwar1, Anumeha Singh2, Ramray Bhat1, Sandeep M. Eswarappa2, Deepak K. Sunit3, 4 and Ambarish Ghosh1, 5; 1Centre for Nano Science and Engineering, Indian institute of Science, Bangalore, India; 2Department of Biochemistry, Indian Institute of Science, Bangalore, India; 3Department of Molecular Reproduction, Development and Genetics, Indian Institute of Science, Bangalore, India; 4Centre for BioSystems Science and Engineering, Indian Institute of Science, Bangalore, India; 5Department of Electrical Communication Engineering, Indian Institute of Science, Bangalore, India; 6Department of Physics, Indian Institute of Science, Bangalore, India.

Cellular interior is a highly heterogeneous and anisotropic environment, whose physical, especially mechanical properties are difficult to measure. Currently, there are many efforts to develop techniques for such measurements, including atomic force microscopy, microplate, shear twisting cytoometry, optical tweezers, optical stretchers, magnetic tweezers, particle tracking microrheology etcetera. Many of these techniques probe the cells from outside, and
therefore not suitable for direct intracellular investigation as would be possible for probes maneuvered within the cellular interior. The purpose of this study is to develop a nanoprobe that can be manipulated inside the cell in a minimally invasive manner, with an extremely high degree of spatial accuracy at high speeds. As we show here, we have developed a helical shaped magnetic nanomotor, primarily made up of silica, polystyrene and iron, that can be internalized by the cells when incubated for around 24 hours. Subsequently, these internalized nanomotors can be actuated remotely inside the living cell by application of a rotating magnetic field created by a tri-axial Helmholz coil. We will report various interesting observations regarding the motion of the motor, which proves how these tiny motors can promptly detect mechanical changes, that too with a micron scale resolution within a living cell. We believe this can lead to novel studies of the properties of the cellular interior at a single cell level and in future lead to various intracellular sensing and delivery applications.

**Chemical/Light Powered Hybrid Micromotors with 'On-the-Fly' Optical Brakes**

Songsong Tang; Nanoengineering, University of California, San Diego, San Diego, California, United States.

Hybrid micromotors capable of both chemically-powered propulsion and fuel-free light-driven actuation and offering built-in optical brakes for chemical propulsion are described. The new hybrid micromotors are designed by combining photocatalytic TiO2 and catalytic Pt surfaces into a Janus microparticle. The chemical reactions on the different surfaces of the Janus particle hybrid micromotor can be tailored by using chemical or light stimuli that generate countering propulsion forces on the catalytic Pt and photocatalytic TiO2 sides, respectively. Such modulation of the surface chemistry on a single micromotor leads to switchable propulsion modes and reversal of the motion directionality that reflect the tuning of the local ion concentration and hence the dominant propulsion force. An intermediate Au layer (under the Pt surface) plays an important role in determining the propulsion mechanism and operation of the hybrid motor. The built-in optical braking system allows ‘on-the-fly’ control of the chemical propulsion through photocatalytic reaction on the TiO2 side to counterbalance the chemical propulsion force generated on the Pt side. The adaptive dual operation of these chemical/light hybrid micromotors, associated with such control of the surface chemistry, holds considerable promise for designing smart nanomachines that autonomously reconfigure their propulsion mode for various on-demand operations.

**Urease-Powered Nanomotors for Enhanced Anticancer Drug Delivery**

Ana Hortelão, Tania Patiño, Rafael Carrascosa and Samuel Sanchez; 1 Institute for Bioengineering of Catalonia (IBEC) The Barcelona Institute of Science and Technology, Barcelona, Spain; 2 Institució Catalana de Recerca i Estudis Avancats (ICREA), Barcelona, Spain.

Urease-Powered Nanomotors for Enhanced Anticancer Drug Delivery

Micro- and nanomotors are structures capable of self-propulsion in fluids, which have been considered interesting for biomedical applications, such as the active transport and delivery of specific drugs to the site of interest. Here, we present the loading of urease-powered nanomotors with the anticancer drug Doxorubicin, as well as the substrate-dependent (urea) drug release and efficient delivery to cells. These nanomotors are based on mesoporous silica core-shell nanoparticles functionalized with urease enzyme. The motion dynamics of these self-propelled silica nanomotors was analyzed using optical tracking and dynamic light scattering. A four-fold increase in Doxorubicin release is achieved by nanomotors after 6 hours exposure to urea, compared to nanomotors in passive conditions (absence of urea). Moreover, active Doxorubicin-loaded nanomotors present an enhanced anticancer efficiency toward HeLa cells, that arises from a synergy between increased drug release and production of ammonia during catalysis. We found that in the presence of urea, Doxorubicin-loaded nanomotors exhibit improved effect on HeLa cells compared to passive carriers, where a higher content of Doxorubicin is uptaken after 1, 4, 6, and 24 hours incubations. Naturally high urea concentrations present in bladder can trigger the motion of anticancer drug loaded nanomotors. This effect generates a more effective drug release, which can be of particular interest for intravesical drug delivery. As a step forward, urease-powered nanomotors, coupled with an antibody, are used as developed to target bladder cancer derived from transitional cell papilloma. The improvement in drug delivery efficiency achieved by enzyme-powered nanomotors may hold potential toward their use in future varied applications, such as the substrate-triggered release of drugs in precise locations.

**Highly Increased Output Voltage with Diverse Textiles in Triboelectric Nanogenerators for a Wide Variety of Soft Robot Application**

Jae-Bum Jeong; Swanit Biswas, Suwoong Lee and Hyek Kim; 1 Gyeongsang National University, Jinju, Korea (the Republic of); 2 Korea Institute of Industrial Technology, Daegu, Korea (the Republic of).

Triboelectric nanogenerator (TENG) with fabrics has been widely studied due to its potential application in smart textiles, so to be used to wearable electronics. The surface property of fabric affects on the output voltage of TENG because the surface charge density depends on the kind of fabrics. We demonstrated the enhanced output voltage of TENG with a variety of textiles. Elastomer was inserted to support between Cu electrodes. In this process, various fabrics, such as cotton, rayon, wool, acetate, silk, nylon, and acrylic, were covered the elastomer to control surface charge. The output voltages were measured by changing surface frictional charge density. The change of output voltage according to frictional electrostatic voltage from 3 V to 25 V is demonstrated. In addition, effect of the moisture regain of various textiles on output voltage is also studied.

**Metal-Oxide Based Micromotors for the Removal of Organic Pollutants and Heavy Metals**

Diana Villa; Jemish Parmar, Katherine Villa and Samuel Sanchez; 1 Instituto de Bioengineering, Barcelona, Spain; 2 Institut for Research of Catalonia (ICREA), Barcelona, Spain.

Water contamination is one of the most persistent problems in public health. Micromotors can act as an efficient tool for water remediation because of the enhance mass transfer by active motion. Bubble-propelled micromotors move due to the bubble-recoil mechanism, which are associated to micro/mixing capabilities, resulting in a potential platform for water remediation applications. The choice of the functional material on the micromotors surface depends on the target pollutants. However, several challenges must be addressed before micromotor-based water treatment technology can be used in practical applications, such as the high cost associated with the use of Pt for propulsion. Moreover, these micromotors are typically fabricated by expensive techniques such as, rolled up technology[1] or electrodeposition methods[2]. In order to obtain efficient and inexpensive micromotors for water treatment, we described cobalt ferrite (CoFe2O4)[3] and Fe3O4-decorated SiO2/MnO2 micromotors fabricated[4] by facile and scalable synthesis methods, respectively.
The CoFe₂O₄ micromotors were fabricated by agglomeration of dried CoFe₂O₄ nanoparticles (NPs), which were previously synthesized via solvothermal routes using Co³⁺ and Fe³⁺ salts as precursors in ethylene glycol. The micromotors, self-propelled without the need of a surfactant, carried out an efficient removal of tetracycline antibiotic from wastewater and, after the reaction was complete, were collected and separated using their magnetic properties. In addition, we proved that CoFe₂O₄ micromotors enhanced the production of hydroxyl radicals via Fenton-like reaction due to the presence of cobalt.

The γ-Fe₂O₃-decorated SiO₂/MnO₂ micromotors consisted of mesoporous silica-based microjets with MnO₂ immobilized on the outer surface and decorated with γ-Fe₂O₃ NPs on the outer surface. They were synthesized by growing silica tubes on a polycarbonate template by sol-gel method[5] and immobilizing MnO₂ and γ-Fe₂O₃ catalysts. The inner layer of MnO₂ act as functional material for both propulsion and removal of pollutants and γ-Fe₂O₃ NPs as photocatalytic, adsorptive and magnetic material. Thus, these micromotors enabled the efficient degradation of organic pollutants (dyes and antibiotics) under visible light irradiation, as well as the removal of heavy metal ions. Regarding their magnetic properties, they were magnetically steered facilitating their recovery and further reuse.

Therefore, these approaches open up new inexpensive alternative methods to fabricate other types of metal-oxide based micromotors for different applications in the environmental field.

bacteria-powered biohybrid microrobots have recently shown to actively transport and deliver cargoes encapsulated into their synthetic constructs to specific regions locally. However, use of synthetic materials as cargo carriers can result in inferior performance in load-carrying efficiency, biocompatibility, and biodegradability, impeding clinical translation of biohybrid microswimmers. We have developed a bacteria-powered biohybrid microrobot using RBCs as autologous cargo carriers for active and guided cargo delivery. RBCs were loaded with anti-cancer doxorubicin drug molecules (DOX) and superparamagnetic iron oxide nanoparticles (SPIONs) and functionalized with biotinylated anti-TER-119. Multifunctional biohybrid microrobots were fabricated by attachment of RBCs to bioengineered motile bacteria, Escherichia coli MG1655 expressing biotin attachment peptides, via biotin-avidin-biotin binding complex. Release of DOX molecules from RBC cargoes was investigated over 120 hours at different pH conditions (3.1 - 9.2) and enhanced release rates were observed at low pH conditions. Autonomous and on-board propulsion of biohybrid microrobots was provided by bacteria (∼10^-5 μm/s), and their external magnetic guidance was enabled by SPIONs loaded into the RBCs. Moreover, bacteria-powered RBC microrobots displayed preserved deformability and attachment stability even after squeezing in microchannels smaller than their sizes, as in the case of bare RBCs. Inherent compliance of RBCs further allowed active deformation and passage of RBC microswimmers through confined spaces only by means of bacterial propulsion, while preserving their motility. In addition, an on-demand light-activated hyperthermia termination switch was engineered for RBC microswimmers to control bacteria population after targeted operations.

RBCs, as biological and autologous cargo carriers in the biohybrid microrobots, offer notable advantages in stability, deformability, biocompatibility, and biodegradability over synthetic cargo-carrier materials. The biohybrid microswimmer design presented here transforms RBCs from passive agents into autonomous, active, and guidable cargo carriers toward targeted drug and other cargo delivery applications in medicine.

G102.08.12 Controllable Dynamic Self-Assembly of Mobile Microrobotic Swarms with Programmable Interrobotic Interactions Berk Yigit, Yunus Alapan and Metin Sitti; Max-Planck Institute for Intelligent Systems, Stuttgart, Germany.

Microrobotic swarms are indispensable for amplifying throughput in high-impact microrobotic applications for targeted drug delivery, medical diagnostics, parallel micromanipulation, and environmental sensing and remediation. Bottom-up assembly approaches present facile means for fabrication of microrobot swarms, owing to their parallel assembly capabilities and reconfigurability enabled by modular constituents. Previous studies showed that single microrobots of controlled size, shape, and function can be formed by dynamic self-assembly of magnetic microparticles. However, their controlled fabrication and operation at high densities has remained a challenge as they are susceptible to coalescing into poorly-defined aggregates due to unintended magnetic dipolar attractions. Here, we show that controlling magnetic interactions via precessing magnetic fields enable massively parallel formation and operation of mobile microrobotic swarms at high densities, with well-defined microrobot morphologies, locomotion characteristics and spatial order. Starting from a dispersed suspension of superparamagnetic particles over a planar substrate, we use precessing magnetic fields (dynamic rotating and static unidirectional fields) to form a swarm of linear chain assemblies, each consisting of 3 to 5 superparamagnetic particles. These chain microrobots locomote on surfaces by applying a tilt to their precession axis. Control over the angles of precessing magnetic field allows tuning magnetic interactions among microrobotic chains from attractive to repulsive. Utilizing unidirectional repulsive interactions that prevent aggregations in the plane of the substrate, we show that microrobots are able to maintain structural and functional integrity over macroscale distances (∼1 cm), even in highly compacted swarms travelling through narrow passages. Moreover, interrobotic interactions enabled control over collective order for achieving a homogeneous spatial distribution and a narrow distribution of nearest neighbor distances indicating spatial organization. These swarms can further achieve directional transport of large cargoes on surfaces and small cargoes in bulk fluids. Our results demonstrate that interrobotic interactions are crucial for operation of dynamically self-assembled microrobots without forming aggregates at high densities, and enables controlling collective order inside microrobotic swarms. Overall, described design approach, exploiting physical interactions among individual robots, enables facile and rapid formation of self-assembled and reconfigurable microrobotic swarms with programmable collective order.

G102.08.13 Algal Microswimmers for Cargo Delivery Oncay Yasa, Pelin Erkoc, Yunus Alapan and Metin Sitti; Max-Planck Institute for Intelligent Systems, Stuttgart, Germany.

Nature exhibits intriguing microscopic swimmers with innate energy harvesting abilities from their local environments. Use of natural swimmers as delivery agents presents an alternative platform to transport cargoes inside the body. Their small sizes and intrinsic properties could allow deep tissue penetration, and in this way, to reach difficult-to-access inner body locations. Although bacteria are heavily utilized as actuators in biohybrid microswimmer design for cargo delivery applications, their acute pathogenicity along with rapid growth in physiological conditions limit their clinical applications to inner body cavities and solid tumors, and necessitate search for an agile biological swimmer with better biocompatibility, such as microalgae. Microalgae, eukaryotic micromotile microorganisms with a facile culture process, present high propulsion (~100 μm/sec), autofluorescence and phototactic guidance capabilities. Chlamydomonas reinhardtii [C. reinhardtii], as a unicellular biflagellate microalga species, has been barely explored as an actuator to fabricate biobased micromotile microswimmers for biomedical applications, mainly due to its inefficient motility inside typical cell culture media such as minimum essential medium with phenol red.

We developed a biocompatible algal microswimmer, powered by a unicellular freshwater green microalga, by integrating polyelectrolyte [PE] functionalized magnetic spherical polystyrene [PS] (1 μm in diameter, 20% iron oxide content) cargoes onto the surface of C. reinhardtii through non-covalent electrostatic interactions. The integration using electrostatic interactions allowed non-invasive and facile fabrication of the biobased algal microswimmers without the requirement for any harsh chemical reaction. PE functionalized microparticles were alternatingly fabricated with oppositely charged poly(allylamine hydrochloride) (positively charged) and poly(sodium 4-styrenesulfonate) (negatively charged) polyelectrolytes using layer-by-layer deposition technique. The fabrication of the microparticles was finalized at the 5th layer with the positively charged PE to allow electrostatic interaction of the microparticles with the negatively charged microalgae. Initially, interaction of the microalgae with PE functionalized surfaces was characterized using quartz crystal microbalance with dissipation monitoring. Then, three-dimensional swimming motility of the constructed biobased algal microswimmers was characterized in the presence and absence of a uniform magnetic field (in x-direction) using transmission digital holographic microscope. Finally, motility of the microalgae was investigated in different biological media, and a model drug, fluorescent isothiocyanate-dextran (a water-soluble polysaccharide) molecule, was delivered to mammalian cells.

To conclude, we demonstrate a biocompatible algal microswimmer which can be utilized, as an alternative to bacterial microswimmers with superior properties, in various biomedical applications.

G102.08.14 Recent Advances in the Powering and Actuation of Nanorobots Using Sound Waves Fernando Soto and Joseph Wang; Nanoengineering, University of California, San Diego, La Jolla , California, United States.
Micro and nanoscale robots consist of microscopic mobile devices that can convert local chemical fuels or external inputs into autonomous propulsion. These small-scale tools can perform multiple tasks while propelled in solution, as their motion allows them to transport cargo or reactive materials, increase recognition events and induce fluid mixing. Such functionality could lead to the improvement in human health and disease treatment. Despite the attractive performance and autonomy of chemically-powered nanorobots, they still present limitations that warrant pursuing alternatives. Specifically, these catalytic microrobots have short life spans or require toxic fuels to operate, and their swimming behaviour is commonly hard to modulate. On the other hand, recently introduced acoustically-powered motors make use of acoustic fields sound waves that are relatively innocuous and easy to manipulate, offer unique advantages for enabling efficient and controllable motion (in different biological media), and allow for diverse surface functionalization.

Here, we present recent advances in the design, powering, actuation and application of ultrasound-based nanorobots. Including the use of ultrasound-propelled asymmetric nanorobots, which have been translated towards various biomedical concepts including targeted drug delivery, bacteria and toxin capture, and intracellular drug delivery [1,2]. The use of ultrasound fields to modulate the propulsion and collective behaviour of chemically propel microorganisms [3,4]. New tools for nanosurgery which consist on ultrasound triggered microcannons, capable of firing nanobullets and penetrate tissue, [5,6] and ultrasound powered automated assembly lines capable of manipulating and isolating particles and live cells[7].

References
holding/detaching gripper by electrostatic force is experimentally evaluated. The electrostatic force is generated by the bipolar electrodes. The proposed gripper is expected to work effectively on thin film/textile objects with elastically-deformable bipolar micro-probes. Due to the module structure, the micro-probe tips can be aligned precisely on the large surface area where the module has photolithographically-defined silver circular electrodes. The other side of the PVDF layer has photolithographically-defined silver serpentine-structured strain gauges aligned with the back-side electrodes. The aligned features enables localized measurements. Relative movement is sensed by measuring the change in charge between overlapping silver traces. Applied force is sensed by measuring the change in resistance of the strain gauges. Object proximity is measured using the strain gauge traces for capacitive coupling sensing. We prove the adaptability of the hybrid bio-actuator applying different training protocols at different frequencies, resulting in a modulation of the force and the relative expression of related proteins.

In parallel, the 3D bioprinting technique has succeeded in developing functional three-dimensional tissues. Although 3D printing of artificial materials has been used to fabricate scaffolds or molds for hybrid bio-actuators, 3D bioprinting of skeletal muscle tissue, together with soft skeletons, has not been reported in the field of hybrid bio-robotics. Here, we present our recent advances in the fabrication of 3D bioprinted hybrid bio-actuators based on skeletal muscle tissue, taking advantage of the unique versatility, rapid-prototyping and simplicity of the technique. We report a full characterization and optimization of the printing from the material point of view, but also paying special attention to the biocompatibility, as well as differentiation and maturation of cells inside the bioprinted hydrogel. Furthermore, we demonstrate myotube alignment, following the direction of printing, by immunostaining and scanning electron microscopy. This result is a unique consequence of the use of 3D bioprinting that is typically difficult to achieve by other means. Finally, we take advantage of the multi-material printing capabilities of the technique to 3D bioprint a hybrid biological actuator whose contractions can be completely controlled by external electric fields. We prove the adaptability of the hybrid bio-actuator applying different training protocols at different frequencies, resulting in a modulation of the force and the relative expression of related proteins.

Living beings have evolved to use coupled algorithms, from breathing to walking. It is known local, often small, clusters of neurons (CPGs) perform these essential functions, in the absence of input from the brain. This modular method of control of whole organisms may present advantages over centralized, computational robotic control. An experimental platform, composed of diffusively-coupled PDMS microreactors each containing the oscillatory, light sensitive Belousov-Zhabotinsky (BZ) chemical reaction has been developed. This method allows rapid testing of methods of CPG design out of coupled oscillators. Further it will aid the design of already existent micronscale, hydrogel robotics through revealing how control of diffusive fluxes within a patterned hydrogel could result in different spatiotemporal patterns of actuation. Experimental observations of quadruped gaits in 4 reactors, and a categorization of both individual, and pairs of reactors within the system will be the focus of the presentation.
To date, new handling techniques of thin film/textile materials such as polymer films, papers, and fabrics have been required in order to develop advanced wearable devices, and many other applications, although the conventional electrostatic chucks work successfully typically for flat and hard wafer in the semi-conductor fabrication. In recent years, our research group has been developing compliant bipolar electrostatic grippers through the past studies. Still the critical issue remains to be solved that the effective area for electrostatic force should be enlarged while the spatial density of bipolar electrodes should be increased. In addition, the insulation between the bipolar electrodes is seriously important to avoid the damage from the breakdown in case of spatially high density of electrodes. To solve this issue by layer-by-layer fabrication, 3D printing technology can be considered one of the most useful for applications in relatively large scale.

The module having bipolar probes consists of three-sublayer (conductor-insulator-conductor) structure. The 80mm-long bipolar probes are arranged at 45-degrees to interface. The dimensions of a rectangle tip surface of the bipolar probes are 1.2mm in width and 1.6mm in height. Conductive and insulating layers are 0.4mm and 0.8mm in thickness, respectively. The bipolar probes are fabricated by a fused deposition modeling (FDM) 3D printer having a 0.4-mm-diameter nozzle. Carbon-mixed and ABS filaments are used for conductor and insulator, respectively.

The force curve is experimentally determined to evaluate the compliance, the maximum attractive force, and other characteristics. Additionally pick-and-place demonstrations for a PP film, a printing paper and a fabric are conducted to show that the module work as a handling/detaching device for thin film/textile objects under particular conditions. Furthermore, even if the influence of residual charge is not negligible due to the applied voltage, the detachment is always successful with an appropriate tilt angle that causes peeling effect in the contact interface between probe tips and objects. Therefore the proposed concept will highly contribute to the fabrication technology in the next-generation robotics.

GI02.08.22
From Soft Actuator to Soft Robot Powered with the Oscillating Belousov Zhabotinsky Reaction Baptiste Blanc1, Ning Zhou1, Hyunki Kim1, Eric Y. Liu2, Ali Aghvami1, Hyunmin Yi1, Bing Xu1, Ryan Hayward3 and Seth Fraden1; 1Brandeis University, Waltham, Massachusetts, United States; 2Tufts University, Medford, Massachusetts, United States; 3UMass Amherst, Amherst, Massachusetts, United States.

Yoshida developed a gel in the late nineties that experiences cyclic swelling and deswelling changes without external stimuli. This self oscillating gel contains a catalyst involved in the Belousov Zhabotinsky (BZ) reaction, an oxydo-reduction cyclic reaction, leading to a cyclic change of solubility of the gel.

Our goal here, is to highlight the engineering principle controlling the mechanical oscillation of the BZ gel and to pave the way to the synthesis of controllable autonomous shape changing hydrogel, which could lead to an autonomous motile hydrogel.

We first present a new synthesis technique, offering high modularity in the gel composition and in its functionalization with the catalyst of the BZ oscillating reaction. Thanks to this experimental advance, we optimize the mechanical oscillation of a BZ homogeneous spherical hydrogel, pointing out the critical swelling limitation arising from the minimal size for a BZ gel to chemically oscillate.

We then present a way to "structure" the hydrogel to maximize its mechanical oscillation, and we finally introduce how we are engineering such gels to make them move.

SESSION GI02.09: Materials and Structure

Engineering Reaction--Diffusion Networks with Properties of Neural Tissue for Control of Soft Robots Seth Fraden, Mike Norton and Thomas Litschel; Brandeis University, Waltham, Massachusetts, United States.

Neural tissue evolved 3.5 billion years after the origin of life, which is a testament to its complexity, and is found in almost all multicellular life, which is a testament to its importance. At the coarsest level of description, neurons are non-linear oscillators that when coupled together in tissue through excitatory and inhibitory connections give rise to complex spatio-temporal patterns. When organized, these patterns are capable of processing and storing sensory information, and actuating musculature. Extrapolating from this general definition of a neuronal network as a spatiotemporal pattern generator, we posit these dynamics can be captured on an abiotic network--diffusion platform. Here, we report advances in soft lithography that allow the engineering of synthetic reaction--diffusion networks capable of producing a wide variety of spatiotemporal patterns. We employ the well-known oscillatory Belousov-Zhabotinsky reaction and develop methods to create diffusively coupled networks over which we design (i) the topology of the network, the (ii) boundary and (iii) initial conditions, (iv) the volume of each reactor, (v) the coupling strength, and (vi) whether the coupling is of an inhibitory or excitatory nature. It is important to note that the engineering principles we identify are general and can be applied to other oscillatory reaction--diffusion systems. An application for the reaction--diffusion based networks developed here is to the field of soft robotics, where the central pattern generator will serve as the controller of an artificial musculature comprised of chemomechanical gels coupled to the BZ layer.

High Power Density, Humidity Driven Actuators for Robotic Applications Omur Cakmak1, Xi Chen and Ozgur Sahin; Columbia University, New York, New York, United States.

Humidity responsive materials are versatile alternatives to common actuators in robotics systems, due to ease of actuation with humidity gradients and pervasiveness of water. We have shown that as a humidity responsive material, Bacillus spores exhibit high work density actuation 1-2. To take advantage of micrometer sized spores in macroscopic systems, it is necessary to assemble spores into larger materials without significantly compromising function. The granular nature of spores makes this a challenging task because spores don’t adhere well to each other due to small contact areas between adjacent spores, thus making it difficult to transfer mechanical energy. We have shown that combining spores with commercially available UV curable optical and electronic adhesives enable centimeter scale actuators with high work density and specific power. This novel composite is water resistant and retains its function after several liquid water contacts. Upon immersion or exposure to humid air from an ultrasonic humidifier, the actuators respond rapidly, in
and generated 36 mW under one-sun illumination (100 mW/cm²) using the module (total active area is 4.4 cm²). This allows the conformal attachment onto three-dimensional surfaces. In our laboratory, we fabricated such ultra-thin solar cells onto 5 by 5 cm² films.

Energy harvesting systems are important topics for robotic field because the electrical power is inevitable for most devices to be driven. Among various energy harvesting systems, solar cells are one of the best solutions because they can generate milliwatts or higher electric power under the sunshine conditions. Recently we developed ultra-thin organic solar cells which possess high power conversion efficiency (PCE), thermal stability, water-proof property and stretchability simultaneously [1-3]. Our solar cells have ultra-thin properties; the total thickness is only 3 μm and the weight is less than 5 g/m², which allows the conformal attachment onto three-dimensional surfaces. In our laboratory, we fabricated such ultra-thin solar cells onto 5 by 5 cm² films and generated 36 mW under one-sun illumination (100 mW/cm²) using the module (total active area is 4.4 cm²).

In this talk, I will show the performance of our ultra-thin organic solar cells and discuss possibilities for the integration of such power sources with actuators and sensors for the soft robot applications.

Piezotronics for Next Generation Robotics
Zhong Lin Wang1, 2; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

Piezoelectricity, a phenomenon known for centuries, is an effect that is about the production of electrical potential in a substance as the pressure on it changes. For wurtzite structures such as ZnO, GaN, InN and ZnS, due to the polarization of ions in a crystal that has non-central symmetry, a piezoelectric potential is created in the crystal by applying a stress. The effect of piezopotential to the transport behavior of charge carriers is significant due to their multiple functionalities of piezoelectricity, semiconductor and photon excitation. By utilizing the advantages offered by these properties, a few new fields have been created. Electronics fabricated by using inner-crystal piezopotential as a “gate” voltage to tune/control the charge transport behavior is named piezotronics, with applications in strain/force/pressure triggered/controlled electronic devices, sensors and logic units. This effect was also extended to 2D materials such as MoS₂. The objective of this talk is to introduce the fundamentals of piezotronics and their application for robotics and human-machine interfacing.

Metallic Nanowires—Fabrication, Microstructure and Properties
Wenting Huang and Gunther Richter; Max Planck Institute Intelligent Systems, Stuttgart, Germany.

Building nanodevices for applications leads to a myriad of challenges on materials and assembly level. Still nanosized objects have the prospect to be building blocks for future complex smart, autonomous or intelligent systems. A challenge for bringing macroscopic building designs and concepts into the nanoworld, that decreasing dimensions lead to changing physical properties and behaviors. Especially systems below 100 nm and above the size of single molecules exhibit peculiar properties. Surfaces, interfaces, grain boundaries, dislocations that influence the behavior of macroscopic devices will dominate the performance of those below 1 μm. Therefore, to stay relevant and open new research areas by breaking through old limits, the interlinkage of microstructure, fabrication and capacity of devices have to be newly addressed in the same length scale.

We present the fabrication of metallic nanowire structures by physical vapor deposition and will briefly discuss the influences of diffusion on the microstructure formation. Examples from 2D-thin film, island, perlocated structures and one-dimensional nanowires will act as illustration.

The changing physical properties, mechanical, electrical and magnetic, are demonstrated by investigations of metallic nanowires. Due to the absence of internal defects, such as dislocations or grain boundaries, tensile strengths close to the predicted theoretical strength are observed. Cu exhibits a tensile strength of ~6 GPa, Au of ~1 GPa. The deformation is created by partial dislocation nucleation and propagation and consequently by twin formation. Since no defects act as scattering center, the conductivity does not increase with decreasing diameter of the nanowires, but remains close to the perfect bulk values. No size effect is observed but a constant conductivity. The magnetic domain structure was studied by electron holography. Only one single domain is present in ferromagnetic metallic nanowires.

In conclusion we show how microstructural tailoring leads to changing physical properties and therefore to improved performances in nanosystems. In the
long term, this might open the path to new research avenues and reintroduce seemingly old materials systems in novel design concept for nanodevices.

Dynamically Tunable Dry Adhesion via Sub-Surface Stiffness Modulation Milad Tatarí1, Amir Mohammadi Nasab1, Kevin T. Turner2 and Wanliang Shan1; 1University of Nevada Reno, Reno, Nevada, United States; 2University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Tunable dry adhesion has a range of applications, including transfer printing, climbing robots, and gripping in automated manufacturing processes. Here, a novel concept to achieve dynamically tunable dry adhesion via modulation of the stiffness of sub-surface mechanical elements is introduced and demonstrated. A composite post structure, consisting of an elastomer shell and a core with a stiffness that can be tuned via application of electrical voltage, was fabricated. In the non-activated state, the core is stiff and the effective adhesion strength between the composite post and contact surface is high. Activation of the core via application of electrical voltage reduces the stiffness of the core, resulting in a change in the stress distribution and driving force for delamination at the interface and a reduction in the effective adhesion strength. The adhesion of composite posts with a range of dimensions were characterized and activation of the core was shown to reduce the adhesion by as much as a factor of six. The experimentally observed reduction in adhesion is primarily due to the change in stiffness of the core. However, the activation of the core also results in heating of the interface and this plays a secondary role in the adhesion change.

10:30 AM *GI02.10.01
Shape-Programmable Magnetic Soft-Bodied Millirobots Metin Sitti; Max Planck Institute for Intelligent Systems, Stuttgart, Germany.

Soft functional active materials could enable physical intelligence for small-scale (from a few millimeters down to a few micrometers overall size) devices and robots by providing them unique capabilities, such as shape changing and programming, physical adaptation, and multi-functional and drastically diverse dynamics. In this talk, our recent activities on design, manufacturing, and control of new shape-programmable active soft matter and untethered soft robots at the milli/micronscale are reported. First, a computational design and fabrication method is introduced to create 2D shape-programmable magnetic soft elastomers that can generate desired large shapes using a programmed non-homogeneous magnetization profile and uniform magnetic field control input. Such magnetic shape change/actuation can happen very fast and wirelessly, which are significant advantages. Next, using such methodology, a grand challenge in small-scale mobile robotics is addressed: how to navigate mobile robots in complex environments with multiple terrains (e.g., on solid surfaces, inside fluids, at the fluid-air interfaces) using multiple locomotion modalities like animals in nature? Using programmed dynamic deformations of the robot’s soft elastomeric body and body torques, such soft-bodied robot is demonstrated to be able to have seven locomotion modalities (undulatory swimming, jellyfish-like swimming, water meniscus climbing, jumping, ground walking, rolling, and crawling inside constrained environments) to be able to navigate on complex environments, such as inside the human body. Moreover, dynamic shape control is used to actively transport and deliver cargos integrated to the robot’s body. Preliminary ultrasound-guided navigation of such soft robots is presented inside an ex vivo chicken tissue towards their medical applications to deliver drugs and genes locally and heat the local tissues for hyperthermia and cauterization.

11:00 AM GI02.10.02
Multimodal Control of Magnetic Millibot for Programmable Collective Rotation Hajun Lee, Jeeyoon Yi, Hyeonseo Song, Junkyu Choe and Jiyun Kim; Mechanical Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Creating individual and collective motions in material based distributed systems, e.g. active matter and self-assembling particles, pose challenges in the design of both physical components and control algorithms that can operate at desired scales. Among them, meso-scale floating magnetic components rotating at liquid-air or liquid-liquid interface have been widely engineered to create patterns balancing magnetic rotation and corresponding hydrodynamic interactions, attributing their potentials to remote actuation and easy fabrication. Most of those systems, however, are only composed of identical components, lowering the diversity and the complexity in programming their spatiotemporal collective behaviors. Here, we develop millimeter-scale polymer based magnetic structures, named as ‘millibot’, and map their multi-modal rotational behaviors in a chosen magnetic field intensity and frequency range. Millibots have identical rectangular shapes but diverse magnetic properties, making them have different map in their rotational behaviors. Using these actuation maps, we are able to selectively control the collective rotation of heterogeneous millibot groups or subgroups in a programmable manner.

To achieve this, we developed three types of millibots with different magnetic properties; a millibot can have the magnetic anisotropy with self-assembled magnetic chains, randomly dispersed magnetic particles, or the mixture of ferromagnetic and superparamagnetic particles. To embed magnetic properties in the millibots, magnetic particles were dispersed in the photocurable polymer, PEGDA diluted with DI water, and shaped via photopolymerization. 2-axis magnetic field generator, whose magnetic field ranges in intensity from 100 to 800 Oe and in frequency from 0 to 4 Hz, was used to drive the rotations in millibots and consequently, we mapped the multimodal rotations of each type of millibot.

We observed shift, shrinkage or expansion of individual rotation mode ranges according to the type of millibots. This allows us to choose and program the collective rotation of entire millibot group or chosen sub-group. To show this capability, we demonstrated that four different millibots exhibiting different rotational behaviors under the certain condition were switched their behavior to identical collective rotation in another condition. Also, fifteen millibots which is composed of three sub-groups were controlled to show diverse collective rotations of sub-groups.

As a result, embedding diverse material properties in the physical components of distributed systems provide an advanced way of designing and controlling the collective behaviors of heterogeneous distributed system in a programmable manner. We expect that this approach will enhance the behavioral capability of meso-scale particle collectives for diverse applications including programmable matter, robotics, bio-medical systems and so on.

11:15 AM GI02.10.03
X-Ray Driven Microswimmers Zhaoyi Xu and Ji Tae Kim; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong.

Light-powered manipulation of small objects in fluids significantly affects fields as diverse as drug/cell delivery, microsurgery, environmental remediation,
and self-assembly/nanofabrication. Although many clever techniques based on UV-visible-NIR light have been devised, new methods that can have sufficient penetrating power into biological bodies are still in great demand. Since discovered by Röntgen, X-rays have long been regarded as the most celebrated light-source for non-invasive, whole-body medical imaging because of its outstanding penetration.

Here, we observed that X-rays can drive propulsive motion of a half-metal coated Janus microparticle in aqueous environment. Using a full-field transmission X-ray microscope (TXM) with synchrotron hard X-rays, we simultaneously triggered and visualized the propulsive motion at single-particle level. Our real-time observation at nanoscale revealed that the motion follows bubble growth induced by radiolysis of water at the metal/water interface under X-ray irradiation. This study opens a potential to operate micro/nanorobots under whole-body medical imaging. In this talk, we will present our results and discuss the prospects of our work for potential applications in medicine.

11:30 AM GI02.10.04
Visible-Light-Gated Reconfigurable Rotary Actuation of Electric Nanomotors Zexi Liang1 and Donglei (Emma) Fan2, 3; 1Materials Science and Engineering, The University of Texas at Austin, Austin, Texas, United States; 2Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United States.

Highly efficient and widely applicable working mechanisms that allow nanomaterials and devices to respond to external stimuli with controlled mechanical motions could make far-reaching impact to reconfigurable, adaptive, and robotic nanodevices. Here, we report an innovative mechanism that allows multifold reconfiguration of mechanical rotation of semiconductor nanoentities in electric (E) fields by visible light stimulation. When illuminated by light in the visible to infrared range, the rotation speed of semiconductor Si nanowires in electric fields can instantly increase, decrease, and even reverse the orientation depending on the intensity of the applied light and the AC E-field frequency. This multifold rotation configuration is highly efficient, instant, and facile. Switching between different modes can be simply controlled by the light intensity at an AC frequency. Experimentations, theoretical analysis, and simulations are carried out to understand the underlying principle, which can be attributed to the optically tunable polarization of Si nanowires in aqueous suspension and an external electric field. Finally, leveraging this newly discovered effect, we successfully differentiate semiconductor and metallic nanoentities in a non-contact and non-destructive manner. This research could inspire a new class of reconfigurable nanoelectromechanical and nanorobotic devices for optical sensing, communication, molecule release, detection, nanoparticle separation, and microfluidic automation.

11:45 AM GI02.10.05
Materials for Actuation and Testing of Miniaturized Robots Fengjin Chai1, Fabian Adams2, Kai Melde1, Stefano Palagi1, Tian Qiu1 and Peer Fischer1, 3; 1Max Planck Institute for Intelligent Systems, Stuttgart, Germany; 2Department of Urology, University Medical Center Freiburg, Freiburg, Germany; 3Institute for Physical Chemistry, University of Stuttgart, Stuttgart, Germany.

Miniaturization is critical for many robotic devices, especially in the field of medical robotics. Numerous small-scale robots have been developed for potential medical applications, such as targeted drug delivery[1], minimally invasive surgery[2], measurement of biological fluids[3], and endoscopic imaging[4]. An essential component of these robots are the miniaturized actuators, which need to be small in size, powerful in the actuation force, safe for the interaction with biological tissues, and ideally untethered for more dexterity of the robots. Traditional electronics based systems are often stiff and if multiple wires are used, they are too bulky for instance for minimally invasive applications. The development of new materials is essential to enable new compact actuators and to simplify robot design.

Here, we present a surface actuator – essentially a thin film – that needs no electrical or light input and that is based on functional material interfaces. The interface consists a two-dimensional array of micro-bubbles that can be resonantly excited by ultrasound. The microfabricated thin film causes strong acoustic streaming, when it is wirelessly excited by the low-frequency ultrasound[5]. This smart surface permits unique addressability and thus enables many degree of freedom actuation of multiple actuators. Although the surface actuator is only hundreds-of-micron in thickness, it is powerful enough to remotely actuate a centimeter-scale robot in water and a miniaturized endoscope for urinary tract video-imaging.

In order to test miniaturized devices, such as our ultrasound-activated acoustic streaming devices and to evaluate their performances, we also developed compact actuators and to simplify robot design.

Here, we observed that X-rays can drive propulsive motion of a half-metal coated Janus microparticle in aqueous environment. Using a full-field transmission X-ray microscope (TXM) with synchrotron hard X-rays, we simultaneously triggered and visualized the propulsive motion at single-particle level. Our real-time observation at nanoscale revealed that the motion follows bubble growth induced by radiolysis of water at the metal/water interface under X-ray irradiation. This study opens a potential to operate micro/nanorobots under whole-body medical imaging. In this talk, we will present our results and discuss the prospects of our work for potential applications in medicine.

Magnetic Colloidal Microswarm for Targeted Delivery Jiangfan Yu1 and Li Zhang1, 2, 3; 1Department of Mechanical and Automation Engineering, The Chinese University of Hong Kong, Hong Kong, China; 2Chow Yuk Ho Technology Centre for Innovative Medicine, The Chinese University of Hong Kong, Hong Kong, China; 3CUHK T-Stone Robotics Institute, The Chinese University of Hong Kong, Hong Kong, China.

In nature, various types of swarm behaviors occur, such as a flock of birds and a swarm of ants, which stem from local communications of limited individuals. Through collective pattern formation and reconfiguration, these animals dramatically change their swarming patterns according to the
environment they interact with. To date, some large-scale robotic systems can well mimic the complex swarm behaviors of natural creatures through algorithm design and wireless communication [1]. However, due to the absence of onboard processors, sensors and actuators, to create a robotic system with functional swarm behaviors at the small scales remains challenging. Herein, we report paramagnetic nanoparticles as building blocks to investigate collective behavior of microbotic swarm in fluid.

Recently, we found a novel method to disassemble paramagnetic nanoparticle chains using a programmed dynamic magnetic field [2]. Thousands or even millions of colloidal agents can be disassembled and spread simultaneously due to hydrodynamic drags and magnetic dipole-dipole repulsive interactions, respectively. As the reversed process, we also presented that the spread colloids can be assembled into vortex-like paramagnetic nanoparticle swarms (VPNS) using a rotating magnetic field [3]. The VPNS exhibits a dynamic-equilibrium structure, in which the nanoparticles perform synchronized motions. Moreover, by tuning the applied magnetic fields, the VPNS was capable of performing multimodal pattern reconfiguration, and we also investigated the reversible merging and splitting of the vortex-like swarms/sub-swarm. We demonstrated that the VPNS is able to pass through curved and branched fluidic channels with high swimming velocity, positioning precision and access rates (over 90%) to a target. Localized energy delivery with tunable and enhanced hyperthermia heating effect was demonstrated as well [4]. In addition, we have discovered a new strategy to reconfigure the paramagnetic nanoparticles into ribbon-like microswarms, which are capable of performing reversible elongation with an extremely high aspect ratio of the dynamic pattern. Our work thus sheds light on the fundamental understanding and control of magnetic micromorbotic swarms.

Designing Self-Powered Nano and Microbots Ayusman Sen; The Pennsylvania State University, University Park, Pennsylvania, United States.

Self-powered nano and microscale moving systems are currently the subject of intense interest due in part to their potential applications in nanomachinery, nanoscale assembly, robotics, fluids, and chemical/biochemical sensing. One of the more interesting recent discoveries has been the ability to design nano/microparticles, including molecules, which catalytically harness the chemical energy in their environment to move autonomously. These "bots" can be directed by chemical and light gradients. Further, our group has developed systems in which chemical secretions from the translating micro/nanomotors initiate long-range, collective interactions among the particles. This behavior is reminiscent of quorum sensing organisms that swarm in response to a minimum threshold concentration of a signaling chemical. In addition, an object that moves by generating a continuous surface force in a fluid can, in principle, be used to pump the fluid by the same catalytic mechanism. Thus, by immobilizing the nano/micromotors, we have developed nano/microfluidic pumps that transduce energy catalytically. These non-mechanical pumps provide precise control over flow rate without the aid of an external power source and are capable of turning on in response to specific analytes in solution. In addition, the catalytic pumps can be harnessed for directional delivery of microparticles in specific locations in space.

Ingestible Self-Propelled Microrobots—Toward In Vivo Use Wei Gao; Engineering and Applied Science, California Institute of Technology, Pasadena, California, United States.

While synthetic micromotors have been evaluated extensively under in vitro conditions for over a decade, their in vivo function has rarely been explored. Zn and Mg based micromotors, powered by body fluids, have shown unique advantages to operate at different regions of the gastrointestinal tract. In this talk, I will highlight several examples of recent in vivo investigations based on these biocompatible and biodegradable biofluids powered microrobots, including precise micromotor tissue localization and retention, in vivo imaging, and enhanced drug delivery. I will also cover some early in vitro studies that paved the way for the current in vivo applications. These works open the door to a number of in vivo and clinical applications of these synthetic motors.

Engineering Hybrid Machines—From Nanobots to 3D BioBots Samuel Sanchez; Smart Nano Bio Devices, Institute for Bioengineering of Catalonia/ICREA, Barcelona, Spain.

The combination of biological components and artificial ones emerges into what we called hybrid machines or robots. Hybrid nano-bots have the ability to convert bio-available fuels to generate propulsion force to swim. They may be eventually used in vivo for transporting drugs to target locations in a controlled manner. Additionally, their active propulsion and multifunctionality of the different components of the nanorarchitecture makes them useful in sensing and cleaning water where they swim. However, before that, fundamental understanding on motion mechanism, materials considerations, in vitro assessment of drug delivery, toxicity, and their shape and size dependence on those parameters is needed. Hybrid nano- and micro-robots combine nanomaterials with enzymes and with motile cells efficient delivery, sensing, imaging and biofilm penetration. On a larger scale, we use 3D bioprinting techniques to fabricate cm-scaled hybrid BioRobots based on the combination of hydrogels and cells that contract in synchrony upon external stimuli, and exercise training, alike artificial muscles.

4:15 PM GI02.11.05
Molecular Direct-Driven Untethered Macro Soft Robots in Liquid—Design, Maneuver and Application Demonstration Zhigang Wu, Liangxiong L, Fen Li, Pan Deng and Kang Wu; Huazhong University of Science & Technology, Wuhan, China.

By extracting the kinetic energy in the molecular cooperation of an active material and its ambient liquid environment, this work reports a new strategy to design and maneuver untethered soft robots in liquid. This strategy gets rid of those tethered pipes/wires which are commonly used for energy transport in current soft robots, without robot design re-designing or changing body materials for the introducing new active materials. Using this newly developed strategy, we demonstrate a world first, molecular directly driven, macro soft robot in a liquid, and a soft robot swarm. This approach may provide a new possibility to design, fabricate and control autonomous robotics in liquid.

Untethered soft robotics inspired from nature with new design, fabrication and control strategies have been totally changing our cognition of robotics.
However, the characteristics of power source forms cannot break through the inherently limitation of thermal/mechanical performance of soft materials. Here, we presented a novel approach through contacting kinds of molecules such as amphiphilic ones with liquids. During the process, the introduced molecules interact with the ambient liquid and lead to a non-equilibrium state, resulting in a higher energy state of Gibbs free energy. Consequently, this energy gap results in a collective molecular movement that can be observed in macro scale due to molecular re-organization in micro scale e.g., oil drops spreading on water. When the molecules of such material leave their initial attached surface on the robot during their molecular re-organization process, a well-directed opposite impulse to their initial attached surface is generated according to the principle of momentum conservation. The movement of soft robots depends on the kinetic energy through a molecular interaction with the external environment without any high energized process or tethered pipes. Further, by deploying materials spatially on the attached robots, the trajectory control can be obtained such as straight going and turning in liquid for single robots. To imitate maneuvering such a robot in practical scenarios, a back dyed robot passed through precisely a toy rockery tunnel following the designed path with an optical detector, and triggered the lighting color change of an LED indicator. Without introducing any mechanical movement components, our approach has a near zero-noise level during the running process. Furthermore, by carefully aligning 32 robots towards a burning flame on an open water surface, we demonstrated a robot swarm that can be highly-centered to the same spot simultaneously to assure a hit on the given target as accurately as possible (here to extinguish the flame).

4:30 PM GI02.11.06
Mechanical Acceleration of DNA Capture and Detection by Robotizing Bio-Photonic-Plasmonic Microsensors Jianhe Guo1 and Donglei (Emma) Fan1, 2; 1Materials Science and Engineering, The University of Texas at Austin, Austin, Texas, United States; 2Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United States.

Efficient capture of deoxyribonucleic acid (DNA) on solid surfaces has received immense research interest for various biotechniques, including DNA extraction, preconcentration, detection, and separation. This work reports an original mechanism to actively accelerate the DNA capture process and significantly reduce the detection time by mechanically rotating bio-photonic-plasmonic hybrid microsensors. The photon-plasmonic microsensors consist of diatom frustules with surface-coated magnetic thin films and uniformly distributed plasmonic silver (Ag) nanoparticles. The diatom frustules are made of silica with ordered arrays of nanopores offering large surface-to-volume ratio and synergistic-plasmonic resonance for the capture and detection of DNA with surface enhanced Raman spectroscopy (SERS). By manipulating with magnetic tweezers, the photon-plasmonic microsensors transport and self-assemble in microwells and microfluidic channels, and rotate with tunable speeds for the capture and detection of DNA molecules. Experiments show the capturing rate of DNA can be significantly enhanced by at least 4 times by controlling the rotation speed of the microsensor to 1200 rpm. At a concentration as low as 80 nM/ml, Raman signals of DNA is obtained 3-time faster than those without rotation. The fundamental mechanism is investigated and attributed to the fluidic boundary layer effect, where the Nernst diffusion layer on the surface of the robotized microsensors is monotonically reduced with flow speed.

4:45 PM GI02.11.07
Micromotor-Enabled Active Drug Delivery to Treat Gastrointestinal Diseases Jinxing Li, Pavimol Angsantikul, Berta Esteban, Liangfang Zhang, Joseph Wang and Fernando Soto Alvarez; NanoEngineering, University of California, San Diego, La Jolla, California, United States.

Advances in bioinspired design principles and nanomaterials have led to tremendous progress in autonomously moving synthetic nano/micromotors with diverse functionalities in different environments. However, a significant gap remains in moving nano/micromotors from test tubes to living organisms for treating diseases with high efficacy. Here we present the first, to our knowledge, in vivo therapeutic micromotors application for active drug delivery to treat gastric bacterial infection in a mouse model using clarithromycin as a model antibiotic and Helicobacter pylori infection as a model disease. The propulsion of drug-loaded magnesium micromotors in gastric media enables effective antibiotic delivery, leading to significant bacteria burden reduction in the mouse stomach compared with passive drug carriers, with no apparent toxicity. Moreover, while the drug-loaded micromotors reach similar therapeutic efficacy as the positive control of free drug plus proton pump inhibitor, the micromotors can function without proton pump inhibitors because of their built-in proton depletion function associated with their locomotion.

9:00 AM *GI03.01.02

Centralized facilities for genetic engineering, or “biofoundries”, offer the potential to design organisms to address emerging needs in medicine, agriculture, industry, and defense. To date, by applying a diversity of new approaches, we have produced the desired molecule or material that has been asked by clients from the pharmaceutical and biotech industries as well as from the DOD. Specifically, we increased the titers of 1-hexadecanol, pyrrolnitrin, pacidamycin D, and clavulanic acid, found novel routes to the enediyne warhead underlying powerful antimicrobials, established a cell-free system for monoterpene production, and produced an intermediate toward vincristine biosynthesis. Furthermore, we have produced small-molecules of linalool and phloroglucinol that, respectively, serve as precursors to JP-10 that fuels missiles and TATB that detonates the warheads. For materials production, we have encoded 7802 individually retrievable pathways to 540 bisindoles in a DNA pool, and created 61 biosynthetic capsaicin variants that could be central to high-performance polymers. In sum, we constructed several megabases of DNA, built hundreds of strains spanning six species (Saccharomyces cerevisiae, Escherichia coli, Streptomyces albidoflavus, Streptomyces coelicolor, Streptomyces clavuligerus and Streptomyces albovinaceus), established two cell-free systems, and performed nearly a thousand assays developed in-house for the molecules.

9:30 AM GI03.01.03
Synthetic Biology for Protein-Based Materials [4]. Fuzhong Zhang; Energy, Environmental & Chemical Engineering, Washington University, Saint Louis, Missouri, United States.

Advances in synthetic biology have enabled the quantitative engineering of dynamic biological processes for the precise control of cellular reaction networks, allowing engineered cells to perform complex tasks and to produce various small molecules, which can be used as biofuel replacements, polymer precursors, nutraceuticals, and pharmaceuticals. Compared to small molecules, the production of macromolecular biomaterials by synthetic biology approaches is strongly lagging. Nature has evolved various types of protein materials with remarkable mechanical properties and functions. To facilitate the practical use of these materials, we aim to engineer bacterial cell factories to overproduce high-performance protein-based materials, such as spider silks. We have developed synthetic biology strategies that allow us to synthesize ultra-high molecular weight spider silks (556 kDa) at gram per liter scales. Fibers spun from our microbiologically produced silk fully replicate the mechanical performance of natural spider silk by all common metrics, i.e. tensile strength (1.03 ± 0.11 GPa), modulus (13.7 ± 3.0 GPa), extensibility (18 ± 6%), and toughness (114 ± 51 MJ/m3). The developed strategy reveals a path to more dependable production of high-performance silks for mechanically-demanding applications while also providing a platform to facilitate production of other high-performance natural materials.

9:45 AM GI03.01.04
Lipid Droplet Microarrays for High Throughput Screening in Synthetic Biology [5]. Aubrey Kusi-Appiah and Steven Lenhert; Biological Science, Florida State University, Tallahassee, Florida, United States.

A current obstacle in the use of synthetic biology for materials synthesis and discovery is the high throughput characterization of novel materials produced by biological organisms. Furthermore, identifying the environmental conditions that allow biological cells to produce the desired materials is challenging due to the large amount of possible cell culture ingredients and conditions. High throughput screening is currently carried out in the pharmaceutical industry for this purpose, but is cost prohibitive for many materials applications. Miniaturization of high throughput screening promises to lower the cost and allow portable screens suitable for academic use. We have developed a novel screening platform compatible with standard cell culture techniques that is scalable to a screen of 50,000 different materials on the area of a single 96-well plate using cell-based assays.[1] The technology is based on lipid droplet microarrays on surfaces where the droplets encapsulate different compounds or nanomaterials. Development of this technology required solving several technical challenges, including scalable fabrication,[2] quantification of the dosage delivered from the droplets,[3] and most recently chemical processing to ensure stability upon immersion into aqueous solution.[4] The technology is now ready to be applied to high throughput screening in synthetic biology.

3D Printing of Engineered Bacteria for the Production of Patterned Living Materials [6]. Anne S. Meyer; University of Rochester, Rochester, New York, United States.

In order to create crisp, defined patterns of biologically-created materials, new technologies need to be developed and implemented. The Meyer lab is developing first-of-their-kind bacterial 3D printers that can deposit engineered bacteria in specific three-dimensional patterns using simple devices and chemistries. Our bacterial 3D printers have fully automated, coordinated control of the pumps and printhead, allowing for high spatial resolution (<mm-scale) printing of bacteria onto wet or dry surfaces. Our printers mix an alginate-containing bacterial culture with a calcium chloride solution upon printing, triggering cross-linking of the alginate matrix to form a stable, biocompatible scaffold to support the bacteria. After printing, the scaffold is removable by dissolving the cross-linked alginate matrix with sodium citrate. We are applying our printer to the fabrication of engineered biofilms, groups of bacteria that live within a spatially structured polymer matrix. We use our 3D printer to deposit engineered E. coli that are able to produce CsgA fibrils, the major protein component of biofilm polymer matrices. These engineered bacteria can stick to the printing surface even after the printing scaffold has been dissolved away, creating free-standing, patterned biofilms. These model biofilms will be crucial for future development of anti-biofilm strategies, for which no reproducible model biofilm test system is currently available, as well as for the reliable production of beneficial living materials, which could be applied
for water and soil purification or mineral extraction.

11:00 AM GI30.01.06
**Bacterial Foundry of the Self-Regenerating and Functional Materials** Anna Duraj-Thatte, Avinash M. Basavanna, Arjirios Sourlis and Neel Joshi; Harvard University, Boston, Massachusetts, United States.

Protein-based materials have been successfully used for several applications in nanotechnology, bioengineering and medicine. Their diverse biofunctions and unique structures make them ideal building blocks to create large scale functional materials. However, there are several challenges: scalable production, isolation, expensive synthesis and processing keep recombinant protein-based materials away from other most commercially successful large-scale living materials such as cellulose or mycelium-based materials.

To tackle this problem, we developed a novel method for the rapid biosynthesis of tailored hydrogels in a single step, directly from bacterial culture, using a protocol that requires no protein purification. The hydrogel scaffold is based on the engineered extracellular matrix protein CsgA, which self-assembles into a fibrous mesh-like network that is 4-7% of hydrogel mass. Most importantly, by genetic engineering of CsgA protein we can modulate a range of rheological properties as well as incorporate any specific functional modules for desired applications. This unique method leaded us to create a novel viscoelastic and shear-thinning 3D printing inks that are entirely biofabricated by genetically engineered bacteria. Due to biofabrication process that we developed, this hydrogel can contain living bacteria capable of producing more living ink or living bacteria can be removed during fabrication. This novel bacterial ink can be used for printing complex large scale materials with specific functions.

11:15 AM GI30.01.07
**3D Printing of Bacteria to Create Living Materials** Patrick A. Rühs; Department of Bioengineering, University of California, Berkeley, Berkeley, California, United States.

Despite recent advances to control the spatial composition and dynamic functionalities of bacteria embedded in materials, bacterial localization into complex 3D geometries remains a major challenge. Here we demonstrate a 3D printing approach to create bacteria-derived functional materials by combining the natural diverse metabolism of bacteria with the shape design freedom of additive manufacturing (1).

For 3D printing we use a recently developed multimaterial direct ink writing technique (2) which allows us to incorporate bacteria in biocompatible inks within the same 3D printed material. Our bioinks are designed by combining different hydrogels to form a paste-like ink, which after printing is crosslinked by low intensity UV light. To obtain accurate 3D printed structures, we determine the ideal rheological properties prior, during and after printing, demonstrating the effect of the printing steps on the bioink. With this approach we are able to obtain a hydrogel which supports bacteria growth while still maintaining a high shape fidelity in 3D printing.

We embedded bacteria in the biocompatible and functionalized 3D printing ink and printed two types of ‘living materials’ capable of degrading pollutants and of producing medically relevant bacterial cellulose. Furthermore, we demonstrate that bacteria proliferation is a function of viscosity and oxygen availability. By fine-tuning the single ink components, we adjust the viscosity to match the growth profile of our cells. With this printing platform, we envision the use of additive manufacturing materials combined together with cells to be used for new and biomedical applications.

11:30 AM GI30.01.08

It is well established that metal-respiring bacteria, such as Geobacter and Shewanella, perform extracellular electron transfer (EET) when grown as biofilms on the surface of electrodes. The electron transport (ET) proteins that enable this microbial electrical wiring in Shewanella have been identified and successfully expressed in *E. coli*, conferring an increase in the amount of current produced over the wild type background. The ability to rationally engineer EET processes in electrochemically active biofilms could result in leap-ahead technological advancements in biomaterials applications including microbial electrosynthesis, bioremediation, and microbial bioelectronics, specifically under austere conditions, such as the ocean. However, these applications are currently limited by a lack of understanding of the physiological constraints of the host bacterium (chassis) to properly and predictably express and orient ET proteins (e.g. c-type cytochromes) in the cell membrane, the ability to rapidly screen a large number of constructs for different ET pathways, and a library of operationally relevant chassis strains. In this talk I will describe results demonstrating the use of a suite of highly-optimized small molecule sensors (Marionette) developed for control over *E. coli* cellular processes to control expression of the *Shewanella* MtrCAB pathway, and accessory electron carriers, in *Marinobacter atlanticus*. First, Marionette sensors were transformed into *M. atlanticus* and assessed for expression of yellow fluorescent protein (YFP) after the addition of 7 different small molecules (choline, vanillin, naringenin, DAPG, cumate, tetracycline, and IPTG) during both planktonic growth and in the biofilm state. For most sensors, a broad dynamic range was observed similar to that demonstrated with *E. coli* when fluorescence was measured during log phase growth. Increasing fluorescence was also observed over time in biofilm associated cells as long as growth medium with small molecule inducer was continuously refreshed. When YFP was replaced with ET proteins, expression of MtrCAB led to an increase in current compared to the wild type strain when induced prior to inoculation into a bioelectrochemical system (BES). However, the effect was not robust enough for biosensing. Moving the MtrCAB pathway from a plasmid construct to the chromosome enabled more control over the quantity of protein expressed, however, no improvement in current was observed. When the same construct was tested in *Shewanella oninesenesis* MR1 lacking the native MtrCAB pathway, current was found to be inducible following biofilm formation. Based on these results, we conclude that although the MtrCAB pathway can be successfully expressed in *M. atlanticus*, further optimization of export of these proteins to the outer membrane and/or connection to the inner membrane electron pool may be necessary. Understanding these constraints will advance the development of engineered bio-electrochemically active biofilms for development of self-healing living materials for energy and next generation electronics for the marine environment.

SESSION GI03.02: Synthetic Biology—Aerospace Applications, Metals and Composites

Session Chairs: Anne Meyer and Petra Oyston
The DOD currently faces a broad range of materials challenges. The changing geopolitical environment has created a need for agile supply chains of critical materials and components. The push for miniaturization and light-weighting has created a need for precise and scalable assembly of materials with limited defects. Additionally, the diverse and challenging operational environments faced by the warfighter has created a need for multifunctional materials that can sense and respond to the human and the surrounding environment. Strategic utilization of synthetic biology has the potential to provide new materials capabilities that can address many of these critical challenges. This talk will highlight work being done in synthetic biology at the Air Force Research Laboratory, Materials and Manufacturing Directorate to enable new solutions to these challenges. Specifically, new strategies and pipelines for the discovery and engineering of novel enzymes and proteins that can be used in the production of critical material components will be discussed.

Microorganisms have the potential to manufacture metallic nanoparticles, irrespective of the source of metal cations, and provide us with new particles with novel functions. To exploit this we are identifying and optimising genetic elements with an aim to increase nanoparticle production and control nanoparticle size and homogeneity; in effect standardising nanoparticle samples by using biology. Whilst developing this process we are exploring its application in the treatment of contaminated waste, water and land. For the former application we are working to remove copper from whisky distillery by-products and for the latter application we are part of a larger collaboration aiming to financially incentivise land decontamination. After using phytoremediation to hyperaccumulate metal contaminants from the soil, plants are harvested, processed and used as a source of metals for bacterial nanoparticle synthesis. Both applications illustrate how synthetic biology might contribute to moving us towards a more sustainable circular economy.

Structural materials synthesized by organisms, such as bones, shells, and wood, exhibit remarkable mechanical properties due to their hierarchical assembly of hard and soft components across the nanometer to the micron scales. While engineering analogs to these materials would open new frontiers, there is currently no route to mimic the 2D hierarchical ordering of natural composites. Here we lay the foundations for bottom-up assembly of engineered living-material composites along the cell body using a synthetic biology approach and demonstrate the hierarchical assembly of these composites confers switchable mechanical properties. We engineer the surface-layer (S-layer) of Caulobacter crescentus to display peptides that permit covalent attachment of proteins, nanocrystals, and protein-based polymers to the extracellular surface without additional engineering. This cell surface binding is uniform, specific, and covalent, and its density can be controlled based on the location of the insertion within the S-layer. Using this platform, we construct composite materials composed of living C. crescentus cells crosslinked by nanocrystals. These ‘hybrid bacterial spheroids’ are 30 times more stiff than cell-nanocrystal composites lacking these crosslinks. Additionally, the stiffness of these composites can be changed dynamically by breaking the cell-nanocrystal crosslinking. Taken together, this work provides a platform for creating hierarchically-assembled living materials with switchable mechanical properties.
This talk will describe an approach for using mass spectrometry and arrays of self-assembled monolayers to perform quantitative experiments in high throughput. The arrays are prepared by individually immobilizing small molecules, proteins, peptides and carbohydrates to self-assembled monolayers of alkanethiolates on gold. This approach allows us to treat the same set of alkanethiolates in the same way in order to remove biological variability. This is particularly useful for screening the activity of enzymes and other molecular modulators. These examples illustrate the broad capability of the SAMDI method to accelerate the design-build-test cycle for materials.

Using this foundation, we have begun studying a promising target for engineering protein-based materials, sourced from the giant squid, called ‘suckerins.’ Suckerins are a class of structural proteins that form sucker ring teeth assemblies that display robust mechanical properties and thermoplastic behavior. We have begun utilizing the incorporated nCA to functionalize suckerin-protein nanoparticles with tuneable diameters between tens to hundreds of nanometers. Suckerins are a class of structural proteins that form sucker ring teeth assemblies that display robust mechanical properties and thermoplastic behavior. TUTORIAL: Life Cycle Analysis from an Industrial Perspective
November 25 - November 25, 2018

* Invited Paper

TUTORIAL
Life Cycle Analysis from an Industrial Perspective
Sunday Afternoon, November 25, 2018
Hynes, Level 2, Room 200

Environmental issues keep steadily increasing, thus there is a strong urge to discuss how materials scientists could more rapidly respond to the worldwide concerns. This joint tutorial effort would be organized by the three symposia together. To ensure the success of such synergistic efforts it is also urged a close dialogue with society so to establish guidelines for policymakers, thus this tutorial will incorporate both the societal and the engineering aspects of life cycle analysis (LCA) would be covered. The main objective of this tutorial is to explore communications pathways between companies and materials researchers that further elevate the profile and challenges of sustainability that represents a societal necessity and a viable and critical topic for research.

1:30 PM
Societal Aspect of LCA Jean-Pierre Birat; ArcelorMittal

Materials are not simply the product of an engineering discipline, Materials Science, but also "social constructs" that have entertained a close relationship with society all through the historical timeline and remain a core element of our modern world, what is called a Key Enabling Technology. How this can be analyzed by parallel approaches of hard and soft sciences will be explained in the class as well as the trystic of economic, environmental and social values of materials. Examples reported in the 13 past SAM conferences will be used as examples.

2:45 PM BREAK

3:15 PM
Engineering Aspect of LCA Alan Rae; IncubatorWorks

The instructor will provide an overview on all the aspects considered in a life cycle analysis aimed to the engineering design of an industrial process. A part of the tutorial will involve the interaction with the audience in order to apply some of the concepts described in the first part of the tutorials to common objects.

4:15 PM Sustainability Challenge

The symposia organizers will divide the participants into groups and a sustainability challenge will integrate the concepts presented by the instructors so to review and facilitate networking among participants and instructors

4:45 PM
Final Remarks

SYMPOSIUM BI01

Sustainable Development in Materials Science and Related Societal Aspects
November 26 - November 28, 2018
Thus we have to examine the conditions in which an outcome could be built linking these two issues. This implies to combine two ways of reasoning: the "properties" and "validity" ones which are self-referential and cannot immediately match or even fit.

Society representations, namely associations, are supposed to understand what should be understood. But benefits (or risks) of nanos could be differently assessed, according to professional experts or the difficulty) of defining what a benefit is. In a classical benefits/risks approach, benefits are often considered in a very technical way: professional experts generally supposed. In a perspective, notably in France, framed by "the imperative of precaution", researches on nanos are confronted to the necessity (and the difficulty) of defining what a benefit is. In a classical benefits/risks approach, benefits are often considered in a very technical way: professional experts are supposed to understand what should be understood. But benefits (or risks) of nanos could be differently assessed, according to professional experts or citizens points of views.

In particular, the benefits of a nanotechnology cannot be assessed only in accordance to its technical properties because properties are only part of the problem. As we can learn from the thematization process of risks, any innovation must be submitted to a validity test, which supposes taking into account social norms, notably that, progressively shaped by public debates, relating to the environment and health topics. Based on a social sciences research dealing with a medical nanotechnology and supported by the French CNRS and the Occitanie Region, we will show that a reasoned development of nanotechnologies must rely on, and combine two criteria: technical efficacy and some kind of legitimation by civil society representations, namely associations.

This implies to combine two ways of reasoning: the "properties" and "validity" ones which are self-referential and cannot immediately match or even fit.

Thus we have to examine the conditions in which an outcome could be built linking these two issues.
The Implementation and Role of Automation and Materials Acceleration Platforms (MAPs) in Material Science Jamie Thompson1,2, Gregory Whiting1 and Camille Petri1; 1NASA Ames Research Ctr, Mountain View, California, United States; 2Materials, Imperial College London, London, United Kingdom.

In the age of automation and cloud computing, scientific research has a huge opportunity to reassess its evolved methodology and reinforce some of its core values. Through the implementation of simplistic hardware, data acquisition systems, cloud-based data storage and non-traditional data analysis methods, a mostly automated scientific system is well within reach of most research laboratories. Aside from the obvious advantages of not having to manually operate an experimental apparatus, as well as increasing potential human error in the collected data, there are several key advantages to automating many day-to-day lab tasks. Topics around these concepts are discussed, and preliminary prototype systems for large-scale lab automation and collaboration are presented.

Using a materials laboratory as a testbed and assessing the processes by which we interact with our experiments, the modern scientific process is studied and critiqued. The question of where innovations during the experimental process occur is asked in order to more accurately predict what the role of humans in a rapidly accelerated form of science will be in the near and distant future.

9:45 AM BI01.01.04
A Bright Tomorrow—Design: STEM Teaching and Learning Through the Integration of Design, Material Science and Synthetic Biology Raymond Oliver; Northumbria University, Newcastle upon Tyne, United Kingdom.

Fashion and creative design are a window on how we have and how we will live. By 2099, we will understand how to design and fabricate materials at the molecular and biomolecular level. In between, the development of 3 and 4D bio-nano hybrid materials with functionalities similar or superior to Silicon will allow the evolution of ‘soft’ machines and programmable surfaces and interfaces with intelligence through associated informatics, VR, AR and AI providing tangible materials 2 materiality 2 material experiences. Putting these together, you create a powerful Design:STEM Interactive platform that can significantly influence and enhance both the fabrication and function of novel products and devices that can significantly effect everyone's Future Ways of Living.

The work described in this paper examines some of the ways in which creative design can guide and interact with materials science and material fabrication leading towards programmable material systems through integrated informatics that leads to innovation in ‘calm technology’ that is burdenless for the user. We will present evidence based examples drawn from our ongoing work as follows:

a) Ambient assisted living for both individuals and communities
b) Sensors, sensing and sentient behaviour for anticipatory healthcare and real time monitoring
c) The development of responsive surfaces and interfaces that serve as real time polyvalent interactive skins for ‘smart’ interior environments
d) Sustainable consumer product packaging through the replacement of synthetic polymers with polysaccharide based natural materials

In addition, we will provide Design:STEM insights from our work on the current research and teaching landscape within the School of Design at Northumbria. Finally, the three axes of Design, Materials and Biology are shown to be a very powerful way to address and collaborate with industry to solve identified compelling human centric needs that can significantly benefit everyday life through direct, multidisciplinary Studio, Lab and workplace learning.

Within the School of Design at Northumbria University, we are implementing new MRes masters courses that bring creative designers, material scientists and synthatic biologists together in a common research and teaching environment to accelerate teaching and making practice to address Design led, Needs driven, Materials anchored and solutions focussed Design:STEM Integration.

10:00 AM BREAK

10:30 AM *BI01.01.05
Research, Teaching and Outreach as Examples of Helping to Go Towards a More Sustainable Future Ivana Aguiar1, Maria E. Perez Barthaburu2, Mauricio Rodríguez Chialanza3 and Laura Fornaro2; 1Grupo de Desarrollo de Materiales y Estudios Ambientales, Área Radioquímica, Facultad de Química, Universidad de la República, Montevideo, Uruguay; 2Grupo de Desarrollo de Materiales y Estudios Ambientales, Departamento de Desarrollo Tecnológico, Centro Universitario Regional del Este, Universidad de la República, Rocha, Uruguay.

We are a research group devoted to materials science research since 2000, and we work in the three aspects of Uruguayan University teaching profession: research, teaching and outreach. We started working on ionizing radiation detectors, but through the years our work has evolved to adapt ourselves to our country’s reality. In 2011, 44% of Uruguayan electricity came from fossil fuels, with a strong dependence on foreign countries. Today, we are self-sufficient and 95% of our production comes from renewable sources, mainly wind and hydroelectric. Our group aligns with this policy, developing semiconductor nanostructures for hybrid polymeric-inorganic solar cells. Another remarkable aspect of our country is that water is a resource widely available, but in the last years the quality of our water has aggravated mainly due to bad agricultural practices. In this line, we develop semiconductor nanoparticles for tertiary treatment of water.

We put a lot of effort, not only in research to develop a more sustainable country, but also in teaching and outreach that helps to create consciousness in the population about new technologies and also to give them tools to create their own opinion. Regarding to teaching, in the last year we embarked on a challenging project to change the traditional lecturing courses, in our Introduction to Nanotechnology course. We decided to introduce the Problem Based Learning approach together with collaborative work with emphasis in sustainability issues, to anchor the assessment in performances directly related to the discipline. Moreover, the course design included face-to-face and virtual activities. At the end, the students increased their commitment and showed a deeper understanding of the topics.

Regarding to outreach, we have been working to bring materials science activities to schools and high schools for over 10 years. We started this path with small steps, performing isolated activities in the Science and Technology Week frame. Afterwards, we carried out different outreach projects, such as “Materials that surround us” and “Materials in our home”. In all our activities, we always carry out hands-on activities and try to emphasize how materials have had a major role in human kind development.

Although the availability of funding has been irregular and there are difficulties to sort out, we believe that the best way of improving materials science in our country and to contribute to a sustainable development is through the education of young students, therefore, we plan on continuing this kind of activities in 2019 and beyond.
To promote sustainable development, we must thoroughly understand the landscape ourselves. The Energy and Sustainability Engineering program at the University of Illinois (EaSE.illinois.edu) was launched with a considerable focus on the possibilities for, and fundamental limitations on, improved efficiency in energy conversion and materials use from a life cycle perspective. We have found, however, that the major challenge faced by our graduate students is not technical understanding, but how to articulate problems and potential solutions in the “big picture” context of development and deployment. The recent books by M. F. Ashby (Materials and the Environment, Materials and Sustainable Development) are among the resources that provide a clear conceptual framework and specific approaches for analysis.

We therefore challenge our students to define the following aspects of any proposal intended to improve sustainability. (i) What are the different objectives at play and the constraints on each one? (ii) What is the quantitative scale of the proposal in terms of technology to be deployed, spatial region and timescale? What does this imply in terms of the materials supply chain? (iii) Does the proposal depend on cost reductions as the technology matures? If so, what is reasonable to expect? (iv) What are the inevitable tradeoffs between the objectives – as well as the unintended consequences – and how should those tradeoffs be valued? (v) Who are the important stakeholders, and how should they be engaged? (vi) What are the demands for financial investment and the probable return on investment? How are these influenced by the hidden cost of externalities (which tends to favor investment in sustainability) and by economic discounting (which emphasizes short-term gains over lifecycle impact)?

In summary: we find that to advance sustainability, scientifically trained professionals need to construct and articulate a comprehensive and compelling business case around the technical possibilities made possible by engineering. I will provide key examples of the above challenges, the ways we attempt to provide insight, and welcome discussion with the audience.

11:30 AM B101.01.07
Can Materials Science Save Us (From Ourselves)? Mark A. Miodownik; University College London, London, United Kingdom.

Despite the long history of materials development, materials science as a distinct discipline is relatively new. It only came of age in the 20th century, brought into existence by necessity, as a result two developments. Firstly, industry needed it to understand the complex materials, on which it and society, was becoming ever more dependent such as the silicon chip, jet engine alloys, polymer composites, optical fibres, medical implants, etc. Secondly, it became increasing clear that materials could not be understood by the study of engineering, physics, chemistry or biology alone. So, as the 20th century progressed, so did materials science as a discipline.

We now live in the 21st century and the power of materials science is immense. It is making possible a world where buildings harvest their own energy, bridges heal themselves, clothes monitor a person’s health, and biomaterials increase the average life expectancy to 100 years of age. This all sounds thrilling, but many alternative realities await us, each driven by different cultural, economic and political forces. In these alternative realities, we could find ourselves in the grip of mass migrations, with declining life expectancy, dealing with global pollution and energy blackouts, to name but a few potential scenarios. Which future will we choose?

In this talk, I argue that much hinges on a deeper understanding by materials scientists of all parts of society. To achieve this, public engagement is not enough, the core of the discipline needs to move beyond its current limits in the physical sciences, to a more people-focused approach to materials design and manufacturing. From an educational perspective, this will require understanding of, or at least an acknowledgment of, the importance of psychology, economics, politics and materials culture. I use a case study of the development of self-repairing cities to illustrate the necessity of such changes to materials science as a discipline.

11:45 AM B101.01.08
Engineering Major Students’ Perceptions of Nanotechnology Haci H. Yolcu; Kafkas Univ, Kars, Turkey.

Nanotechnology will be among the most needed workforce areas in the near future. It is also a creative and highly dynamic field of innovative research areas that displays numerous open fields for future graduates. The central thesis of this paper is to better understand undergraduate engineering students’ awareness, exposure, and motivation towards nanotechnology, how those constructs correlate with each other, and whether there are differences by gender or year of study. This exploratory study used mixed methods to answer the research question. Results revealed that engineering students have more motivation to pursue further nanotechnology knowledge or study than they have exposure or awareness about nanotechnology. The results showed that male students have more awareness about nanotechnology than female students. Educational implications are that it is necessary to provide students with more opportunities to learn about and study nanotechnology during their undergraduate experience. While students are interested in learning more, their current levels of awareness and exposure may hold them back in pursuing nanotechnology-related careers.
help in the process of material selection for product design projects.

The Sustainable development 5-step methodology [2] developed by Prof. Michael F. Ashby and Dr. Didac Ferrer, which helps students structure their analyses of the sustainability of a technological development will also be presented. Drawing on data in CES EduPack [1] the methodology encourages students to identify the scope of a development and the stakeholders involved, before fact finding on different aspects and pulling together the newly gained knowledge into a considered opinion.

Alongside the materials selection tools that are a standard part of CES EduPack and can illustrate trade-offs in price and performance, these tools and methodologies help students see the bigger picture around their material decisions.

2:00 PM *BI01.02.02
Focusing on Sustainability—Raising Awareness of the Materials–Sustainability Nexus Ashley White1, Ivana Aguiar2, Jonathan Cullen3, Martin L. Green4, Anthony Ku5, Elizabeth Kupf6, Alan Rae2, Julie M. Schoemung7, Richard Souza8 and Margeaux Wallace9, 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Universidad de República, Montevideo, Uruguay; 3University of Cambridge, Cambridge, United Kingdom; 4National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 5National Institute of Clean-and-Low-Carbon Energy, Mountain View, California, United States; 6The Pennsylvania State University, University Park, Pennsylvania, United States; 7IncubatorWorks, Painted Post, New York, United States; 8University of California, Irvine, Irvine, California, United States; 9Materials Research Society, Warrendale, Pennsylvania, United States; 10GE Global Research, Niskayuna, New York, United States.

As technology enablers, materials play a pivotal role in solving the key challenges our society will continue to face, such as carbon dioxide mitigation, access to clean energy and water, and a dependable supply of raw and recycled materials for infrastructure, devices, and consumables. Meeting these challenges will require new approaches to materials science as well as expertise from related fields, including other scientific and engineering disciplines, sociology, economics, and policy. In recognition of the complexity of tackling sustainable development issues and the importance of materials to enabling solutions, the Materials Research Society (MRS) Board of Directors approved the creation of the Focus on Sustainability Subcommittee of the Public Outreach Committee. The subcommittee’s formation was an important step in the evolution of MRS’s sustainability-related programming and other activities.

This talk will cover the history and evolution of sustainability efforts within MRS, concentrating on the recent impacts of the Focus on Sustainability subcommittee. Its activities have included professional development seminars and workshops, symposia and tutorials, a dedicated booth at MRS meetings, industry panel discussions, hands-on activities, poster sessions, and a series of high-profile panel events organized in collaboration with the MRS Energy & Sustainability journal entitled “Materials for Energy Sustainability by 2050.”

Moving forward, the challenge for us as sustainability enthusiasts is to engage and integrate with the broader materials science community and other related disciplines. Towards that goal, this talk will discuss newer efforts to involve the broader MRS membership in our sustainability activities, raise awareness of the materials–sustainability nexus, and bring a higher level of understanding of the role different materials sub-disciplines play in sustainable development—the defining challenge of our time.

2:30 PM OPEN DISCUSSION

2:45 PM BI01.02.04
PodQESST—A Case Study for a New Form of Science Communication Sebastian Husein, Joseph Karas, Michelle Jordan and Marianna I. Bertoni; Arizona State University, Tempe, Arizona, United States.

This talk will showcase a form of communication severely under-utilized in the scientific community—namely, podcasts. Podcasts are an audio file made digitally available on the internet, typically accessible to anyone by computer or mobile. While early forms of this communication medium have been available since the 1980s, modern podcasts have grown rapidly in popularity since 2004 [1]. Reports estimate over 44% of the U.S. population over the age of 12 has listened to a podcast, with 80% of listeners following an average of 7 podcasts per week [1]. Podcasts are therefore rapidly becoming one of the largest information dissemination methods. Scientific communities must begin engaging at the intersection of podcasting and social media networks, which have become essential in circulating information [2].

Currently, scientific research is often locked away in niche websites and academic journals, with much of the research process (i.e., development of experiments, analysis of collected data, and peer review) obscured by technical jargon and complex topics. While some scientific achievements may spread into popular culture and news, most Americans receive science news by “happenstance rather than intentionally” with only ~17% both actively and frequently seeking it out [3]. To maximize positive societal impact, the scientific community must actively pursue new forms of science communication to both inform the general public and open dialogue between researchers and those potentially impacted by the research.

Through podcasts, collection and dissemination of scientific knowledge can follow a story-telling format. Our podcast, PodQESST, hosted by two Ph.D. students, examines the research process by following the human experience. Rather than discussing complex scientific concepts, this podcast interviews graduate students and research professors about how their work evolved, from conception to process, and in some cases, to real-world implementation and influence. By using this story-telling format, research work and scientific advancements can become relatable to audiences with little to no scientific background. Additionally, communities of current graduate student are potentially strengthened through this shared experience and may impact retention rates in STEM, enhancing workforce development. The impact of this podcast on perception of science and interest in STEM careers is currently being tracked among pre-university students and university students from 8 U.S. institutions partnered through the Quantum Engineering and Sustainable Solar Technology (QESST) Engineering Research Center.

How Can Sustainability Become Tangible? Serious Games and Digital Tools Help Learners Develop Sustainability Competences Vasiliki Kioupi; Imperial College London, London, United Kingdom.

Sustainable development is a complex concept, but it is also powerful and transformative. In order for students to make sense of its holistic, interdisciplinary and participatory nature they should become engaged in meaningful educational activities that reveal interconnections between social,
economic and environmental aspects, take into account stakeholder viewpoints and at the same time assist them to develop sustainability competences. Serious games and digital tools for sustainability help shape students’ attitudes when making important decisions regarding sustainability and also think systematically and critically about taking courses of action and evaluating them. In contrast to games designed predominantly as free-time activities taken up for leisure or competition, serious games may be played seriously or casually, but are not intended to be played primarily for amusement. This definition of serious games embraces both digital and analog games whose focus is on a “serious” goal, be it education, skill training, self-development or increased work motivation, etc. Game-based and experiential learning are fun and creative, giving the opportunity to participants to experience real-world situations but in a safe and controlled environment where they can test their ideas, express their opinions, develop strategies and check the outcomes. Also, the focus is on engagement, interaction with peers and reflection on the results and processes. Digital tools help students develop their own questions and hypotheses related to sustainability issues, investigate their current state, understand stakeholder involvement, select alternative courses of action, develop criteria for evaluation and weigh different scenarios in terms of their sustainability capacity to produce viable solutions. Through these educational activities, students develop important knowledge and skills that are required in order to achieve the vision of a sustainable society as it is articulated by the Sustainable Development Goals (SDGs). Those include systems thinking, anticipatory, normative, strategic, collaboration, critical thinking, self-awareness and integrated problem-solving competences.

Responsible Research and Innovation—Some Societal and Ethical Issues
Joelle Lischetto-Alnot; Univ of Lorraine, Nancy, France.

Today, the concept of “responsible research and “responsible innovation” (RI) is one of the main preoccupations in the field of science and technology studies. If nanomaterials and nanotechnologies have of course opened hope for a better quality of life in our societies with a lot of progress and applications, they are not without asking some questions regarding their potential effects, toxicity, and by the way, some ethical issues. Recurring debates shake not only the scientific community, but also citizens, leading sometimes to controversial and contradictory positions. The traditional balance cost-benefit, and the classic “precautionary principle”, gave way to an “uncertainty principle”, and the necessity of considering differently nowadays the question of risk and safety. In fact, if we want to avoid a gap between researchers and citizens, science and society should not be regarded as two distinct spheres, and the way for that is rather to establishing a better and more trustful relationship between science and society. In order to achieve this objective, one of the outcomes could then consist in promoting an interdisciplinary dialogue. In the European Union (UE), responsible research and innovation is becoming an increasingly part of policies, particularly throughout the EU’s Horizon 2020 research work program “Science with and for society” (2018-2020): the challenge is, facing to the evolution of science and society and the open science context, to develop innovative ways connecting science to society, through an inclusive

4:30 PM BI01.02.07
Pathway Toward Sustainable Development of Next Generation Photovoltaics—A Detailed Study on Research Trends Through Social Network Analysis
Jun-Seok Yeo and Yeseul Jeong; Korea Institute of S&T Evaluation and Planning (KISTEP), Seoul, Korea (the Republic of).

Organic-inorganic hybrid perovskite solar cells (PeSCs) have attracted great attention as next-generation photovoltaics due to their high efficiency, low manufacturing cost, facile solution-processability, light weight, and mechanical flexibility. Since the advent of the PeSCs, the researchers have devoted a lot of efforts to improve the PeSC-performance, boosting the progress in the power conversion efficiency (PCE) of over 20%. This progress has gradually shifted the focus of the PeSC research to study of reliability and cost-effectiveness of the PeSCs. In this study, we systemically investigate these research trends of the PeSCs for their sustainable development and market entry by using ‘Social Network Analysis (SNA)’. For SNA data, SCI(E) papers on PeSCs published from 2009 to 2017 are collected, and classified into two categories (research fields and commercialization factors). Next, we conduct respective networks visualization, networks topological analysis, and node centrality analysis. With the aid of SNA, the technology and knowledge networks (flows) for PeSC research fields are investigated in terms of countries, research institutions, research fields, and commercialization factors.

4:45 PM SYMPOSIUM WRAP-UP DISCUSSION

SESSION BI01.03: Sustainability in Industry and Agriculture
Session Chairs: Jean-Pierre Birat and Khosrow Ghavami
Tuesday Morning, November 27, 2018
Sheraton, 3rd Floor, Hampton

Self-Healing Polymers Using Reversible Supramolecular Metal-Ligand Interactions
Ulrich S. Schubert, Stefan Zechel, Marcel Enke, Stefan Götz and Martin D. Hager; Friedrich-Schiller-University Jena, Jena, Germany.

Metallo-supramolecular polymers are an interesting class of polymeric materials since they combine the typical character of metals and polymers leading to novel and outstanding features. Furthermore, metal-ligand interaction can feature a reversibility of the binding enabling the design of novel self-healing materials.[1]

For this purpose, terpyridine moieties were incorporated into the side chain of different copolymers using the RAFT polymerization technique.[2,3]

Subsequently, metallo-supramolecular polymer networks were prepared by the addition of different metal salts.[4] The healing of the metallopolymers strongly depends on the chosen metal salt. In particular, the metal as well as the counter ion has a strong impact on the healing behavior.[3] Interestingly, the crosslinking with manganese(II) chloride resulted in the best scratch healing ability (Figure 4). Furthermore, the metallopolymers were studied by temperature-dependent rheological measurements and the supramolecular bond life-time (τb) was determined by the crossover of G’ and G”[A correlation between the presence of the crossover as well as the ability to close cracks could be revealed. Thus, the mechanical properties could be correlated with the self-healing performance of supramolecular networks.[3]

8:15 AM BI01.03.02
The Biomaterial Age Javier Gomez Fernandez; SUTD, Singapore, Singapore.

The history of humanity can be summarized in different periods dominated by the use of a new material bringing a new paradigm and a revolution in engineering, becoming in a short time the engine of development of that historical period. The ages of stone, bronze and iron are clear examples of how certain materials have transformed society and its economy. Nowadays the equivalent to these materials is plastic. Driven initially by a continuous demand from the WWII, the production of plastic began a vertiginous development, finally surpassing in production to all the rest of materials used outside the field of construction in the decade of the 60s.

The first voices of alarm about the impact of plastic on the environment occurred also in the 60s, with the first observations of the accumulation of plastic waste in nests of seabirds. While these early studies were anecdotal and remote for most, today virtually no one is unaware of a problem in continuous growth. We are in a difficult situation; as a society we have developed a greater awareness of the impact of our actions on the environment in general, and the impact of plastic in particular. Moreover, unlike other environmental problems, the problem of plastic is indisputably anthropogenic and easily observable. However, the production of plastic it is accelerating. If in the 50s, we were producing half a million tons of plastic a year, now we are close to the five hundred million tons. At the current rate in 2050 we will double that amount, requiring one fifth of the world's oil production to produce plastic. The apparent failure to produce feasible solutions, both by scientists and legislators, is mainly because the solutions being considered implicitly assume that humanity has reached a kind of technology summit with the invention of plastic and its methods of manufacturing. As legislators we fail because, in the absence of alternatives, we can only limit very specific uses of plastic. As scientists we are failing because we are trying to find materials that replace plastic to make objects that have not been designed to be made with plastic. Moreover, not only the objects, in our search for solutions we also impose the mode of manufacture of the plastic and that is the basis of our industrial system. We mistakenly assume that necessity is the motor of development, but the question we should be asking ourselves is not how can we change an economy and society molded around plastic to get rid of our addiction to it. The question should be: What comes after the plastic and what kind of society will it bring? In this talk we will explore the role that biomaterials will play in the future of manufacturing and the emergence of new economic models, giving rise to what we have called "the biomaterial age". The role of bio-inspired engineering, 3D printing, or new models of organic waste processing will be covered as key pieces in this transition.

8:30 AM BI01.03.03
IMERYS—Sustainable Development for Innovative Mineral Based Solutions Claire M. Theron; External Innovation, IMERYS, Suwanee, Georgia, United States.

Imerys is the world leader in mineral-based specialties for consumer goods, industrial equipment and construction. Its Corporate Social Responsibility is central to the Group's long-term strategy, supporting growth and underpinning long-term relationships with all stakeholders.

While Imerys operates on a global level, the group is committed to play a role in society, to meet its obligations to the countries and communities within which it does business by empowering our people, caring for our planet and building for the future together with our stakeholders. Through these commitments the Group contributes to sustainable development and foster positive changes including regional projects covering education, sanitation, health and diversity, renewable energy, and biodiversity such eradication of invasive species, preservation of protected species.

Following main international standards, in-house Sustainable Development (SD) Challenges have yielded 847 projects during the last 13 years. Those projects are aligned with Imerys high priority areas, such as diversity and inclusion, education, environment management, climate change and relation with communities. The group’s commitments in Imerys Code of Ethics and Business Conduct and CSR Charter are available to all detailed in policies, procedures and protocols gathered on Imerys intranet.

An example of Imerys contribution includes lightweighting of vehicles by delivering functional additives (High Aspect Ratio talcs) to polymers industry. The 3G HAR® product enables weight reduction of the automotive plastic injection-molded parts while its production uses 63% less electricity than previously. Imerys is also active in cosmetics, offering its ImerCare® range is P-Scrub, product using 100% natural minerals designed as an eco-friendly alternative to plastic microbeads.

In agriculture, Imerys Mechanical Insecticides offer three natural mineral solutions, based on diatomaceous earth or kaolin (DiaFil® 610, Celite® 610 and IMERGARD™) which provide effective environmentally friendly solutions.

Building on existing systems and initiatives and going beyond compliance, a program fully aligned with the United Nations' Global Compact and Sustainable Development Goals is being implemented. The ambition is clear: anchoring sustainable development at the heart of the Group's overall strategy and mobilizing employees at every level to achieve Corporate Social Responsibility targets.

9:00 AM BI01.03.04
Sustainable Construction Materials for XXI Century Khosrow Ghavami; Pontificia Universidade Catolica de Rio de Janeiro, Rio de Janeiro, Brazil.

New constructions are being erected scraping the skies with nearly 1000m high. And still in spite of all the advances a large percentage of people of the world live in misery without the minimum of nourishment, clean drinking water and decent housing. Industries are demanding more and more raw materials, existing now mainly in developing countries and creating havoc on earth searching for and exploiting the lands holding these needed raw materials. Nature is responding with climate changes, freak storms and other disasters. The big centralized industries are not able or rather not willing to stop polluting our environment by reducing carbon emissions. Their ambition is to be the owners of the Earth, and do what they think is good for their bottom line, and not the working people of the planet. Now, sustainability goes together with moderation, meeting basic needs and a general well-being of the population. Sustainability of our environment makes possible that a greater part of the population can follow up a life’s dream or at least ability to have a decent meaningful life through preserving remaining natural resources available for the future generations. In schools and universities, yet, only the industrial non-renewable materials such as cement, concrete, steel and recently composites made of polymers research and application. The study of Non-Conventional Materials and Technologies, NOCMAT, has been started in the years of the seventies of the last century. A new line of research has been initiated to investigate local renewable materials such as bamboo, vegetable fibers, soil composite, which is called Kah-gel in Persian language. These materials have been used as construction materials for thousands years, recycled materials, such as rice husk and sugar cane ash among others. This paper will present the recent results of research on NOCMAT and their application in practice. To improve the durability of the studied materials, nano-particles applied in kah-gel and also impregnated into bamboo culm. To achieve the final objective to tune a fine nanocoating of vascular bundles’ of bamboo, internal wall has been done through the interfacial compatibility, based on self-assembling interactions, between the NFs-surface and the lignin-cellulose walls of bamboo vessels.
The lithium-ion battery (LIB) recycling market is becoming increasingly important because of the widespread use of LIBs in every aspect of our lives. Mobile devices and electric cars represent the largest application areas for LIBs. Vigorous innovation in these sectors is spurring continuous deployment of LIB powered devices, and consequently more and more LIBs will become waste as they approach end of life. Considering the significant economic and environmental impacts, recycling is not only necessary, but also urgent. The WPI group has successfully developed a closed-loop recycling process, and has previously demonstrated it on a relatively small scale 1kg spent batteries per experiment. Here, we show that the closed-loop recycling process can be successfully scaled up to 30kg of spent LIBs from electric vehicle recycling streams, and the recovered cathode powder shows similar (or better) performance to equivalent commercial powder when evaluated in both coin cells and single layer pouch cells. All of these results demonstrate the closed-loop recycling process has great adaptability and can be further developed into industrial scale.

9:45 AM BI01.03.06
Reclaiming Sb Metal from Lead Alloy with Electrochemical Method Qiang Wang; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Antimony is a widely used element in human’s daily life. For example, Sb2O3 plays role as flame retardant in plastics, coatings, and electronics; functioning as a hardener, 2wt % to 7wt % of antimony metal is added into lead metal to fabricate electrode for lead-acid battery; and antimony can work as catalyst for synthesizing chemicals. In 2016, antimony mine production in the word was 130,000 t, and China, the leading producer, accounted for about 76.9 % of the production. The strong dependence of antimony industry on the import of Chinese antimony drives USA and Europe to seek solution of reclaiming and recovering antimony from secondary resource. Herein, an innovative method composed of electrochemical and chemical reactions is proposed to purify antimony from lead alloy, which is treated as anode in an “H” shape electrolytic cell. Stainless steel sheet works as cathode, and potassium hydroxide solution is applied as electrolyte. O2 is purged into the cathode at the beginning, and the electrolytic cell works in the principle of metal-O2 battery, when voltage is applied on the two electrodes. Lead, antimony, and other metals dissolve into the electrolyte as ions at the first stage. When the ions inside the electrolyte accumulated to a certain amount, O2 is switched off without interference of the electrolysis. At this second stage, lead alloy of the anode dissolve into electrolyte successively, but lead metal deposits on cathode side simultaneously. Lead ions concentration stops increasing, and antimony ions concentration keeps on rising. When antimony concentration is high enough, the electrolysis is stopped, and Na2S is added into the electrolyte to precipitate lead ions in the stage 3. Almost all the lead can be removed from electrolyte, leaving antimony inside, by taking advantage of the low value of Ksp (PbS). At the last step, antimony can be extracted from the electrolyte at low potential of -1.25 V (vs Hg/HgO), leaving other impurity, such as As, Sn, Al inside with low concentration under 50 ppm. The electrolyte can be re-used for the next circle. This flow sheet can purity lead and antimony metals from lead alloy, with lead purity of 99.2 wt% and antimony purity of 92 wt%, and antimony recovery efficiency is ~ 82%. Because the electrolyte can be used repeatedly, no waste is generated in the whole process.

Stage 1. Cathode: O2 + 4e- + 2H2O → 4OH- (1)
Anode: Pb + 4OH- - 2e- → PbO2 + 2H2O + SbO2 + 2H2O (the main oxidation reaction) (2)
Sb + 4OH- - 3e- → SbO2 + 2H2O + SbO2 (3)

Stage 2. Cathode: PbO2 + 2H2O + 2e- → Pb + 4OH- (4)
Anode: Pb + 4OH- - 2e- → PbO2 + 2H2O (the main oxidation reaction) (5)
Sb + 4OH- - 3e- → SbO2 + 2H2O (6)

Stage 3. PbS + S2 → PbS4 (7)
Stage 4. Cathode: 4OH- - 4e-→ O2 + 2H2O (8)
Anode: Sb2O3 + 2H2O + 3e- → Sb + 4OH- (9)

10:00 AM BREAK

10:30 AM BI01.03.07
Cellulose Nanomaterials in 3D Printing and Aerogels—High-Performance Nanocomposites Rigoberto C. Advincula; Case Western Reserve University, Cleveland, Ohio, United States.

Sustainable and renewable materials start with the use of biobased feedstocks or derived raw materials for direct utilization (little conversion or synthetic procedures). The preparation of nanocellulose materials from a variety of sources include agricultural, non-agricultural, and can vary in properties depending on the method of preparation and high fiber source. Cellulose nanocrystals (CNC) and cellulose nanofibers (CNF) have various uses for the fabrication of polymer nanocomposites, making them useful as an additive for improving thermo-mechanical properties and perhaps improving processability. In this talk, we will focus on the use of CNC derived from various sources, Abuaca, coconut fibers, miscanthus grass, mango seeds, etc. The mode of raw materials can be from processed pulp or directly from the agriculture or plant source. These nanofiller materials have been utilized in two types of applications: nanofiller materials for 3D printed parts via SLA, FDM, or VSP and the preparation of smart aerogels with nanoclay. The former enabled strengthening of the thermo-mechanical properties of the 3D printed object and the latter results in a highly porous lightweight media useful also for oil-water separation and clean-up. The talk will discuss the methods of synthesis, fabrication, and characterization for their intended application and a pathway of high value adding from sustainable materials and its societal and technopreneurship impact.

10:45 AM BI01.03.08

There were approx. 1.2 billion motor vehicles in the world in 2015 and industrial forecasts predict the number of cars may reach 2 billion cars globally by 2035. Even with an increasing development of Li-ion technology, lead-acid batteries (LABs) remain the most popular power supply for automotive industry and there are no signs of decline in this market as LABs are also present in state-of-art hybrid and fully electric vehicles. A major challenge facing the lead-acid technology is, however, its toxicity and the environmental impact of lead. To address these issues, we need to develop novel processes to recover high value of lead from spent lead acid batteries. It is critically important to develop sustainable methods with a minimal pollution and low energy consumption in comparison with the traditional smelting and hydrometallurgical routes. We propose a process where Pb-containing battery waste is dissolved into deep eutectic solvents (DES), followed by an electrochemical recovery of metallic lead to provide a low-energy, low-temperature and an environmentally friendly alternative to recycling of spent batteries. In our work, cyclic voltammetry and chronoamperometry were used to determine the mechanism and electrodeposition behaviour of lead, while ICP-OES and EXAFS provided insight into speciation of lead in DESs, and SEM and XPS were used to characterise the lead electrodeposits.

Closed Loop Recycling of Electric Vehicle Batteries to Enable Ultra-High Quality Cathode Powder Mengyuan Chen, Xiaotu Ma and Yan Wang; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

The lithium-ion battery (LIB) recycling market is becoming increasingly important because of the widespread use of LIBs in every aspect of our lives. Mobile devices and electric cars represent the largest application areas for LIBs. Vigorous innovation in these sectors is spurring continuous deployment of LIB powered devices, and consequently more and more LIBs will become waste as they approach end of life. Considering the significant economic and environmental impacts, recycling is not only necessary, but also urgent. The WPI group has successfully developed a closed-loop recycling process, and has previously demonstrated it on a relatively small scale 1kg spent batteries per experiment. Here, we show that the closed-loop recycling process can be successfully scaled up to 30kg of spent LIBs from electric vehicle recycling streams, and the recovered cathode powder shows similar (or better) performance to equivalent commercial powder when evaluated in both coin cells and single layer pouch cells. All of these results demonstrate the closed-loop recycling process has great adaptability and can be further developed into industrial scale.
The reform of CO2 through photocatalytic processes to obtain products with high energy value and compatible with the current energy infrastructure, is a compelling strategy to minimize the emission of CO2 at atmosphere, one of the main greenhouse gases. However, practical application of such a photocatalytic system requires significant efforts for improved CO2 photoreduction performance and product selectivity. Thus, in the present work, CuO nanoparticles were combined with Nb2O5 in order to improve the photocatalytic properties of these semiconductors in the CO2 photoreduction process. The Nb2O5/CuO heterojunctions were prepared via solvothermal treatment method, while that experimental tools, such as FESEM, HRTEM, and DRS were employed to evaluate the microstructural and electronic properties. The physicochemical properties of the Nb2O5/CuO heterostructures were characterized and evaluated in the ability of the CO2 photoreduction with different electrolytes (pure water, sodium oxalate, and KBrO3) under ultraviolet radiation (UVC). The use of these electrolytes besides conducting the formation of a certain product enables the elucidation of the mechanisms of the CO2 photoreduction process. Further, the Nb2O5/CuO heterostructures was active also to CO reduction in CH4, HCOOH and CH3COOH, besides this result demonstrated that CO is intermediate in the CO2 reduction to all products. The synthesized heterostructures showed photocatalytic activities superior to the pure Nb2O5 and the TiO2 (P25). This improvement could be attributed to the formation of junctions between CuO and Nb2O5, which facilitated charge transfer, and suppressed the recombination of electron/hole pairs. The FESEM and HRTEM analyzes show that CuO nanoparticles were uniformly distributed on the surface of Nb2O5, showing the formation of a junction between the oxides.

Why Non-Conventional Materials are Answers for Sustainable Agriculture Caue Ribeiro de Oliveira; Brazilian Agricultural Res Corp, Sao Carlos, Brazil.

Fertilizers undoubtedly are key factors for agricultural productivity, but their widespread use is continuously impacting the farmers’ economic balance and, indirectly, being associated to many environmental impacts – such as volatilization or lixiviation. These impacts might be significantly reduced if the nutrients could be supplied in constant, controllable rates – as controlled release systems – however any technological alternative should be capable to offer affordable prices and large production scales, since these are often applied in hundreds of kgs per hectare. Therefore we have proposed a strategy to produce composite fertilizers where the matrix is composed by nutrients, i.e., all the constituents play a nutritional role for plants. This strategy allows, for instance, the controlled delivery of phosphate from hydroxyapatite nanoparticles dispersed in a nitrogen-rich matrix (even urea or partially polymerized urea). Recently, we noticed that similar strategies are applicable to sulfur (S), often neglected about its importance as nutrient. The production of S-rich polymeric matrices, using elemental S and biopolymers, provide means for multiple nutrient administrations, by integrating these nutrient matrices to mineral phosphates as dispersed nanoparticles as composites. This structure was shown as very adequate for microorganism colonization (e.g. A. niger), which accelerates the S oxidation to sulfates (which are properly absorbed by plants) while imposes a local acidification solubilizing the mineral phosphates to absorbable species. This complex system can be extend to other structures, keeping very high total nutrient contents (higher that 30% wt) and easy processing steps, since these features allows the fertilizer production by high-output techniques such as extrusion.

Sustainable Crop Protection Management in Sub-Saharan Africa Through Biodegradable Seed Wraps Tahira Pirzada and Saad A. Khan; Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Plant parasitic nematodes are one of the major constraints on yield and production of food crops throughout the world. While abamectin has broad nematicidal activity, its poor mobility in soils compromises its efficiency against nematode infestation. Using abamectin as a model pesticide, we present an innovative and cost effective approach for crop protection from plant parasitic nematodes, using a lignocellulosic matrix ‘wrap and plant’ methodology. In our ‘wrap and plant’ approach, we have used abamectin loaded matrices as wraps for seeds to be planted in the soil. To better understand the effect of various processing parameters and nature of the pulp on final properties of the matrix, we have produced lignocellulose matrices using pulp refined at various time intervals. Resulting hand sheets are characterized by the controlled release of abamectin which is incorporated into the matrices through sorption. Pulp refining time as well as various physical and chemical properties of the matrix are found to affect its tendency to let the germinating roots penetrate it and also the release rate of abamectin. We perceive that by varying refining time of the pulp, we can obtain matrices that facilitate in slow and sustained release of abamectin which results in long term nematicide protection to the growing plant roots. We have used these results to develop pilot scale paper rolls which are currently used in field trials in various regions of Africa and initial field trials demonstrate promising results regarding better crop protection in nematode infested soils in Benin and Kenya.
The INEMI project on Value Recovery from Used Hard Disk Drives (HDDs) is an industry-academia-government lab-NGO partnership whose vision is creating a global, circular economy for HDDs. Hard disk drives have a special role in electronics: they are ubiquitous, having been designed to be replaceable and interchangeable in products as diverse as computers, servers, and sensor/monitoring equipment. In Phase 1 of the project, an INEMI multi-stakeholder team developed the groundwork and created a momentum for a Phase 2 collaborative project to build an integrated, sustainable, adaptive CE system for end-of-use HDDs. The project framework has been modeled after sustainable management of common pool resources on which many people rely for their livelihoods. Dr. Elinor Ostrom (2009 Nobel Laureate in Economics) laid out a framework for how people and organizations develop voluntary, community-based solutions involving adaptive, self-governing systems that effectively manage common pool resources without the need for government regulations or privatization. We have applied this framework explicitly to HDDs, as a first demonstration. Phase 1 was built on stakeholders identifying decision pathways for HDD refurbishment, component reuse, and material recovery, incorporating economic and resource recovery analyses, and identifying how they interplay. The Phase 1 findings showed the existence but not the value recovery based on these decisions and established the basis for a more effective, implementable system. The Phase 2 team included a broad cross-section of electronics stakeholders necessary for a working CE supply chain: HDD designers and manufacturers, different types of users/owners (and discarding) of HDDs, IT asset managers, technology developers, reuse and recycling companies that do both pre-processing and final processing, standards development organizations, and R&D organizations that can fill critical technology and materials gaps to increase value recovery and make the circular economy a reality. The US Department of Energy’s Critical Materials Institute is playing an important role by creating new technologies for rare earth metal resource recovery, as well as by using this analysis to propose specific recommendations to strengthen the US manufacturing base. The INEMI team designed and completed Demonstration Projects that showed new, technologically and economically viable pathways for value recovery that enable creation of a Circular Economy.

Recovery of Electronics Waste to be Converting into Functional Devices Roberto Basea; Inst Politecnico National, Distrito Federal, Mexico.

Today, processing technologies have generated negative environmental impact as emission of toxic gases and degradation of the earth when certain products are placement in landfills leading to environmental pollution and several biological risks, which damage societies to sustain the planet for future generations. As electronics waste, grain-oriented iron foils, graphite films, and Mo-Zr ferrites has been identified as interesting candidates. Therefore, uncommon physical properties from such materials are available when it is converting technologically. A strategy such as Life-Cycle Assessment (LCA) is employed here to take into account all stages of the life cycle of electronics waste, including processing technology, manufacturing processes, use phase, and end-of-life routes to quantify the recycling performance as a function of the physical parameters that will characterize these to operability into a functional device. Hence, structure and conduction properties in waste materials are exploring by using X-ray diffraction, Raman spectroscopy and electrical characterization techniques with emphasis on knowledge of their physical behavior. Researching waste materials will provide theoretical basis for open-loop recycling, where trends related to green engineering should be attained with material recycling for adaptive structures as functional devices using different performance principles compared to those used with silicon devices.

The access to raw materials is an economic and major geopolitical stake for the 21st century. Some key elements considered today in the emerging devices for the Internet of Things (IoT) must be substituted or saved (by orders of decades) in a drastic way in the near future. Since tens Billions electronics objects are being disseminated all over the world in homes, buildings, cars, roads, etc., it is obviously a major concern to revisit the economic, technological, and societal models to develop a sustainable electronic industry that will care about its impact right from the conception of these objects. III-V semiconductors present interesting properties and are already used in electronics, lightening and photonic devices. More particularly alloys containing Ga, In and Sb are increasingly used by the semiconductors industry for high frequency operation, WIFI technology, high power devices, lasers for communications, sensors… This sector accounts for about 90% of world consumption of gallium for example. With the huge increase of IoT devices there is a real challenge to be able to maximize the consumption of these elements or substitute them but more abundant one to fulfill the same function. In this contribution, we will show strategies to develop processes either to save or substitute In, Ga and Sb to realize specific functions such as light emission

University, West Lafayette, Indiana, United States; 2Seagate, Technology, Bloomington, Minnesota, United States; 3International Electronics Manufacturing Initiative INEMI, Austin, Texas, United States.
and detection, and sensors with technologies compatible with large-scale integration. An important aspect of the work will be devoted to synthesis on large area nano-powders with the concern for compatibility with CMOS processes. We will show that bulk material (InP, GaAs and GaSb substrates) could be substituted by thin layers elaborated on a standard Si(100) microelectronic substrates. Selective deposition will also be considered to put the materials only at the place where it is needed. The physical properties of In, Ga, Sb containing semiconductors elaborated on a silicon platform will be shown and compared with those elaborated on III-V substrates. Demonstration of LEDs emitting in the visible and infra-red region will be shown. As an ultimate solution, 2D materials elaborated on large scale 300 mm Si substrates will be presented and their physical properties will be exposed.

Synthesizing Pr4+ / Dy3+ Doped Nd2O3 Nanoparticles from Nd-Fe-B Magnets Sourced from E-Waste
Samane Maroufi, Rasoul Khayyam Nekouei and Veena Sahajwalla; UNSW, Sydney, New South Wales, Australia.

The global supply of rare earth elements (REEs), is under considerable strain. As many countries have no suitable ore deposits within their territories, and deposits elsewhere are both limited and finite, the recovery of REEs through recycling is essential. Currently, less than one percent of REEs are recovered via recycling. Nd-Fe-B permanent magnets are now one of the most widely used type of rare-earth magnets which are implemented in a variety of applications such as electric power generation (computer and laptop hard drive) and transportation (hybrid and electrical vehicles). Given the growing demands for lightweight products with high magnetic strength to support the miniaturization of equipment in many existing and emerging applications, demand for Nd-Fe-B magnets is, likewise, expected to continue to rise, particular for the clean energy/transport sectors.

In this study oxidation-reduction process was used for the recovery of rare earth elements (REEs) (i.e. Nd, Pr, and Dy) from Nd-Fe-B permanent magnets. Nd-Fe-B permanent magnets collected from e-waste were subjected to an oxidation process at 1000°C for 60 minutes followed by carothermal reduction at 1450°C for 60 minutes using waste tyre rubber-derived carbon (WTR-DC) as a reducing agent. Fe-based metal and rare earth oxides (REO) phases were successfully separated from the original magnets. The distribution of elements (i.e., Nd, Dy, Pr, Fe, B, Al, and C) between the Fe-based metal and oxide phases were investigated via Inductively Coupled Plasma (ICP), Energy-Dispersive X-ray Spectroscopy (EDS)/Electron Probe Microanalysis (EPMA) elemental mapping. REEs were confirmed as the main components of the oxide phase and it was shown that the REEs did not remain in the Fe-based metal phase. The oxide phase mainly contained REEs (i.e., Nd, Dy and Pr) and a minor amount of B and Al.

Using REEs (i.e., Nd, Pr and Dy) derived from Nd-Fe-B magnets we applied a low temperature urea-based homogeneous precipitation method and synthesized crystallized RE (i.e., Nd, Pr and Dy) OHCO3 nanoparticles with diameters of 40-50 nm and high specific surface area of 60 m² g⁻¹. The synthesized REOHCO3 was used as a precursor for the synthesis of REO nanoparticles through a thermal degradation process at 700°C. FE-SEM images revealed that the synthesized REO nanoparticles inherited their parent’s morphology. X-ray diffraction spectrum of the synthesized REO nanoparticles showed cubic phase of Nd2O3 with no additional peak corresponding to the secondary phases of Pr and Dy. High resolution TEM (HRTEM) micrographs and electron diffraction of the selected area (SAED) of the as-synthesized REO nanoparticles exhibited the deformation in crystalline structure, shrinkage of the crystalline size and decrease in interplanar distance value indicating that Nd3⁺ in Nd2O3 host lattice were replaced with dopants of Pr3⁺ and Dy3⁺.

Nanoparticles from the Gas-Phase—A Technical, Ecological and Economical Answer for Sustainble Future Energy Applications?
Sophie M. Schnurre and Tim Huelser; Institute of Energy and Environmental Technology e.V., Duisberg, Germany.

Sustainability should be the objective of every future technology. Especially nanotechnology has shown that worries and concerns of consumers may hamper the development of nanomaterials. Therefore, it is indispensable for a sustainable fabrication of products containing engineered nanoparticles (ENP) to have no adverse effects on the environment. In the face of the conflict between immediate marketing of innovative products containing engineered nanoparticles and precautionary assessments with regard to potential environmental and human risks, a multi-disciplinary approach to work out functional, social and economic effects was established. Within this approach, first, the design and synthesis of sustainable nanomaterials on the pilot plant scale and, second, different aspects along the value chain are considered. Here, political regulations, social and economic effects, technological and social risk potential as well as barriers to economic growth are crucial from the synthesis to the implementation into applications.

For ceria nanoparticles (pure as well as doped), an enormous marketing potential is expected due to their presumed low toxicity and multiple application possibilities. We present methods (e.g. doping particles with Europium) to tune particle morphology, which allows to identify particles in biological systems and enhance low temperature catalytic properties. Results of end of life cycle assessment using new models of nanoparticle distribution scenarios are displayed.

As another application oriented material, we chose silicon nanoparticles, since this material is a candidate for anode material in lithium batteries because of its high storage capacity, good availability of raw material, cost-efficient production method and its sufficient long-term stability.

We demonstrate the formation of silicon nanomaterial by homogeneous gas-phase reactions as a direct and highly economic way to produce the required high-purity raw material for battery applications. We developed a value chain for lithium ion battery materials with respect to market, patent and literature analyses as well as the innovation potential. Here, the synthesis process, the manufacturing, the utilization phase and the end of life phase are taken into account.

The tools will form the basis of a “value chain” regulatory process, which allows NM to be assessed for different applications on the basis of available data and the specific exposure and life cycle concerns for that application. To determine the technology readiness level (TRL) of a technology a scheme has been worked out, which shows a timeline that is divided into laboratory-, pilot plant- and industrial-scale from today to 2030. Technology related topics such as material, processing, component development, assembly and the final product are integrated into scheme. Technology options like social and economic chances as well as limitations like risk potential, social risks and barriers to economic growth are considered.

Massive Production of Energy Materials from Fe-P Waste Slag with Novel Technics for Sustainable Development
Guixin Wang, Yun Wei, Yujia Peng, Fei Xu, Yao Cai, Shunxing Wang and Yangping Yan; College of Chemical Engineering, Sichuan University, Chengdu, China.

Recycling solid waste slag as functional materials at low energy consumption and low environmental impact still faces challenges for sustainable development. A novel and green route has been proposed for the synthesis of energy materials like LiFePO4, FePO4, (FePO4)α(OH)2 using Fe-P waste slag with a melting point of 1400 °C via a hydrothermal reaction at no more than 200°C, and the by-product is only water. A 2L autoclave was utilized to synthesize these materials by stirring to further decrease reaction temperature and shorten reaction time. FePO4 or Fe(PO4)α(OH)2 can be obtained by changing the mass ratio between Fe₃P₄ slag, H₃PO₄ and H₂O₂, while LiFePO4 can be obtained by using the raw materials of Fe₃P₄ slag, LiOH, H₃PO₄ and H₂O₂. As the autoclave was cooled to room temperature, a solution with solid particles appears. After being washed, filtered and dried in air, fine product powders were obtained. The reaction process was investigated with thermodynamic calculation and thermogravimetric analysis. The as-
obtained solution and powders were characterized with various techniques, and key factors affecting the synthesis were discussed. The as-obtained FePO₄ or Fe₃(PO₄)₂(OH)₂ can be further used to synthesize LiFePO₄. The electrochemical performance of the as-synthesized LiFePO₄ samples was evaluated with galvanostatic charge/discharge tests, cyclic voltammetry and electrochemical impedance spectroscopy. The LiFePO₄ samples obtained with one step or two steps all have specific electrochemical activity, and the specific capacity can reach 110 mAh/g at 1.0C current rate. In order to improve the electrochemical performance of the samples, glucose was adopted to supply carbons to improve conductivity via calcining at 300 °C and 700 °C in a quartz tube furnace full of Ar. The emissions from the tube furnace were inert an ammonia water to form a NH₄HCO₃ solution. The effects of H₃PO₄ and H₂O₂ on the composition and electrochemical performance of the samples were investigated in detail. After carbon modification, the discharge capacity of the LiFePO₄ samples can reach 150 mAh/g at 1.0C current rate, and the capacity fade after 100 cycles is only 1%, which is comparable to the commercial LiFePO₄ synthesized with expensive raw materials. The successful conversion of alloy with a high melting point into energy materials at low temperature can be used for other alloys, which decreases energy consumption and waste emissions, shortens the traditional reaction process, as well as improves resource utilization efficiency.

4:15 PM BI01.04.08
A Novel Closed-Loop Process for Recycling LiFePO₄ and Graphite Xiaotu Ma, Mengyuan Chen and Yan Wang; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

With the rapid consumption of fossil fuel, lithium-ion batteries (LIBs) are widely used in an ever-growing list of consumer electronics, electric cars, energy storage, and other applications. Although LIBs have reduced environmental problems caused by fossil fuel, the spent LIBs waste has become another big problem. Moreover, the shortage of the supply of materials will be a potential risk for LIBs. Therefore, in order to protect the environment and ensure industry sustainability, it is necessary to develop technologies to recover and recycle spent LIBs efficiently and economically. A novel closed-loop hydrometallurgical process for recycling spent LIBs has been developed in our group. The advantages of this technology include no sorting, high-quality recovered battery materials, high efficiency, and applicability to any size and shape of spent LIBs. Here we show the method for recovering cathode, olivine structured lithium iron phosphate, LiFePO₄ (LFP), and anode, graphite. LFP, with high power capability, low cost, non-toxicity, excellent thermal safety, and high reversibility, has been commercialized as cathode materials. After leaching various spent LIBs and filtration, the mixture of FePO₄, graphite and other impurities can be extracted from the remainder. Then the remainder is leached in a HCl solution and FePO₄ is dissolved as FeCl₃ and H₃PO₄ solution. The mixture solution is used to precipitate FePO₄ by adjusting the pH as the precursor to recover LFP. Similarly, graphite and other impurities remain after filtration. The mixture is washed and dried. Then, the mixture is heated at different temperatures in air to remove impurities and crystallize the graphite. The results show good electrochemical performances of recycled cathode and anode materials. Also, this will reduce the production cost, mitigate the shortage of resources and solve environmental problems.

Development of Integrated Technologies for Conversion of Industrial Waste CO₂ to MeOH and Other Value-Added Chemicals via Thermochemical Route Sebastian Chirambatte Peter and Soumyabrata Roy; Jawaharlal Nehru Centre for Advanced Scientific Research, Bengaluru, India.

Two most imminent scientific and technological problems that the mankind is facing now, is that of energy and climate. The energy production and utilization in modern society is mostly based on the combustion of carbonaceous fuels like coal, petroleum and natural gas the combustion of which produces CO₂, which alters earth’s carbon cycle. 30 billion of tons of CO₂ per year get emitted globally as waste from the carbonaceous fuel burning and industrial sector, which if converted to valuable chemicals have the potential to change the economy of the world. We, in our lab are trying to address both issues and are keen upon translating our innovative technologies from the lab to the industrial and commercial scale. The CO₂ conversion technology is in the developmental stage for commercialization. We are capturing CO₂ from industrial flue stream (of any composition) and thermo-catalytically converting it to value added chemicals/fuels methanol, carbon-monoxide, methane, dimethyl ether, C₂-C₅ & C₅-C₁₁ gasoline hydrocarbons. The end to end conversion product in the thermo-catalytic pathway which could not be commercially realized yet due to problems of low catalytic conversion, limited conversion, energy efficiency of the technology and most importantly high cost of hydrogen. We at JNCASR, are working towards solving these bottlenecks of the overall technology through synthesis of efficient catalysts and designing more energy efficient reactor systems. Catalyst design is at the heart of all these technologies and we are developing customized catalysts and reactor systems for targeted product conversions as per the need of different industries. The catalysts have been synthesized through extensive structure property relation study corroborating with 1st Principle DFT calculations. Advanced CFD calculations are used to design energy efficient reactor systems. Nano structuring in the group 13 element doped C₂Z systems showed highly enhanced conversion and methanol selectivity. At present we are scaling up the end-to-end process, the success of which might lead to opening of new directions in CO₂ conversion technology. We are in the process of taking our technology to the pilot plant scale during the course of which we are running for the 20 million-dollar NRG Carbon Cosia XPRIZE, which is a global competition for promoting commercially viable novel technologies for solving CO₂ and climate change issues.
efficacy is fundamental to meet future food demands in a sustainable way. In the present work, we propose a novel S-fertilizer based on the chemical modification of S8 cyclic structure into a linear amorphous form, more available to oxidizing microorganisms, as an approach to improve the oxidation rate. In order to design this type of material, we applied the recently developed inverse vulcanization technique, a simple copolymerization method that guarantees better processing control for sulfur and allows the formation of functional sulfur-rich polymers. In addition, this technique involves some green chemistry principles, such as the lack of solvent use and excellent atom economy. Soybean oil was selected as comonomer for the reaction as a cheap, non-toxic and renewable feedstock. The S-oxidation achieved by the polysulfide products revealed to be more than 50% superior than S8, and the soybean oil fraction of those materials displayed a role as carbon source for microorganism activity. Therefore, the results could support the sustainable development of a non-conventional S-fertilizer with enhanced efficiency and multifunctional properties.

Amino-Moiety Designed Novel Ionic Liquids for Highly Efficient and Selective Extraction of Platinum Group Metal from Hydrochloric Acid Solution
Chisato Hanazawa, Atsushi Muramatsu and Kiyoshi Kanie; IMRAM, Tohoku University, Sendai, Japan.

Platinum group metals (PGMs) are of significant importance for modern technologies and advanced materials. However, the continuous high demand and scarcity of PGMs are critical issues. Correspondingly, we need to challenge recycling technologies to fill the gap between demand and supply. Conventional organic solvent extraction is widely applied to the practical recovery method of PGM ions. Recently, ionic liquids (ILs) are considered as an alternative green solvent for PGM extraction. In our previous study, we have reported a metal-selective deprotection-mediated Pd(II) extraction by use of ILs with tetrahydropyran-2H-yl-protected thiol moieties. 1) Also, the functionalization of ILs, regarded as task-specific ILs (TSILs), is a promising technique to introduce PGM extraction ability into ILs. In the present work, we have designed and synthesized novel ILs with amino moieties in order to develop the selective recovery method of Pt, Pd, and Rh ions for industrial use. All TSILs (Cn (n means alkyl chain length of dialkylamines) forming a pale-yellow IL state at room temperature were immiscible in water. We next investigated the PGM extraction ability of Cn for Pd(II), Pt(IV), and Rh(III) ions. The initial PGM ion concentrations in the aqueous solutions were adjusted to 100 ppm. Influence of HCl concentration on the extractability was examined in the range from 0.30 M to 4.0 M. The extraction experiments of the PGM ions into the Cn-based IL phases (400 mg) from the aqueous phase (2.0 mL) was carried out by mixture of the solution in a vial, followed by vigorous shaking. The extractability was evaluated through the difference of PGM concentrations in the aqueous phase before and after extraction with IC-PEF measurements. Both dihexylamino-substituted C6 and dioctylamino-substituted C8 exhibited excellent extractability (> 80%) towards Pt(IV) and Pd(II) ions in HCl concentration range from 0.30 to 4.0 M. However, the extractability of dibutylamino-substituted C4 was significantly decreased with an increase in HCl concentration, possibly because of the instability of C4 at higher HCl concentrations. The extractability to Rh ions reached at 73% at maximum for C8 in 3.0 M HCl solution, which exceeded that for C6, 51%. We considered that the high extractability of C8 was attributed to the high hydrophobicity. The extraction/back-extraction abilities of Cn were also investigated.

Efficient Photothermal Water Evaporation from Inked Filtration Paper
Zhiqiang Wang1, 2 and Ming Su1; 1Northeastern University, Boston, Massachusetts, United States; 2Tianjin Normal University, Tianjin, China.

Water evaporation with natural solar energy attracts much attention due to its wide applications as well as energy saving. However, this heating process is very slow under 1 sun shining. So current technology, which needs a large surface, collects the solar irradiation as much as possible, and concentrates the heat to accelerate this process. For future technology, evaporation upon local heating at air-water interface can be facilitated with energy saving, because such locally temperature gradient in the air-water system, compared to the heating scheme of bulk water, can effectively increase the heat utilization. Apparently, the implementation of such emerged photo thermal desalination technique is highly dependent on exploration of excellent photo thermal materials to absorb and evaporate water efficiently. In this work, we reported a low cost high efficient evaporating material. Such an evaporating system achieved an extremely high water production rate of 1.34 kg h−1 m−2 and 89.9 % energy efficiency under 1 sun radiation. The excellent performance is attributed to the combination of multiple properties simultaneously exhibited by this as-prepared material, including its intrinsic blackbody-like high absorption, extremely low thermal loss to environment (low evaporating temperature and 1D water transporting), and automatic water transportation to the evaporating surface by capillary force through the huge microchannels. We also found the general relationships, not limited in our materials but all solar evaporating materials, between evaporating rate, energy efficiency and evaporating surface temperature. Following this relationship, people may control the steam temperature and the evaporating rate for some purpose, respectively.

Improving the Efficiency of N Fertilizers Using Thermoplastic Starch-Modified with Molecules High N Levels
Amanda S. Giroto1, Caue Ribeiro de Oliveira1 and Gelton G. Guimaraes2; 1LNNA, EMBRAPA Instrumentation, São Carlos, Brazil; 2Epagri, Itajaí, Brazil.

Nitrogen (N) deficiency has been considered as the most important limiting factor for crop yield, explaining the high N fertilizer application worldwide. Among all the N-containing molecules urea is the most used due to its high N content, however, its efficiency is limited by losses such as leaching and volatilization. For this reason, we propose the production of a fertilizer based in urea-melamine-thermoplastic starch using a one-step method aiming to control the nitrogen release as a nutrient. The extrusion process used has been showed to be a simple, continuous, high throughput method, capable to promote melamine incorporation, which was responsible to increase the interaction among urea and starch. The results reveal that melamine plays an important role as structure modifier, increasing the effective use of available N for plants in pot experiments. The characterization shows that this material is a polymeric blend, possible to be processed by continuous method (extrusion) leading a plastic granule, with high homogeneity and high nutrient contents. Pot trials (using maize) shown that this material increases the N efficiency (based in the actual available N) leading to a significant nutrient residual in soil useful for future cultures, confirming that this product might replace with advantages the conventional N fertilizers.

Polymers are known to be more combustible than other structural materials, and hence flame retardant formulations are frequently added. Recently it has been shown that many of these formulations, especially those containing halogenated compounds, are toxic and leach into surrounding water and soil. This concern is even more pressing when biodegradable polymers are used, where the degradation process facilitates the environmental release of the toxicant. Here we report on a study of the toxicity of resorcinol diphosphate, RDP, a phosphorous based flame retardant additive. RDP is easily compounded into homopolymers or polymer blends when adsorbed onto clay, where it also facilitates compatibilization. In this study, we show that when included into PLA, RDP appears to have no deleterious effects on cell adhesion, proliferation, and differentiation. When RDP-Clay is added to polystyrene, it has an advantageous influence. Cells do not adhere to PS, but when RDP Clay is added, cell plating efficiency and cell proliferation is drastically improved and the doubling time is comparable to that of the cells plated on PS. In contrast to the cells on PS, those on the PS-RDP-Clay and PLA-RDP-Clay scaffolds underwent differentiation, where large amounts of hydroxyapatite deposits were found. With the appearance of what is believed to be hydroxyapatite deposits (biomineralization), RAMAN spectroscopy will be used to determine any possible developments of an extracellular matrix on the PS-RDP-Clay and PLA-RDP-Clay scaffolds. Additionally, RT-PCR will be conducted on days 28 and 42 in order to evaluate the presence of all genes that may be associated with osteogenic or odontogenic differentiation. Even though further in-vivo testing is required, these results indicate that the probable toxicity of RDP is low, since RDP-Clay preserves both cellular proliferation and function.

B101.06.06
Improved Dispersion of Asphaltenes in Heavy Oil by the Addition of Base and Either Acidic Copolymers or Aliphatic Compounds Terminated with Functional Groups
Myong-Guen Jo, Kwang-Hwan Ko and Joon-Seop Kim; Chosun University, Gwangju, Korea (the Republic of).

Recently, we have been attempting to develop the dispersants for the improved dispersion of the asphaltenes that presented in heavy crude oil and became gel or precipitated upon the agglomeration. It has been known that effective dispersants for asphaltenes in heavy crude oil should have the following factors: a proper amounts of aromatic and functional groups that can interact with those of the asphaltenes, low molecular weight (MW < 10,000) because of the better solubility to heavy crude oil, amphiphilicity for the improved dispersion because the asphaltenes have both polar and non-polar units, and alkyl chains of proper lengths for the better miscibility with heavy crude oil. Thus, in the course of the present work, we prepared two types of dispersants, analyzed their chemical structures, and determined the effects of the dispersants on the dispersion of the asphaltenes. The two types of the dispersants were low MW styrene copolymers and various aliphatic alcohol, carboxylic acid, or amine compounds. In the first part of the work, we compared the effects of the types of the functional groups of the oligomeric styrene copolymers on the asphaltenes dispersion. It was found that the sulfonic acid groups were better than the carboxylic acid groups on the dispersion. In addition, it was also observed that the more carboxylic acid groups in the acidic unit enhanced the dispersion. Furthermore, as expected, with decreasing MW of oligomers, the dispersion behavior of the asphaltenes became more improved. In the second part of the work, we investigated the effects of the addition of the aliphatic acids on the asphaltenes dispersion. It was found that when the types of functional groups and alkyl chain lengths of aliphatic compounds did not affect the asphaltenes dispersion in the heavy oil significantly. However, it was observed that the addition of NaOH to the heavy oil containing aliphatic alcohol or carboxylic acid compounds enhanced the dispersion of asphaltenes strongly. Interestingly enough, even the addition of NaOH to the heavy oil also improved the asphaltenes dispersion, at least to some extent. Furthermore, it was seen that the effect of the NaOH addition to the heavy oil containing aliphatic acids became more pronounced than that to the heavy oil containing aliphatic carboxylic acids. Especially, the NaOH addition improved the asphaltenes dispersion more significantly in the heavy oil containing 2-ethylhexyl alcohol than normal alcohols, having shorter or longer alkyl chains. Thus, we have been trying to find the reason why the base, i.e. NaOH, influences the asphaltenes dispersion; we will present our interpretation on the results.

B101.06.07
Processing of Sulfur–Phosphate Composites—Use of Synergy to Improve the Fertilization Roles
Gelson G. Guimarães1, Amanda S. Giroti2, Rodrigo Klaic2 and Caue Ribeiro de Oliveira3; 1EPAGRI-EEI, Empresa de Pesquisa Agropecuária e Extensão Rural de Santa Catarina, Itajaí, Brazil; 2Embrapa Instrumentação, Empresa Brasileira de Pesquisa Agropecuária, São Carlos, Brazil.

An environmentally-friendly alternative to phosphate fertilization is the supplementation of P from rock phosphates, however, these sources do not have P readily available to plants. In this sense, the reduction of particle size from grinding techniques have been studying to increase the solubility of the phosphate minerals. However, a difficult presented during this process is the tendency of agglomeration of the particles, preventing them from maintaining nanometric dimension. Elemental sulfur (S) comes up as a dispersant potential that through the acidity generated by the S oxidation to sulfate (SO4^2-) can aid in the solubilization of mineral phosphates. The fungus Aspergillus niger has the ability to oxidize sulfur, besides to have a high production capacity of organic acids such as citric acid, oxalic acid, and gluconic acid that increased the solubilization of phosphorus. Thus, A. niger presents two mechanisms that may favour the solubilization of phosphates: first by natural acidification provide by oxidation of S and the second by organic acids production. In this work, a composite was designed based on a matrix of S^0 prepared by low-temperature processing, reinforced by rock phosphate (P) particles acting as P fertilizer, and with encapsulation of Aspergillus niger as an oxidizing microorganism. The effects of dispersion of the phosphate particles on the elemental sulfur matrix and starch were evaluated, as well as the natural acidification provided by the oxidation of S^0 and the production of organic acids in the solubilization of P from the natural phosphate. In addition, after the release of P and SO4^2-, from the composite-fertilizer incubated in the soil, the dynamics and interaction of P with the colloidal fraction of the soil were analyzed using P K-edge X-ray absorption near-edge structure (XANES). The inclusion of A. niger provided a means for improved S^0 oxidation and concomitant faster P release. The proposition of a granule fertilizer with a simultaneous dispersion of particles of phosphate rock, elemental sulfur, and A. niger spores can allow the reduction of pre-processing (e.g., for soluble fertilizer production) and reduces the indirect costs related to the conventional acid solubilization process and waste treatment. Soil inoculation studies, probed by XANES, indicated that the composite structure played a role in nutrient fixation and immobilization, showing that nutrient dynamics was governed by the local pH. This fully integrated material (a smart fertilizer) is an innovative strategy for eco-friendly agronomic practices, providing high nutrient delivery with minimal source pre-processing.

B101.06.08
Nanocomposites Fertilizers Biologically Activated for an Efficient Supply of Sulfur and Micronutrients to Plants
Rodrigo Klaic1, 2, Amanda S. Giroti1, Gelson G. Guimarães1, Caue Ribeiro de Oliveira1, Teresa C. Zangirolami1 and Cristiane S. Farinas1; 1Embrapa Instrumentação, Empresa Brasileira de Pesquisa Agropecuária e Extensão Rural de Santa Catarina, Itajaí, Brazil; 2EMBRAPA-EEI, Empresa de Pesquisa Agropecuária e Extensão Rural de Santa Catarina, Itajaí, Brazil; 3Department of Chemical Engineering, Federal University of São Carlos, São Carlos, Brazil.

Many commercial fertilizers are based on the application of elemental sulfur (S^0) and oxides metallic to supply sulfate and micronutrients to plants. However, the soil ability to solubilize oxides and promote the S-oxidation is low, since it is dependent of the presence of microorganisms capable of carrying out such biological reactions. To overcome this limitation, different strategies have been explored to improve the availability of sources of nutrients such as S^0 or oxides of P. An interesting alternative is the application of microorganisms to promote the oxides solubilization and...
the S-oxidation in the field. The filamentous fungi Aspergillus niger has been applied to promote the phosphorus solubilization from phosphate minerals as well as bioremediation and bioleaching of metals from mining sites. Besides, previous studies also revealed that A. niger can promote the biological oxidation of S° as well as the oxides solubilization. However, the major challenge is to develop a material that would favor the integration of both oxides particles and microorganisms in a single granule to promote oxides solubilization that could be processed and stored, thus when applied in the field the granule would be activated to allow microorganism to solubilize the oxide, this is an innovative concept of "biofertilizer in granule". Herein, we proposed to produce a composite (granule) based on the dispersion of nanoparticles of S° and oxides in a polysaccharide matrix (polymeric gelatinized starch) with simultaneous encapsulation of A. niger spores. Three oxides model (ZnO, MnO and CuO) besides S° were used to produce different configurations of composites. The oxides were physical-chemical characterized as well as the composites produced. Experiments were performed to evaluate the effect of bio-activation of the composite by A. niger and consequent oxides solubilization and S-oxidation in a liquid medium and in soil. The results showed that all the different composites produced (St/Zn, St/Mn, St/Cu, St/Mix and St/Mix+S+) increased solubility of the dispersed material. The effects of dispersion of the oxides and S° particles in starch matrix was analyzed using field emission gun scanning electron microscopy and X-ray microtomography, a high dispersion of the particulate materials was observed with low agglomerates formation. Nevertheless, the St/Mix+S+ show the best results for oxides solubilization, besides being a source of multi-nutrient (S, Zn, Mn and Cu). The St/Mix+S+ also showed considerable shelf time and when evaluated under greenhouse conditions, it showed an efficiency comparable to the experiment carried out with soluble commercial fertilizer for the cultivation of Italian ryegrass (Lolium multiflorum Lam.). This strategy opens a new route for development of smart fertilizer capable of making feasible the use of source of micronutrients of low solubility for plant nutrition.

Removal of Fluoride from Groundwater Using Alfu Metal Organic Framework (MOF) Impregnated Polyacrylonitrile Beads
Sankha Karmakar, Debasish Roy and Sirshendu De; Indian Institute of Technology (IIT) Kharagpur, West Midnapore, India.

Novel mixed matrix hollow beads were prepared by phase inversion technique using polyacrylonitrile (PAN) as base polymer and aluminum fumurate (Alfu) metal organic framework (MOF) as additive. The beads were characterized in terms of surface morphology, surface charge, surface area and contact angle. With the incorporation of the hydrophilic Alfu MOF, contact angle of the corresponding beads decreases from 80° to 51° indicating an increase in hydrophilicity. The 10 wt% incorporated beads sustained upto 150 hours of operation with fluoride concentration of 10 mg/l at flow rate of 1 l/day. Regeneration study and leaching of aluminum were also investigated.

Exploring the Stability and Electronic Properties of Za Doped Hematite Surfaces for Photoelectrochemical Water Splitting
Joseph Simfukwe1,2, Refiwi E. Mapasha1, Artur Braun1 and Mmantsae Diale1; 1University of Pretoria, Gauteng, South Africa; 2Physics, Copperbelt University, Kitwe, Zambia; 3Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland, Switzerland.

First principles studies of Zn doped (0001) and (012) surfaces of hematite for enhanced photoelectrochemical water splitting have been carried out. Doping was confined to planes in close proximity to the termination region, precisely from the top most layer to the third inner layer (plane P1, P2 and P3) of Fe atoms. The two surfaces and the three doped layers were found to be thermodynamically stable and would prefer oxothionene formation under oxygen rich conditions. The analysis of electronic properties reveals that even with mono doping of Zn on the top most layer (P1) of the (0001) α-Fe2O3 surface, the band gap can be decreased without impurity states in the band gap which normally acts as recombination centres. The doping of Zn atom on P2 and P3 (second and third layer respectively) of the (012) surface narrowed the band gap from ~1.43 eV to ~1.0 eV for both systems, without any impurity states in the band gap. Furthermore, the conduction band minimum (CBM) of P2 and P3 of the (012) surface also became wavier and delocalized suggesting improved electron mobility of hematite, while the CBM of the (0001) surface shifted upward between ~0.05eV and ~0.3 eV. The observed upward shift in the CBM is likely to enhance photoelectrochemical splitting of water with a smaller application of external bias. Analysis of the charge density difference plots showed concentration of charge mainly at the top of the surface, which is the termination region. This suggests facile transfer of charges to adsorbed molecules due to the closeness of the charges to the adsorbate. The concentration of the charges at the surface, the decreased band gap and the absence of recombination centres within the band gap suggest improved photocatalytic activity of the Zn doped α-Fe2O3 surface.

Novel Fluorescent Polymer Sensor for Nitroaromatics Explosives Detection in Solution and Vapor Phase
Vishal Kumar and Soumitra Satapathi; Indian Institute of Technology Roorkee, Roorkee, India.

The highly sensitive and reliable detection of explosives such as nitro substituted compounds (DNT, TNT and TNP) is of paramount importance for civilian and military security. NACs are also recognized as poisonous or carcinogenic explosive chemicals to the environment. Currently, explosive detection either relies on canines or highly sophisticated measurement techniques, such as mass spectrometry, gas chromatography, Raman spectroscopy, etc. High cost and/or complexity of these techniques limit their wide availability, especially in the field. Compared to those fluorescent polymers are particularly interesting for fluorescence based rapid detection as they exhibit large signal amplification due to the delocalization and rapid diffusion of excited states throughout the individual polymer chains. Moreover, the fluorescence polymers having high PL quantum efficiency, favorable redox potential and easy synthesis scheme need to be explored which can act as excellent electron donor for rapid electron transfer to NACs having electron-withdrawing nitro groups on the aromatic ring in order to make them as efficient optical sensor with ultra-high sensitivity.

Here, we report the synthesis and multimodal sensing applications of a highly emissive and electron-rich alanine based dansyl tagged copolymer P(MMA-co-Dansyl-Ala-HEMA) (DCP) which exhibited high sensitivity and selectivity towards DNT, TNT and TNP in solution at lower range of μM level and also with saturated vapour of NACs. The high quantum yield of the co-polymer (77.3%) makes it an ideal candidate for sensing in solution as well as in vapor phase. In solution, the fluorescence signal from DCP co-polymer gets significantly quenched upon addition of aliquots of DNT, TNT, and TNP caused by photo-induced electron-transfer i.e. quantified by plotting Stern–Volmer plot (KSV = 1.1×105 M⁻¹, 1.3×105 M⁻¹ and 1.6×10⁴ M⁻¹ for DNT, TNT and TNP). The quenching mechanism was further established by time-resolved fluorescence and steady state absorption spectroscopy which was found to be predominantly dynamic in nature as lifetime of polymer (14.9 ns) is reduced to 13.9, 13.9 and 13.8 ns for DNT, TNT and TNP. The energetics of sensing process was calculated by Density Functional Theory (DFT) studies this is also in good agreement with the obtained result. To explore the possibility of using the fluorescent co-polymer as sensor array, a prototype thin film polymer sensor was fabricated using drop-casted thin film of DCP which was able to detect saturated nitroaromatic vapor in real time with high selectivity. The initial fluorescence intensity of the 20 nm thin film of DCP was quenched to 19% for DNT, 13% for TNT and 4% for TNP in just 2 min.

In summary, this work opens up a novel approach for designing light weight and compact prototype sensor for field use as well as for environmental monitoring.

Nanoscale metamaterials exhibit extraordinary optical properties and have been proposed for various technological applications such as biosensing, superlenses, subwavelength optics, etc. In this talk, our recent efforts in developing a new class of novel nanoscale 2-phase hybrid metamaterials in vertically aligned nanocomposite (VAN) form has been reviewed. Such hybrid systems consist of transition metal nitrides and metals. Taking advantages of the long term stability and thermal stability of transition metal nitrides, we have demonstrated highly stable and mechanically strong metamaterials systems with tunable optical properties, including highly anisotropic reflectance, obvious non-linear optical properties indicating inversion symmetry breaking of the hybrid material, large permittivity tuning and negative permittivity response over a broad wave length range, and superior mechanical strength and ductility. The study demonstrates the novelty of the new hybrid plasmonic scheme with great potential in versatile material selection, and, tunable nanopillar spacing and dimension, all important steps towards future designable hybrid plasmonic materials.

**Introducing Novel Hybrid Ion Exchange Membrane and ANAMMox Bacteria to Improve Nitrogen Removal Efficacy of Microbial Fuel Cell**

Gourav D. Bhowmick, Koushik Adhikary, Makarand M Ghangrekar and Arunabha Mitra; IIT Kharagpur, Kharagpur, India.

Emission of greenhouse gases due to the burning of fossil fuels led to climate changes drastically over the last few decades, which drives the researchers from all around the globe to seek for alternative renewable sources. On the other hand, high energy consuming wastewater treatment systems need to be replaced with less energy demanding or even energy harvesting treatment systems as wastewater is considered to be the reservoir of high energy content. Microbial fuel cell (MFC), a bio-electrochemical system (BES), can be a reliable alternative over the conventional wastewater treatment systems by simultaneously producing bio-energy through oxidising organic matter present in wastewater anerobically using electrogenic bacteria as biocatalyst. In MFC, removal of nutrients from wastes have largely focused on exploiting organic matter cycle reactions, whereby reactive forms of nutrients are converted to unreactive simpler forms e.g. ammonia to inert nitrogen gas. To remove excess nitrogen present in wastewater, it is required to incorporate processes that primarily involves the elimination of NH₃ followed by reduction of NOₓ. Hence establishment of suitable conditions to facilitate both nitrification and denitrification is necessary. A hybrid membrane structure is developed to permit the exchange of both anions and cations in either way from anode to cathode of the MFC. The cation exchange part of the hybrid membrane was made of ceramic separator blended with 20% Montmorillonite as excellent cation exchanger and anion exchange part with poly(2,6-dimethyl-1,6-phenylene oxide) (PPO) via bromination and subsequent quaternization. Fish processing wastewater was used as target wastewater with chemical oxygen demand (COD) to nitrogen (N) ratio (C/N) of less than one g COD/g N for concurrent denitrification and ANAMMox were assessed in two different MFCs with a working volume of two litre each. MFCs were fabricated one with only cation exchange membrane (CEM) and another one with as fabricated hybrid ion-exchange membrane (HEM) named as R-1 and R-2, respectively. The polarization study revealed the maximum power density of 252 and 163 mW/m² with the respective coulombic efficiency of 18.7 ± 1.2 % and 14.8 ± 1.4 % for R-1 and R-2. The marginally lesser power production of R-2 was because of the competition for electron donor (organic matter) inside the anodic chamber for concurrent denitrification and ANAMMox process. The COD removal efficiency was observed to be 81 ± 3 % and 86 ± 4 %, respectively for R-1 and R-2. The ammonium (NH₄⁺) and total kjeldahl nitrogen (TKN) removal efficiency were found to be around 88 % and 92 % for R-2, which were almost two times higher than R-1 (46 % and 50 %, respectively) conforming hypothesis of introducing HEM with ANAMMox bacteria for treating nitrogen rich fish processing wastewater with superlative efficacy compared to the existing treatment systems for real-life futuristic applications.

**A Direct Z-Scheme Enhanced Photocatalytic CO₂ Reduction Over g-C₃N₄ Under Visible Light by Coupling of FeWO₄**

Reshma Bhosale¹, Sharsti Jain¹, Santosh Kumar² and Satischandra Ogale¹; ¹Indian Institute of Science Education and Research Pune, Pune, India; ²University of Bath, Bath, United Kingdom.

With increase in the energy demand and thereby the increased consumption of fossil fuels huge amount of anthropogenic CO₂ is released into the atmosphere leading to green-house effect and global warming. One approach which is being actively pursued to address this problem is CO₂ reduction to value added fuels using solar energy which is abundantly available. Many semiconductor materials are investigated for photocatalytic CO₂ conversion. Among them, a new and novel organic photocatalyst, namely graphitic carbon nitride (g-C₃N₄) has emerged as a sustainable, cost effective and environmental friendly semiconductor. It is a promising candidate which absorbs in the visible region (band gap of 2.7 -2.8eV) and has favorable band alignment. Nevertheless, the photocatalytic efficiency is still moderate due to rapid recombination of photogenerated carriers before they could participate in surface reactions. Therefore, coupling of C₃N₄ with other semiconductor has proved to be an effective pathway to promote the activity through the spatial separation of excited electrons and holes across the interface.

In the present work, we introduce a new visible light photocatalyst material FeWO₄ (band gap 1.8-2.5eV) which belongs to the fascinating family of wolframite type system with monoclinic structure. To the best of our knowledge, FeWO₄ has not yet been investigated in the field of photocatalysis. In our work FeWO₄ was synthetically coupled with g-C₃N₄ by wet chemical method. The obtained composite exhibited direct Z scheme mechanism due to appropriate band matching of FeWO₄ with respect to g-C₃N₄ band edges as confirmed by Mott-Schottky plots and Diffuse Reflectance Spectroscopy. Such a Z-scheme without any mediator is a highly beneficial system in the photocatalysis context, as the electrons with high reduction ability in photosystem PS-I and holes with high oxidizing ability in PS-II are preserved and subsequently utilized for respective surface reactions. Therefore, the composite of FeWO₄ with g-C₃N₄ showed an impressive yield of 30µmol/g of CO₂ representing a six-fold increment in photocatalytic CO₂ reduction as compared to pristine C₃N₄. Also, the composite was observed to be stable for CO evolution till 18 hours over which it was tested.
Evaporation from micro/nano structures is a ubiquitous phenomenon which plays an important role in nature and industrial applications, such as transpiration in plants, mammalian perspiration, electronic cooling and water desalination. Thin film evaporation from nanoporous membranes is a promising thermal desalination approach because it utilizes the passive capillary pumping of liquid to the evaporating interface and allows for high heat transfer rates due to the large evaporating area in addition to the capillary pumping driving force. In this study, solar energy was used as a heat source to evaporate seawater through in-house fabricated polyvinylidene fluoride (PVDF) nano/micro-porous membranes. Compromising between the available area for evaporation via changing pore size and the available material for conductive transfer of heat to the liquid thin film is complicated. Since more porous membrane increases the evaporation surface area and at the same time this leads to having less conductive material for heat transfer which at the end will reduce the evaporation rate. The main objectives of this study are, firstly to investigate the pore size effect on the vapor flux by fabricating flat-sheet membranes via a phase inversion process with 12 wt% of PVDF and 500 µm thickness, and varying preparation parameters such as relative humidity and exposure time to achieve different pore sizes. Secondly to examine the thermal conductivity effect by blending different concentrations of fumed silica (1, 2, 3, 4, or 5 wt%) with the polymeric solution. The fabricated membranes were characterized by scanning electron microscopy (SEM), contact angle analyzer (CA), Fourier transform infrared spectroscopy (FTIR), capillary flow porometry (CFP), porosity and AFM, to further understand the observed thin film evaporation effects. The preliminary results showed, the mean flow pore diameter of the fabricated membranes are 117.2 nm, 123.3 nm and 206.6 nm and there porosity 28.4 %, 46% and 33% respectively. Also, the contact angle analyzer proved the hydrophobicity of these fabricated membranes since the contact angle was found to be above 95°.

Furthermore, this study is aiming to show that the polymeric membrane can be implemented as an alternative effective material in thin film evaporation applications with lower cost compared to commercial ceramic alumina anodiscs (AAO).

Development of Solar Absorbing Nanoporous Membranes for Direct Solar Seawater Desalination

Arwa A. Alishareif1, Mona B. Bahnman1, Faisal Almarzooqi1 and Evelyn N. Wang2; Khalifa University, Abu Dhabi, United Arab Emirates; 2Massachusetts Institute of Technology, Boston, Massachusetts, United States.

In nature solar energy is the primary driving force for the formation of fresh water. Solar based desalination is an attractive technology to meet the ever-increasing water demand.

In this study we develop efficient and optimized nanoporous membranes for direct solar desalination of seawater. We developed black-body like membranes that maximize solar absorption via the structural design and coating. The structural design involves hierarchical shapes that increase roughness and hence forth increase surface area available for solar energy absorption. This is done via simple and low-cost phase inversion membrane fabrication, developed within our labs. The blackbody-like membranes we develop should poses high thermal conductivity, which is the other objective we focus on in this investigation.

To fabricate our envisioned solar absorbing membranes, we developed two distinct approaches, 1) flat-sheet membranes via phase inversion and 2) chemical vapor deposition. In the first, we use polyvinylidene fluoride as the active membrane material. We modified it to incorporate micro/nano particles which are known to have high surface area and good optical and thermal properties. These are graphene nanoplatelets and activated carbon. In the second, we use Anodised Aluminium Oxide (AAO) membranes as the base material and grown high absorbance blackbody like multilayered 3-dimensional graphene coating.

The absorbance of each membrane was measured using a UV(vis) spectrometer. The structures of the prepared membranes were characterized and observed by scanning electron microscopy (SEM) and Atomic Force Microscopy (AFM). The Meanflow Pore Size (MPS), Bubble Point Pore Size (BP) and Pore Size Distribution (PSD) were measured using a capillary flow porometer. Also, the porosity was calculated experimentally using a gravimetric method. Contact angle measurements were also performed to find out the hydrophobic/hydrophilic nature of the membranes.

All membranes are tested in a device fabricated specifically for the purpose of this study. The membranes are tested for their ability to evaporate seawater using direct sun light. Measurements of mass fluxes and temperatures are taken, and the overall efficiency of the device is calculated. This study aims at demonstrating these solar absorbing membranes as the core enablers for future direct solar desalination technologies.

The absorbance of the graphene coated AAO was measured using a UV(vis) spectrometer and was found to be 97%. The fabricated membrane with activated carbon (3.5,7g) where characterized and measured the porosity and were obtained to be 35.9%, 65.3%, and 56.8%. The MPS was measured at around 5.61, 6.95, and 2.88 µm for 3, 5 and 7g of activated carbon and also The BP was measured 14.72, 20.83 and 14.61 µm respectively. The complete set of results will be included in the full submission.

9:30 AM

Application of Ion Exchange Membranes in Enhancing Algal Production Alongside Desalination of Saline Water in Microbial Fuel Cell

Neethu B. Pankaj Sarkar and Makarand M Ghangrekar; Indian Institute of Technology Kharagpur, Kharagpur, India.

In the present world scenario where water scarcity around the world coincides with fresh water consumption, there is an increasing demand for a technology that can provide clean water. Microbial fuel cells (MFCs) can be used to treat wastewater along with generation of bioenergy in the form of electricity using microorganisms and natural biological processes. The demand for fresh water and clean energy is driving the need for converting an MFC into an algae-based Microbial desalination cell (MDC) that can support algal growth in addition to desalination of saline water. Ion exchange membranes (IEMs) are most commonly used for desalination of saline water and is a promising tool which, when oriented properly, can be applied in the MDC for algal production. In this study, a five-chambered MDC was designed by placing an alternating series of cation exchange membranes and anion exchange membranes between an anodic compartment (Synthetic wastewater) and cathodic compartment (Chlorella Pyrenoidosa). The middle compartment, either side of which constituted concentrated chamber, was fed with saline water with two different TDS concentrations, namely 2.5 g/L and 5.0 g/L. Algal-based MDC was analyzed for wastewater treatment efficiency, desalinating capacity, power generating efficiency and algal production and overall performance was compared with MDC without algae in catholyte. A maximum operating voltage of 125 mV was produced during the operation of algal-based MDC with TDS of 5 g/L in the middle chamber against 96 mV for TDS of 2.5 g/L due to change in internal resistance. Similarly, a better performance in terms of electricity generation and TDS removal was observed in MDC assisted with the algal cathode as compared to the one without algae in catholyte. The algal-based MDC with 5 g/L TDS in middle chamber exhibited the best results among all other combinations giving a maximum power density of 45.52 mW/m² and TDS removal rate of 71 ± 2 %. The five-chambered MDC also demonstrated effective algal growth in the cathodic chamber and simultaneous TDS removal in desalination chamber along with energy recovery using photosynthetic oxygen, produced by microalgae, as the cathodic electron acceptor. Based on this experimental performance evaluation, it can be inferred that algal-based MDC can provide a promising and sustainable approach for wastewater treatment with the capability of simultaneous desalination, algal production, and electrical energy recovery.

9:45 AM
Red Mud-Fly Ash-Based Geopolymer as an Alternative Construction Material

Zhaotong Yang and Jianyu Liang; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Today, the concrete industry is one of the largest producers of greenhouse gases, emitting 5% of the man-made CO2 every year. To reduce this carbon footprint, geopolymers have attracted extensive interest as potential alternatives to Portland cement (OPC) the material traditionally used in structural concrete. Depending on the synthesis recipe of the geopolymer, the manufacturing process may be much less energy intensive and have a very small carbon footprint when compared with the OPC production process. Many different raw materials have been used to synthesize geopolymers, such as various natural minerals and industrial byproducts that are high in both amorphous silica (SiO2) and alumina (Al2O3). A new synthesis method for geopolymer, sourced from two hazardous industrial wastes, red mud (RM) slurry and fly ash (FA) powder, has been developed in this study. Thermal properties including mechanical behavior, thermal shrinkage, weight loss, microstructure change, and crystallization of the RMFA geopolymers were investigated. After curing for fourteen days, RMFA geopolymers exhibited compressive strengths greater than 17MPa. Reaching this strength is significant, since the ACI (American Concrete Institute) building standards require a minimum of 17MPa for use in structural cement. It should also be noted that in geopolymer materials, as with OPC, the strength continues to increase over time. Thermal tests found the materials to be thermally stable up to 600°C, with the retention of mechanical strength. The synthesis process developed in this study provides significant advantages: the removal of the energy-intensive drying process and the repurposing of two overabundant industrial wastes.

A Novel Fire Retardant Solution to Mitigate the Onset of Wildfires

Yuan Xie1, Xianghao Zuo1, Joshua Vilkas2, Pik Hoi Lam1, Nicole Jacobsen3 and Miriam Rafailovich1; Stony Brook University, Stony Brook, New York, United States; 2Hebrew Academy of Nassau County High School, Uniondale, New York, United States; 3Wilson Area High School, Easton, Pennsylvania, United States.

The dangers of wildfires are brought to attention as they frequently ravage wooded areas like California and Greece. The current resolution is reactive rather than preventive, and involves dropping chemicals after the start and expansion of the fire. Additional concerns include the application of non-eco-friendly ingredients to quench the fires. The goal of this research is to engineer aqueous solutions that are sprayed onto leaves prior to the onset of fires to inhibit fires from spreading uncontrollably. Here we describe the results of a formulation that was used on the leaf species, Cornus kousa, a subspecies of the Cornus, or Dogwood family.

The experiments were conducted on three categories: fresh picked leaves, oven-dried leaves, and naturally fallen leaves. FTIR analysis of the leaves indicated that fresh leaves consisted of water (2/3 of the mass) while the dried leaves were predominantly of cellulose. Fresh leaves were coated with a thick waxy layer, while the drying process removed some of the surface wax. Different solutions were first formulated where contact angle goniometry was used to optimize the wetting properties for both dry and fresh leaves and viscometer was used to determine the optimal viscosity for spray applications. The solutions were then applied by spraying onto fresh leaves and piles of dried leaves. Burning tests were performed both on leaf piles, and individual leaves, using a propane torch. The flame was applied continuously for five seconds and then removed, and the time to self-extinguish was recorded together with the extent of the spread of the fire.

Results indicated that for fresh leaves, in the absence of the spray, the fire persisted till at least ½ of the mass was consumed and for the dried leaves the entire mass was consumed before the fire was removed. With the addition of the spray, the fire self-extinguished immediately after the flame was removed, and the fire during the application of the flame consumed less than 25% of the mass. Similar results were obtained for both wet and dry leaves. FTIR and RAMAN spectroscopy was performed at each stage in the testing in order to determine the underlying mechanism leading to the flame retardant properties.

The toxicology of the solution and the individual components is being tested on grass and vegetable plants. Preliminary data, thus far, had not found any significant differences in root size or germination rate between the control plants culture and those watered with the undiluted solutions. The results of ongoing experiments regarding sequestration of the chemicals in the leaves and fruits will be presented.

3D Printing for a Sustainable Approach to Constructions

Marcio Stefancich1, Berry Hendriks2, Alessandro Zampieri1 and Waduh Alzahmi1; 1Dubai Electricity and Water Authority, Dubai, United Arab Emirates; 2Cybe Constructions, Oss, Netherlands.

While 3D printing is having a large impact on many industrial sectors, its contribution in the constructions sector is still in its infancy. Construction is one of the bigger contributors to greenhouse gases and thus, an increase in the efficiency of this process can have a significant societal and environmental impact.

However, dimensional scale factors, optimal printer and nozzle configurations, and, most importantly, the properties of the printable materials (e.g. cement) are still open questions ripe for developments and active research.

Moreover, societal acceptance of a completely novel concept for constructions, where delivery times and construction methodology are substantially different from a model that was substantially unchanged in the last several hundreds of years, is still uncertain.

From a technological point of view, the cement commonly used in construction has long setting times and rheological characteristics that make the direct 3D printing process complex. The use of specialty additives allows tweaking the relevant parameters, but the extrusion process of materials with paste-like rheology and the achievement of structural performances compatible with large scale buildings had been elusive for several years.

Harsh climatic conditions and the preference to print directly on site make things even more complicated due to the variability of environmental conditions affecting the material properties. The lack of established standards, due to the novelty of the approach, adds to the uncertainty level. However, the combination of novel materials combined with specific printing technology, opens the way to fascinating scenarios in a traditionally conservative sector.

From the social acceptance point of view, the revolutionary short building times, the strict adherence of the final product to the initial design and the substantial reduction of the construction crew are all aspects that need to be tested on the final clients. We report here on the first example of a 100+ m² building for civil use, with complete regulatory authorities’ certifications, successfully 3D printed in situ.
Carbon Quantum Dots Deposited Chemically Modified β Cyclodextrin Based Biocompatible Thermoresponsive Composite Hydrogel for Transdermal Drug Delivery Arpita Roy1,2, Sagar Pal1 and Santantu Dhara1; 1Applied Chemistry, IIT (ISM), Dhanbad, Dhanbad, India; 2School of Medical Science and Technology, IIT Kharagpur, Jharkhand, India.

In this study, we have developed a novel thermoresponsive composite hydrogel material (cl β-CD/pVCL/CQDs) by free radical mechanism and ex-situ deposition of carbon quantum dots (CQDs) on chemically crosslinked β cyclodextrin polymeric network [poly(-vinyl caprolactam) (pVCL) crosslinked with β cyclodextrin (β-CD-pVCL)] in presence of crosslinker diethylene glycol dimethacrylate (DEGDMA)]. Here in also, we have explored the effect of carbon dots deposited polymeric matrix on transdermal drug delivery. The potentials for use of different, non-cement based, materials for buildings with enhanced performances and reduced environmental impact (e.g. adobe) and the associated materials, technology ans societal related challenges will, finally, be explored.
With the development of marine fishery, the amount of waste shrimp shells has been grown tremendously leading to serious environment pollution and resource waste. Converting the waste shrimp shells to the value-added products is a meaningful way to solve the problems. Among the products, the chitin-based material has been attracted wide attention due to its biodegradability, non-toxicity, and physiological inertness [1]. However, the traditional method of preparing chitin-based material form shrimp shells needs acid and alkali repeated treatment and additional modification step [2]. It is meaningful to develop a green and simple strategy of chitin-based material synthesis from shrimp shells.

Herein, we report a green and simple method to prepare chitin/Zn composite using deep eutectic solvent (DES) aqueous solution. The used DES aqueous solution involved three functions, namely decalcification, deproteinization and Zn-loading. Under the optimal conditions, the chitin/Zn composite material with 34.6 wt% zinc, 0.2 wt% calcium carbonate and 2.5 wt% protein was obtained, which presented antibacterial effect against Gram-negative bacteria *Escherichia Coli* and Gram-positive bacteria *Bacillus subtilis* at certain bacterial concentration. The reason for calcium removal and zinc loading may be ion exchange and investigated by experiments with metal salt aqueous solution. Protein removal was ascribed to aggregation proved by particle size analysis and morphology observation.

Sustainable Synthesis of Monodisperse Starch-Based Magnetic Polymer Beads Through Molecular Rearrangement of Glucans from Natural Starch

Ke Luo, Ki-Baek Jeong, Sang Mook You and Young-Rok Kim; Kyung Hee University, Yongin, Korea (the Republic of).

Magnetic polymer beads (MPBs) have attracted extensive attention due to their excellent properties of instant action and contactless control driven by the external magnetic field. With combination of inherent features of magnetic particles and polymer, MPBs are used for various biological applications, such as immunomagnetic separation, which is a powerful and widely used technique in bioassay through the selective concentration and isolation of the biological and chemical target molecules from some complex and heterogeneous matrices. However, the conventional methods for synthesis of MPBs are still facing substantial challenges, such as potential toxicity, complicated process, and high energy consumption, which limit their applications and large-scale production. Short-chain glucan (SCG), a linear homopolymer of glucose linked with α-(1,4) glycosidic bonds, could be a promising polymer for synthesis of MPBs due not only to its abundance, renewable nature, low cost, and biodegradability, but also to its intrinsic properties of crystallization and self-association in aqueous solutions without need of energy consumption. Herein, we report a fairly simple and environmental friendly approach for the fabrication of starch-based magnetic polymer beads (SMPBs) with uniform shape and size through rearrangement of SCG produced by enzymatic debranching of waxy maize starch. The paramagnetic materials, dextran-coated iron oxide nanoparticles (Dex@IONPs), were readily incorporated into the starch microstructure and rendered a superparamagnetic property to the SMPBs. The morphology and size of resulting SMPBs turned out to be modulated by Dex@IONPs in concentration dependent manner, of which Dex@IONPs was assumed to be acting as a seed inducing the epitaxial crystallization of SCG and further transforming it into homogeneous microparticles. The surface of SMPBs was readily functionalized with antibody through one step reaction using a linker protein. The immuno-SMPBs showed great capture efficiency and specificity (>90%) to target bacteria. Furthermore, the captured bacteria along with antibody and linker protein were effectively eluted from the surface of SMPBs by free maltose, indicating the excellent recyclability of SMPBs, making this new material suitable for various chromatographic applications. The biocompatible nature of this materials would also be advantageous for its potential applications in diagnostics and delivery of drugs or physiologically active compounds to a target sites.

3:45 PM BI01.09.05

Green Synthesis of Amino-Functionalized Starch Magnetic Beads and Its Application as Recyclable and Rapid Efficient Removal of Bacterial Pathogens in Drinking Water

Sang Mook You, Young-Rok Kim and Ke Luo; Kyunghee University, Yongin, Korea (the Republic of).

Microbial contamination of drinking water is still a cause of major outbreaks of diarrheal diseases and deaths, particularly in developing countries. Polymeric magnetic particles (PMPs) are promising materials for removal of bacterial pathogens from drinking water because of their intrinsic permanent magnetic properties. Nevertheless, current methods for their synthesis generally requires complicated procedures and large energy consumption, which unfavorably hinder their practical implementation of bacterial removal from drinking water. In addition, functionalization of PMPs using recognition elements, such as antibodies, aptamers, and phages, is not suitable for this purpose, since most of contaminated drinking water environments are polymicrobial. In this study, we report a fairly simple and low-cost approach for the fabrication of starch magnetic microparticles (SMMPs) through spontaneous rearrangement of short-chain glucan (SCG) produced by enzymatic debranching of waxy maize starch. The surface of SMMPs was readily functionalized with poly-L-lysine through hydrogen-bonding interaction. The poly-L-lysine-coated SMMPs (PLL@SMMPs) showed great capture efficiency (>90%) for bacteria in water regardless of gram-positive and gram-negative under slightly acidic conditions (pH 5-6). Furthermore, we found that the surface charge of Gram-negative bacteria varied depending upon the length of lipopolysaccharide (LPS) O-side chains since the phosphate groups are mostly located in the inner core of LPS. Upon the presence of LPS, PLL@SMMPs showed greater capture efficiency for Gram-positive bacteria compared to that of Gram-negative bacteria at the same pH-level. More importantly, the captured bacteria were effectively eluted from the surface of PLL@SMMPs by aqueous ammonia solution along with recycling use, making them promising candidates for practical implementation not only for rapid capturing and removal of bacterial pathogens from drinking water but also for the sample preparation giving aid to bacterial detection and identification.

Spectroanalytical and Microstructural Investigation for Arsenic Removal from Water Media by Modified Ceramic Filter Membranes (Mo-CFM) for Household Water Treatment Application

Amrita Kaurwar, Manoj K. Tiwari, Ajay Khooha, Ajit Kumar Singh, Abhineet Nighojkar and Anand Seksaria; 1Indian Institute of Technology Jodhpur, Jodhpur, India; 2Raja Ramanna Centre for Advance Technology, Indore, India; 3Shri Govindram Seksaria Institute of Technology and Science, Indore, India.

This study aims to evaluate the effect of modified ceramic filter composition in removing As (V) ions from water media. The filter composition was modified through the addition of low-cost iron-rich waste powder into the local clay-saw dust mixed ceramic matrix. The modified ceramic filters (Mo-CFM) membranes were manufactured with dimensions of 10 cm by 10 cm and 1.5 cm thickness. The membrane fabrication involved mixing of local clay with an equal volume fraction of sawdust and 5% volume fraction of iron-rich waste. The raw materials and modified ceramic membranes were characterized using Energy dispersive X-ray fluorescence (EDXRF) and scanning electron microscopy. The arsenic solution was prepared in the laboratory and filtered through the modified ceramic units. The effect of prominent parameters like – pH, initial pressure head and arsenic concentration on their arsenic removal efficiency by Mo-CFM was examined. The concentration of arsenic before and after filtration process was assessed using Atomic absorption spectroscopy. The spectroanalytical results displayed high removal efficiency up to 99% for the As (V) ions. The ED-XRF and SEM images of
cерамические мембранные после процесса фильтрации показали присутствие арсениевой адсорбции на пористой поверхности модифицированной силикатной мембраны (Mo-CFM).

**Detection of Cd Ions Using an Ion-Selective Field Effect Transistor with a Chalcogen-Doped Gate Oxide for Water Quality Monitoring**

Priya Vinayak¹, Sushma Yadav², Ajeet Singh¹, Soumen Sahai¹, Henam Sylvia Devi¹, Sameer Sapra¹, Madhusudan Singh² and Bhaskar Mitra¹; ¹Indian Institute of Technology Delhi, New Delhi, India; ²Institut für Physikalische Chemie und Elektrochemie, Leibniz University, Hannover, Germany.

The American Cancer Society lists cadmium and its compounds as group 1 carcinogens in humans as exposure to these species through food, water, and the air is known to increase the lifetime risk of cancer. In this work, we report a field-effect transistor (FET) based electrolyte insulator semiconductor (EIS) sensor with a CdSe doped silica gel used as the sensing membrane. The EIS structure has a metallic layer as the back contact and the sensing membrane as the top layer with a pseudo-reference platinum electrode as top contact. The electrolyte consists of spiked cadmium acetate solutions and 0.1M KNO₃. The back contact (150 nm Al) was first deposited, with a Cr/Au (10nm/50nm) capping layer using thermal evaporation at 4.2 x 10⁻⁶ Torr, followed by a rapid thermal annealing step at 450°C. Silica gel synthesis was carried out using hydrolysis and condensation of tetraethylorthosilicate in ethanol, distilled water, and HCl. Thin film X-ray diffraction (XRD) measurements on spin-coated silica gel revealed amorphous silica sol-gel formation. CdSe nanoparticles (~3.4nm) with photoluminescence (PL) and absorbance peaks at 570nm and 562nm, respectively, were mixed with the silica sol to form a stable ink. This ink was spin-coated over a silicon wafer with 100 nm of thermal oxide. Capacitance-voltage (CV) measurements were carried out using an AC voltage of 50mV superposed on a DC voltage ramp in the range -1.5V to +1.5V at the 100 kHz. The CV curve was detected in current mode with the Stanford Research SR830 lock-in amplifier (gain = 1M Ohm). Threshold voltage shifts (ΔVT) were extracted from the CV curve was monitored as a function of varying Cd concentration (1M to 10⁻⁷M) in solution. The relationship between the shift and the concentration is linear down to the detection limit of 1 ppm in this initial study, which establishes this baseline FET-based platform for real-time detection of Cd ions in the environment in a low-cost and sustainable manner.

**NFL Pros vs MSE Profs—Sizing Up the Competition for MSE Faculty Positions**  
Mark D. Losego, School of Materials Science & Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Professional athletes are often described as “elite” — reaching a level of athletic excellence that most of us agree we can never achieve. At each level, from Pop Warner to High School to College, football players are cut from teams based on performance until an “elite squad” of 1,696 Pros play each Sunday in the U.S.’s National Football League (NFL). Interestingly, materials science and engineering (MSE) departments across the U.S. employ roughly the same number of professors (~1700), and unlike an NFL player whose average career is only 3 years, MSE professors often retain their position for 30 years. Considering these numbers, it is fair to ask: Who is more elite NFL Players or MSE Profs?

This talk will provide a light but insightful look comparing the competition and process for reaching both the NFL field and an MSE professorship. While elite performance and “total commitment to one’s craft” are obvious similarities, many parallels in “intangibles” come into play when making that final hiring decision, including: specialization / flexibility (e.g., every football team only needs 1 place kicker), character (e.g., Johnny Manziel), your pedigree (DI vs. DIII) and your network (e.g., Christian Hackenberg’s recent move to the Raiders). Perhaps most importantly, though, we must remind ourselves that the faculty hiring committee (like NFL coaches) are human and use a mix of logic and emotion (unless you are Bill Belichick) to reach a final hiring decision — so bringing the proper mix of substance and excitement along with a little luck is usually what’s necessary to land that perfect job. But if you decide that a position outside of academia suits your lifestyle better, that’s ok — then you can relax on Sundays while both the NFL Pros and the MSE Profs
practice their craft (only one of which provides millions of fans amusement).

2:00 PM *BI02.01.02
Finding and Landing an Academic Position  
Michael L. Chabinyc; University of California, Santa Barbara, Santa Barbara, California, United States.

After many years of academic training, one’s main priority turns to finding a job. Of the many career options available for materials researchers, finding an academic position is one of the most challenging. The application process for an academic position requires significant preparation, but it does not need to be a Sisyphean task. This talk will discuss the expectations for faculty candidates, provide tips for preparing the components of an applications, and outline what to expect from the interview process. One of the key messages is that time management is critical.

2:30 PM *BI02.01.03
From Application to Appointment—First Steps Towards a Faculty Position in Materials Engineering  
David F. Bahr; Purdue University, West Lafayette, Indiana, United States.

The initial stages of embarking on a career in academia can be daunting to the candidate (like any career path choice), and at times may seem opaque. This presentation will address some of the common stages that occur in becoming a faculty member in a materials engineering program, and compare and contrast positions within an MSE program, and when a materials researcher is joining a unit which does not offer an MSE (or related) degree. Common points in application materials for faculty positions for a range of departments, schools, and universities will be noted; in particular the presentation will highlight the need to demonstrate independent thought and ownership of research activities, maturity and dedication to education at the appropriate level of the institution, and articulating a vision of career success at both short and long term time scales. Discussion will be prompted on topics which often arise during phone and in-person interviews, ranging from student advising vision, balancing teamwork versus independence within a unit, to identifying audiences in the hiring process. Finally, some details of perceived pitfalls in the process will be presented.

3:00 PM BREAK

3:30 PM *BI02.01.04
Embracing Internationality—Becoming a Faculty Member Abroad  
Daniel R. King; Hokkaido University, Sapporo, Japan; Global Station for Soft Matter Research, Sapporo, Japan.

Working in academia in a foreign country provides for unique opportunities and experiences that would be difficult to achieve through a traditional domestic position. While teaching and training young students anywhere can be fulfilling, introducing students to the benefits of “internationality” is something that is best experienced away from one’s home country. Japan, while possessing the third largest economy on Earth, is still ethnically homogenous, with foreigners making up less than 2% of the total population. Combined with a declining birth rate, the need for foreigner workers will continue to increase, resulting in more opportunities for foreigners to access positions in academia. In this presentation, I will outline the path I followed from being a PhD candidate in the United States (University of Massachusetts Amherst) to the position I have today, as an Assistant Professor at a National University in Japan (Hokkaido University). Specifically, I will address the following topics: finding positions in foreign countries; overcoming and dealing with language barriers; forming a research group and “fitting in” in a foreign environment; understanding and applying for funding; and the future of international faculty working abroad. I hope to express the successes as well as the struggles I have encountered through my journey. Through this presentation I aim to demonstrate the type of people who could be successful in this type of career, and hope to introduce a new path as faculty members at international universities.

4:00 PM *BI02.01.05
A Perspective on Pursuing the Academic Path  
Rebecca Kramer-Bottiglio; Yale University, New Haven, Connecticut, United States.

In this talk, I will discuss my path to academia, experiences with proposal writing, and insights on pursuing an academic career. I will also discuss young investigator and career award opportunities. I intend to keep the talk brief to allow for an engaging interactive session based on topics of interest to the audience.

4:30 PM PANEL DISCUSSION: MARK LOSEGO, MICHAEL CHABINYC, DANIEL KING, DAVID BAHR, REBECCA KRAMER-BOTTIGLIO

SESSION BI02.02: Reaching Tenure through Research, Teaching and Service I
Session Chairs: Allen Kimel and Lisa Rueschhoff
Tuesday Morning, November 27, 2018
Sheraton, 3rd Floor, Dalton

8:30 AM *BI02.02.01
Navigating Your Career with Confidence  
Susan B. Sinnott; The Pennsylvania State University, University Park, Pennsylvania, United States.

As you prepare for a career in higher education, it is not always clear how best to navigate the choices available. This presentation will summarize the ways in which materials science and engineering in academia has changed over the last decade, the implications for the field more broadly, and projections for the future. In addition, thoughts on best practices for navigating the career landscape will be discussed that should be helpful for your current job search or to prepare you for future opportunities.

9:00 AM BI02.02.02
Women in Physics in Ireland—Role Models are Out There  
Yvonne Kavanaugh1, Sheila Gilheany2, Eilish McLoughlin3, Miryam Byrne4, Miryam Arredondo5 and Katja Poppenhaeger5; 1Institute of Technology Carlow, Carlow, Ireland; 2Institute of Physics, Dublin, Ireland; 3Institute of Physics, Dublin, Ireland; 4Dublin City University, Dublin, Ireland; 5National University of Ireland Galway, Galway, Ireland; 6Physics, Queens University, Belfast, United Kingdom.

Physics is one of the core disciplines in Materials Science and Engineering. Therefore, it is important for the next generation of researchers, especially
Research carried out in Ireland has shown that females are successful when they engage with physics. In particular female researchers are very successful in obtaining research funding when compared to other disciplines. Ireland has seen strong females in academia challenge the status quo and this has resulted in positive initiatives to encourage the promotion of females in academia. A study carried out in 2016 by the Higher Education Authority in Ireland captured the typical scissors view, where women are in the majority in the lower paid jobs in academia and greatly underrepresented when looking at the professor and the senior executive management level. This has resulted in the Higher Education Authority making gender equality in higher education a national priority as part of its funding compact with higher education institutions. It has also resulted in the linking of national funding to the attainment of Athena Swan Bronze Awards. This has focused attention on women in STEM, in particular. The Minister for Higher Education has highlighted the lack of movement towards gender equality in STEM and is responsible for the creation of a National Taskforce on Gender Equality. The Taskforce have reported and have produced a list of recommendations to target inequality in the higher education sector.

This presentation tells the story of where women in Physics in Ireland are currently. It demonstrates how this is enabled by government policy. It reinforces the role the International Conference for Women in Physics has in tracking the journey and how Project Juno is enabling the physics community to improve gender equality.

9:45 AM *BI02.02.03

One of the most important lessons learned during grad school is that the vast majority of literature is either incorrect, incomplete, and/or so limited in its applicability to be of little use. The same can be said of career advice, no matter how well-intended or hard-earned. As with literature, the trick—often only recognized in hindsight—is separating signal from noise and synthesizing new insights from multiple inputs plus the researcher’s own datasets, experience, perspective, and interests. As in research, outliers can be incredibly useful, pointing to a need to recast the question and/or reinterpret the data using a different model. They can also be distracting and frequently over-weighted during analysis. Unfortunately, a career is an experiment with too many variables and too few data points to be effectively optimized; fortunately, there are many paths to (and definitions of) a successful academic career.

With the above caveats in mind and far too much reliance on the life-as-an-experiment analogy, a case study involving a transition from a national lab to academia will be presented as a vehicle for discussing and interpreting advice and guidance that too often went unheeded. Your mileage may vary, and free advice is worth what you paid for it, but close inspection will hopefully enable the identification of useful needles of guidance from a haystack of clichés.

9:45 AM BI02.02.04
Training the Next Generation of Materials Scientists to Embrace Broader Impacts and Share Their Work with the General Public Julie Nucci, Cornell Univ, Ithaca, New York, United States.

The Pew Research Center surveyed AAAS scientists in 2014 to inquire about the public’s limited knowledge of science. 86% of respondents stated this is a major societal problem. A second question drilled down into the reasons for this lack of science literacy in the general population. AAAS scientists were asked to rate “not enough K-12 STEM”, “lack of public interest in science news”, “lack of media interest in science”, and “too few scientists who communicate findings” as major or minor reasons. Not surprisingly, the AAAS scientists list their lack of communication as the least important reason for this public shortcoming. I disagree. If the majority of scientists and engineers deemed public communication as important as their research or professional practice, then the public understanding of STEM topics would surely be much better than it is now. This is particularly true for materials scientists, given the dearth of public knowledge of MSE. In an effort to change this at Cornell University, I partnered with WSKG, my local NPR/PBS affiliate to create a new course, ENGRG 3360: Developing Communicative Practice Through Transmedia and Community Engagement. I co-developed and co-taught the course with WSKG’s Director of Science Content, Services, and Programming and we launched it in S2018. Students created publically accessible presentations/videos, leveraged social media platforms to share their science and engineering endeavors, and mentored local high school students. We used the PechaKucha as an innovative presentation format to develop students’ abilities to identify and communicate their key idea in a clear message tailored to a target audience. The video phase of the course was a team effort, with teams composed of high school students, undergraduates, and graduate student. Our high school population, a group of twelve local students spending their entire senior year on the Cornell campus exploring engineering, participated in video production and played the very valuable role of assessing the suitability of the content created for teenagers and the general public. Students were also required create technical social media posts throughout the semester. While they are comfortable with social media in their social lives, it is paradigm shift for them to use these platforms for professional endeavors. We trained the students to do so and gave them ample opportunity to hone these skills.

#CornellEngComm was created to track the content created and Twitter emerged as the social media platform of choice. Video and presentation content created by the students is being aligned to NYS and national education standards and lesson plans are being created for PBS Learning Media, a web-based resource used by students and teachers nationwide. In this talk, I will discuss course development and the partnership with public media. Samples of student work will be shown and opportunities for leveraging the content created will be discussed.

10:00 AM BREAK

10:30 AM *BI02.02.05
Navigating a Career in Academia—From Application to Pre-Tenure and Early-Tenure—Lessons Learned Along the Way Nazanin Bassiri-Gharb1, 2; 1George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Getting ready for a career in academia can seem at times a daunting task, but after years of preparation through doctoral studies and subsequent post-doctoral work, multiple applications to open positions and interviews, finally a match is made. In many cases, however, the process leading to this point is not only the beginning of a lifetime of learning, but also (and maybe even more so) the beginning of an even bigger challenge. The challenge is that of establishing oneself as a new and independent researcher, educator and mentor... and of course, along the path, make it through the tenure process. While tenure is still seemingly the biggest hurdle to pass in the academic career, the process need not to be necessarily an obstacle. The pre-tenure and early tenure years can be instead some of the most satisfying and fulfilling time in the academic life of an early-stage scientist.

This talk will address some of the approaches to tenure – from the start of the tenure-track, through the critical review, tenure, and finally early-tenure stages – that will allow you to enjoy the process and not lose the spirit of wonder: because losing the sense of wonder is much worse than not making tenure. The author will draw on her personal experience through the pipeline, as well as some of those of her close friends and colleagues. She promises to not embellish the truth (yes, chances are things will get tough at some point!), but also not to depress the attendees with endless counts of “a series of
unfortunate events”. And while there is no such a thing as “happily ever after”, she will share some of the ways of keeping the happy before and after tenure.

11:00 AM #BI02.02.06
Future Faculty Expectations Bryan D. Huey; Materials Science and Engineering, University of Connecticut, Storrs, Connecticut, United States.

An academic's day has changed very little in the last several centuries—you think, share ideas with others, critique, and occasionally sleep. Of course the scope, structure, and finances of universities have shifted more dramatically, but still the expectations of faculty members remain remarkably similar:
create knowledge; serve your institution and more broadly your profession; teach and mentor the next generation. The practical reality, though, is that we are all essentially small business owners, keeping our 'product' viable through publications, talks, student dissertations, funded grants, outreach, and even tangible results. The merit systems (financial, tenure, and respect of your peers) reward and indeed demand excellence in these important areas—all of them. But will universities, and faculties, function the same in the future? Increasing trends towards online learning may be particularly disruptive to the traditional model. How can prospective and new faculty, and their institutions, harness this trend instead of fighting it?

11:30 AM PANEL DISCUSSION: GEOFF BRENNECKA, SUSAN SINTT, NAZANIN BASSIRI-GHARB, BRYAN HUEY, YVONNE KAVANAGH

SESSION BI02.03: Reaching Tenure through Research, Teaching and Service II
Session Chairs: Allen Kimel and Victoria Miller
Tuesday Afternoon, November 27, 2018
Sheraton, 3rd Floor, Dalton

1:30 PM #BI02.03.01
From “Being Taught” to “Teaching”—A Personal Perspective of a Young Faculty Member Eva Hemmer; University of Ottawa, Ottawa, Ontario, Canada.

This presentation will provide a snapshot on the journey of a materials scientist from Germany moving via Japan to Canada. It will not only tell about the geographical, but also about the scientific and academic journey, and how studying materials science and engineering can lead to an academic position in a chemistry department, conducting research on multifunctional lanthanides in molecules and nanomaterials. In this context, some experience from the time being a PhD student, from the period discovering new countries and research areas as a postdoctoral fellow, and the recent ongoing adventure of starting an independent research group as assistant professor will be shared with the audience. Also, first teaching experiences will be illuminated: another potential (and unexpected) source of culture shock. While the search for the ultimate recipe for the straight forward achievement of a scientific and academic career is still going on, some of the basics that may be required for a scientific trip by any young researcher or scientist will be suggested for discussion. These basics clearly include curiosity, self-motivation and an open mind, not to forget about endurance as well frustration tolerance, while great mentors are found to play a very important role at each stage of career.

2:00 PM #BI02.03.02
From a Personal Experience as a Teacher of an Advanced Course on Materials Micromechanics—How the Background Gap Between Basic Materials Education and Advanced Topics Can be Filled with the Aim of Not Disappointing Enthusiasm of Students Not Suitably Informed on the Preliminary and Basic Notions Needed to Know Roberto Contore; Chemistry, Materials and Chemical Engineering, Politecnico Milano, Milano, Italy.

The aim of this paper is showing that the student expectations can be not disappointed if they are personally involved in a learning itinerary where firstly their passion, ambition and intelligence are appreciated and stimulated. As consequence they will consolidate their self confidence and will accept to measure their real capability to learn notions indispensable to acquire a sufficient and rewarding preparation, not as a tool to overcome the profit examination but mainly to acquire consciousness of being able to win a challenge, sometimes sounded very difficult because of lacks in a previous basic background. In this way this experience might be useful to approach other challenges that unavoidably will meet in their study a professional career. The word of order of a teacher should be identifying best talents and mainly discovering talents which often are hidden in a mass of students who, for several reasons like their familiar and cultural environment or also for a certain personal shyness, tend to do not recognize even to themselves.

The main step of such a learning itinerary, applied to a master course of materials micromechanics will be described with reference to the adopted textbook: FUNDAMENTALS OF MICROMECHANICS OF SOLIDS, Jianmin Qu and Mohammed Cherkaoui, Wiley, 2006. Meaningful home-works will show as examples of final course results and a related brilliant career promoted as well.

2:15 PM #BI02.03.03

Educational institutions that foster inquiry and innovation prepare students for future careers in science and engineering. Inviting students, as young as high school age, to engage in materials science research is mutually beneficial to aspiring scientists, as well as the university faculty who engage them. A case study for such work details research performed by high school students contributing to the Soft Robotics Toolkit. The open source nature of the soft robotics field presents opportunities for students outside of a university research lab to participate and advance the field. Exposing secondary school students to this rapidly growing field allows for evolution of the soft robotics industry in new and imaginative ways. Students at The Haverford School in Pennsylvania are developing materials-based approaches to soft robotics problems. From this, they gain fundamental knowledge in materials, develop technical communication skills, and are empowered to innovate in the future. As a co-curricular program, secondary school students, ranging in age from 13 to 18 years, collaborated to successfully design and build solutions to fundamental materials issues and prototype a soft robotic device to achieve a goal meaningful to them. In year one of the program, students developed gelatin-based actuators which are biodegradable and edible. In year two, the team developed a simple, one-step fabrication process for building actuators and applied them in a glove. The students collaborated with an art teacher to program the glove to transfer motion from accomplished to novice artists. This group now has a new skill set and confidence in the field to allow them to approach larger problems. This presentation will discuss the technical merits of their work as well as the broader benefits to the field of materials science. In a controlled study, we found that when students were presented with an opportunity to innovate: synthesizing a novel solution to authentic problems without the constraints of a prepared kit, common at the high school level, they were more creative and less constrained in future projects or design.
Challenges. Outreach programs like this generate interest in the field of materials science and present opportunities for faculty to perform outreach that will generate the creative and prepared students they want in their laboratories. Soft robotics is just one application of accessible materials science outreach. This presentation will detail methods of developing this type of unique outreach initiative across the materials science field. Making students aware of what is possible will inspire the next generation of materials scientists, while stimulating the current practitioners with creative new ideas.

2:30 PM BREAK

3:00 PM BI02.03.04

Understanding the Impact of Design in High School Outreach Camps Kaitlin Tyler, Nicole Johnson-Glauch, Leon Dean and Jessica A. Kroostad; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Outreach camps are an effective route to increasing interest in STEM disciplines, especially for underrepresented groups. They are also common components in the broader impact plans for many early career researchers. However, there is very little basis for understanding which aspects of outreach camps lead to positive outcomes. This is due in large part to the difficulty in comparing existing camps both within specific STEM disciplines and across them. As a result, there is little science-based guidance for the development of effective outreach camp structure or content. Because of this, we specifically target the process of design in outreach camps due to its importance in engineering degree programs. By comparing different methodologies for incorporating design thinking through a qualitative multi-case study across four engineering disciplines, we have begun to assess whether design can be used to positively affect outcomes of STEM outreach camps and provide guidance for outreach development.

3:30 PM BI02.03.05

Nanovation—An Interdisciplinary Outreach Program to Train the Next Generation of Scientists and Entrepreneurs Rita Blaik¹ and Sarah Tolbert²; California NanoSystems Institute, University of California, Los Angeles, Los Angeles, California, United States; ³Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, California, United States; ⁴Materials Science & Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Entrepreneurship plays a crucial role in economic development by promoting technological innovation and job creation. A lack of experience and training in technology entrepreneurship is a problem that often persists up to and including doctoral training, and many universities are at a loss as to how to prepare students interested in an entrepreneurial career path. In order to address this pain point, the California NanoSystems Institute at UCLA created the Nanovation Competition outreach program in the 2016-2017 academic year. In this after-school competition, teams of middle and high school students in Southern California compete with the help of UCLA STEM graduate student mentors to generate nanotechnology-based product ideas and develop business plans which they then pitch in a “Shark Tank”-style event. The nanotechnology topics are primarily based on CNSI’s Nanoscience Institute led by Professor Sarah Tolbert, which is a teacher training program now its 14th year aimed at bringing cutting-edge nanoscience concepts to classrooms in the greater LA area. The larger goal of the Nanovation program is to introduce the growing culture of technology and entrepreneurship to students at an earlier age, which can foster economic growth in Southern California.

In addition to explaining the nature and goal of our Nanovation competition, this presentation will discuss the outcomes of this program over the last two years and cover strategies for fostering positive volunteer and mentoring experiences, creating robust professional development for graduate students and K-12 teachers in STEM and entrepreneurship, and winning financial support to sustain these programs over the long-term.

3:45 PM BI02.03.06

Collaboratively Creating Research-Inspired Materials Science and Engineering Outreach Activities Anne Lynn Gillian-Daniel, Matthew Stilwell, Wendy Crone and Nicholas Abbott; MRSEC, University of Wisconsin–Madison, Madison, Wisconsin, United States.

The emphasis that NSF places on meaningful, effective Broader Impacts can be challenging for researchers developing research proposals. An effective strategy for dealing with the challenge is to collaborate with groups who focus on science, technology, engineering, and math (STEM) outreach to the public. By integrating research and education, the University of Wisconsin Materials Research Science and Engineering Center’s (UW MRSEC) works with researchers to create research-inspired materials science and engineering (MSE) educational resources and programs. These resources, including classroom laboratory experiments, hands-on outreach activities, and research programs for teachers, are designed to inform and excite K-12 students, teachers, and public audiences about MSE research and its applications to the world. The UW MRSEC works with researchers to develop broader impacts plans that align with their goals and interests. For example, some faculty members have collaborated with us to develop outreach activities by modeling the cutting-edge instrumentation funded through an equipment proposal. Other faculty members have supported and hosted a teacher in the Research Experience for Teachers (RET) program. Through the RET, Wisconsin teachers perform research in the laboratory of the faculty members and develop new classroom curriculum based upon their summer research experiences. The new curriculum modules are implemented and evaluated in the RET fellow’s classroom the following school year. The modules can then be adapted for other audiences and outreach venues. Following development and adaptation, UW MRSEC members work with faculty to field test new resources, evaluate them for engagement and efficacy, and iteratively improve them. The faculty members and their students then present the completed activities at outreach events both on and off the UW campus. These activities can also be disseminated online on the MRSEC education website, in-person during workshops, and in professional education journals. Examples of research-inspired educational resources developed by faculty for NSF proposals and the UW MRSEC, along with avenues for dissemination, will be shown as part of the presentation.

4:00 PM BI02.03.07

Funsizephysics—A New Tool for Presenting Your Research to the Public Leigh M. Smith¹, Jocelyn Bosley² and Shireen Adenwalla²; ¹Department of Physics, University of Cincinnati, Cincinnati, Ohio, United States; ²Department of Physics and Astronomy, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

During our scientific training we spend much time preparing ourselves for writing scientific papers, proposals and teaching students. In contrast we spend very little time (almost none) on preparing ourselves to communicate our ideas to the public, and these are extremely different tasks. This is truly unfortunate since our communications to the public are becoming a more important and essential part of our outreach efforts. In this presentation I will describe a new NSF-funded effort to develop a new website (funsizephysics.com) which makes it particularly straightforward to develop graphically pleasing web-based presentations to the public. While it is certainly not easy to design a good and informative page which gets across the excitement and importance of your research in an accessible way, working within your research group can make the process easier and at the same time help to train your students. Funsizephysics now makes it easy to have multiple authors for a page. Have a graduate student draft their work and then have other members critique the good points and bad points of the web page. Then iterate with an eye to improving the presentation. In this presentation we will provide some
simple guidelines and hints which we think can help your outreach efforts.

We acknowledge the support of the National Science Foundation through grants DMR-1725823 and DMR-1726026.

4:15 PM PANEL DISCUSSION: EVA HEMMER, JESSICA KROGSTAD, RITA BLAIK, HOLLY GOLECKI, MATTHEW STILWELL, LEIGH SMITH

SESSION BI02.04: Navigating the Funding Pipeline
Session Chairs: Victoria Miller and Lisa Rueschhoff
Wednesday Morning, November 28, 2018
Sheraton, 3rd Floor, Dalton

9:00 AM *BI02.04.01
Funding Opportunities in Materials Engineering at the US National Science Foundation Alexis C. Lewis; Civil, Mechanical and Manufacturing Innovation, National Science Foundation, Alexandria, Virginia, United States.

This presentation will describe funding opportunities related to Materials Science and Engineering at the National Science Foundation, including current programs, new opportunities, and planned focus areas. Additionally, the NSF Merit Review process will be discussed, including components of a successful proposal, finding the right home for your research, and proposal writing tips for early career faculty.

9:30 AM *BI02.04.02

Maneuvering the diverse and complex funding pipelines has become a significant challenge for even the most promising researcher, and poses a threat to the future of materials science in academia. David Stepp brings nearly twenty years of experience at the U.S. Army Research Office to provide insight and perspective on the "why," the "what" and the "how" underpinning one of the preeminent materials science funding agencies worldwide. This talk will focus on suggested approaches that apply to all funding agencies, both in the U.S. and abroad. It will also include a discussion of some of the most common misunderstandings held by materials science researchers when soliciting funding.

10:00 AM BREAK

10:30 AM *BI02.04.03

Transformative breakthroughs most of the time do not originate from the investigations of materials in the equilibrium state but in contrary at the margins of stability, in a regime at the limit or outside of the textbook knowledge within the discipline. In this context, this presentation will embrace materials and processing science approaches that are far from the thermodynamic equilibrium domain, i.e., directionally solidified eutectic structures, highly doped piezoelectric and thermoelectric materials, and other oxide materials with cage structures for electron emission. The intent is to elucidate the complex interplay between phase transitions for electronic/magnetic phase separation and untangle the interdependence between structural and electronic effects. I will also discuss what I consider to be promising research concentration areas within ceramics research for the aerospace materials for extreme environments portfolio of Air Force Office of Scientific (AFOSR), including the focused development of a ceramics processing science laboratory for ceramic matrix composites, the development of materials for use in the hypersonic regime.

11:00 AM PANEL DISCUSSION: ALEXIS LEWIS, DAVID STEPP, ALI SAYIR

TUTORIAL: 3D Printing of Passive and Active Medical Devices
November 25 - November 25, 2018

* Invited Paper

**TUTORIAL**

3D Printing Methods for Medical Applications
3D printing methods enable distributed manufacturing, mass customization, and rapid prototyping of medical devices. The tutorial "3D Printing Methods for Medical Applications" seeks to impart information to the audience on the use of 3D printing methods to process polymer, metal, ceramic, and biological materials. This course includes coverage of 3D printing principles, advantages of 3D printing over traditional subtractive manufacturing processes, materials for 3D printing, 3D printing methods, and applications of 3D printing.

8:30 AM
**3D Printing Technologies for Healthcare** Roger Narayan; University of North Carolina at Chapel Hill and North Carolina State University

Laser-based processes may be used for additive manufacturing and bioprinting of structures with unique microscale and nanoscale structures. We have demonstrated use of matrix assisted pulsed laser evaporation- direct write for layer-by-layer processing of cells and scaffold materials. Three-dimensional patterning of cells and cell-scaffold composites have been demonstrated using this approach. We have also recently examined additive manufacturing of three-dimensional structures using two photon polymerization. In two photon polymerization, ultrashort laser pulses are used to selectively polymerize photosensitive resins and form complex microscale and/or nanoscale structures. The nonlinear nature of two photon absorption enables polymerization of structures with features below the diffraction limit. Recent medical applications of two photon polymerization have involved fabrication of microneedle arrays and scaffolds for tissue engineering. Our results indicate that matrix assisted pulsed laser evaporation- direct write and two photon polymerization are attractive techniques for additive manufacturing and bioprinting, respectively.

9:30 AM BREAK

10:00 AM
**Printing Cells: Process Challenges and Application** Wei Sun; Drexel University and Tsinghua University

3D Bio-Printing uses cells and biomaterials as building blocks to fabricate personalized 3D structures or functional in vitro biological models. The technology has been widely applied to regenerative medicine, disease study and drug discovery. This presentation will report our recent research on printing cells for construction of micro-organ chips and for building in vitro 3D tumor models. An overview of advances of 3D Bio-Printing will be given. Enabling methods for cell printing will be described. Examples for 3D Printing of tissue engineering model, drug metabolism model and disease model will be reported, along with results of printing parameters on cell viability and 3D tumor structural formation, characterization of cell morphologies, proliferations, protein expressions and chemoresistances. Comparison of biological data derived from 3D printed models with 2D planar petri-dishes models will be conducted. Discussions on challenges and opportunities of 3D Bio-Printing will also be presented.

11:00 AM
**3D Printing of Hard Biomaterials** Amit Bandyopadhyay; Washington State University

3D Printing (3DP) or Additive manufacturing (AM) is an approach to process parts directly from its computer aided design (CAD) file. AM is changing the landscapes of current industrial practices. On-demand manufacturing using 3DP technologies is a new trend that will significantly influence many industries and product design protocols. Since there is no need for any part specific tooling, different parts can be built using the same machine. Most of these parts are near net-shape and require only small finishing operation. Unlike even 10 years back, when most of these 3DP produced parts were used for touch and feel, and design optimization, functional parts via additive manufacturing is becoming common in most industrial sectors.

We have worked on additive manufacturing of hard materials, primarily metals and ceramics, over the last two decades. We have used fused deposition modeling, laser engineered net shaping and powder bed based 3D printing processes. Using these 3DP approaches, we have manufactured parts with compositional, functional and structural gradation mostly for space and biomedical applications. I will focus on some of the key success stories from our research, as well as current challenges in the field.

Emerging Organ Models and Organ Printing for Regenerative Medicine

Ali Khademhosseini; Department of Bioengineering, Chemical Engineering, Radiology, University of California, Los Angeles, Los Angeles, California, United States.

Engineered materials that integrate advances in polymer chemistry, nanotechnology, and biological sciences have the potential to create powerful medical therapies. Our group aims to engineer tissue regenerative therapeutics using water-containing polymer networks called hydrogels that can regulate cell behavior. Specifically, we have developed photo-crosslinkable hybrid hydrogels that combine natural biomolecules with nanoparticles to regulate the chemical, biological, mechanical and electrical properties of gels. These functional scaffolds induce the differentiation of stem cells to desired cell types and direct the formation of vascularized heart or bone tissues. Since tissue function is highly dependent on architecture, we have also used microfabrication methods, such as microfluidics, photolithography, bioprinting, and molding, to regulate the architecture of these materials. We have employed these strategies to create miniaturized tissues. To create tissue complexity, we have also developed directed assembly techniques to compile small tissue modules into larger constructs. It is anticipated that such approaches will lead to the development of next-generation regenerative therapeutics and biomedical devices.

Laser Based Direct Write Techniques for Studying Cellular Interactions

Douglas B. Chrisey and Jayant Saksena; Tulane University, New Orleans, Louisiana, United States.

Due to their ability to carry out both additive and subtractive processing of a wide range of materials in a non-contact manner with superior precision and speed, lasers are a promising tool to create reproducible constructs for cell-based assays. Laser direct write technologies—as such as our custom-designed matrix-assisted pulsed laser evaporation (MAPLE) bioprinting system—combine the power of laser processing with computer-aided design to allow us to print as well as ablate cells, cell aggregates and biomaterials with high resolution. Here, we present some interesting applications of the excimer laser driven MAPLE platform for cell printing and ablation, tissue dissection, biomaterial micromachining and 3D microbead fabrication for studying interactions between cells and their microenvironmental cues in vitro. We have printed breast and colon cancer cells, fibroblasts and macrophages in spatially defined patterns on hydrogel substrates and live rat mesenteric tissue to develop physiologically relevant models for cancer cell migration and invasion. We have micromachined spoke and channel patterns into PDMS substrates to analyze competitive cell migration in context of cancer and atherosclerosis. We have also developed a reproducible and customizable wound healing assay using laser ablation of adherent cells. We have fabricated and patterned 3D microbeads encapsulating heterogeneous cell types to elucidate cancer-adipose interactions. Finally, we have dissected user-specified regions of excised mouse colonic tissue to create testable sections. Our work demonstrates the immense versatility of laser based direct write technologies in biology and medicine.

3D Printing of Passive and Active Medical Devices—A Clinician-Scientist's Perspective

Shervanthi Homer-Vanniasinkam1, 2, 3; 1Division of Surgery & Department of Mechanical Engineering, University College London, London, United Kingdom; 2Vascular Surgery, Leeds Teaching Hospitals NHS Trust, Leeds, United Kingdom; 3Division of Surgery, University Hospitals Coventry & Warwickshire/University of Warwick, Coventry/Warwick, United Kingdom.

The burgeoning field of 3D printing is rapidly invading the medical sphere with an ever-expanding portfolio of applications in healthcare. Since Charles Hull invented stereolithography in the early 1980s, this printing technology has evolved greatly, and to an exponential degree, in the last decade. The applications of 3D printing in medicine are many, and growing. In this talk, some important uses of the technology will be presented, and, as time permits, discussed from a clinician-scientist’s perspective.

In surgery, 3D printing is being increasingly utilised in patient-specific surgical planning to aid intraoperative navigation in complex operative procedures, using precise personalized anatomical information; in producing implants and prostheses; and in educating and training young surgeons. Other applications include 3D bio- and molecular printing of functional living constructs and organs, in drug delivery, and for custom-made medical equipment and products e.g surgical tools and instruments.

Several groups of researchers, including clinician-scientists, are working on exciting developments in areas embracing all aspects of patient care from surgical procedure planning to printing scaffolds and tissues for clinical implantation. Whilst currently there is widespread interest in harnessing this technology in all fields of medicine, in order to realize the full potential of 3D printing, it is perhaps important to prioritize areas in which to focus our research and development endeavours. Clinician involvement in this process is vital, so that minds can be focused on unmet clinical needs. Currently, despite the huge strides made by 3D printing in recent years, there remain challenges for the routine implementation of this technology in the clinical sphere; these include the time taken to prepare the object or device ie long processing times (and hence, limited applicability in the urgent and emergency settings), the accuracy of the devices or models produced, the expense of doing so (despite the decreasing costs of the printers) and importantly, the associated regulatory aspects.

The clinical community is both excited by the promise of what 3D printing can deliver in terms of patient care, and wary of some of the potential dangers of wholly embracing this new field. Thus, it is important for clinicians, scientists and industry to develop a scientifically and socially conscious platform from which to foster the further development of this technology within clearly defined and ethically responsible boundaries. We should jointly strive to achieve this goal so that the promise that 3D printing holds for improved healthcare, is realized.

9:30 AM BM01.01.04

Towards the Development of Perforant Silicone Elastomeric Compositions for 3D Printing of Customizable Parts

Remi Thiria1, Karsten Schlichter2, Jean-Marc Frances3 and Damien Djam1; 1R&D, Elkem Silicons NA, York, South Carolina, United States; 2Elkem Silicons France, Lyon, France.

Due to their outstanding properties like biocompatibility, hypoallergenicity, chemical inertness, thermo-stability resistance and flexibility at low temperatures, soft silicone elastomers are the material of choice in many healthcare applications such as prosthesis, drug delivery, implantable devices, comfort care, audiology and implantable devices.

Traditional manufacturing processes such as casting and injection molding, are currently used for the preparation of biocompatible materials or medical devices however there is a strong need for customized silicone parts.
Additive manufacturing (AM) and especially 3D printing is a tool that offers increased design freedom and enable users to redesign existing parts but also create entirely new parts that can not be manufactured with any of the current traditional manufacturing processes. This technical lecture will introduce the new challenges and benefits of AM to make personalized silicone elastomers against the traditional ways of conception/processing. Due to its low elastic modulus and poor shape retaining ability during the layer-by-layer process, silicone elastomer AM could be technically challenging. A good understanding of the relationship between input and output parameters during the AM is key. Mastering such parameters along with the 3D printer machine and the silicone chemistry have allowed us to predict both the aspect and performances of the 3D printed part.

9:45 AM BM01.01.05
Patient-Specific Printing of Bioreorbable and Biocompatible Ceramics by Lithography-Based Ceramic Manufacturing Shawn M. Allan1, Martin Schwenzenwein2, Daniel Bomze3 and Johannes Homa4; 1Lithoz America, LLC, Troy, New York, United States; 2Lithoz GmbH, Vienna, Austria.

Lithography-based Ceramic Manufacturing (LCM) has emerged as a state-of-the-art technology for the production of dense high-performance ceramics in field of additive manufacturing (AM). LCM polymerizes ceramic slurries, which consist of ceramic particles dispersed in a photocurable binder matrix, in a layer-by-layer manner using light. The green-body is durable enough for handling and mechanical post-processing. After the AM process, the green-body is thermally processed to remove the polymer binder and densify the ceramic. Tremendously diverse and complex parts can be fabricated directly from CAD files. Parts formed by LCM exhibit the same mechanical properties as parts formed by conventional manufacturing processes. LCM allows fabrication of bio-inert zirconia, an exceptionally tough ceramic, for permanent bone replacements and dental implants, crowns, bridges and orthodontic products. LCM also enables the structuring of bioreorbable ceramics like tricalcium phosphate (TCP) or hydroxyapatite (HA). These bioceramics are used in the biomedical field for patient-tailored implants, derived from CT scans. This provides the best compatibility for the patient and easy-to-use handling for the surgeon. The freedom of design facilitates cell scaffolds with defined macroporosity (e.g. cancellous bone shape) for the ingrowth of cells and vascularisation, allowing the delivery of nutrients and the removal of metabolic waste. This contribution gives an overview about the capabilities of the LCM process, potential applications as well as current challenges. Resolution, reproducibility, surface roughness of the different materials and economic feasibility will also be topic of this presentation.

Framed Biopapers—Degradeable Substrates for Printing, Handling, Stacking and Device Integration of 3D Printed Tissue Constructs Russell K. Pirlo1,2; 1Chemistry, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2Radiological Sciences, Uniformed Services University of Health Sciences, Bethesda, Maryland, United States.

Despite the expanding use of 3D bioprinting and a growing number of commercially available 3D bioprinters, there has been limited effort to develop a universal cell and tissue culture platform that enables the plethora of new approaches made possible with 3D printing. Traditional cell culture formats like the well-plate and transwell insert are routinely employed as the receiving container for bioprinted tissues but they present challenges when it comes to perfusion, harvesting, transfer of the printed tissues and accessibly to other tools and instruments. The ability to fabricate tissues in “freeform” is one of the advantages of 3D bioprinting, yet tissues remain confined to the receiving substrate, or lack a method of registration with other devices. The U.S. Naval Research Laboratory has developed “framed biopapers” as a novel and potentially universal format for 3D printing, handling, stacking and transferring tissues with registration between layers and devices. In its most basic application, a single framed biopaper may be used as the base substrate for freeform 3D bioprinting. In this way, the framed biopaper provides a method to handle the 3D printed construct and easily releases the tissue construct through dematerialization of the biodegradable biopaper. Additionally, the frames of the biopaper provide for a registration mechanism for transfer from one bioprinting or biofabrication tool to another, as well as to bioreactors and analytical instruments, such as a microscope or plate reader. Furthermore, framed biopapers enable an asynchronous layer-by-layer fabrication approach whereby sheet-like layers are printed to individual biopapers and allowed to mature independently before stacking. This allows for a specific application of growth factors or stimuli and the construction of complex heterotypic tissues, especially those with a laminar architecture. Finally, we envision that the frame of the biopaper may even be used as a surgical guide for implantation of tissue constructs, precision engineered to fit into a defect/void with alignment of implant and native vasculature and other tissue architecture for more rapid suture, anastomosis and integration into the body.

11:00 AM BM01.01.07

Various manufacturing innovations have been developed to facilitate tissue bioprinting processes for better biomedical applications. Among them, maskless (including extrusion-, laser- and inkjet-based) three-dimensional (3D) bioprinting is a revolutionary advance for printing arbitrary cellular patterns as well as creating heterogeneous living constructs. Thus far, effective printing of cell-laden viscoelastic fluids and printing-induced injury to living cells still pose a significant challenge to ensuring the scale-up of robust bioprinting. Using laser bioprinting (laser-induced forward transfer) and inkjet bioprinting as two jet-based model printing systems, we have been studying the bioprint jettability and printability as well as printing-induced cell injury problems, aiming to achieve robotic bioprinting. The jettability and printability of cell-laden viscoelastic bioprinted tissues are defined and characterized using material properties and printing conditions-related non-dimensional numbers. The printing-induced cell injury and post-transfer cell viability are estimated based on the process-induced cell thermomechanical loading during the cell droplet formation and landing processes. In this talk, the perspective of ongoing bioprinting research and various bioprinting technologies are first introduced. Then the jettability and printability of cell-laden viscoelastic bioprinted tissues are discussed using the dimensionless Ohnesorge and capillary numbers to capture the influence of material properties along with the Weber number to capture the influence of printing conditions. Furthermore, the modeling of laser-induced cellular droplet formation and landing processes is presented, and the relationship between the mechanical loading information and post-transfer cell injury/viability is established using an apoptosis signaling pathway-based modeling approach. Finally, this talk shares some thoughts regarding basic scientific challenges related to bioprinting.

11:30 AM BM01.01.08
Photocurable Thiol/Yne Resins for the Manufacturing of Functional Biocompatible Structures Thomas Grieser; Institute of Chemistry of Polymeric Materials & Christian Doppler Laboratory for Functional and Polymer Based Ink-Jet Inks, University of Leoben, Leoben, Austria.

The last years have seen an increasing interest in the development of photo-polymerizable monomers providing low cytotoxicity and high thermo-mechanical properties in their cured state. This fact can mainly be explained by the rapid progress in UV based additive manufacturing technologies such as stereolithography, digital light processing or 3D ink-jet printing, which enables the fast, accurate and individual fabrication of biocompatible structures.
In this context also the tissue compatibility of photopolymers has to be considered in particular for medical devices that are in direct contact with blood or bone.

In this contribution, the versatility of the thiol-yne photo-click reaction\(^2\) for the fabrication of biocompatible photopolymers is shown at the example of tailor-made alkylene and thiol monomers. For that purpose, commercially available acrylate monomers were modified using the carbon and oxa michael addition reaction to obtain multifunctional alkylene building blocks.

It turned out that these synthesized monomers offer curing rates similar to the acrylates, while providing much higher conversion and lower monomer cytotoxicity. This reaction leads to highly uniform polymeric networks exhibiting a sharp and defined thermal glass transition together with outstanding impact resistance, which makes these polymers interesting for challenging applications such as medical implants.\(^3\) Not only non-degradable, but also degradable monomers were designed, enabling the selective adjustment of the resorption behavior of the resulting polymers.\(^4\)

The herein described monomer systems pave the way towards the individual fabrication of tissue compatible photopolymers with tunable thermo-mechanical properties and resorption behavior.

**11:45 AM BM01.01.09**

Manufacturing Microstructured Medical Devices Using Multi-Step 3D Printing Technologies

Roger Narayan; North Carolina State University, Raleigh, North Carolina, United States.

In this presentation, the use of multi-step 3D printing technologies, which incorporate digital micromirror device-based stereolithography, two photon polymerization, pulsed laser deposition, matrix assisted pulsed laser evaporation, piezoelectric inkjet printing, and/or micromolding, to create small-scale medical devices for transdermal drug delivery will be considered. Microneedles are small-scale lancet-shaped devices that may be used for delivery of pharmacologic agents into the skin. We have use 3D printing techniques to microneedles such as digital micromirror device-based stereolithography and two photon polymerization to create microneedles with well-defined tips and complex shapes directly from computer models. Printing techniques including pulsed laser deposition, matrix assisted pulsed laser evaporation, and piezoelectric inkjet printing have been used to decorate the 3D printing microneedles with medically active agents. For example, visible light dynamic mask microstereolithography and micromolding have been used to prepare microneedles out of poly(methyl vinyl ether – co – maleic anhydride) (PMVE/MA); coatings containing agents such as amphotericin B and miconazole have deposited on the microneedles using piezoelectric inkjet printing. Disk-diffusion studies demonstrated the antifungal activity of the inkjet-printing-modified microneedle arrays. Examples involving the use of multi-step 3D printed microneedles for various medical applications will be considered.

Laser Direct Energy Deposition Additive Manufacturing of NiTi Shape Memory Alloys

Reginald F. Hamilton, Beth Last, Emily Jenkins and Todd Palmer; Engineering Science and Mechanics, The Pennsylvania State University, University Park, Pennsylvania, United States.

Additive Manufacturing (AM) has gained significant attention in processing shape memory alloys because they have circumvented many of the challenges associated with the conventional methods. Shape memory alloys are a class of multifunctional materials that undergo large shape changes, and upon heating or removing external stimuli “remember” their original shape and form. Underlying reversible solid-state atomic and microstructure length scale phase transitions beget the bulk scale memory. Consequently the shape memory alloy behavior can be tailored using manufacturing techniques that provide freedom to design the microstructure. The AM techniques for NiTi are either powder-bed based technologies such as Selective Laser Melting, or flow-based methods such as Laser Directed Energy Deposition (LDED). LDED deposits powder through nozzles directly into the laser focus melt pool. LDED AM is a potential tool for in-situ, i.e. during fabrication, microstructure design. The laser-based layer-by-layer AM techniques can result in microstructural anisotropy, which is characterized in terms of the grain and microconstituent morphologies. During the additive manufacturing (AM) process, individual passes and layers are deposited. The deposition of passes and layers creates overlapping regions between adjacent passes and interfacial zones between successive layers. Within the overlapping and interfacial regions, previously deposited material is remelted is also reheated as heat is conducted away from the solidifying material. The remelting and reheating in these local regions will bring about microstructure anisotropy. Multi-scale deformation measurements correlate microstructure to underlying physical mechanisms in order to establish the interrelationships between novel fabrication technologies and shape memory functionality. The purpose of this work is to correlate the layerwise built-up microstructures to the shape memory behavior of LDED AM NiTi shape memory alloys.

**2:00 PM BM01.02.02**

Hydrogel Bioinks for 3D Printing Applications

Jason Burdick; University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Hydrogels represent a class of biomaterials that have great promise for the repair of tissues, particularly due to our ability to engineer their biophysical and biochemical properties. 3D printing approaches are now being developed to process hydrogels into structures with the appropriate shapes and patterns for tissue repair; however, printing processes are often not compatible with hydrogels optimized for a desired cell response. Thus, we have developed techniques to both screen hydrogels for a desired cell response and to process these materials into printable bioinks.

Towards MSC chondrogenesis, we have developed a screening platform using the patterning of photocrosslinkable norborneo-modified hyaluronic acid hydrogels with biochemical signals. These include peptides that mediate cell-matrix adhesion (i.e., RGD) or cell-cell adhesion (i.e., HAVD). When cells are encapsulated within the hydrogels incorporating orthogonal gradients, optimal formulations can be identified through imaging of MSC differentiation markers (e.g., Sox9, aggrecan). As these are non-viscous precursor solutions, they are difficult to 3D print using traditional printing approaches, such as extrusion-based printing. With extrusion-based printing, a bioink must flow during extrusion, but then be rapidly stabilized post-extrusion to maintain the desired printed structure. To address this, we have developed two approaches to 3D print non-viscous bioinks: (i) curing the material with light through a
encapsulate cells with high cell viability. Ultimately, the design of new bioinks and printing processes will lead to successful applications of 3D printing in the repair of tissues.

3:00 PM **BM01.02.03**

**3D Printed Ceramic-Metal Composites to Minimize Metal Ion Release from Articulating Surfaces of Load-Bearing Implants**

Anmit Bandyopadhyay, Anish Shivaram, Murat Isik, Jose Avila and Susmita Bose; School of Mechanical and Materials Engineering, Washington State University, Pullman, Washington, United States.

Cobalt-chromium-molybdenum (CoCrMo) alloys are widely used in load-bearing implants, specifically in hip, knee, and spinal applications, due to their excellent wear resistance and their being economic compared to titanium-based alloys. However, due to wear induced metal ion release from the implants and poor biocompatibility at implant-tissue interface, there is a significant interest to find an alternative to CoCrMo alloy. We hypothesize that adding calcium phosphate (CaP) based ceramic in the form of hydroxypatite can minimize metal ion release concerns in CoCrMo alloy. CoCrMo-CaP composite coatings were processed using a commercial laser-engineered net shaping (LENS™) system. After LENS™ processing, CoCrMo alloy was subjected to laser surface melting (LSM). Samples were investigated for microstructure, phase stability, and wear induced damage. It was found that wear resistance of CoCrMo was enhanced by ~ 5 times due to the formation of an in situ tribofilm of CaP's, and achievement of a fine dendritic microstructure in the case of LSM treated CoCrMo. In vitro cell material interactions study using human osteoblasts cell line was performed. For in vivo, rat and rabbit distal femur models were used for a period of 5 and 12 weeks. In vitro and in vivo study showed improved biological response for surface modified CoCrMo compared to untreated CoCrMo approximately a 5-fold increase in osteoid formation. Our results show that careful surface modification treatments can simultaneously improve wear resistance and in vivo biocompatibility. The presentation will focus on processing as well as physical, mechanical and biological characterization of 3D printed CaP-CoCrMo composites with a focus on minimizing metal ion release.

3:30 PM **BM01.02.04**

**3D Printing of Multifunctional Tissue Engineering Scaffolds**

Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong.

Tissue engineering has advanced significantly over the past three decades and many human body tissues may be regenerated successfully, providing desired functions in the human body. A few approaches are used for human tissue regeneration, which include cell- factor- or scaffold-based tissue engineering. Using scaffolds to assist tissue regeneration has been the dominant approach. In scaffold-based tissue engineering, it is important to develop suitable scaffold materials and employ appropriate scaffold manufacturing technologies to make desirable scaffolds, which will lead to successful tissue regeneration. Many materials have been investigated for different scaffolds and scaffold fabrication techniques have been studied by numerous researchers. Materials for tissue engineering are generally biodegradable polymers and scaffolds are produced by either non-designed manufacturing techniques (e.g., solvent casting/porogen leaching) or designed manufacturing techniques. Using designed manufacturing, which includes a host of additive manufacturing technologies (the so-called “3D printing”), for scaffold fabrication has distinctive advantages and has therefore attracted great attention in the tissue engineering field. However, some 3D printing technologies impose stringent requirements for stock materials and studies have been conducted on preparing stock materials and on evaluating the physical and mechanical properties of scaffolds made of these stock materials. Furthermore, existing, general 3D printing technologies may not be suitable for constructing multifunctional tissue engineering scaffolds in which biological molecules or even live cells need to be incorporated. Hence, new 3D printing technologies specifically for handling delicate biomolecules and/or cells are urgently needed. Our group has investigated selective laser sintering (SLS), a well-established 3D printing technology, for making osteoconductive and osteoinductive scaffolds for bone tissue engineering. In this process, we developed nanocomposite materials as scaffold materials which provided osteoconductivity. For the novel scaffolds, we also incorporated a growth factor which provided osteoinductivity. Our studies showed that bone tissue regeneration was greatly promoted with the SLS-formed multifunctional scaffolds. We have also developed a low-temperature, extrusion-based 3D printing technique for constructing relatively strong scaffolds with the incorporation of biomolecules or cells. Very promising results were obtained using this new 3D printing technology. This talk will give an overview of 3D printing and its application in tissue engineering. It will introduce our work in this area and discuss issues in scaffold design and 3D printing.

4:00 PM **BM01.02.05**

**Inkjet Printing of Melanin as a Biocompatible Functional Electronic Material**

Ashkan Shafiei1, Elham Ghadiri2, Warren Warren2 and Anthony Atala1;1 Institute for Regenerative Medicine, Wake Forest School of Medicine, Winston-Salem, North Carolina, United States; 2Chemistry, Wake Forest University, Winston-Salem, North Carolina, United States.

Biocompatible electronic has become a focus of attention owing to the need in biomedical applications. Smart electronic devices capable of communicating with biological structures such as human tissues and organs are the requirement for many sophisticated purposes in medicine. Melanin is one of the most stable biopolymer, found in almost every live organism, versatile for application in the emerging field of bioelectronic devices. Melanin pigments are found in human skin, hair, eyes and the brain in different forms. For many years, it was viewed simply as a coloring agent with some photoprotective properties, but that view always ignored some obvious features. The functionality of melanin as a natural pigment is defined (although not fully understood) by its physical and chemical properties, such as its featureless broad UV-NIR optical absorption, antioxidant properties, and temperature/water dependent photocconductivity. Melanin also shows in vivo and in-vitro biocompatibility. All these properties identify melanin as a unique alternative for using as the functional material in the bioelectronic devices.

This paper report the inkjet printing of synthetic melanin nanoparticles with different size for electronic applications. Inkjet printing deposition with computer-assisted abilities can pattern different types of materials on various flexible or rigid substrates. Inkjet printing deposits pattern with Pico-liter size droplets of the functional materials with micrometer resolution. This economic consumption makes this technique much more affordable compared to other deposition techniques such as spin coating and dip coating.

Through solution-based chemical synthesis, we have prepared melanin nanoparticles with controlled size and chemical structures of melanin-like nanoparticles, pheomelanin and eumelanin. The active layer of the electronic device consists of melanin nanoparticles based film prepared with inkjet printing technique. Nanoparticles solutions with different sizes of 70 nm, 100 nm, and 250 nm were printed on transparent conductive electrode using Jetlab II Microlab, piezoelectric printer. The optoelectronic and photophysical processes in the films are studied using steady-state UV-NIR diffuse reflectance spectroscopy and ultrafast time-resolved broadband pump-probe spectroscopy technique. Using ultrafast broadband spectroscopy
measurements, we identified the spectral signature of excited state formation and compared excited state relaxation in melanin nanoparticles with different sizes. This research can open up the new avenue of research toward biocompatible electronic manufacturing.

4:15 PM BM01.02.06
Rheology and Direct Ink Writing of Strong Cellulose Reinforced Composites
Michael Hausmann1,2, Gilberto Siqueira1, Rafael Libanori2, Patrick Rihs1, Dimitri Kokkinis2, Tanja Zimmermann1 and André Studart1; 1Empa, Swiss Federal Laboratories for Materials Science and Technology, Dubendorf, Switzerland; 2ETH Zürich, Dubendorf, Switzerland.

Cellulose nanocrystal (CNC) is a bio-based and renewable material extracted from wood and algae or produced by bacteria. The alignment of CNCs is crucial for direction specific enhanced mechanical properties in composite applications. We utilize direct-ink writing (DWI) to assemble complex cellulose-based geometries with controlled orientation and spatial distribution of nanocrystals within the printed structure. Using polarized imaging we correlate the dynamic flow behavior of CNC-based inks with the quality of nanocrystal alignment occurring during 3D printing. In order to control the quality of alignment during the 3D printing process, the printing pressure and the viscoelastic properties of the material have to be well characterized. After printing, the resulting part and its mechanical properties are determined in order to create composites with well-defined properties. By understanding the effect of the concentration of reinforcing nanocrystals on the rheological properties of the ink during the printing process, 3D objects with improved printability and mechanical properties were obtained. Our findings pave the way towards the fabrication of high-performance materials with renewable resources using a cost-effective additive manufacturing technique.

4:30 PM BM01.02.07
Structure-Function Relationships of Varying Microarchitecture and Surface Topography of 3D Printed Ti-6Al-4V Fabricated by Selective Laser Melting
Cambre N. Kelly1, Nathan T. Evans2, Cameron W. Irvin2, Savita Chapman2, Ken Gall2 and David L. Satsal2; 1Duke University, Durham, North Carolina, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States; 3Medshape, Atlanta, Georgia, United States.

As the manufacturing of medical devices via additive manufacturing (3D Printing) continues to increase, better understanding of structure-function relationships of microarchitecture and surface topography are needed. Selective laser melting (SLM) of Ti-6Al-4V of implants with interconnected porosity have become widespread in orthopedic and other load bearing applications where porous structures encourage bony ingrowth and the stiffness of the implant can be tuned to reduce stress shielding. SLM allows high resolution control over design, including the ability to introduce porous surfaces or regions with spatial variations in pore size, shape, and connectivity. Investigation of the effect of construct microarchitectural design and surface topography on mechanical behavior of 3D printed Ti-6Al-4V showed a dominating effect of porosity on monotonic and fatigue behavior as compared to solid samples. Irrespective of surface treatment and resulting surface roughness, the fatigue strength of 3D printed samples containing bulk or surface porosity was approximately 20% to 25% of the ultimate tensile strength of identical printed porous material. For the vast range of microarchitectures which can be fabricated to tune construct porosity and resulting stiffness, creation of predictive models of fatigue behavior based on monotonic properties would allow for rapid iteration of design for devices with microarchitecture specified not only to patient anatomy, but also bone quality and loading profiles for tailored reduction of stress shielding.

4:45 PM BM01.02.08
3D Printed Functional and Biological Materials on Moving Freeform Surfaces
Zhijie Zhu, Shuang-Zhuang Guo, Tessa Hirdler, Cindy Eide, Xiaoxiao Fan, Jakub Tolar and Michael McAlpine; University of Minnesota, Minneapolis, Minnesota, United States.

Conventional 3D printing technologies typically rely on open-loop, calibrate-then-print operation procedures. An alternative approach is adaptive 3D printing, which is a closed-loop method that combines real-time feedback control and direct ink writing of functional materials in order to fabricate devices on moving freeform surfaces. Here we demonstrate that the changes of states in the 3D printing workspace in terms of the geometries and motions of target surfaces can be perceived by an integrated robotic system aided by computer vision. A hybrid fabrication procedure combining 3D printing of electrical connects with automatic pick-and-placing of surface-mounted electronic components yielded functional electronic devices on a free-moving human hand. Using this same approach, cell-laden hydrogels were also printed on live mice, creating a model for future studies of wound-healing diseases. This adaptive 3D printing method may lead to new forms of smart manufacturing technologies for directly printed wearable devices on the body and for advanced medical treatments.

Vascularized Heterogeneous Cardiac Tissue Network by a Direct Patterning with a 3D Bioprinter
Joonan Kim and Jin Seok Lee; Sookmyung Women's University, Ithaca, New York, United States.

3D bioprinting is a widely used technology to dispense cell-laden biomaterials for rapid fabrication of complex 3D tissue constructs or artificial organs. To date, many studies have been investigated the deposition and patterning of cell-laden bioinks with a 3D bioprinter. However, the precise positioning, reasonable mechanical properties, and controlled cell distributions of constructs in 3D bioprinting system still remains technical challenges. In this study, we developed heterogeneous cell-laden microchannel network using human umbilical ven endothelial cell-cardiomyocytes by a direct patterning with a 3D bioprinter. We fabricated 3D tissue constructs consisting of the core (human umbilical ven endothelial cell -laden collagen) and the sheath (cardiomyocytes-laden gelatin methacrylate). We could achieve a stable 3D multilayered core-sheath structure with the reasonable elastic modulus. This system also facilitated cell alignment and migration within each constructs and promoted vascular network with high cell viability. Calcium imaging was used to optically probe intracellular calcium ion signals during excitation-contraction coupling in cardiomyocytes within 3D vascular network.

This paper presents the new approach for fabricating vascularized heterogeneous 3D scaffolds and highly controlled deposition technique of bioinks. The cell-laden 3D constructs could be extended to serve as in vitro models for clinical cardiovascular disease researches and cardiovascular tissue regenerations.
Three-Dimensional Printing of Magnetic Data Storage Structures

BM01.03.05

Periodontal ligament (PDL) with structural connectivity between cementum and alveolar bone tissues has key functions to optimize positional stabilities of teeth, transmit and absorb various stresses under masticatory/occlusal loading conditions, or promote tissue remodeling by mechanical stimulations. The oriented PDL formations with micron-scaled dimensions and calcified interfacial tissue formation with fibrous tissue anchorages are challenging in bone-ligament complex neogeneses. We investigated the 3-D microarchitectures, which can spatiotemporally organize PDL for fibrous connetive tissue formations.

The periodontal regeneration scaffolds had three compartmentalized microarchitectures; cementogenesis platform (~200um), PDL-guiding architectures, and bone scaffolds. After computer designs, 3-D printing system manufactured micron-scaled wax molds and biodegradable material (poly-e-caprolactone; PCL) was casted into wax molds. The architectures were characterized with micro-CT, SEM, and confocal microscope for topographies. In in-vitro human PDL cell cultures and in-vivo subcutaneous model system, cell orientations or angulations were analyzed with nuclear morphologies and deformations.

In in-vitro experiments, microgrooves on scaffold architectures can angularly organize and geometrically control cell orientations for 7-day and 21-day cultivations. In particular, micro-patterns on microarchitectures can predictably and accurately control PDL cell orientations with high proliferations. Moreover, microgroove-patterned scaffolds promisingly provided more predictable cell alignments and cell orientations were significantly angular-controllable with statistical difference in in-vivo.

The additive manufacturing system can fundamentally manufacture various microarchitectures with micro-scaled patterns, which are designed in CAD. Based on topographical cues, PDL stem cells can be spatiotemporally regulated for fibrous connetive tissue and mineralized tissue formations as well as scaffolds can control specific orientations of ligament cells and tissues. Therefore, the investigation demonstrates the compartmentalized microarchitectures facilitate to regenerate periodontal complexes which have structural similarities to natural periodontia.

BM01.03.03

3D Printing of Antimicrobial PLA/GO Nanocomposite Implants

Viavvedhan Jayanthihakiriksharn1, Digiqiyv Shind1, Prabir Patra1, Tae Won B. Kim2, Sarosh Patel2 and Tarek Sobb3; 1Biomedical Engineering, University of Bridgeport, Bridgeport, Connecticut, United States; 2Mechanical Engineering, University of Bridgeport, Bridgeport, Connecticut, United States; 3Orthopaedic Oncology, Cooper University Health Care, Camden, New Jersey, United States; 4Computer Science and Engineering, University of Bridgeport, Bridgeport, Connecticut, United States.

Graphene based medical implants have sparked widespread interests in the field of 3 D bioprinting due to its anti-microbial nature, very large aspect ratio associated with its 2D structures, and its ability to form functionally graded printable structures with polymers. Here we explore the 3 D printing of Poly L-lactic acid/Graphene oxide (PLA/GO) nano-composite for its anti-microbial property as bone implant and scaffold for bone cell proliferation. The nanocomposites were prepared through FDM (Fused deposition modelling) and our laboratory built LDM (Liquid deposition modelling) 3D printing. GO was dispersed in 1,4 dioxane using ultrasonication followed by dissolving PLA in the GO dispersions. LDM utilized the viscosity driven controlled stretching of the PLA/GO solution to print the solid structural form onto a heated bed that vaporizes the solvent and leaves behind the required structure. For the FDM process, the nano-composite was fed in the form of a filament. We utilized the dried and powdered form of the nano-composites to form the essential PLA/GO filamentous structures using the filament extruder. We plan to integrate electrostatic jetting of PLA/GO nanocomposites through the micro nozzle using FDM system for attaining controlled porosity and microstructure, thereby closely mimicking the bone microenvironment. Anti-microbial activity of GO was measured with staphylococcus aureus, 60% reduction of bacterial growth was achieved.

A Multi-Structured 4D Stent with Large Deformation and Faster Temperature Response

Je Hoon Oh1, Wonjin Jo2, Jongbeom Ghim3, Myoung-Woon Moon4 and Kuy Hwan Oh1; 1Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of); 23D Printing Group, Computational Science Research Center, Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

4D printing is a technology that makes the 3D printed structure deformed by responding the environmental stimuli such as water, temperature or UV. Especially, 4D printing has been actively studied for applications in medical devices such as a stent or a scaffold, which can be deformed under body fluid conditions to the intended shape. Even though the 4D structures transform properly under temperature or water, one may wait for longer duration to achieve its final configuration, which is not desired in medical level application.

In this presentation, we introduce a multi-structured 4D stent with large deformation and faster response to the small temperature change. A multi-structure 3D printing scheme is presented by printing a raster line in curved or coiled configuration by using a fused deposition modeling (FDM) type 3D printer with a shape memory polymer (SMP). The printed configurations in several curved shapes such as wavy or coiling shape were achieved by setting two main parameters of the interval between the printer bed and the nozzle as well as the filament flow rate. As increased the interval from 0.2~0.3 mm to 1~2 mm, the flow speed of 3 times faster than the normal printing conditions, the extruded raster line patterns were changed from straight to wavy or coiled.

Since the thermoplastic SMP has a viscoelastic property, the configuration of the printed patterns was formed by a liquid rope-coiling effect that is a phenomenon based on buckling instability of viscoelastic material. It was also found that by tuning the deformation temperature below or above the glassy temperature, Tg, of the SMP, the curved line was deformed 1.5 times more than the straight line with much faster recovery rate. By alternating stacking layers printed with the curved line pattern over the straight line pattern, we fabricated a 4D stent structure with larger and faster response to warm temperature of our body fluid. It is expected that this 4D stent can alleviate the problem of blood vessel scarring during the insertion of the stent.

Three-Dimensional Printing of Magnetic Data Storage Structures

Corey Breznak and Paris von Lockett; The Pennsylvania State University, University Park, Pennsylvania, United States.

Traditionally, barcodes encode data in a binary format by using groups of parallel lines with varying distance between them. Although a barcode is simple to print, the complexity of the data that can be stored is limited. This research aims to design a method to encode more complex forms of data with higher information densities using 3-d printed magnetic structures. The work presented investigates the basic principles for 3-d magnetic patterning as a means of information storage, tagging, and/or part identification.

In this work, a structure is fabricated using proscribed patterns of magnetic and nonmagnetic regions. These structures are similar to present day barcodes, where the magnetic regions generate an external magnetic field, the stray field, that can be interrogated with a Hall effect or similar magnetic probe. The regions of magnetic and nonmagnetic field can be spaced apart at varying distance, or the thickness of each region can be varied, both of which affect the resolution of the magnetic signature of the stray field generated by the pattern. The patterns yield a magnetic equivalent to the binary optical nature of barcodes.
codes. Unlike with the fabrication of barcodes, other processing variables influencing the stray field of the structure can be altered to add complexity to the data encoding. For example, by using hard magnetic powders such as barium hexaferrite, which consists of magnetically anisotropic plate-like particles, the magnetic regions can be oriented in arbitrary directions yielding more intricate stray fields, and consequently more complex magnetic signatures and higher information density.

This work first provides a proof of concept using neodymium magnets inserted into a 3-d printed patterned structure to produce the stray field, which is characterized using a gaussmeter. The creation of this structure is the simplest proof of concept of a magnetic bar code. A second proof of concept 3-d prints both the nonmagnetic and magnetic parts of the structure using Protopasta magnetic filament (consisting of PLA with 45 wt.% iron particles) and standard ABS filament in a dual material FDM printer. Printing alternating regions of magnetic and nonmagnetic material form the now passive magnetic structure. A force gauge with a magnetic tip is used to determine the signature of the stray field resulting from the magnetic pattern. Finally, a computational model is developed to simulate stray field and resulting signature of the printed magnetic structures for comparison with experiments.

Future work includes using magnetic filament consisting of hard magnetic particles such as barium hexaferrite, whose magnetic anisotropy facilitates complex magnetic alignments within the magnetic regions of the printed structure. Complex alignments allow increasingly sophisticated magnetic signatures, permitting an increase in the complexity of stored data, as well as an increase in information density.

3D Printing of Multifunctional Hydrogel Actuators for Biomedical Application

Youzhou Yang, Jianfeng Zang, Hanchuan Tang and Yueying Yang; School of Optical and Electronic Information and Wuhan National Laboratory for Optoelectronics, Huazhong University of Science & Technology, Wuhan, China.

Hydrogels are wet and biocompatible and are used as scaffolds for tissue engineering, vehicles for drug delivery, actuators for optics and fluids, and model extracellular matrices for biological studies. Three-dimensional (3D) printing methods, especially direct ink writing, have been widely used, allowing the rapid and complex design and fabrication of hydrogels. Taking advantages of 3D printing, hydrogels with different properties can be easily manufactured. Lots of existing works have reported 3D printing of tough hydrogels for biomedical application. We employed responsive particles embedded in hydrogel precursor as the ink for the direct ink writing process. Subjected to the in situ external fields, the as-prepared precursor was printed in well-designed paths with on-demand properties. In this way, we prepared hydrogel actuators not only with notable mechanical property, but also with large deformation and programmable deformation mode. Moreover, using our strategy we demonstrate a soft active bandage that can rub the ointment on affected areas with a controllable manner, and an untethered gripper for medicine.

3D Printed Tissue Engineering Constructs Embedded with Electrospun Nanofiber Mats Using Various Biomaterials

Suk-Hee Park, Young Won Kim, Han Bit Lee, Ye Ji Yoon and Yong Son; Korea Institute of Industrial Technology, Ansan-si, Korea (the Republic of).

Recently, the most important issues in the tissue engineering field are to mimic the natural extracellular matrix (ECM) and to manufacture the customized structures with patient-specific morphology. These are the critical factors for regulating functions of cultured cells and being used as the clinical-level applications. In these respects, nanoscale fabrication and 3D printing technologies have attracted much attention from the scientists and engineers in the relevant fields. In this presentation, we are going to introduce new hybrid bio-printed constructs, which consist of 3D printed parts and electrospun nanofiber mats. When it comes to electrospinning process, it could formulate not only randomly-network fibrous mat of it natural processed form but also highly-oriented fiber arrays. Depending on the fiber orientation, the cultured cells on the scaffolds could be modulated in terms of their biological functions and behaviors. The biomaterials for 3D printing could be classified to two groups; i) thermoplastic rigid polymers and ii) hydrogel-based bio-ink. When the thermoplastic biomaterials, for which polycaprolactone (PCL) was used in our studies, were combined with the electrospun mats, they were effectively supportive to sustain the morphologies of nanofiber mats. Since the supportive constructs were fabricated in the way of CAD/CAM-fashioned process, they were expected to overcome various obstacles in practical uses of the fragile nanofiber scaffold and meet the needs for clinical applications in specific surgeries. As for the hydrogel-based materials, which physically involved living cells, they were 3D-printed in the layer-by-layer manner. When the layering of bio-inks were processed with insertion of nanofiber mats between the hydrogel layers, the integrated constructs had enhanced properties in terms of structural resolution as well as mechanical toughness and stiffness. The improved performances of fiber-reinforced hydrogel constructs were expected to achieve the morphological and biophysical mimicry of native soft tissues. Taken together, the combinatorial fabrication techniques involving 3D printing and electrospinning would allow for a wide range of feasible applications in the scaffold-based tissue engineering.

3D Printing and Post-Processing of PEEK Structures and Their Potential Applications to Bone Tissue Engineering

Suk-Hee Park, Seong Je Park, Ji Eun Lee, Han Bit Lee, Jae Won Choi and Yong Son; Korea Institute of Industrial Technology, Ansan-si, Korea (the Republic of).

3D printing, CAD/CAM-based processing approach, has been considered as an effective tool to satisfy the many requirements in the trends of manufacturing industry changing rapidly from mass production to mass customization. Fused deposition modeling (FDM), or material extrusion (ME) in ASTM terminology, has been one of the most commonly and widely used processes owing to its various advantages, such as low-cost material and hardware, simple processing mechanism, and wide material usage. Recently in the industry of 3D printing manufacturing fields, high-strength polymers with reliable performances have attracted much attention from the relevant researchers and engineers. In this presentation, we introduce the FDM-based 3D printing and the post-processing of polyetheretherketone (PEEK), which is one of the representative super engineering polymers. PEEK is the material as difficult to be processed as its high mechanical performance. We first developed custom-made 3D printing system, which was able to deal with the engineering plastic materials. Specifically, the 3D printer included several thermostatic control systems to modulate the environmental conditions of printing, such as the temperature of the surrounding air in the printing chamber. The use of temperature-controlled conditions in not only the nozzle but also in the chamber instead of room temperature was necessary in order to stably print the engineering polymers without defects or delamination in the final product. We studied the optimized parameters for the stable printing process, such as nozzle/chamber temperature, nozzle speed, printing tool-path, and extruding rate. With these process parameters, the maximum tensile strength of the resulting PEEK parts was achieved at approximately 80% of the bulk material property. In addition, we studied the effects of heat treatment on the mechanical property and crystallinity. The heat-based post-processing could improve the tensile strength up to 90% of the bulk material property, which was comparable to mechanical properties of bone. Based on the optimized conditions from process design to post-process, we tested the feasibility of manufacturing of orthopedic products and bone implants.

Thiol-Yne Photo-Click Chemistry—Towards Biocompatible and Tough Photopolymers for 3D Printing

Delara Hartmann, Andreas Oesterreicher and Thomas Grieser; Institute of Chemistry of Polymeric Materials & Christian Doppler Laboratory for Functional and Polymer Based Ink-Jet Inks, Montanuniversität Leoben, Leoben, Austria.

Recent years have seen an increasing interest in the development of photo-polymerizable monomers providing low cytotoxicity and high impact resistance in their cured state. This fact can mainly be explained by the rapid progress in UV based additive manufacturing technologies such as stereolithography,
digital light processing or 3D ink-jet printing which enables the fast, accurate and individual fabrication of biocompatible structures for hard tissue engineering. In this contribution, the versatility of the thiol-ynel photo-click reaction for the fabrication of biocompatible photopolymers is shown at the example of tailor-made bi- and multifunctional alkynyl and thiol monomers. This reaction leads to highly uniform polymeric networks exhibiting a sharp and defined thermal glass transition together with outstanding impact resistance [1] making these polymers interesting for challenging applications such as medical implants. A particular focus was set on the development of low odour thiols as promising alternatives to commercially available mercapto propionic acid derivates. Thiol-ynel resins based on these monomers provide both, high reactivities comparable to those of acrylates and mechanical properties appropriate for the fabrication of medical devices in their cured state. The herein described monomers pave the way towards the fabrication of tailor-made photopolymers suitable for hard tissue engineering.

*In Vitro Perforation of the Round Window Membrane via Direct 3D Printed Microneedles* Aykut Aksel1, Wenbin Wang1, Daniel N. Arteaga2, Miguel Arriaga1, Yan Wang1, Hirobumi Watanabe1, Karen Kasza1, Anil K. Lalwani1, 2 and Jeffrey W. Kysar1, 2; 1Mechanical Engineering, Columbia University, New York, New York, United States; 2Otolaryngology, Columbia University, New York, New York, United States.

We report the use of Two-Photon-Polymerization (2PP) lithography to manufacture precision microneedles for the purpose of intracochlear drug delivery. The cochlea, or inner ear, is a space fully enclosed within the temporal bone of the skull, except for two membrane-covered portals connecting it to the middle ear space. One of these portals is the round window, which is covered by the Round Window Membrane (RWM). A longstanding clinical goal is to deliver therapeutics into the cochlea to treat a plethora of auditory and vestibular disorders. Standard of care for several difficult to treat diseases calls for injection of a therapeutic substance through the tympanic membrane into the middle ear space, after which a portion of the substance diffuses across the RWM into the cochlea. The efficacy of this technique is limited by an inconsistent rate of molecular transport across the RWM.

A solution to this problem involves the introduction of one or more microscopic perforations through the RWM to enhance the rate and reliability of diffusive transport. Hence, ultra-sharp polymer microneedles specifically designed to perforate the RWM are made using direct 3D printing via 2PP lithography.

The needles are 3D printed, developed and mounted on sterile 23 Gauge blunt syringe tips for practical use. The needles are then used to perforate freshly excised guinea pig membranes. The perforation force is collected, and the resulting holes are analyzed via confocal microscopy, which has the benefit of visualizing the fibers that give the RWM its mechanical properties.

The microneedle has tip radius of curvature of 500 nm and shank radius of 50 µm. It perforates the RWM with a mean force of 1.19 mN. The resulting perforations performed in-vitro are lens-shaped with major axis equal to the microneedle shank diameter and minor axis about 25% of the major axis, with mean area 1670 µm². The major axis is aligned with the direction of the connective fibers within the RWM. The fibers were separated along their axes without ripping or tearing of the RWM suggesting the main failure mechanism to be fiber-to-fiber decohesion.

The needles are imaged using a Scanning Electron Microscope (SEM) after use, and it is seen that the tips of these microneedles are bent to some extent, limiting their reusability. Therefore, radii of curvature of the tips are systematically changed in order to find an optimal shape for the needles with the purpose of enhancing the mechanical strength and preventing blunting.

These results establish a foundation for the use of 2PP as a means to fabricate microneedles to perforate the RWM and other similar membranes requiring precision manufacturing of complex geometries. The small perforation area along with fiber-to-fiber decohesion are promising indicators that the perforations would heal readily following in-vivo experiments. An optimal needle geometry is currently being researched for the purpose of RWM perforation.

*Study of Fusion in 3D Printing of PLA/Graphene Composites* Yuval Shmueli1, Xiaoxin Wang2, Steven Wu3, Derek Zheng4, Lan Jiang5, Caroline Zeng6, Dilip Gersappe7, Miriam Rafailovich1; Matthew York7 and Zhuolin Xia1; 1Stony Brook University, Stony Brook, New York, United States; 2Padua Franciscan High School, Parma, Ohio, United States; 3Clear Lake High School, Houston, Texas, United States; 4Monta Vista High School, Cupertino, California, United States; 5University High School, Irvine, California, United States; 6Wayzata High School, Plymouth, Minnesota, United States; 7Case Western Reserve University, Cleveland, Ohio, United States.

Fused deposition modeling (FDM) printing is an emerging 3D printing technology in which thermoplastic filaments are extruded and deposited in certain manner according to computer input design. Polylactic acid (PLA) is a common biodegradable polymer being used in FDM printing and has great potential to be the main component in future biomedical devices. However, since it has poor thermal conductivity properties it is often leads to failing interfilaments fusion and hence reduces the overall product mechanical and functional properties.

In this work we incorporate graphene nano platelets (GNPs) to examine their effect on the thermal profiles during printing and the resulted mechanical properties. We studied the conditions of different nozzle temperatures and varied the distance between adjacent filaments and between deposited layers by adjusting the Gcode input to the printer. We used high resolution infra-red thermal camera to monitor the temperatures at the printing process. Then we correlated these profiles with (scanning electron microscopy) SEM analysis and dynamic mechanical analysis (DMA) properties of the printed structure. We also used microbeam small angle X-ray scattering (SAXS) measurements to study the macrostructure of the printed filaments as function of the radial position from the interfilaments interface to the filaments core. In addition, we modeled the temperature profiles and the flow mechanics of GNPs flow in the polymer matrix using Lattice Boltzmann Modeling (LBM).

We show the great effect of GNPs inclusion on the fusion process while printing and how it affects the resulted properties and can be used in future potential applications. The experimental results combined with the modeling results enable us to present the optimal conditions and composition to improve the fusion and hence the strength of the printed structures.

We Acknowledge support from the National Science Foundation (Inspire Award No. 1344267) and The Morin Foundation Trust.

*Self-Folding of 3D Printed Shape Memory Polymers with High Degree of Shrinkage* Akhiro Nojiri1, 3, Eiji Iwase2, and Michiako Hashimoto1, 2; 1Digital Manufacturing and Design Centre, Singapore University of Technology and Design, Singapore, Singapore; 2Pillar of Engineering Product Development, Singapore University of Technology and Design, Singapore, Singapore; 3Department of Applied Mechanics, Waseda University, Tokyo, Japan.
Self-folding is a strategy to fabricate 3D shapes from planar sheets. 3D printed planar structures have been demonstrated to form 3D shapes via self-folding due to shrinkage of 3D-printed polymers. The degree of polymer shrinkage due to heat is typically low, and achievable 3D shapes have been limited in size and complexity. In this work, we demonstrated self-folding of a polyurethane-based shape memory polymer (SMP) printed by a fused deposition modeling (FDM) 3D printer. SMP transfers from rubber states to glass states by the change of temperature, and this phase transition is typically used to memorize specific shapes. We used this characteristic not for shape memory but for self-folding. When SMP is printed in rubber states by FDM, internal stress is introduced to the printed SMP structures on the build plate. Above its glass transition temperature \( (T_g) \), the SMP structure releases internal stress and shrinks. This shrinking is due to the phase transition and the release of internal stress. We demonstrated that the 2D structures consisting of 3D printed SMP were readily transformed to the 3D structures through this mechanism. We achieved to control the degree of shrinking by varying (1) printing temperature, (2) FDM nozzle speed and (3) multilayer design of the planar sheet. These parameters allowed defining bending angles and directions of resulting 3D structures (such as valley folds, mountain folds and their combinations) due to the difference in the internal stress between adjacent layers of SMP printed under different conditions. The folding angle of 3D printed SMP sheets was precisely controlled between -180° to 180° by changing the printing parameters. The developed principles allowed fabricating complex 3D shapes ranging from a dice to a crane.

We highlight that the polyurethane-based SMP patterned by 3D FDM printer exhibits high degree of shrinking. In our demonstration, the radius of curvature of the resulting structures was as small as 1.8 mm, which was one order smaller than the corresponding structures consisting of 3D printed polyactic acid (PLA). As the result, fabrication of complex 3D structures on the order of millimeters was readily achieved. The use of SMP added an advantage; the 3D structures after shrinking were memorized. The obtained structures were recovered above glass transition temperature \( (T_g) \) multiple times after manually deformed. Overall, we demonstrated fabrication of the 3D structures with shape memory via programmed shrinkage of 2D structures printed by FDM. Unlike previous demonstrations, our design principle relied on the phase transition of SMP that offered high degree of shrinkage, which permitted fabrication of complex structures with the combination of anisotropic folds and convex/concave features.

BM01.03.14

The Effect of Surface Roughness of 3D-Printed PLA Scaffolds on the Cell Attachment, Proliferation and Differentiation of Dental Pulp Stem Cells Kuan-Che Feng1, Wenqi Zhao2, Benjamin Chung1, Bhuvana Murthy1, Ethan Ho1, Rushi Patel1, Antony Deluxe2, Marcia Simon1 and Miriam Rafailovich1; 1Stony Brook University, Stony Brook, New York, United States; 2Milton Academy, Milton, Massachusetts, United States; 3Herricks High School, New Hyde Park, New York, United States; 4Woodbridge High School, Irvine, California, United States; 5Northfield Mount Hermon School, Gill, Massachusetts, United States; 6Wheatley High School, Old Westbury, New York, United States; 7Haroon High School, Ann Arbor, Michigan, United States.

Three-dimensional (3D) printed scaffolds provide a promising approach in the field of tissue-engineering for its ability to precisely control scaffold architecture at the micron-scale. Previous studies have shown that topographical features on the surface of scaffolds can determine the efficiency of cell attachment and proliferation; yet, little is known about their effect on cellular differentiation. Here, we aimed at investigating the influence of the surface roughness of 3D-printed polyactic acid (PLA) scaffolds on cellular response. We conducted experiments with three different thicknesses of sharkskin and samples of pure PLA, all produced by the FDM 3D printer. The sharkskin employer is known to affect the cell behavior. We investigated the effect of the printing process on the cell attachment and differentiation of dental pulp stem cells on these substrates. We also analyzed the effect of surface roughness on the cell attachment, proliferation and differentiation of dental pulp stem cells. The results showed that the sharkskin employer significantly increased the cell attachment and proliferation, while the pure PLA scaffolds did not show any significant differences. These results indicate the potential of using 3D printing technology to control the surface morphology of dental pulp stem cells.
nanoparticles as a coating on PLA. This coating can promote a rapid and prolonged release of silver ions able to inhibit biofilm formation. PLA scaffolds were printed using two 3D printers, a Makerbot Replicator 2X and Ultimaker 2 Extended+, with corresponding filaments, and characterized with a laser microscope and FTIR. The Brunst method was used with two concentrations of AgNO3 (0.1M and 0.01M) and 0.001M NaBH4 for the in situ deposition of silver nanoparticles. We tested the ability of the PLA-AgNO3 scaffolds to inhibit biofilm formation and growth against two strains of bacteria, Staphylococcus aureus (gram-positive) and Escherichia coli (gram-negative). The PLA-AgNO3 scaffolds were also evaluated for the interaction of the modified surfaces with Dental Pulp Stem cells (DPSCs).

We found significant differences in surface chemistry and roughness of scaffolds produced by different printers. PLA scaffolds coated with 0.1 M nanoparticle showed significantly smaller size of the biofilms for both microorganisms than the one with 0.01 M nanoparticles. Bacterial adhesion and biofilm formation was higher on Ultimaker 2 Extended+ printed scaffolds for both strains. The DPSCs had a similar correlation and attached better to the Ultimaker samples in comparison to the Makerbot samples.

3D Printing of Synthetic Materials for Structural Implants Ken Gall1, Duke University, Durham, North Carolina, United States.

In this talk I will overview the 3D printing of biomedical implants from synthetic materials, including soft polymers (PCU), hard polymers (PEEK), and metals (Titanium). We will focus on basic materials science regarding the mechanical properties of the printed structures and relationships between structural porosity and resulting mechanical properties. Examples of how the basic science research has supported translation into various implants will be provided. Discussion will also center on regulatory paths for various printed implants, and the opportunities new materials and new printign methods could play in the future of medicine.

8:30 AM BM01.04.02

Multifunctional 3D Printed Implant/Biomaterial Surfaces Richard Jackson1, Stephen Patrick1 and Joe Bear2,3; 1University College London, London, United Kingdom; 2Kingston University, London, United Kingdom.

Stem cell proliferation, adhesion and differentiation on implants and biomaterial substrates are affected by the three dimensional morphology, topology, and interconnectivity of their immediate environment. This in turn means that the chemistry of, and the biochemistry at the material surface is of paramount importance. For example, the hydrophobicity of polymer objects means initial cell adhesion is insufficient in many cases which is of critical importance in bone implants. In this paper we show that by 3D printing polymers using Selective Laser Sintering (SLS) it possible to control porosity and use that porosity to chemically modify the materials properties of the implant.

We present results on the synthesis of nylon-12 scaffolds by 3D printing and demonstrate their versatility as matrices for cell growth, differentiation, and biomineral formation. We demonstrate that the porous nature of the printed parts makes them ideal for the direct incorporation of preformed nanomaterials or material precursors, leading to nanocomposites with very different properties, such as tunable hydrophobicity, enabling conducive or non-conducive environments for cell growth.

Additives such as those derived from sources such as tetraethyl orthosilicate applied at a low temperature promote successful cell growth, due partly to the high surface area of the porous matrix. The incorporation of pre-synthesized nanomaterials such as iron oxide nanoparticles led to a material that showed rapid heating in response to an applied ac magnetic field, showing promise for the control of gene expression and chemical-free sterilization. These methods also avoid using altered polymer feedstocks and contaminating or even damaging commonly used selective laser sintering printers, as well as being compatible with each other and interchangeable with each other in the modification process.

We believe this technique for chemically treating 3D printed matrices has great potential for use in addressing current issues surrounding bone grafting, implants, and skeletal repair, and a wide variety of possible incorporated material combinations could impact many other areas.

8:45 AM BM01.04.03

3D Printing of Silk Fibroin/Calcium Phosphate for Bone Regeneration Vincent Fitzpatrick1, Jin Guo1, Chunmei Li1, Sagvan Balata2, Alekya Karpuragu1, Michael Strunk2 and David Kaplan1; 1Tufts University, Medford, Massachusetts, United States; 2Zimmer ETEX, Cambridge, Massachusetts, United States.

Non-union bone fractures are a major issue in orthopedic surgery, from diagnosis to healthcare costs, and more importantly regarding treatment-related complications (Nandra et al. 2016). While autografts are the gold standard for non-union fracture repair, they can be associated to pathological symptoms at the donor site, including pain, risk of infection, blood loss, and increased operative time (Silber et al., 2003; Sass0 et al., 2005). These fractures are also limited by the amount of donor material available, which is usually harvested on the iliac crest. Allografts, on the other hand, alleviate donor site issues and are available in larger quantities, but do not provide the same quality of patient outcomes as autografts, especially in terms of osteoconductivity (Lohmann et al., 2000; Bostrom et al., 2005). Therefore, there is a need to find alternative solutions to both techniques, using new biomaterials and a tissue engineering approach. This includes the use of synthetic bone fillers such as calcium phosphate (CP)-based materials and biological factors like growth factors or miRNAs to improve bone regeneration. However, these bone fillers do not allow refined control of the geometry of the graft, and seldom offer adequate porosity for rapid colonization of the implant by cells, efficient exchange of nutrients and timing of implant degradation with replacement by newly synthesized bone. Additive manufacturing techniques like 3D printing provide tight control of geometry and porosity, and are therefore of interest for non-union bone fracture repair. These techniques include pre-fabricated and fully set CP scaffolds, which reduce operative time and prevent the risk of setting failures.

In this study we developed a slow setting reactive CP-based bionik, using silk fibroin as a binder, and used this bionik to generate porous 3D constructs for bone regeneration. These structures were bioincompatible and presented adequate mechanical properties in physiological conditions, and their shape was well-controlled even for complex geometries. Finally, their porosity could be precisely tuned to be within a range compatible with efficient osteogenesis (Karageorgiou & Kaplan, 2005). From a biological perspective, our 3D constructs induced osteoblastic differentiation in vitro, and we observed a rapid cell response and efficient neo-
osteogenesis when combined with biological factors, namely bone morphogenetic protein 2 (BMP-2) and miRNA-214 inhibitor. Furthermore, the materials could be loaded with antibiotics, providing an encouraging solution to prevent infections in patients of non-union fractures, which has been associated with a myriad of symptoms in patients, including deformities and limb-length inequalities (Jain & Sinha, 2005).

Overall, our 3D-printed CP/silk fibroin constructs offer an exciting research avenue in patient-specific treatment of non-union bone fractures, while reducing the risk of negative side effects and eliminating the need for donor site surgery.

9:00 AM BM01.04.04
3D Printing of Spatially Patterned Magnetically Responsive Hydrogels Patricia Monks1,2, Robert Murphy1, Shane Clerkin1, John Crean1, Dermot F. Brougham2 and Andreas Heise1; 1Department of Chemistry, Royal College of Surgeons in Ireland, Dublin, Ireland; 2School of Chemistry, University College Dublin, Dublin, Ireland.

Hydrogels, having similarities to the extracellular matrix and having excellent water retention capabilities, have emerged as a biocompatible material for applications in tissue engineering and as drug delivery devices. Next generation gel applications include as “bio-inks” for 3D printed bio-materials for cell scaffolding and ultimately organ printing. To realise this potential, it is critical to finely control the deposition of the hydrogel in the printing process to produce high fidelity structures.

Due to their small size, superparamagnetic iron oxide nanoparticles offer distinguishable advantages from bulk, arising from rapid reorientation of their moments. This results in rapid heating in AC magnetic fields and in attractive forces in permanent magnetic fields irrespective of initial moment orientation. The integration of magnetic nanoparticles into hydrogels has the potential to alter the properties of the original material and create a hydrogel matrix that can be manipulated in situ using magnetic fields.

We are working towards the incorporation of magnetic nanoparticles in the fabrication of novel 3D printable architectures which allows for unique applications as stimulus responsive materials. Specifically, high resolution printing (~100 μm) of these structures, will facilitate control over magnetic response with cellular resolution. The potential for high throughput with printed gel bed arrays also opens up new screening possibilities.

An open-source 3D printer was successfully built and modified to allow extrusion of hydrogels with parameters of moderate temperature and pressure that will support cell viability. Magnetic nanoparticles were synthesised, stabilised and incorporated homogenously into a printable hydrogel network with concentrations of up to 120 mM Fe which yields a temperature rise of 15°C in bulk.

A star copolypeptide based ink, which spontaneously forms hydrogels through hydrophobic interactions, allows for rapid prototyping enabling the fabrication of defined intricate microstructures. The chemical design allows the bulk phase of the hydrogel to remain intact after application of shear (during extrusion) due to its self-recovery behaviour. Here we demonstrate: (i) reproducible and robust extrusion of a polypeptide hydrogel network; (ii) spatial patterning of thermally active components and drug loading, and; (iii) in situ manipulation using applied magnetic fields with high resolution thermal mapping. The technical development of the responsive nanocomposite gels and preliminary results showing cell specification will also be described.

A 3D Microdevice for the Isolation of Cancer-Associated Circulating Cells Within the Bloodstream Elise Bou1, Kayum Jiménez Zenteno1, Aurore Estève1, David Bourrier1, Christophe Vieu1, Bernard Malavaud2 and Aline Cerf1; 1LAAS-CNRS, Toulouse, France; 2Department of Urology, Toulouse Cancer Institute, Toulouse, France.

This work introduces an engineered 3D microdevice for the capture of circulating tumor cells (CTCs) directly from the bloodstream. Our innovation relies on an intravascular label-free device enabling the trapping of CTCs based solely on their physical characteristics.

CTCs are tumor cells detaching from a primary tumor to reach the bloodstream. They represent a reliable tool for diagnostic and prognostic purposes as an alternative to solid biopsies. Therefore, many technologies have been developed to isolate CTCs from blood. In vitro systems are limited by the volume of blood that can be analyzed, manipulation factors including blood sampling and preprocessing, as well as cellular exposure to high pressure levels. In vivo approaches could offer the advantages of probing higher volumes of blood, increasing the interrogation frequency, and preserving the viability of collected cells. Thus, our approach combines both the advantages of a label-free and an in vivo isolation of CTCs.

Our capture devices are designed to be inserted into the human forearm vein through a conventional medical catheter. They are composed of a microfilter and a guiding strip. Both parts are fabricated in Nickel through a two-step process using photolithography and electrodeposition. The first step consists in the fabrication of the filtering membrane containing uniformly distributed micrometric pores. In a second step, the walls of the microfilter and the guiding strip are produced. After fabrication, microfilter are mounted onto the guiding strips in order to obtain 3D-like devices perpendicular to the incoming flow.

The prototype has been validated in vitro using a fluidic platform mimicking in vivo conditions of blood pressure and flow velocity. We succeeded in capturing human prostate cancer cells (PC3) spiked into whole blood in a few minutes, with no blood preprocessing required and with extremely low contamination levels. We also succeeded in capturing cells injected into the bloodstream of a rat model confirming its robustness to withstand in vivo conditions as a further step towards its application in clinical routine. Captured cells can be easily characterized and collected for further functional and downstream analysis. This minimally invasive technology could offer high-quality information to physicians and serve as a tool for personalized therapeutic follow-up in clinical routine.

3D Printing Scaffolds Based on Calcium Phosphate and Glass Slurries Optimized Using Statistical Experimental Design Carlos Paez1, Natalia Jaramillo1, Claudia P. García1, Alejandro Pelaez2, Sebastian Restrepo1, Niza Otero1 and Ana Moreno1; 1National University of Colombia, Medellín, Colombia; 2Universidad Cooperativa, Medellín, Colombia.

Wound healing in oral tissues (i.e. gingiva and bone) exhibit a complex equilibrium between eukaryotic and prokaryotic cells. Ceramic 3D printing allows rapid prototyping of scaffold with controlled features as shapes, porosity, size, connectivity and differential density layers to mimic bone structure. However, bulk are strong related with chemical composition and thermal processing to obtain degradability and bioactivity. The slurry plasticity affects the size layer and mechanical properties during “green” state. Experimental design approach implies the use of statistical tools that allow the multivariate analysis with the minimum number of experiments to mixtures.

The aim was to optimize a ceramic paste based on calcium phosphate and bioglass to produce 3D printing scaffolds for dentistry. A full factorial statistical design was conducted to optimize the plasticity of calcium phosphate and bioglass slurry. Plasticity ad-hoc model included variables defined as particle size and ratio calcium phosphate/bioglass. Sintering was conducted at 950°C/3h. Scaffold characterization was conducted using XRD, FTIR and SEM. Biological characterization includes bacterial adhesion of S. mutans as oral bacterial model.

Optimized Surface response of plasticity was found using 70 wt% calcium phosphates, 30wt% bioglass. Successful scaffolds were produced by 3D printing- They shown a Schwarz Diamond shape, interconnected pores, wide size pore distribution and minimum thickness layer (~200 µm). XRD diffractogram shows presence of β-TCP and amorphous glass. S. mutans shown a reduced adherence to 3D printing scaffold compared to control. Synergy between 3D printing, material processing and Statistical Experimental Design can be considered as robust methodology to develop new scaffolds with potential use in dental applications.

Preparation and Application of Functional Polymeric Nanoparticles Based on Poly(methacrylate)s Stephanie Schubert, Turgay Yildirim and Paul Klemm; Friedrich-Schiller-University Jena, Jena, Germany.

The development of functional polymeric nanoparticles is essential for breakthroughs in nanomedicine. By tuning the polymer characteristics and subsequently applying optimized formulations for the procedure of nanoparticles, tailored nanoparticles with varying release properties, degradation behavior, targeting groups and size distributions can be developed. For the preparation of polymeric nanoparticles, nanoprecipitation is a good choice since it is a facile, mild, and low energy input process. In combination with high-throughput devices such as microfluidics, pipetting robots, inkjet printers, and automated analytical instrumentation, the abilities of nanoprecipitation can broaden tremendously with significant effects on new applications. Selected examples in the field of gene- and drug delivery vehicles will be presented, e.g. dual pH-value and redox responsive nanoparticles and polymersomes based on a methacrylate copolymer library [1,2,3]. The functionalization of the polymers with Raman active targeting structures enables the label-free visualization of cell uptake processes [4].

In this research, we will demonstrate for the first time the use of 3D printing to realize customizable high-throughput ultra-high density arrays of 3D microelectrode probes for biological applications. The electrode density in the probe is several thousand per square centimeter; an order of magnitude improvement over the current state of the art. The proposed probes are critical in achieving a better understanding of biological systems such as the dense neural networks in a brain or enabling the next-generation neural interface for neural prosthetics. The electrodes of the probes are fabricated in a layer by layer fashion from a dense aerosol stream of silver nanoparticle ink from an aerosol-jet 3D printer. Probes with extremely high aspect ratios (up to 30:1 height to diameter ratio or more) are achieved with heights exceeding 2 mm. Flexibility and versatility of this technique are demonstrated by the realization of a variety of microelectrodes and tip geometries. Further, we have studied and optimized the electrode metallurgy; mechanical properties; electrical isolation and response; adhesion to soft and hard substrates; and biocompatibility. As a result of this investigations, a complete process parameter control was developed to adjust the mechanical properties of the electrode arrays over a wide range of strong-brittle and ductile-tough behavior. Further, we also report the buckling behavior of high aspect ratio electrodes under compression and their correlation with materials grain size have been reported.

Robust Hydrogel-Solid Hybrids in Biomedical Applications Hyunwoo Yuk and Xuanhe Zhao; Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Taking advantage of superior biocompatibility and tissue-like physical and mechanical properties, hydrogels have found a widespread usage in various sectors of biomedicine. Despite their unique advantages, integration of hydrogels in biomedical applications typically suffers from several technical challenges. Particularly, weak and unstable assembly between hydrogels and other solids (e.g., inorganic materials, polymers, and tissues) significantly limits the realization of functional hydrogel-based biomedical applications. Recently, we have developed a range of technologies to achieve robust interfacial bonding between hydrogels and other solids, enabling the new class of robust hydrogel-solid hybrids. In this talk, taking advantage of this new developments, we will discuss various examples of experimental translation of robust hydrogel-solid hybrids in biomedicine. We will first cover general mechanisms for robust wet adhesion of hydrogels followed by specific example applications, including hydrogel hybrid neural probes for long-term neural sensing and modulation, hydrogel skins for diverse polymers with arbitrary shapes, and tissue adhesives for flexible devices.

Designing shape morphing materials featuring dynamic molecular motions in response to external stimuli will enable the development of next generation smart materials. Traditional shape morphing design relies on (1) engineering the (de)hydration process and (2) programming the heat-induced shape changing polymers. Incorporating smart molecular systems and controlling their dynamic features across the nano-to-macroscopic scale, in combination with the state-of-the-art 3D printing technology could enable the development of fast-responsive 3D printing materials. In this presentation, we report the synthesis of a polypseudorotaxane-based 3D printing inks that consists of α-cyclodextrins and dimethacrylamide polyethylene glycols. After 3D printing and photo-crosslinking, the mechanically interlocked rings in the polypseudorotaxane network can be switched between stationary and randomly shuttling states through the (de)protonation their hydroxyl groups. This nanoscale ring motion is aligned in a synchronized manner, resulting in fast shape morphing macroscopically. Copolymerizing acrylate monomers with the polypseudorotaxanes affords a copolymer network, which respond to pH and ionic strength. We also performed dual-material 3D printing using two hydrogel inks mentioned above, and fabricated a hybrid monolith with multiple shapes macroscopically. Our work demonstrates that, by switching the ring motions in a molecular interlocked architecture in combination with pH/ionic-sensitive moieties, a fine spatiotemporal control of the hybrid 3D printed object’s shape morphing process has been achieved.

Development of a Ceramic—Polymer Biofilament to Obtain Scaffolds Using Additive Manufacture Claudia P. Garcia1, Paula A. Nevado1, Alex Lopera1,2, Marlon Rincon Fulla1,2, Juan Luis Palacio1, Maria A. Zaghete3, Glenda Biasotto3, Juan Rivera2, Hugo Estupinán4 and Carlos Paucar5; 1Física, Universidad Nacional de Colombia sede Medellín, Medellín, Colombia; 2Ciencias, Instituto Universitario Pascual Bravo, Medellin, Colombia; 3Universidade Estadual Paulista Júlio de Mesquita Filho – Unesp, Araquara, Brazil; 4Materiales, Universidad Nacional de Colombia, Medellín, Colombia; 5Quimica, Universidad Nacional de Colombia, Medellin, Colombia.

One of the most common materials to be used in scaffolds for osseous regeneration applications are calcium phosphates (CaPs) and more specifically bicalcic phosphates (BCPs) because to their properties of osteoconductivity, biocurarability, biocompatibility and composition similar to the mineral phase of the bones. In the manufacture of scaffolds it is important to consider not only the biocompatibility but also the porosity, topography, morphology and mechanical behavior that are adequate to promote osteogenesis and angiogenesis. The additive manufacturing (AM) offers many possibilities to control these characteristics entering in the field of personalized medicine satisfying the particular needs of each patient. Currently research in the manufacture of scaffolds for bone regeneration from CaP are focused on obtaining formulations of ceramic pastes with the appropriate rheological and mechanical characteristics to be used in 3D printing on bioploters with ceramic paste printing kits. Many of these formulations are expensive due to the conditions of obtaining, storing, handling and the difficulty to guarantee repeatability of the appropriate conditions of each print in time as well as the high cost of the bioploter or appropriate printing kit for each paste. In this work a biofilament to be used in any low cost commercial 3D printer was developed. The biofilament is a ceramic / polymer composite based on calcium phosphates (CPs) and polyacrylic acid (PLA). The chemical route used to obtain the particles of CPs was the combustion method in solution. This method allowed to obtain in a simple way nanoparticles with a good price / quantity ratio. X-ray diffraction showed that the particles without thermal treatment consisted of the mixture of hydroxyapatite (HAP) and tricalcium phosphate (both alpha and beta phases), while the heat treatment of the CPs at 800°C for 2 hours enhanced the crystallization of HAP and B-TCP. Field Emission Electron Microscopy showed that the powders obtained with and without thermal treatment consisted of porous aggregates of micrometric size conformed by 100 nm nanoparticles. These powders were used to obtain biofilaments by hot extrusion in a Wellzoomextrude equipment with a Ceramic-Polymer ratio of 15%-75% weight respectively. The biofilaments obtained were characterized by scanning electron microscopy, EDS, FTIR, biodegradability and cytotoxicity. The filaments were tested in a low cost cast filament printer (Micromake 3D-Delta printer) obtaining different pieces with appropriate geometries to be used as scaffold.

Cell Proliferation Assessment of PLA and Alumina Scaffolds Fabricated by Additive Manufacturing Jhon A. Ramirez, Valentina Ospina, Angie Alejandro Rozo, Maria Isabel Viana, Sebastian Ocampo, Sebastian Restrepo, Neil Aldrin Vasquez, Carlos Paucar and Claudia P. Garcia; Universidad Nacional de Colombia sede Medellín, Medellín, Colombia.

Every day around the world people are being diagnosed with some kind of disease where the only solution is to replace the damage tissue or organ. Tissue Engineering is an alternative and promising approach that pretends to replace the damaged tissues or organs by using structures known as scaffolds which mimic the extra cellular characteristics of the specific tissue what is desired to replace where later healthy cells obtained from the patient will be harvested in an appropriated media to guarantee in vitro proliferation, compatibility and normal tissue growing at the moment of the implantation. The scaffolds could be biodegradable and be completely replaced with new tissue which is the case of the poly-lactic acid (PLA) that degrades to form lactic acid, nevertheless, there are also biocompatible scaffolds that do not degrade and are also bioinert which is the case of the scaffolds made with alumina which, despite not interacting with the surrounding tissue, are being studied thanks to their excellent mechanical properties. The triply periodic minimal surfaces (TPMS) are mathematically defined so that they occupy a minimum area given a boundary in R³ presenting crystallographic groups symmetry that repeat three-dimensionally guaranteeing an interconnected porosity. The porosity percentage and pore size can be controlled from the design, being this a great advantage for scaffolds design for the use in regenerative medicine. In this work scaffolds based on two different geometries were fabricated by additive manufacturing (AM): one based on a TPMS, the Schwarz D surface, and another one based on a rectangular geometry with orthogonal through-holes. For the scaffolds fabrication two different materials were used: PLA in filament form, and alumina in printable paste form. The obtained scaffolds structure was characterized by X-ray diffraction and scanning electron microscopy and the cell proliferation was assessed for each geometry and material using fluorescence microscopy and DNA quantification by nanodrop. The additive manufacturing allowed to obtain scaffolds with the assessed materials guaranteeing the pores interconnection in each one of them. Curve surfaces fabricated with PLA were more favorable for cell attachment and proliferation of the CHO K1 cell line.
Fused deposition modeling (FDM) printing is an emerging 3D printing technology in which thermoplastic filaments are extruded and deposited in certain manner according to computer input design. FDM is a rapidly developing new area where new methodology is required to explore phenomena far from equilibrium. In this study, we use in-situ synchrotron X-ray scattering and high resolution infra-red imaging to study in-situ the relationship between the extrusion parameters, the filaments deposition directionality and the internal structure of the nanocomposite. In two steps study we place first “home-made” extrusion setup and then open-walls 3D printer in the beamline. 

The results are then compared with Lattice Boltzmann Modeling which simulates the welding between filaments as a function of nozzle parameters, printing protocols, and the system thermodynamical response function. In filled systems, using in-situ X-rays scattering, we observed the effect of extrusion shear forces on the orientation of the nanoparticles and the influence of the particle/polymer interactions on the polymer crystallization. This phenomenon (“Transcrystallization”) leads to templating of the polymer crystalline structures by the fillers which, we show, can enhance the thermal, mechanical and electrical properties of the printed nanocomposite structures, under directional control by the printing algorithm. The results of in-situ printing measurements show how the parameters of sample temperature, printing orientation and materials composition affect the internal structure and crystalline structure formation.

We Acknowledge support from the National Science Foundation (Inspire Award No. 1344267) and The Morin Foundation Trust.

**3D Printed Functionalized Organic Electrochemical Transistors for Glucose Sensing**

Jiaxin Fan, Darren Majak and Manisha Gupta; Electrical and Computer Engineering, University of Alberta, Edmonton, Alberta, Canada.

The invention of organic semiconductors unravels new possibilities for fabricating electronic devices specially with 3D printing techniques. The development of flexible and wearable biosensing devices, based on organic electronics, has received a great amount of attention due to demands for affordable, non-invasive, and continuous monitoring of physiological parameters for healthcare and biomedical diagnostics. PEDOT:PSS based organic electrochemical transistors (OECTs) are ideal candidates for flexible and customizable biosensors which, due to the simple device structure and material stability, can be fabricated with 3D printing techniques.

In this study, we have 3D printed functional OECTs, using an Optomec Aerosol Jet 5X 3D printer with commercially available materials. These devices were assembled as follows: first, a Parylene C substrate was thermally deposited, then a gate electrode as well as the source and drain electrodes were printed with commercially available platinum and silver nanoparticle ink respectively, the channel was then printed using PEDOT:PSS ink, and finally the passivation layer was printed with commercially available UV-curable polymer that was cured in-situ. The printed OECTs with similar channel dimensions \((W=95\, \text{mm}, \, W/L = 4, \, d=374\, \text{nm})\) have shown high peak transconductance \((g_{m}=998.3\, \text{mS})\), low threshold voltage \((0.51\, \text{V})\) and high current ON/OFF ratio \((I_{\text{ON}}/I_{\text{OFF}}=3.3\times10^5)\).

Functionalization improves the capability of detecting a particular analyte. OECTs have been demonstrated as glucose sensors, which show electrical response to changes in glucose concentration levels. Expanding on this work, we have also conducted studies of surface immobilization of glucose oxidase (GOX), which is commonly used for glucose detection. We have conducted the functionalization by the standard technique of dip-coating and also implemented 3D printing of the GOXs. Results from glucose measurement with no functionalization and with the dip-coated and 3D functionalized will be presented here.

**3D Printing of Hexagonal Boron Nitride Nanocomposites for Biomedical and Electronic Applications**

Linda M. Guiney, Nikitha D. Mansukhani, Adam E. Jakus, Shag Y. Wallace, Ramille N. Shah and Mark C. Hersam; Northwestern University, Evanston, Illinois, United States.

Two-dimensional (2D) materials possess a broad range of interesting properties enabling applications in energy, electronics, and biomedicine. Additionally, the field of three-dimensional (3D) printing has become increasingly attractive for both biomedical applications as well as printed electronics. By incorporating 2D materials into 3D printable inks, their properties can be harnessed for functional and customizable biological constructs, specifically in bioelectronics. For example, as implantable electronics are developed, thermal management will be a major challenge, where even small changes in temperature can result in deleterious perturbations to the surrounding tissue. Thus, there is a need for thermally conductive but electrically insulating flexible materials that can be incorporated into novel electronic implants. Hexagonal boron nitride (hBN) nanocomposites offer one potential solution due to their thermally conductive yet electrically insulating nature in addition to the high biocompatibility of hBN. Here, a high-content hBN-polymer nanocomposite ink is reported, which can be 3D printed to form mechanically robust, self-supporting constructs. To achieve these 3D printable nanocomposites, hBN is dispersed in poly(lactic-co-glycolic acid) and extruded at room temperature to form complex architectures that maintain their shape upon extrusion and can span large gaps without sagging or deformation. These constructs possess high mechanical flexibility and stretchability following 3D printing at compositions of up to 60% vol. hBN (solids content). The enhanced thermal conductivity, up to 2.1 W K\(^{-1}\) m\(^{-1}\), due to the presence of hBN within the matrix suggests utility in thermal management applications. Furthermore, the constructs show high levels of cytocompatibility with human mesenchymal stem cells for up to one month, suggesting their utility for printed bioelectronics.

**3D and 4D Printing of Biomedical Grade Thermoplastic Polyurethanes (TPUs) and Nanocomposites**

Rigoberto C. Advincula; Case Western Reserve University, Cleveland, Ohio, United States.

The use of 3D printing to create prototypes and devices from biocompatible polymeric materials has appended the design functionality of polymeric materials for biomedical devices enabling rapid development for new applications. Biomedical grade polymers can be further classified into thermoplastics, thermosets, and elastomers based on their thermo-mechanical properties. However, it is not as simple as the classification into these groups when it comes to their intended in-vivo or in-vitro applications. The transition to a final phase or cross-linked structure results in new properties. This is more evident with the choices of 3D printing methodologies (FDM, SLA, SLS, VSP) which can make use of blended or formulated compositions. We have demonstrated the 3D printing of biomedical grade thermoplastic polyurethanes (TPU) with compatibility to mammalian NIH 3T3 cells. However, 4D printing allows the design of new materials and applications based on integrating the chemistry of conversion with the printing mode. In this talk, we demonstrate the fabrication of concept objects and elastomeric actuators based on the use of biomedical grade TPU melts and extruded viscous solutions. The result is an extrudable precursor nanocomposite elastomer which can be printed via viscous extrusion printing (VEP) or VSP and then converted to an elastomeric actuating material with very high cyclic compressibility. Other work based on the use of SLA, SLS, FDM, towards high strength nanocomposite and biomaterials will be discussed.
The ability to three-dimensionally interweave biological and functional materials could enable the creation of devices possessing unique and compelling geometries, properties, and functionalities. Indeed, interfacing active devices with biology in 3D could impact a variety of fields, including regenerative bioelectronics, smart prosthetics, biomedical devices, and human-machine interfaces. Biology, from the molecular scale of DNA and proteins, to the macroscopic scale of tissues and organs, is three-dimensional, often soft and stretchable, and temperature sensitive. This renders most biological platforms incompatible with the fabrication and materials processing methods that have been developed and optimized for functional electronics, which are typically planar, rigid and brittle. A number of strategies have been developed to overcome these dichotomies. Our approach is to use extrusion-based multi-material 3D printing, which is an additive manufacturing technology that offers freeform, autonomous fabrication. This approach addresses the dichotomies presented above by (1) using 3D printing and imaging for personalized, multifunctional device architectures; (2) employing ‘nano-inks’ as an enabling route for introducing diverse material functionality; and (3) 3D printing a range of functional inks to enable the interleaving of a diverse palette of materials, from biological to electronic. 3D printing is a multiscale platform, allowing for the incorporation of functional nanoscale inks, the printing of microscale features, and ultimately the creation of macroscale devices. This blending of 3D printing, functional materials, and ‘living’ platforms may enable next-generation 3D printed devices, from a one-pot printer.

Collagen hydrogels show promise for use as bioinks in extrusion-based 3D bioprinting. However, compared to some other natural and most synthetic hydrogels, collagen displays slow gelation times and poor mechanical stability, resulting in inferior printing characteristics. Recent efforts to improve the printability of collagen have shown that the rheological properties of collagen bioinks are a good indication of their printing accuracy. However, little is known about the effect of surface tension of bioinks and its effect on printability. In this study, we examine how hydrophobic surface coatings affect the contact angle of collagen bioinks and how this relates to printing accuracy. Type I collagen hydrogels were either fabricated to form a final collagen concentration of 4, 8, or 12 mg/mL, and riboflavin crosslinked gels were fabricated by adding 0.5 mM riboflavin and photocrosslinking with blue light for 10 seconds at the beginning of bioink dispensing for both contact angle and printability testing. Contact angle measurements were taken on glass coverslips either cleaned with 70% ethanol or coated with a polysiloxane solution (Rain-X™) and printability was assessed by printing lines (50 x 0.8 mm) on cleaned or coated glass coverslips using a Fab@Home 3D printer. Collagen drops printed on coated glass had dramatically higher contact angles than those printed on uncoated glass. On uncoated glass, collagen concentration had a more modest effect on contact angle than that of the coating. The addition of riboflavin did not have a significant impact on contact angle. The accuracy of printed lines increased with both collagen concentration of the bioink and the use of coated glass. Similar to the contact angle measurements, the effect of the coating decreased as collagen concentration increased. For printability testing, this is likely related to the fact that 12 mg/mL bioinks on uncoated glass were already approaching the 0.8 mm intended line width imposed by the diameter of the printing nozzle. These results will be used to change printing accuracy without changing bioink formulation and allow for a wider range of printabilities with finer resolution in the future.

Characterization and Validation of 3D Printed Polycarbonate Urethane for Biomedical Applications Andrew T. Miller, Natalia von Windheim, and Ken Gall
Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina, United States; 3restor3d, Durham, North Carolina, United States.

Polycarbonate urethanes (PCUs) are gaining in popularity in many biomedical applications due to their low stiffness, biocompatibility, and high strength. As a thermoplastic, PCUs can be 3D printed through a process known as fused deposition modeling (FDM). FDM offers many benefits such as: cheaper, faster, and easier prototyping, custom or complex geometries and architectures, and potentially even final component or device manufacturing. However, such processing will have implications on the material microstructure and ultimately the mechanical properties, particularly fatigue performance. The purpose of this study was to assess the effects and viability of FDM with PCU in an effort to realize new opportunities in the biomedical field for this promising soft material.

PCUs of three different hardnesses (75A, 85A, and 95A) were obtained in pellet form. Test samples were formed through either injection molding (IM) of pellets or extrusion into filament and then processing via FDM. Material structures were characterized through DSC, DMA, 1H NMR, and FTIR. Mechanical tests included monotonic tension, compression, shear, and tensile fatigue. In addition, monotonic tension and tensile fatigue tests were performed on printed crosshatch scaffolds, which are fundamental to the biomedical field, to probe the effects of architecture.

FDM parameters were identified that resulted in samples consistently >99% solid. Monotonic tests indicated FDM samples matched IM in terms of tensile failure stress, while exhibiting significantly larger failure strain. Shear tests demonstrated no significant difference in shear strength between FDM and IM samples, which indicates strong layer bonding for FDM samples. Fatigue tests show an apparent improvement in strain-based fatigue for FDM samples. When plotted against stress amplitude, fatigue data indicates that solid FDM samples successfully matched IM samples in tensile fatigue despite the small percentage of voids. The crosshatch architecture resulted in a minor detriment to fatigue performance, even after adjusting for porosity. However, the effects were small relative to stiffer materials such as PEEK and titanium. Overall, the results show great promise for printed specimens of PCU, both solid and with architecture.

This study demonstrated the effectiveness of FDM as a processing method for PCU based on the performance of FDM samples. The results are both unexpected and significant, as they indicate potential for printing soft devices while maintaining a high level of performance, including in fatigue. This is
promising for biomedical applications where custom geometries or complex architectures utilizing a soft, biocompatible material are desired. Potential applications are numerous, ranging from transvaginal meshes to custom, composite osteochondral devices.

Hierarchical Co-Assembly Enhanced Direct Ink Writing Longyu Li, Qianming Lin and Chenfeng Ke; Chemistry, Dartmouth College, Hanover, New Hampshire, United States.

The development of smart materials and devices has attracted increasing attention owing to their capability of altering the macroscale properties in a controlled manner. Integrating these synthetic functional materials with 3D printing technology, i.e. the extrusion-based direct ink writing (DIW) enables the amplification of their nanoscale properties into the macroscale by taking advantage of the controlled hierarchical assembly and pre-designed macroscale 3D geometry. Currently, small-molecule-based 3D printing materials are very rare owing to the difficulties of facilitating 3D printability as well as preserving their molecular functions macroscopically. In this presentation, we report a general approach of integrating functional small molecules into 3D printing materials and transferring their molecular features to the macroscale through supramolecular templation, post-printing hierarchical co-assembly, and covalent crosslinking. A variety of inorganic and organic inks were 3D-printed, and their superstructures were refined by post-printing hierarchical co-assembly. Our method not only enhances the printing resolution up to one order of magnitude, but also enables precise spatial control over nanoscale features as well as macroscopic shape change over a large scale. Fluorescence tracking experiments provided a molecular understanding of the dynamic co-assembly process at the macroscale and enabled the development of simultaneous color- and shape-changing 4D printable materials in response to the external stimuli. Furthermore, we showcased a benzene-1,3,5-tricarboxamide-based monolith capable of expanding and contracting through the insertion and removal of the correspondent supramolecular pillars. We believe that this new approach will initiate the development of small-molecule-based 3D printing materials and greatly accelerate the development of smart materials and devices that are capable of accomplishing complex tasks in response to environmental stimuli.

3D Printing of Shape-Memory Thermoplastic Polyurethane for Biomedical Applications David Safirman1, Natalia von Windheim2 and Ken Gall1; 1MedShape, Inc., Atlanta, Georgia, United States; 2Duke University, Durham, North Carolina, United States.

Thermoplastic polyurethanes are used in a variety of biomedical devices, such as catheters, implantable defibrillators, wound care dressings, and orthopaedic implants. Due to their easy melt processing, these polymers areideal for 3D-printing via fused deposition modeling. Prior studies of the shape-memory behavior of thermoplastic polyurethanes has been limited to either cast, pressed, or injection molded parts. The overall goal of this work is to determine the effect of build orientation on thermo-mechanical properties, mechanical behavior, and shape-memory performance of a 3D-printed shape-memory thermoplastic polyurethane. A biomedical grade shape-memory thermoplastic polyurethane was extruded into 3.0 mm filament for 3D-printing via a LulzBot TAZS. ASTM D638 Type V dogbones and rectangular samples were printed in each of three build orientations (flat, on-side, and vertical). The print speed was set to 500 mm/min and the nozzle temperature was 215°C. Dynamic mechanical analysis (TA Q800) was used to determine the glass transition temperature and rubbery modulus. Tensile behavior was determined using an MTS Inspert 2 with a laser extensometer according to ASTM D638. Toughness was calculated as the area under the stress-strain curve. Unconstrained recovery for each build orientation was assessed with a 180° bend recovery test. The glass transition temperature as determined from the peak of the tan delta curve was nearly equivalent for all three build orientations at 78°C. However, the storage modulus was increased for the flat orientation at 1515 MPa, compared to 1042 MPa and 1122 MPa for the on-side and vertical orientations, respectively. Rubber modulus above the glass transition temperature was nearly equivalent amongst the build orientations at 29 MPa. All tensile samples displayed linear elastic behavior, followed by yielding and plastic deformation. The on-side and flat orientations displayed strain-hardening; however, the vertical build orientation did not experience hardening at higher strains. The failure strain was 70, 152, and 212% for the vertical, on-side, and flat orientations, respectively. The ultimate stress was 19.8, 30.8, and 44.4 MPa for the vertical, on-side, and flat orientations, respectively. The toughness was 13.1, 37.3, and 63.5 MJ/m² for the vertical, on-side, and flat orientations, respectively. Shape-recovery was near 97% for each build orientation for the bend recovery test. Unconstrained shape-recovery was not dependent upon build orientation; however, tensile properties improved when the flat build orientation was used. However, a 70% failure strain in the vertical build orientation is still 10x greater than other common FDM thermoplastics, such as ABS or nylon. These superior mechanical properties will allow for the design and manufacture of complex biomedical devices.

3D Patterned Hydrogels for Controlled Growth Factor Release Pengrui Wang; University of California, San Diego, La Jolla, California, United States.

3D printed hydrogels can provide dimensional control over the release of molecules enveloped in them. Owing to their controllable degradability, capability to protect envelope molecules from degradation, hydrogels provided physiochemical interactions with agents such as growth factors to regulate their release kinetics. Amongst the commonly used hydrogels, heparin have shown prolonged release due to its high negative charge density. Researches have shown heparin gels can trap positively charged molecules such as growth factors by electrostatic forces to delay their delivery. Another negatively charged hydrogel, hyaluronic acid, has been widely engineered for applications such as wound healing and cosmetic surgeries due to its role in granulation and cell migration. Recent development in 3D printing of modified hyaluronic acid has inspired its application in controlled drug release. Engineered release of growth factors are potent strategies for regulating cell regeneration in tissue engineering, but spatially patterning them in a facile manner to achieve releasing of multiple factors in a controlled manner is still challenging. Additionally, mathematical modeling of the drug release from engineered structure is also lacking. In this work, we presented a heparin and hyaluronic acid-based hydrogel system that was 3D printed to allocated multiple growth factors at different locations within the same construct to achieve sequential release over weeks. Mathematical models of release kinetics were developed and verified. Furthermore, we have observed the stimulus effect on angiogenesis in vitro and tissue regeneration in vivo from engineered sequential release. We hope that our findings could provide a more comprehensive understanding of release kinetic of hydrogels for the community.

BM01.05.09
In the past decade, the development of microelectromechanical system (MEMS) and smart nanocomposite materials has enabled roboticists to construct miniature three-dimensional (3D) mobile machines with programmable morphology and motility from two-dimensional (2D) materials through self-folding (1, 2). These self-folded micromachines wirelessly driven by electromagnetic fields exhibit great potentials in revolutionizing current procedures in minimally invasive medicines by means of targeted drug delivery, micro-tissue transplantation, and robotic cell scaffolds (3, 4). However, self-folded functional micromachines are mostly limited to their monotonous cylindrical structures, such as tubular, helical, and spiral shapes, which in turn constrains the possibility of integrating multiple functionalities into a single machine.

Owing to the progress in 3D printing techniques with the resolution at micro/nano scales, robotic micromachines with sophisticated 3D shapes and spatially controlled mechanical properties can be engineered via direct-laser-writing (DLW) on polymers capable of spatiotemporally modulating the cross-linking degree (5). Extra functionalities can be extended on the printed structures simply by incorporating other functional materials. In this work, 3D printed compound microstructures, which is impossible to be implemented through folding 2D materials, are devised to be a robotic microtransporter composed of a helical propeller for wireless-controlled propulsion and an Archimedes screw for delivering therapeutic micro-agents. We demonstrate such compound machines can implement on-demand loading, encapsulation, and transport of multiple, various therapeutic micro-agents, ex. different sizes of cells and various kinds of drugs. Furthermore, using environmentally stimuli-responsive hydrogels as the printing materials endow the micromachines with sensing and shape morphing capabilities, also known as 4D printing. By coordinating the sensory input with shape morphing output, the control loop can be closed without external imaging feedback and intricate integrations of sensors and actuators, paving the way of autonomous targeted delivery inside the human body.

Microstructuring and Characterization of Redox-Active Polydopamine Films Jing Lin, Dominik Blaimer, Sven Daboss and Christine Krantz; Ulm University, Ulm, Germany.

Polydopamine (PDA) a synthetic eumelanin polymer is highly interesting as thin film surface modification for a multitude of applications ranging from adhesive coatings for cell immobilization\(^1\) to biomimetic electron gates for artificial photosynthesis\(^2\). The polymerization of dopamine can be obtained via a chemical process at basic pH values higher than 7.4\(^3\). Improved control of surface morphology can be achieved via electrochemical deposition e.g. by cyclic voltammetry, leading to thin films offering various functional groups such as amines, imines and phenolic groups at conductive surfaces.

In this contribution, we report the microstructured deposition of PDA using pulsed electrochemical deposition techniques, in order to improve film uniformity and thickness. To form microspots of PDA, scanning electrochemical microscopy in direct mode\(^4\) was used with the substrate as working electrode and the microelectrode as the counter electrode. The electron transfer properties of the microspots were investigated in dependence on the pulse number, the distance between substrate and microelectrode, the RG value (ratio of the radius of the insulating sheath and the electrode radius) of the microelectrode and the used redox mediator. As PDA has redox-active phenolic/quinone groups, surface properties of the polymer can be electrically switched. Our group recently introduced a new type of AFM-SECM probe bearing a conductive colloid\(^5\). Such conductive colloidal probes will be modified with polydopamine films and first results on force spectroscopy under potential control will also be presented.

Electron transport in proteins and peptides is crucial for energy conversion in biological processes including photosynthesis, respiration and enzymatic reactions. Therefore, the important goal of the fundamental research is to provide insight into the mechanisms determining peptide-mediated electron transport. Peptides are known to adopt variability of structural motifs and when suitably designed, they can also serve as components of biosensing devices or nanoscale bioelectronic circuits. In this area of research, significant progress has been made due to the development of experimental methods, which enable fabrication of nanoscale junctions with peptide monolayers bridging two conductive electrodes. Among them, scanning probe microscopy (SPM) offers unique capability to investigate electric properties of individual molecules or molecular films. Such approach involves entrapment of the assemblies of molecules between two metallic contacts established by metal support and conductive probe of SPM. When the bias voltage is applied between the contacts, the resulting current flow depends on the properties and structural features of peptide molecules forming the assembly including their length, secondary structure, dipole moment, the nature of the constituent amino acids or charge. Importantly, SPM-based method enables control of the mechanical strain or stress of the molecular film incorporated into the junction.

Among variety of structural motifs, α-helical peptides were proved to be efficient mediators of electron transport. However, their use is limited to compounds containing at least 8 amino acid residues. To overcome this problem, we have designed molecular junctions utilizing β-hellicomimetic foldamers based on oligourea backbone. These particular compounds possess important features: (a) it is possible to synthesize oligoureas containing side chains of all natural amino acids; (b) the folding process of oligomers is not affected by the nature of side chains. Such characteristics make them highly robust, tunable and hence useful in the studies of electron transport processes. Additionally, only four acyclic residues are sufficient to drive complete helical turn formation. We have demonstrated that oligoureas may act as efficient electron transport mediators and the oligourea helix is more stable than the helix formed by peptides. Interestingly, electron transmission through longer analogs shows strong directional dependence, which is characteristic for diode-like behavior.

Controlling the Mechanism of Charge Transport via Au-Azuin Junctions by Chemically Modulating Protein-Electrode Interactions Jerry A. Freerik, Gilad Porat, Mudi Sheves, Israel Pecht and David Cahen; Weizmann Institute of Science, Rehovot, Israel.

A tremendous effort has been made by researchers to explore the possibility of using biomolecules, including proteins, in molecular electronics. The idea is to exploit their built-in functionalities, introduced by millions of years of evolution, for the task of electron transport. However, despite great progress that was made, fundamental questions regarding the effects of relative energies, of the contacts and protein-contact coupling, as well as the nature of the internal electrostatic potential profiles remain unclear.

We will report on the results, obtained from a systematic study of conductance, current-voltage plots and IETS measurements at low temperatures to investigate the mechanism of charge transport via different Az-Au-Az junction configurations. In all the configurations that were studied Az was covalently bound to a Au substrate on one side and chemical modifications were carried out with linker molecules to the contact that was made on the opposite side of the protein. The conductance and IETS profiles obtained from different configuration strongly suggest that by chemically fine-tuning the coupling strength to the electrodes, we can switch the tunneling mechanism ‘IN’ and ‘OUT’ of resonance. The shape of the conductance plots, intensity of the IETS spectrum and the barrier height ( ) values, obtained from fitting the I-V curves, provide the position of the frontier energy levels with respect to the electrode Fermi level, indicating that the energy levels are pushed apart upon increased coupling (fits simple MO/tight binding models). This shows that the energy-level alignment in Az-based junctions can be regulated by chemical modifications of the electrical contact to the protein. The results presented here provide a strategy suitable for altering the transport mechanism through solid state protein monolayers, by chemically modifying the interaction between the protein and the linker in protein based two-terminal device, i.e., without a gate electrode.

9:30 AM BM02.01.04
Electron Transport Through Linear Peptide Cunlan Guo; College of Chemistry and Molecular Sciences, Wuhan University, Wuhan, China.

Biomolecules display great potential for future functional molecular electronic devices, due to biomolecules’ unexpected conductance, multiple structure, unique bio-recognition and self-assembly. Peptides are suitable as one of the building blocks to bridge conductive electrodes in solid state electronic devices. To design and apply peptide junctions for solid state devices, the relations of peptide electron transport to their amino acid composition and structure need to be understood as well as the peptide electronic structures on the electrode surface. Such information may also help understanding the electron transfer processes that occur in/with proteins in biological energy conversion, sensing and signaling systems. Here, we take linear peptides as the model and construct series peptide junctions on the solid state. Combining theory and calculations, we studied the controlled ways to modulate the electrical properties of peptide junctions which display a versatile, readily available tool for future (bio)electronic applications.

Acknowledgments: The author thanks all the kind helps from the collaborators.

Discovering the Structural Factors Governing Proton Transport in Self-Assembled Peptide Fibers Obad Silberbush1, Subhashish Roy1 and Nurit
The ability to de-novo design peptides (short proteins segments) to self-assemble into functional structures has attracted an extensive attention in recent years, especially towards their implementation in biomedical and biotechnological applications. Many of the self-assembling peptide sequences include charged amino acids, making the resulting nanostructures amenable to proton conduction. Motivated by the opportunity to employ this phenomena in novel bioelectronic applications, the aim of the work I will present was to discover the structural factors that govern proton transport processes in these biomimetic structures. I will demonstrate that proton transport is enhanced significantly by the introduction of even a single charged amino acid into the sequence of a hepta-peptide that self-assembled into fibrils. Moreover, I will show that acidic residues are more effective than basic ones in promoting proton-conduction of the peptide fibrils due to two orders of magnitude larger doping effect, and a threefold higher charge carrier mobility value. I will further demonstrate that both structural motif of the monomeric peptides and the secondary assembling structure have a critical impact on proton conductance of their assemblies. I will show that assemblies originating from helical structures exhibit higher conductivity than assemblies of β-sheet forming peptides with a similar sequence. Nanotube forming D, L γ cyclic peptides with β-sheet structure, however, demonstrated superior conductivity to both linear assemblies. The amount of charge carriers’ density was found to be structural independent and that peptide molecule configuration and self-assembled structure influence proton mobility. Finally, I will demonstrate that acidic molecules can be used for external doping of the peptides assemblies.

Mechanisms of Charge Transport and Large Tunnel Magnetoresistance Across Ferritin-Based Molecular Junctions Christian A. Nijhuis; National Univ of Singapore, Singapore, Singapore.

Electron transport (ET) is important in countless biological processes including enzymatic catalysis or photosynthesis. The efficiencies of ET over long distances in biological systems can be remarkably high. Unraveling the underlying mechanisms governing long range ET across such systems is not only interesting from a fundamental point of view, but could also lead to interesting technological applications in biomolecule-based sensors or biomolecular electronics. We study ET across biomolecular junctions of ferritin which is a cage-like iron storing protein consisting of 24 subunits with an outer diameter of 12 nm and inner diameter of 8 nm. We found that the ET mechanism is independent of the temperature when the ferritin is loaded with iron, but temperature independent when no iron is present. Junctions formed with Ni bottom-electrodes and ferritin monolayers show a tunneling magnetoresistance of 30% at room temperature. Finally, I will also discuss ET in the inverted Marcus region observed across molecular diodes; this ET mechanism may be also relevant to biological systems.

11:00 AM BM02.01.07
Large-Scale Conformational Changes Induce Tunable Electronic and Mechanical Functionality in Proteins Sibel Ebru Yalcin1, J. Patrick O’Brien1, Atanu Acharya2, Yangqi Gu3, Winston Huynh4, Sophia M. Yi1, Subhayotti Chaudhuri2, Victor Batista2 and Nikhil S. Malvankar1; 1Molecular Biophysics and Biochemistry, Yale University, New Haven, Connecticut, United States; 2Chemistry, Yale University, New Haven, Connecticut, United States; 3Molecular, Cellular and Developmental Biology, Yale University, New Haven, Connecticut, United States; 4Biomedical Engineering, Yale University, New Haven, Connecticut, United States.

The ability to understand and modulate charge transport in molecules is of central importance in many basic chemical and biological processes and for the development of electronic devices. This charge transport sensitively depends on molecular conformations. Large-scale conformational changes are particularly attractive because they can serve as information carriers for switches in memory and logic devices. However, conformations affecting conductivity were previously found to remain local and < 2 Å, thus yielding at most a 10-fold change. Here we report the ability to control molecular conductivity via conformational switching at an unprecedented scale.

Although biomolecules are considered electronic insulators, Geobacter sulfurreducens pili protein filaments show metal-like conductivity [Malvankar et al. Nature Nano 6, 573 (2011)]. However, very little is known about how to manipulate the conformation of pili in order to controllably switch conductivity. Lack of solved structures for pili, previous assumptions of homology-based models of pili filaments, and the common perception that proteins are electronic non-conductors have led to great scepticism about conductivity in these biomaterials.

To overcome these hurdles, here we directly visualize the structure of individual pili using infrared nanospectroscopy. This imaging platform has empowered us to engineer conformational changes that facilitate π-stacking of aromatic rings, enhancing both pili conductivity and stiffness. This controlled conformational change constitutes a unique combination of tunable electronic and mechanical properties in pili.

Atomic force microscopy showed that individual Geobacter sulfurreducens pili protein filaments undergo > 20 Å conformational change that propagates over micrometer-lengths of pili upon changing the environment or amino acid composition of pili. Infrared nanospectroscopy revealed that this conformational change is driven by an internal structural transition in pili. A suite of complementary experimental and computational methods such as X-ray diffraction, raman, fluorescence emission spectroscopy and circular dichroism further demonstrated this structural transition in pili. Molecular dynamics simulations confirmed that conformational change in pili leads to improved stacking of aromatic residues to enhance their conductivity and stiffness. Our studies thus establish nanoscopic approaches to visualize and quantify large-scale conformational changes in biomolecules and present novel strategies for tuning their structure and conductivity. The demonstrated conformation-induced conductance switching in proteins will guide the creation of a new class of programmable biomaterials with precisely controlled electronic and mechanical properties. Such tunable biomaterials will aid in the development of seamless, bidirectional interfaces between biology and electronics to transduce mechanical and chemical stimuli into electrical signals.

11:15 AM BM02.01.08
Proton Conductivity in a Thin Film of Self-Assembled Peptides Takuma Narimatsu and Yuhei Hayamizu; Tokyo Institute of Technology, Otsuka, Japan.

Developments of bio-inspired materials have shown a remarkable progress due to their biocompatibility and environmentally-friendly functions. Proton conductivity is a one of the keys in biological function. Learning from natural proteins which have high proton conductivity, researchers have recently demonstrated high proton conductive bio-materials, such as natural protein and polysaccharide. Peptides are another candidate to promote the development of biomaterials with high proton conductivity. Due to its short amino acid sequence, we can design and synthesize arbitrary peptide sequence. The self-assembly of peptides has been intensively investigated and there are variety of peptides known to spontaneously form fibrils in solutions.
In this work, we design a series of peptides which contains simple amino acid sequence to investigate the proton conductivity of their thin films on a silicon wafer. Using a drop-casting method, we formed thin film of peptides on Si-wafers, and characterized the conductivity by electrochemical impedance spectroscopy. We found that these peptide thin film shows an over 5 mS cm⁻¹ of conductivity at room temperature, and this value is higher than those of pure water. Moreover, the conductivity depend on amino-acid residues as well as its crystallinity. This result indicates that proton conductivity could be designed by the peptide sequence.

11:30 AM BM02.01.09
Energy Transport in RNA—Fundamental Design Principles and Applications for Sensors Juan M. Artes Vivas, Y Li, P Feldstein, MP Anantram, J Hihath.

Energy transport is a critical process in biology, being crucial in respiration and photosynthesis. Different biomolecules have evolved to be exquisitely tuned to transfer and transport energy (including excitons and charges) with astonishing efficiency. Recent literature shows multiple examples of this natural design in different biomolecules, including proteins and nucleic acids. As a recent example, I will present recent results we obtained studying charge transport in nucleic acids, including DNA:RNA hybrid sequences from E. Coli.

The continued discovery of new RNA modalities (non-coding, micro, enhancer, etc.) has resulted in an increased desire for detecting, sequencing, and identifying RNA segments for a variety of applications in food safety, water and environmental protection, plant and animal pathology, clinical diagnosis and research, and bio-security.

We have recently demonstrated that molecular conformation profoundly influences the conductance of nucleic acids and that RNA can support long-range charge transport in specific sequences. We show that single-molecule conductance techniques can be used to extract biologically relevant sequence and opens new possibilities for developing electrically-based sensor and diagnostic platforms.

Peptide Folding Influence on Electronic Properties of Bioinspired Peptide Based Materials Nurit Ashkenasy; Ben Gurion University of the Negev, Beer Sheva, Israel.

The three dimensional structure of proteins has a critical role in determining their functional behaviour in nature. As a result, proteins' misfolding is directly associated with different illnesses. The capture of these structure function relationships in self-assembled peptide nanostructures can provide a flexible handle to control their function. In this presentation, I will demonstrate the manipulation of the properties of bioelectronic materials and hybrids by the modulation of the folding of their peptide monomeric units.

I will first demonstrate the influence of subtle changes to the peptide backbone on the electronic properties of semiconductor nanostructures can provide a flexible handle to control their function. In this presentation, I will demonstrate the manipulation of the properties of bioelectronic materials and hybrids by the modulation of the folding of their peptide monomeric units.

In this study, the electronic properties of GaAs functionalized with dipeptides with the same sequence (Val-Tyr) but different backbone registry were characterized. Changes both to the electron affinity and the surface potential will be demonstrated, with the magnitude of which depends on the backbone registry. In the second example I will present, specifically designed self-assembling peptides bearing natural, as well as non-natural side chains, that promote electron conduction have been used. I will demonstrate that the self-assembly medium can be used to control the specific interactions deriving the self-assembly. These interactions, as a result, influence the resulting peptide nanostructure morphology and conductivity. All together these examples demonstrate an exceptional flexibility in controlling the properties of peptide based bioelectronic materials.

Proton-coupled electron transfer (PCET) reactions play a vital role in a wide range of energy conversion processes. This talk will focus on recent advances in the theory of PCET and applications to artificial photosynthesis and photoreduced nanoparticles. The quantum mechanical effects of the active electrons and transferring proton(s), as well as the motions of the proton donor-acceptor mode and solvent or protein environment, are included in a general theoretical formulation. This formulation enables the calculation of rate constants and kinetic isotope effects (KIEs) for comparison to experiment. A combined experimental and theoretical study of a series of substituted benzimidazole-phenol model systems inspired by the Tyr-His redox proton relay found in photosystem II provides insight into the physical principles underlying proton relays. Theory predicted a concerted two-proton transfer process associated with the electrochemical oxidation of the phenol, accompanied by a decrease in the redox potential of the phenol and a small KIE, when the benzimidazole substituents are strong proton acceptors such as primary or tertiary amines. Subsequent electrochemical, spectrophotometric, and KIE experiments were consistent with these predictions. More recent efforts to design a concerted three-proton transfer process associated with oxidation have also been successful. These bioinspired molecular systems demonstrate the potential use of multi-proton relays to enable the transport of protons over longer distances along specified pathways, as well as the tuning of redox potentials through this movement of positive charge. In a different direction, experiments have shown that photoreduced ZnO nanocrystals react by PCET with organic hydrogen atom acceptors such as the nitroxyl radical TEMPO. The application of PCET theory to these systems indicates that the electron transfers from the conduction band of the ZnO nanocrystal to TEMPO concerted with proton transfer from a surface oxygen of the ZnO nanocrystal to the oxygen of TEMPO. Moreover, proton diffusion from inside the nanocrystal to reactive sites on the surface was found to explain the experimentally observed nonexponential kinetics. These applications illustrate the significant role of theory in the design of both molecular and heterogeneous catalysts to control the movement and coupling of electrons and protons.

Bioelectronic Control of pH and Applications Marco Rolandi; Department of Electrical Engineering, University of California, Santa Cruz, Santa Cruz, California, United States.

The concentration of H+ measured by pH plays an important role in many biological processes including energy conversion in mitochondria and archaea, enzymatic activity, and neuronal excitability. Using pH/PdHx as a transducer between electronic and H+ currents we have created bioelectronic devices that are able to control H+ concentration in solution and modulate pH at different biologically relevant levels. Here, I will present recent results on how we can use this pH modulation to control enzymatic activity in bioluminescence, targeted drug delivery, and cellular function during proliferation and growth.

Conjugated Polymer Nanoparticles as Versatile Bioimaging Probes Anitha Ethirajan1, 2; 1Hasselt University, Institute for Materials Research, Hasselt, Belgium; 2imec Associated lab IMOMEC, Diepenbeek, Belgium.

Conjugated polymers have been extensively studied for their opto-electronic properties in the field of organic electronics. In the recent years, they have emerged as promising class of materials for bioimaging owing to their excellent optical properties. Moreover, new synthesis procedures have enabled custom-built functional conjugated polymers that facilitate the one-pot synthesis of semiconducting polymer nanoparticles (NPs) with tunable properties and interesting functionalities for use in biomedical applications.1-10 The possibility to formulate hydrophobic conjugated polymers as water-based nanoparticle dispersions allows for the employment of these versatile materials in biological systems. In this contribution, the potential of interesting class of conjugated polymer nanoparticles (CNPs) for bioimaging will be addressed. Additionally, poly(p-phenylene vinylene) (PPV)-derivative based CNPs will be focussed due to their interesting optical properties, design flexibility for surface functionalization, and benign biological characteristics.

PEGylation strategy has been widely used for surface functionalization of nanoparticles for imparting stealth effects. In this study more profound insight into the various ways in which PEG, with different chain lengths, can affect this particular type of bioimaging probe will be highlighted.11 Subsequently, the consequences of PEGylation on the colloidal, optical and biological characteristics using cell populations within the central nervous system of the bioimaging probe will be shown.

Alongside surface functionality, NP size is one of the most critical concerns for biomedical applications as it has been identified to play a key role in biological processes like cellular uptake, biodistribution and cytotoxicity. Effective internalization by cells is essential to achieve the successful application of NPs for bioimaging objectives. In addition, adjusting the size can have an influence on the optical properties of conjugated polymer NPs. In here, the potential consequences of lowering the size of functional PPV-based NPs on the optical and biological characteristics of a conjugated system specifically designed for bioimaging purposes will be shown.12

The obtained results valorize the potential of conjugated polymers in biomedical applications and open bright prospectives as well as unexplored pathways for these materials.

Magneto-Mechanical Forces Coupled Nanostraw Electroporation System for Enhanced Intracellular Delivery During Cancer Immunotherapy Andy Kah Ping Tay and Nicholas A. Melosh; Stanford, Menlo Park, California, United States.

According to the American Cancer Society, 1.8 million new cases of cancer are expected in 2018. Despite better treatments, mortality rates of cancer like melanoma remain high. Chimeric Antigen Receptor (CAR)-T cell, with on-going clinical trials, offers a promising strategy to engineer immune T cells that recognize and kill cancer cells. Unfortunately, it is difficult to deliver genes and integrate them into the genome of T cells (∼10% efficiency) for effective cancer immunotherapy.

Here, we describe a technique where we integrated magneto-mechanical modulation of cell deformability and intracellular cargo trafficking with magnetic nanoparticles (MNPs) during nanostraw electroporation (NE) to boost the transfection efficiency of Jurkat cells, a model cell line of T cells, from 12.8% to 48%. This method created minimal cellular stresses, as measured with intracellular calcium levels and RNAseq data, compared to other transfection techniques, leading to 2-3 folds shorter waiting time to generate high cell numbers (10⁹) for therapies.

We first compared the efficiencies to deliver a fluorescent protein plasmid with viruses (lentiviruses with Ubiquitin or EF1-α promoters), biochemical
polymers (Fugene, Lipofectamine), bulk electroporation (Biorad Gene Pulser, Lonza Nucleofector) and NE System (NES), and found similar efficiencies, about 10-20%, for Jurkat cells. It was shown that biomechanical forces enhanced transfection in adherent cells. To test if this holds true for non-adherent Jurkat cells, we utilized FDA-approved starch-coated magnetic nanoparticles (MNPs) with cyto-protective effects to generate magneto-mechanical forces. Starch-coated MNPs were biocompatible, and were membrane-bound and internalized after 24 hrs of incubation. We applied static magneto-mechanical forces to the Jurkat cells during NE and found that this boosted the transfection efficiency from 12% to 30% due to a decrease in physical distance between NES and Jurkat cells which minimized the loss of plasmid cargo. After NE, we applied low frequency (to avoid generating heat) alternating magneto-mechanical forces through internalized MNPs to perturb the cytoskeletal network connected to the nuclear envelope. This increased intracellular cargo trafficking and opening probability of the nuclear pore complexes to enhance cargo entry into the nuclei. This modulation step further increased the transfection efficiency from 30% to 48%. Next, by monitoring calcium stress signals and RNaseq, we found that across all the different transfection methods, NES with magneto-mechanical modulation resulted in minimal cellular stresses and treatment did not significantly lengthen cell doubling time unlike other techniques. Actin perturbation also promoted membrane resealing after electroporation. As FDA has approved T cell isolation using magnetic beads like we did, we plan to next apply the concept of magneto-mechanical modulation to enhance T cell transfection efficiency for cancer immunotherapy.
Plants comprise our primary source of food, but are also a source of oxygen, renewable energy, materials, medicines and regulators of the ecosystem. Stomata, the microscopic pores in the leaves of plants are fundamental to the plant function as they control the photosynthesis and transpiration rate. When the stomata are open the plant can exchange gases with the environment and allow the water evaporation enabling photosynthesis and transpiration. Abscisic acid, ABA, also known as the stress hormone, plays an essential role in the signaling mechanism that triggers the stomata closure. Here we report for the first time the use of a bioelectronics device for electronic control of stomata in intact plants. The organic electronic ion pump is an electrophoretic device that allows precise delivery of ions and charged biomolecules with high spatiotemporal resolution. This device has been mainly applied in mammalian systems for therapy. For the delivery of the phyto-hormone ABA we used a new generation of the ion pump that is based on glass capillary and has an overall diameter of 60um. The small diameter of the pump allows easy insertion in leaves of intact plants through the epidermis into the internal area of the leaf. We demonstrated that the stomata close after delivery of ABA with the ion pump and that the stomata close to the pump closer faster than the ones further away implying dose dependence. In addition we didn't observe any significant wound effect from the insertion of the pump signifying the potential of our method as non invasive. With our technology we can offer a new tool for fundamental understating of plant physiology but also adaptation of plants to environmental changes.

**SESSION BM02.03.03: Charge Transfer in Bacterial Systems**
Session Chairs: Renata Bilewicz and Xiaodong Chen
Tuesday Morning, November 27, 2018
Sheraton, 2nd Floor, Independence East

**8:45 AM *BM02.03.01**
**Electron Transfer andTransport in Multi-Heme Proteins**
Jochen Blumberger; University College London, London, United Kingdom.

Certain bacteria have evolved an astonishing survival mechanisms in response to low oxygen concentrations. When cytoplasmatic O2 becomes scarce they start to grow μm-long electrically conducting cellular appendages to export electrons from the cytoplasm to extracellular space for reduction of extracellular substrates (e.g. rocks!) in place of O2. Recently it was shown that arrays of Fe-containing multi-heme cytochromes (MHC) confer electric conductivity to those appendages, which garnered much interest for their use in ionanotechnological applications, e.g. bio-compatible field effect transistors. Here I will present recent experimental measurements probing electron transfer (ET) and electron transport (ETp) through multi-heme cytochromes (MHCs) as well as their interpretation by theory, electronic structure calculations and molecular dynamics simulation. I will discuss recent pump-probe spectroscopy results on Ru-labeled MHCs aimed at the determination of heme-heme ET rates and intrinsic electron flow in aqueous MHCs and the measurement of the I-V characteristics of dry MHCs in bioelectronic junctions (scanning tunneling microscope and protein monolayer junctions). While the ET mechanism appears to be well established for MHCs in aqueous solution, the ETp mechanism in single protein bioelectronic junction remains elusive partly due to the complexities of the electrode-protein interface and the resulting challenges for molecular modelling.

**Proton-Coupled Extracellular Electron Transport via Microbial Outer Membrane Flavocytochromes**
Yoshidehi Tokunou; Kazuhiro Hashimoto; and Akihiro Okamoto; 1National Institute for Materials Science, Tsukuba, Japan; 2The University of Tokyo, Tokyo, Japan.

Bacterial electron transport to a solid substrate or electrode located extracellularly is accomplished by unidirectional electron flow via an array of more than twenty heme redox centers arranged in the outer membrane c-type cytochrome complex (OM c-Cyts). This interfacial electron transport between OM c-Cyts and solid substrates is termed extracellular electron transport (EET). The rate of EET is largely enhanced by self-secreted flavin molecules associated with the formation of semiquinone (Sq) state as a binding redox cofactor in the OM c-Cyts. However, the more negative redox potential of bound flavin Sq than the hemes in OM c-Cyts is energetically unfavorable for the kinetics of EET. Given the primary focus of related work in the recent past has been the electron carriers and the redox potential landscape of reaction centers, the importance of associated proton transport has not been widely investigated in EET. We, herein, show that proton transfer in the OM flavocytochromes limits the rate of EET in Shewanella oneidensis MR-1. Using an in vivoelectrochemical assay, we observed a large kinetic isotope effect (KIE) following D2O addition (< 4%), specifically when EET was the rate-determining step for the current production of lactate oxidation. Replacing flavin cofactors with twelve analogous molecules, the rate of EET correlated well with their pKa at the nitrogen atom at position-5 (N(5)) in the isoalloxazine ring calculated by a quantum chemical approach. Because higher pKae, represents stronger proton acceptability at N(5) in flavin associates and limits the rate of EET. We will further discuss about the rate-determining step of proton transport coupled with the redox reaction of the bound flavin cofactor in OM c-Cyts, with dataset for solvent KIE with partial deletion of OM c-Cyts complex.

**9:15 AM BM02.03.03**
**How Do Electrons Pass Through Multi-Heme C-Type Cytochromes?**
Kavita Garg; Materials and Interfaces, Weizmann Institute of Science, Rehovot, Israel.

Multi-heme cytochrome c (CytC) proteins are key for transporting electrons out of cells, to allow intracellular oxidation to proceed, also in the absence of O2. While the mechanism of the process is not well understood at the molecular level, these hemes may well function as "molecular wires", which makes such multi-heme cytochromes of prime interest for, e.g., potential bioelectronics and bio-sensing and integrating such proteins into electronic circuits is an exciting prospect. Figuring out how electrons pass through these proteins is a scientific challenge. We tackle this by measuring solid state electron transport (ETp) along dry multi-heme protein monolayers, a process that has similarities with, but also clear differences from ET in aqueous solution.

Earlier we studied ETp for a variety of proteins, using "dry" monolayer junctions, with structurally bound H2O retained. In such junctions the donor and acceptor, used in ET in solution, are replaced by nm - mm sized metallic contacts. Electron transport is measured as current, I, in function of applied voltage, V (I-V characteristics) and temperature, T (I-V-T). Here we ETp across two multi-heme CytC-type proteins: the membrane-bound MtrF (deca-heme CytC), the globular STC (tetra-heme CytC) and bilayers of these proteins. Transport is measured between Au electrodes. These proteins show length-normalized conductance that is 1,000x higher than what we measured across single heme (Cytochrome C), or heme-free protein monolayers, but similar to monolayers of conjugated organics. dI/dV of the junctions were also measured using lock-in-amplification at low temperatures, to calculate the protein and protein-contact energy level landscapes, involved in electron conduction. Conductance is found to be temperature-independent (320-80K), suggesting tunneling as limiting transport mechanism. Modelling of the I-V curves was done using Simmons's model and Landauer model, results of which are consistent with that electron transport can be described as tunneling and that protein-electrode coupling, rather than transport in the proteins is rate-
known as bacterial nanowires. To explore the role of biological electron conduits in long-distance (micrometer scale) electron transport along cellular conduits naturally evolved for biotic-abiotic coupling, a fundamental understanding has special implications for a new generation of bioelectrochemical systems. The activation energy of this process matches those obtained from electron hopping calculations through the Mtr-Omc cytochrome pathway. Since EET of EAB networks shared similar characteristics to electron hopping in conductive polymer matrices, including a DC-like mechanism in the low frequency region, and AC induced additional electron hopping when the applied frequency is above the critical frequency (10^4 Hz). The current work represents a strategically new approach for non-invasively probing EET with rationally defined micro-environment and cellular interactions across a wide range of length scales, which is expected to open up new opportunities for tackling the fundamentals and implications of EET.

Core/Shell Bacterial Cables—A One-Dimensional Platform for Probing Microbial Electron Transfer

Huan-Hsuan H. Hsu and Xiaocheng Jiang; Tufts University, Medford, Massachusetts, United States.

Comprehensive interpretation and interrogation of extracellular electron transfer (EET) mechanisms of electrochemically active bacteria can provide valuable information to enhance microbial fuel cells performance, which, however, are still restricted by the intrinsic complexity of natural biofilm. Here, we design core/shell bacteria-encapsulating cables as a one-dimensional model system to facilitate EET studies, where demonstrate the precise modulation of fiber diameters (from 6.9±1.1 mm to 25.1±2.4 mm) and bacteria interactions. As-formed bacterial cables exhibit that their conductivities are highly dependent on the bacteria density as well as the nature and number of intercellular interconnections. The closely contacted bacteria promote the development of high density self-assembling nanomaterials at cellular interfaces which can be directly translated to the increase of EET efficiency (16.2 mS cm⁻¹) as compared with isolated, remotely-connected bacteria samples (6.4 mS cm⁻¹). Introducing exceeding concentrations of soluble electron acceptors during cell culture, however, substantially suppresses the formation of cellular interconnections and leads to significantly reduced conductivity (2.5 mS cm⁻¹). Frequency-dependent measurements further revealed EET of EAB networks shared similar characteristics to electron hopping in conductive polymer matrix, including a DC-like mechanism in the low frequency region, and AC induced additional electron hopping when the applied frequency is above the critical frequency (10^4 Hz). The current work represents a strategically new approach for non-invasively probing EET with rationally defined micro-environment and cellular interactions across a wide range of length scales, which is expected to open up new opportunities for tackling the fundamentals and implications of EET.

Design, Synthesis and Characterization of a Bioanode for Microbial Fuel Cells

Jérémie-Luc Sanchez and Christel Laberty-Robert; Laboratoire de Chimie de la Matière Condensée de Paris, Sorbonne Université-Faculté de Sciences et d’Ingénierie, Paris, France.

Today the need for clean energy technologies appears urgent. Therefore, the idea of harvesting the metabolic activity of microorganisms becomes feasible. Amidst those devices microbial fuel cells focus on converting chemical energy from organic matter into electricity by gathering electrons produced by bacteria degrading these molecules. Such fuel cells may be used as renewable energy sources, but a lot of challenges need to be addressed before we can see them as an efficient, stable and profitable technology. Many approaches to tackle these problems exist. For instance, the electronic transfer between the bacterium and the electrode can be improved by working on the organism or the consortium used to degrade the organic matter. Here we rather seek to improve the material and the architecture of the electrochemical system and especially those of the bacteria-colonized anode. We start from the observations of the limitations of current carbon felt electrodes for microbial fuel cells to design a better system. This work focuses on the conception of the bioanode of a microbial fuel cell by electrospinning. This process allows the shaping of nano to micro-scaled polymer fibers through electrically-assisted extrusion. We obtain a nonwoven mat of polymer fibers which is made conductive by the addition of anisotropic carbon-based materials. The colonization of these hybrid carbon polymer electrodes by the electroactive bacteria Shewanella oneidensis is conducted through diverse approaches: core-shell encapsulation or natural biofilm development. Once prepared, the anode is then integrated into a functional lab-scale fuel cell in order to evaluate its electrochemical characteristics. The impact of the colonization of these conductive electrodes on the electrochemical performances of a full bio fuel cell will be discussed.

Hotwired Life—What Can Bacterial Electron Conduits Teach Us About Biological Energy Conversion and Bioelectronics?

Moh El-Naggar; University of Southern California, Los Angeles, California, United States.

Microorganisms have evolved exquisite electron conduits, including multiheme cytochromes, to extend their metabolic reach to external abiotic surfaces. This process, known as extracellular electron transfer (EET), is being heavily pursued for wiring microbes to electrodes in renewable energy technologies. Here we focus on biophysical measurements, electron transfer simulations, and electron cryo-tomographic studies of the multiheme cytochrome conduits that perform EET in the dissimilatory iron-reducing bacterium Shewanella oneidensis MR-1. We show how the electron transport rates gleaned from single molecule conductance measurements and stochastic simulations can be linked to electrochemical measurements of single cells and whole biofilms. We also describe our current understanding of the distribution and functionality of extended multiheme cytochrome networks along filamentous membrane tubes known as bacterial nanowires. To explore the role of biological electron conduits in long-distance (micrometer scale) electron transport across cellular membranes and across cells, we report in vivo electrochemical measurements of redox conduction through cells linking electrodes, and show that the activation energy of this process matches these obtained from electron hopping calculations through the Mtr-Omc cytochrome pathway. Since EET conduits naturally evolved for biotic-abiotic coupling, a fundamental understanding has special implications for a new generation of bioelectrochemical technologies and living electronics that that harness the advantages of microbes in detecting external signals (e.g. biosensors) or hosting synthetic genetic circuits (e.g. biocomputing).

Mimicking Biological Energy Systems—From Multilayer Membrane Stacks to Molecular Electron Conduits

Lars Jeuken; George R. Heath; Ee Taek Hwang; Valentin Radu; Menggu Li; Anna Sitkan; Khizar Sheikh; Katherine Orchard; Chong Yong Lee; Manuela A. Gross; Tai Kwon Park; Emma Ainsworth; Colin Lockwood; Stefan Frielingdorf; Tadafumi Adschiri; Oliver Lenz; Erwin Reisner; and Julea N. Butt; 1School of Biomedical Sciences and Astbury Centre, University of Leeds, Leeds, United Kingdom; 2Department of Chemistry, University of Cambridge, Cambridge, United Kingdom; 3Advanced Institute for Material Research, Tohoku University, Miyagi, Japan; 4Centre for Molecular and Structural Biochemistry, School of Chemistry, and School of Biological Sciences, University of East Anglia, Norwich, United Kingdom; 5Institut für Chemie, Technische Universität Berlin, Berlin, Germany.

In nature, energy systems rely on efficient electron transfer across redox chains for charge transport across lipid membranes. Multilayered or stacked lipid
membranes spatially organize and compartmentalize these energy processes, while greatly increasing the lipid membrane surface area. Here, I will present two approaches aimed to mimic these fundamental features of bioenergetics.

Long-distance charge separation in photosynthesis was mimicked by coupling dye-sensitized TiO₂ nanocrystals and CdS quantum dots to two decaheme protein, MtrC and OmcA from *Shewanella oneidensis* MR-1, where the decahemes form a ~7 nm long molecular wire between the light harvesting nanoparticle (NP) and the underlying anode. The system is assembled by forming a densely-packed decaheme film on an ultra-flat gold electrode, followed by the adsorption of monolayer of NP. The step-by-step construction of the decaheme/NP system is monitored with (photo)electrochemistry, quartz-crystal microbalance with dissipation (QCM-D) and atomic force microscopy (AFM). When using TiO₂ nanocrystals, dye-sensitized with a phosphonated bipyridine Ru(II) dye, photocurrents are observed that are dependent on the redox state of the decaheme, confirming that electrons are transferred from the TiO₂ nanocrystals to the surface via the decaheme conduit. In other words, TiO₂/decaheme wires function as hybrid photodiodes in which the decaheme traps the conduction-band electrons from TiO₂ before transferring them to the electrode. To the best of our knowledge, the TiO₂ nanocrystal/decaheme system is the first demonstration of a photobioelectrochemical system that uses a redox protein to mimic charge separation found in biological photosystems.

Stacked lipid membrane system were mimicked by using poly-L-lysine to electrostatically assemble multilayers of negatively charged lipid membranes on gold electrodes. When membrane enzymes are incorporated, either an ubiquinol oxidase (cytochrome b₅₃ from *Escherichia coli*) or an oxygen tolerant hydrogenase (the membrane-bound hydrogenase from *Ralstonia eutropha*), cyclic voltammetry (CV) reveals a linear increase in biocatalytic activity with each additional membrane layer (oxygen reduction or hydrogen oxidation, respectively). Electron transfer between the enzymes and the electrode is mediated by the quinone pool that is present in the lipid phase. We deduce by atomic force microscopy, CV and fluorescence microscopy that quinones are able to diffuse between the stacked lipid membrane layers via defects sites where the membranes are interconnected. This assembly is akin to that of interconnected thylakoid membranes or the folded cristae of mitochondria and have significant potential for mimicry in biotechnology applications such as energy production or biosensing.

Biological Electron Transfer Over Centimeter Distances in Cable Bacteria
Rob Cornelissen¹, RaghavendraTT. Eachambadi¹, Robin Bonné², Silvia Hidalgo Martinez²,³, Ji-Ling Hou¹, Jeanne S. Geelhoed¹, Jan D’Haen¹, Henricus T. Boschker²,³, Roland Valcke⁵, Bart Cleuren⁶, Jean V. Manca¹ and Filip J. Meyesman¹,³, 1X-LAB, Hasselt University, Hasselt, Belgium; 2Department of Biology, University of Antwerp, Antwerp, Belgium; 3Department of Biotechnology, Delft University of Technology, Delft, Belgium; 4Institute for Materials Research, Hasselt University, Diepenbeek, Belgium; 5Molecular and Physical Plant Physiology, Hasselt University, Hasselt, Belgium; 6Theoretical Physics, Hasselt University, Hasselt, Belgium.

Biological electron transfer is generally thought to occur over nanometer to micrometer-scale distances, as is the case in cellular respiration or extracellular electron transport via conductive nanowires in metal-reducing bacteria. Yet, various lines of evidence suggest that the recently discovered multicellular cable bacteria¹ can induce biological electron transfer over centimeter-scale distances²,³ – three orders of magnitude longer than previously observed. However, up until now, no direct quantification of an electrical current flow through a cable bacterium filament has been reported.

In this contribution we present some recent insights and advances on the characterization of the electron transport and the conductive structures in cable bacteria. Using SEM, TEM and AFM, we examined in detail the cell envelope of cable bacteria filaments. A fiber network residing in the periplasmic space was discovered, which we propose to be universally present in different species of cable bacteria. The fibers are running in parallel to the longitudinal axis of the filaments. Using amperometric measurements on custom-built electrodes, we successfully measured the conductivity of single intact cable bacteria filaments as well as isolated periplasmic sheaths that contain the fibers. These results demonstrate that the periplasmic fibers are indeed responsible for long-distance electron transport in cable bacteria.

Understanding the conductive structures of the cable bacteria and the associated mechanism of long-distance electron transfer will not only help to understand the role of cable bacteria in their natural environment, but could also enable the development of new applications in bioelectronics.

11:45 AM BM02.03.09
Electrochemical Investigation of Extracellular Electron Transport Through *Pseudomonas aeruginosa* Biofilms
Leonard Tender¹, Matthew Yates¹, Scott Saunders² and Dianne Newman³; ¹Center for Bio/Molecular Science and Engineering, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; ²Biology and Biological Engineering, Caltech, Pasadena, California, United States.

Electroactive microorganisms (EM) can utilize a non-corroding electrode as an inexhaustible electron acceptor or donor for respiration and/or metabolism. During the past 6 years we have applied electrochemical gating measurements (EGM) using interdigitated microelectrode arrays (IDA) to study multi-cell-length-long extracellular electron transport (LE-DET) through electrode-grown EM biofilms. For all biofilms we have examined thus far, EGM reveals that the biofilms act as redox conductors, whereby LD-DET occurs via electron transfer reactions among immobilized extracellular redox cofactors. Here, we apply EGM to study LD-DET occurring in the pure-culture *Pseudomonas aeruginosa* biofilm (PAB). *P. aeruginosasecretes* phenazines, small redox molecules, which among other things, export electrons resulting from respiration by oxygen-limited cells residing deep in PAB. It is conventionally thought that this occurs by physical diffusion of phenazines out of PAB. Our results indicate however that an appreciable amount becomes immobilized within PAB, imparting redox conductivity to the biofilm. Moreover, PAB appears to have different affinities for the different phenazines – with pyocyanin (PYO) contributing most to LD-DET. A model is presented in which PYO exhibits bounded diffusion analogous to certain redox polymers. *P. aeruginosa* is an opportunistic pathogen which forms biofilms in the lungs. The results presented have implications for improved treatment strategies.

SESSION BM02.04: Light and Oxygen Mediated Charge Transport
Session Chairs: Pau Gorostiza and Eleni Stavrinidou

1:30 PM *BM02.04.01
Self-Assembly and Electron Transport of Photosystem I in Tunneling Junctions and Soft Photovoltaic Devices Yan Chiechi1,2, Andreas Herrmann2, Xinai Qui3, Olga Casianeda Ocampo1,2, Mark Loznek, Henry de Vries1,2 and Pavlo Gordielchuk4, Stratingh Institute for Chemistry, University of Groningen, Groningen, Netherlands; 2Zernike Institute for Advanced Materials, University of Groningen, Groningen, Netherlands.

Photosystem I (PSI) is a trimeric protein complex capable of converting light into spatially separated electron/hole pairs. In Nature, this process is used to convert light-energy into chemical-energy to drive photosynthesis. Ex vivo, the electron/hole pairs can be injected directly into electrodes and/or redox couples, turning PSI complexes into nanoscale photovoltaic devices with an internal quantum efficiency of unity. Because PSI is a membrane protein, the complexes are flat and the edges are non-polar, facilitating self-assembly on (electrode) surfaces. However, they assemble with an equal probability of the two possible orientations of the electron transport chain, meaning they will inject holes and electrons with equal probability, resulting in zero photocurrent. We successfully biased this orientation through functionalizing the surfaces of electrodes with either hydrogen-bond donors or ionic groups to exploit the slight differences in the nature of the polarity of the two faces of PSI to demonstrate thin-film, solid-state bio-photovoltaic devices.

The focus of this talk will be examining the mechanism of charge-transfer through self-assembled monolayers of complexes of PSI with and without orientational bias. We find that, in all cases, non-resonant tunneling is remarkably efficient even though tunneling electrons do not interact strongly with the electron transport chain. Rather, the effect of built-in electric field generated by the alpha helices in the periphery of the complexes dominates transport. Using the insights gained from these studies, we used phage display to find linker units capable of biasing the self-assembly of complexes of PSI completely in one direction. We then inserted nano-structured electrodes into microfluidic chips made by soft lithography. When the electrodes are properly functionalized, PSI self-assembles on them resulting in soft, stretchable photovoltaic devices in a single fabrication step. We followed the performance of the devices over time, showing that they are capable of self-regeneration via the circulation of active PSI through the devices in operando.

2:00 PM *BM02.04.02
Oxidative Stress is Tightly Regulated by Cytochrome c Phosphorylation and Respirasome Factors in Mitochondria Alexander Guerra-Castellano, Antonio Diaz-Moreno, Gonzalo Perez-Mejias, Carlos A. Elena-Real, Katsukia Gonzalez-Arzola, Sofia M. Garcia-Mauriño, Miguel A. De la Rosa and Irene Diaz-Moreno; Institute for Chemical Research - cisCartuja, Seville, Spain.

Respiratory cytochrome c has been found to be phosphorylated at tyrosine 48 or 97 in the post-ischemic brain upon neuroprotective insulin treatment, but how such post-translational modification affects mitochondrial metabolism is unclear. Here, we report the structural features and functional behavior of phosphomimetic cytochrome c mutants, which were generated by site-specific incorporation at position 48 or 97 of p-carboxymethyl-L-phenylalanine (PCMF) using the evolved tRNA synthetase method. We found that the point mutations do not alter the overall folding and heme environment of cytochrome c, but significantly affect the whole oxidative phosphorylation process. In fact, the electron donation rate of the Y97/CMF mutant heme protein to cytochrome c oxidase, or complex IV, within respiratory supercomplexes was higher than that of the wild-type species, in agreement with the observed decrease in reactive oxygen species (ROS) production. Direct contact of cytochrome c with the respiratory supercomplex factor HGH1A (hypoxia inducible domain family member 1A) is herein first reported, with the Y97/CMF mutant heme protein exhibiting a lower affinity than the wild-type species. Interestingly, phosphomimetic cytochrome c also exhibited a lower caspase-3 activation activity. Altogether, these findings yield a better understanding of the molecular basis for mitochondrial metabolism in acute diseases, such as brain ischemia, and could thus allow the use of phosphomimetic cytochrome c as a neuroprotector with therapeutic applications.

A Novel Biological p-n Junction for Modulating the Proton Transport in Bacteriorhodopsin Yan Xiang1,2; 1Southen New Hampshire University, Manchester, New Hampshire, United States; 2Beihang University, Beijing, China.

Hampered by the absence of evidence and theoretical model of biological semiconductor, the unidirectional electron transport via the p-n junction structure between functional proteins and abiotic materials remains a challenge for bioelectronics. Bacteriorhodopsin (bR), a representative transmembrane protein, has demonstrated exceptional optoelectronic effects in bR/semiconductor hybrid materials and offers a possible pathway for addressing this challenge. In the present work, bR is found to be an n-type semiconductor with an indirect electron transition. Thereby, we successfully explain the mutual cohesion and unidirectional interfacial electron transport between bR and p-type semiconductor, specifically, the enhanced yet stable photocurrent, in regard to optoelectronics and the acceleration of the bR photocycle, via a distinctive bio-p-n junction mechanism. We believe the concept of protein based p-n junction will underscore research on bioelectronic applications for bR and its homologues.

New Insights on the Electrical Resistive Switching Behavior of Eumelanin—Toward Memory Application Devices Manuel Real1 and Abdelaziz M. Gouda; Engineering Physics, Polytechnique Montréal, Montréal, Quebec, Canada.

Eumelanin is a black biopigment present in flora and fauna [1]. It features fascinating properties such as radical scavenging, metal chelation, photoprotection, broadband optical absorption and hydration-dependent electrical conductivity [2]. Remarkable research efforts have been devoted to unravel its optical and electrical properties to integrate eumelanin in optoelectronic and energy storage devices [3]. A debate whether eumelanin is an amorphous semiconductor (ASC) or a mixed ionic-electronic conductor (MIEC) is open among the scientific community. The discovery of a resistive switching behavior in eumelanin pellets [4] along with theoretical simulations that predict the existence of mid-gap states in eumelanin have been considered primary evidence for the ASC model [5]. Recently, it has been proposed that adsorbed water would activate a comproportionation equilibrium between redux active eumelanin moieties, favouring a Grothuss-like charge transport [6]. Even though the MIEC conduction model excludes the ASC model, the causes of the resistive switching are not well understood.

In this work, we fabricated wet and dry Sepia eumelanin pellets (hydrated at different percentages of relative humidity (%RH) or processed in Ar glove box), sandwiched in coin cell configuration, using Cu and stainless-steel electrodes. Hydrated samples show a reproducible resistive switching over many cycles with an on/off ratio of ca. 10^−4. Dry samples switch only during the first cycles, with an exponential I-V behavior. SEM images of Cu electrodes taken after the electrical characterization of wet samples reveal CuO dendritic structures. These dendrimers could bridge the two electrodes. The I-V electrical response of dry samples could be interpreted as evidence of an electronic transport in bulk eumelanin thus supporting the ASC model.

Understanding the mechanisms of the resistive switching behavior and shedding light on the electrical properties of eumelanin under different hydration conditions is critical to demonstrate eumelanin-based memory devices.

Biohybrids from Organic Semiconductors and Photosynthetic Bacteria Gianluca M. Farniola¹, Francesco Milano¹, Roberta Ragni¹, Marco Lo Presti¹, Simona la Gatta¹, Angela Agostano¹² and Massimo Trotta¹²; ¹University degli Studi-Bari Aldo Moro, Bari, Italy; ²Dipartimento di Chimica Università degli Studi di Bari “Aldo Moro”, Bari, Italy, CNR IPCF UOS BARI, Bari, Italy.

The Reaction Center (RC) is the photoenzyme used by photosynthetic bacteria, such as the purple Rhodobacter Sphaeroides R26, to convert solar energy into charge separated states with efficiency close to 100% [1]. Upon its isolation from the living bacterium, the RC retains stability and enzymatic activity in surfactant aqueous media and is envisaged as a promising biological system to generate new photoactive materials for bioelectronics [2]. However, the applicability of RC in bioelectronic devices is strictly related to (a) finding suitable deposition methods enabling controlled orientation of the protein on conducting or semiconducting substrates and (b) employing chemical strategies to enhance the protein light absorption in the visible region. A
successful approach to extend the RC visible absorption is covalently binding tailored organic molecules that harvest white light and efficiently transfer it to the protein [3, 4]. A variety of molecular fluorophores acting as efficient antennae will be presented, highlighting their role in the enhancement of biohybrids’ photoconversion efficiencies. The lecture will also discuss strategies to efficiently affix the RC on organic semiconductors layers in photoconversion devices and to embed the RC in polymeric thin films at the electrodes [5].

Design and construction of smart supramolecular architectures by the multiple combination of different enzymes assembled with tailored linkers will be also presented as a proof of the concept that supramolecular bioinspired machineries based on the functioning of the bacterial RC photoenzyme can be developed for solar energy conversion.

Coupling Electron and Proton Transfer—The Lesson From the Photosynthetic Reaction Center Massimo Trotta1, Francesco Milano1, Roberto Ragni2 and Gianluca M. Farinola2; 1Istituto per i Processi Chimico Fisici, Consiglio Nazionale delle Ricerche, Bari, Italy; 2Department of Chemistry, Università degli Studi di Bari Aldo Moro, Bari, Italy.

Photosynthetic reaction centers from photosynthetic bacteria are integral membrane proteins able to transform the electromagnetic radiation associated to solar light in a biological hole-electron couple amenable for being used in a number of possible applications. The hole-electron couple formed upon light absorption is characterised by a long-living property: the charge-separated state can survive from 100 milliseconds to 3 seconds, depending on the environmental conditions.

One of the key issues for this extent lifetime of the dipole within the scaffolding of the protein is that the formation of the charge-separated state draws proton, from the aqueous solution within the inner part of the protein, eventually modulating the redox chemistry of the final electron acceptor. The role of the proton uptake from the photoenzymes during its functioning will be addressed along with some possible consequences on the applicable use of the Reaction Center as organic-biological biohybrid.

4:45 PM BM02.04.10
Intracellular Au Nanocluster Photosensitized Bacteria for Solar Fuel Production Hao Zhang1 and Peidong Yang1,2; 1Department of Chemistry, University of California, Berkeley, Berkeley, California, United States; 2Material Science Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

The demand for renewable and sustainable fuel has prompted the rapid development of advanced nanotechnologies to effectively harness the copious flux of solar power. Although the solar-to-energy efficiencies of inorganic semiconductor devices can easily surpass 20%, the transduction of solar energy into photoconversion devices and to embed the RC in polymeric thin films at the electrodes aims to link preassembled biosynthetic pathways with inorganic light absorbers. This strategy inherits both the high light-harvesting efficiency and the superior catalytic performance of solid-state semiconductors and whole-cell microorganisms, respectively. Recently, we have demonstrated a version of membrane-bound CdS nanoparticle on nonphotosynthetic bacterium, Moorella thermoacetica for artificial photosynthesis. To eliminate potential mass and energy losses during transporting electrons across cell membranes, the spatial conjugation between inorganic material and microorganism could be designed in cytoplasm. Here, we introduce an intracellular, biocompatible light absorber, namely gold nanoclusters (Au NCs), to circumvent the sluggish kinetics of electron transfer for existing PBSs. Translocation of these Au NCs into nonphotosynthetic bacteria enabled photosynthesis of acetic acid from CO2. Besides, Au NCs also serve as reactive oxygen species (ROS) inhibitors to maintain high bacterium viability. Taking the dual advantages of light absorption and biocompatibility, this new generation of PBS can efficiently harvest sunlight and transfer photo-generated electrons to cellular metabolism, realizing CO2 fixation continuously over several days. Moreover, intracellular PBS represents a promising platform to investigate the charge transfer, and leads to a deeper understanding of the burgeoning complex nexus of inorganic materials and biological systems.
The charge transport investigation through peptides and proteins offers an unique opportunity to study the supramolecular interaction, information transmission, and even bio-catalytic process in biological systems, however the single-molecule experimental measurement of charge transport through peptides and proteins remained as experimental challenges due to the difficulties in the binding of peptides/proteins on electrodes and also the extraction of low current signals through the single peptide/proteins junction. On the other hand, the calculations predicted that the conductance of peptides junctions exhibited low conductance, while the experimental measurement provides relatively high conductance, then what is the dominated conduction channel through the single peptide/protein?

Here we studied the charge transport properties through a series of peptide-supramolecular interactions, including hydrogen bonds and π-π stacking, and we measured the supramolecular charge transport between two peptides anchored on two separated gold electrodes using scanning tunneling microscopy break junction (STM-BJ) technique. The combined molecular dynamic simulations further revealed the conformation evolution of supramolecular peptides junctions. It is found that the supramolecular interaction between the peptides offer the conduction channel, and the charge transport through the supramolecular process could be further tuned by the environments.

As perspective, we further applied the technique to investigate the charge transport through an enzyme, oxidoreductase, and our preliminary results suggested that the charge transport process are correlated to the bio-catalytic process, which offer an unique testbed to look into the bio-catalysis from the single-molecule level.

Transducing between ion and electron currents is a key challenge underpinning the emerging field of bioelectronics [1]. In general, ions (including protons) are the dominant signal carrying entities in biology, and modern electronics relies on semiconductors where the carriers are electrons and holes. Solid state ionic conductors (SSICS), whilst not rare, are somewhat few and far between – so-called ionic glasses such as silver iodide or sodium alumina being classic and early examples. Of more relevance to bioelectronic applications are polymeric-SSICs and there are several well-known examples such as DuPont’s Naion (a proton transport membrane). Polymeric matrices such as polyethylene oxide can also conduct ions when suitably ‘doped’ (or solvated depending upon your nomenclature) with for example, water or lithium perchlorate [2]. Finally, several biopolymeric matrices such as melanin and proteins [1, 2, 3] show respectable proton conductivities when hydrated.

In my talk I will present several examples of polymeric and biopolymeric SSC materials and exemplify the ‘conduction physics’ at play. I will also describe recent progress in utilising these materials as transducing elements in hybrid and all-organic transistors which represent prototype bioelectronic logic elements [4, 5].

Electron transfer is central to all life processes. Every living cell must get rid of a large number of electrons left behind in metabolism when nutrients convert into energy. Electron transfer in proteins occurs through either tunneling or hopping a few nanometers via inorganic cofactors. However, the common soil bacteria Geobacter sulfurreducens transfer electrons over hundreds of micrometers, to insoluble electron acceptors or syntrophic partner species. These bacteria use surface appendages called pili for extracellular electron transport, allowing them to survive in environments that lack membrane-permeable electron acceptors such as oxygen. Near room temperature, the conductivity of wild-type pili exhibits temperature dependence similar to that of metallic polymers, which recently was confirmed independently. However, the composition and structure of pili as well as the mechanism of pili conductivity has remained unclear.

I will present our recent structural, molecular and biophysical studies to identify the mechanism of metallic-like conductivity in pili. We elucidate the physical mechanism of electron transport by measuring the electrical and optical conductivity of pili from multiple mutant strains as a function of molecular length, temperature, frequency, pH and stacking. We demonstrate that intrinsic conductivity of individual pili can be accurately described by...
nearest-neighbor, tight-binding model as predicted theoretically for quasi-one-dimensional materials. To determine the molecular architecture responsible for conduction, we are using a suite of complementary experimental and computational methods such as molecular dynamics, x-ray diffraction and near-atomic resolution cryo-electron microscopy. Our studies suggest a pi stacking-like interaction in pili, that can cause intermolecular electron delocalization, conferring metallic conductivity to pili. Furthermore, increasing p-stacking in pili improves their crystallinity, yielding a longer mean free path for electrons, and stronger electronic coupling in pili which is 1000 times higher than other proteins or DNA. Pili thus represent a new class of electronically functional proteins that can transport electrons at rates and distances unprecedented in biology. These findings will help development of genetically programmable biomolecular materials with tunable functionality through precise control of their electronic and protein structure.

9:30 AM BM02.05.04

Biological charge transfer processes are mostly based on the controlled diffusion of charges (electrons, protons, ions) across specific pathways within proteins over distances of ~100 nm. Rather recently, long electron transfer has been found in bacterial wires for distances of few μm’s, which is probably also mediated by proteins. With this biological inspiration, we report here on the formation of free-standing films that were formed from the serum albumin protein, which were bioinspired functionalized to exhibit efficient electron transport on the centimeter length scales. Furthermore, we show that the protein-based films can be functionalized in a different way for the formation of efficient ionomers with measured ionic conduction of >5 mS/cm at room temperature. Our formed films have attractive mechanical properties, with a high elastic modulus of ~160 MPa, but at the same time they are highly stretchable, capable of stretching more than 4 times their length. They have high resistance to harsh organic solvents and acids, they are very easy to form, and have a very low price tag with materials cost of around a $1/cm². We believe that our newly formed films can be used as a universal scientific test bed for exploring protein-based long range conduction, and even can find themselves in various applications, from biomedical ones all the way to membranes for fuel cells.

9:45 AM BREAK

10:15 AM BM02.05.05

We present a combined theoretical study of density functional theory and molecular dynamics simulations of a copper-binding protein azurin from Pseudomonas aeruginosa and some selected mutants. Contrary to previous studies where only the copper complex and its surroundings were considered, we here analyzed, for the first time, the whole structure of the protein. We found that the peripheral part actually also plays an important role in the electronic structure at energies close to the Fermi level [1]. Furthermore, our results are in good agreement with recent experiments [2]. We also explored the role of thermal fluctuations and how they affect both the geometrical conformation and the electronic structure.

10:30 AM BM02.05.06

A great effort has been made in recent years to incorporate proteins as functional components in electronic junctions [1]. A number of studies report the surprising efficiency of electron transport (ETp) in proteins, as well as temperature-independent conductance over distances of up to ~10 nm, calling into question the applicability of known ETp mechanisms to these systems. From molecular and organic electronics we know that the positions of the molecule’s frontier energy levels, relative to the electrodes’ Fermi level (EF), play a key role in charge transport. In protein electronics, very little is known about these energy levels; to make things worse, the leading “normal” method to determine these levels, photoemission spectroscopy has not yet been applied successfully to protein monolayers.

Gating measurements provide an ideal platform to study energy levels by means of modulating the positions of the frontier orbitals, relative to those of the electrodes. However, geometric considerations make implementing a gate in protein-based junctions challenging, primarily due to the difficulty in binding proteins inside nano-gaps.

Here we report a new method that does allow for gating of proteins, and in a highly reproducible manner, to provide an energy level description of ETp in Azurin (a blue copper, bacterial electron-transfer protein). Drain and gate gold (Au) electrodes are separated by ~80 nm, on a SiO2 substrate (fabricated by electron-beam lithography), with an AFM tip acting as the source. Source-drain current-voltage measurements at different gate bias, and gate-bias sweeps at low source-drain bias, show reversible gate-induced conductance in Azurin. Current onset was observed only at positive VG, indicating that transport in Azurin is dominated via the tail of the LUMO. The importance of Cu(I) in Azurin for ETp was tested by comparing measurements with Apo-Azurin, i.e., Cu-depleted Azurin. The results emphasize the contribution of the Cu(II) ions towards energy alignment for efficient ETp.

Comparing gating measurements performed with an Au and a Pt AFM tip as source, shows that a lower VG is required to induce a current onset in Azurin with Au than with Pt tips. Furthermore, the difference in measured work function of Au and Pt electrodes, served as reference to calibrate VG with the energetic distance from the Fermi level to the LUMO tail. Calibrating the energy in this way quantitatively allows for gating of proteins, and in a highly reproducible manner, to provide an energy level description of ETp in proteins inside nano-gaps.

Eumelanin, as a subset of melanins, is a type of biological pigments and is widely present in living organisms. Eumelanins are synthesized in the melanocytes by templated antioxidative polymerization using 5,6-dihydroxyindole carboxylic acid (DHCA) and 5,6-dihydroxyindole (DHI). Molecular subunits are formed into oligomeric macromolecules that π-stacked into microstructures. Despite the chemical similarity of subunits, it is challenging to reproduce eumelanins in a synthetic way due to the absence of templates. Research herein focuses on synthesizing biologically-derived melamins with various topographies and examine structure-property relationship. Microscopic structures of melamins are controlled by the templates made of tripeptides sequences. Three types of peptides including aspartic acid (D), phenylalanine (F), and tyrosine (Y) are self-assembled with various sequences to form distinct templates, which can formulate melamins into fibrous or sheet-like microstructures. These class of melanin electrodes with tunable microstructures would serve as the next generation biodegradable charge storage materials that can power various types of biomedical electronics devices. Microstructures are characterized using scanning electron microscopy (SEM) and Brunauer-Emmett-Teller (BET) surface area measurement. Electrochemical performance of electrodes are examined by cyclic voltammetry and chronopotentiometry within aqueous electrolytes containing either Na⁺ or Mg²⁺. Structural changes along with chemical signatures are analyzed by Fourier transform infrared and raman spectroscopy after coordinating with cations.

11:00 AM DISCUSSION SESSION

SESSION BM02.06: Materials and Systems for Bio-Inspired and Bio-Compatible Electronics
Session Chairs: Irene Diaz-Moreno and Wenjing Hong
Wednesday Afternoon, November 28, 2018
Sheraton, 2nd Floor, Independence East

1:30 PM *BM02.06.01 Peptides as Bio-Inspired Electronic Materials and Sensing Motifs Andrew Abell1,2, John Horsley1,2 and Jingxian Yu1,2; 1University of Adelaide, Adelaide, New South Wales, Australia; 2Centre for Nanoscale BioPhotonics, Adelaide, South Australia, Australia.

Bio-inspired molecular electronics is a particularly intriguing paradigm, as charge transfer in proteins/peptides, for example, plays a crucial role in energy storage and conversion processes in all living organisms. However, the structure and conformation of even the simplest protein is complex, and as such, model synthetic peptides containing well-defined geometry and pre-determined functionality, present as ideal platforms to mimic nature for the elucidation of fundamental biological processes, while also advancing the design and development of single-peptide electronic components and other devices. We present studies on intramolecular electron transfer in synthetic peptides of well-defined helical conformation and also ill-defined geometry, using electrochemical techniques and constrained density functional theory simulations. Two definitive electron transfer pathways are apparent, the nature of which is dependent on secondary structure. Electrochemical results indicate that peptides constrained by either Huisgen cycloaddition, ring-closing metathesis or lactam-bridge exhibit remarkable positive formal potential shifts (> 460 mV) and significant electron transfer rate constant drops (up to 15-fold), which represent two distinct electronic ‘on/off’ states. The additional backbone rigidity imparted by the side-bridge constraints leads to an increased reorganization energy barrier to restrict the torsional motions necessary for facile intramolecular electron transfer along the backbone. A clear mechanistic transition from hopping to superexchange, stemming from side-bridge gating, is apparent. The electronic properties of peptides can be fine-tuned through both structural and chemical manipulation, to reveal an interplay between backbone rigidity and electron rich side-chains on electron transfer. The side-bridge constraints provide an additional electron transport pathway, to provide two distinct forms of quantum interferometers. The effects of destructive quantum interference occur essentially through the backbone and the additional tunnelling pathway provided by the side-bridge in the constrained β-strand peptide, as evidenced by a correlation between electrochemical measurements and molecular junction conductance simulations for both linear and constrained β-strand peptides. In contrast, an interplay between quantum interference effects and vibrational fluctuations is revealed in the linear and constrained helical peptides. Collectively, these findings not only augment our fundamental knowledge of charge transfer dynamics and kinetics in peptides, but also open up new avenues to design and develop functional bio-inspired electronic devices, such as on/off switches and quantum interferometers, for practical applications in molecular electronics. These studies also provide an opportunity to develop peptide-based sensors for detecting biological Zn²⁺ and also protein-protein interactions, aspects of which will also be discussed.

2:00 PM *BM02.06.02 Mechano-Adaptable Electrodes for In Vivo Electrophysiological Interfacing Xiaodong Chen; Nanyang Technological University, Singapore, Singapore.

Polymeric microelectrode arrays are emerging as a new generation of biointegrated microelectrodes to transduce original electrochemical signals in living tissues to external electrical circuits, and vice versa. So far, the challenge of stretchable polymer microelectrode arrays lies in the competition between high stretchability and good electrode–substrate adhesion. The larger the stretchability, the easier the delamination of electrodes from the substrate due to the mismatch in their Young's modulus. Here, I will present our recent work on designing mechano-adaptable electrodes and their application for conformally recording the electrocorticograph signals from rats.

2:30 PM BREAK

3:00 PM *BM02.06.03 Dynamic Materials Inspired by Cephalopods Alon Gorodetsky; University of California, Irvine, Irvine, California, United States.

Cephalopods, e.g. squid, octopuses, and cuttlefish, have captivated the imagination of both the general public and scientists for more than a century due to their visually stunning camouflage displays, sophisticated nervous systems, and complex behavioral patterns. Given their unique capabilities and characteristics, it is not surprising that these marine invertebrates have emerged as exciting models for novel materials and systems. Within this context, our laboratory has developed various cephalopod-derived and cephalopod-inspired materials with unique functionalities.5 Our findings hold implications for next-generation adaptive camouflage devices, sensitive bioelectronic platforms, and advanced renewable energy technologies.

Single Molecule Detection of Markers with a Label-Free Bio-Electronic Sensor

Cinzia Di Franco, Matteo Ghittorelli, Domenico Alberga, Giuseppe F. Mangia, Gerardo Palazzo and Gaetano Scamarcio; 1Chemistry, Università degli Studi di Bari Aldo Moro, Bari, Italy; 2Università degli Studi di Bari Aldo Moro, Bari, Italy; 3Università degli Studi di Brescia, Brescia, Italy.

Label-free single-molecule detection has been achieved so far by funnelling a large number of ligands into a sequence of single-binding events with few recognition elements host on nanometric transducers. Such approaches are inherently unable to sense a cue in a bulk milieu. Conceptualizing cells’ ability to sense at the physical limit by means of highly-packed recognition elements, a millimetric sized field-effect-transistor is used to detect a single molecule. To this end, the gate is bio-functionalized with a self-assembled-monolayer of trillions of capturing anti-Immunoglobulin-G and is endowed with a hydrogen-bonding network enabling cooperative-interactions. The selective and label-free single-molecule IgG detection is strikingly demonstrated in diluted saliva while 15 IgGs are assayed in whole serum. The suggested sensing mechanism triggered by the affinity binding event, involves a work-change that is assumed to propagate in the gating-field through the electrostatic hydrogen-bonding network. The proposed immunoassay platform is general and can revolutionize the current approach to protein detection.

Fast Dissolving Transient Electronics Incorporating Peptide Insulator

Soek Daniel Namgung, Min-Kyu Song, Taehoon Sung, Jaehun Lee, Misong Ju, Ki Tae Nam and Jang-Yeon Kwon; 1School of Integrated Technology, Yonsei University, Incheon, Korea (the Republic of); 2Department of Material Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Transient electronics has been suggested as one of the formats of human implantable devices, since the device disappearing within human body at programmed time may reduce risk of immune response or inflammation caused by remaining rigid electronic components. There have been many demonstrated applications including biosensors, circuits, memories, RF antennas and etc, in which silicon dioxide (SiO2) has been frequently used as an insulator. However, SiO2 still has limit on slow dissolution rate and it may cause inflammation at the targeted organ. Toxicity issue, also, can arise because insulator is the largest part of device, and the absolute amount of insulator might exceed appropriate range, as a device is expanded to circuit application. From this context, we suggest specific tyrosine-based peptide sequence, Tyr-Tyr-Ala-Ala-Cys-Ala-Tyr-Tyr (YYACAYY), as an insulator component, since it has high biodegradability, intrinsic biocompatibility, and previously shown high dielectric constant. In this report, we fabricated biocompatible and biodegradable thin film transistors (TFTs) consisting of tungsten (W) conductor, zinc oxide (ZnO) semiconductor and peptide insulator. The device structure is bottom gate top contact, in which 100 nm-thick W and 30 nm-thick ZnO are patterned using shadow mask, and 400 nm-thick YYACAYY peptide that is dissolved in trifluoroacetic acid(TFA) is spin-coated. The device shows field effect mobility of ~21.80 cm2V-1s-1 and ON/OFF current ratio of ~105, which are comparable to SiO2 based TFT. The device further dissolves at 37 °C in bio-fluids such as deionized water, phosphate-buffered saline (PBS, pH~7.4) and bovine serum, and it is optically observed that all the device components dissolve within 12 hours, which is faster than that of SiO2 based TFT. The fast dissolution is attributed to peptide film, and dissolution rate of the film at 37 °C in deionized water is ~1300 Å/m, which is ~20,000 times faster than that of e-beam deposited SiO2, that is previously reported. Mechanism on dissolution of peptide film is inspected through X-ray Photoelectron Spectroscopy (XPS) analysis and destruction of overall device interfaces incorporating peptide film is investigated through cross-sectional Transmission Electron Microscopy (TEM) analysis. In conclusion, peptide insulator is newly suggested toward transient electronics as an alternative of SiO2 insulator, in which the peptide shows advantages on high degradability, biocompatibility and high dielectric constant. Biocompatible and biodegradable TFT incorporating peptide film is further demonstrated and shows moderate device performance and fast dissolving property. This strategy to select fast dissolving material at human implantable device may significantly reduce the risk of inflammation within human body.

Exploring Fast Proton Transfer Events Associated with Lateral Proton Diffusion on the Surface of Membranes

Nadav Amdursky; Schulich Faculty of Chemistry, Technion–Israel Institute of Technology, Haifa, Israel.

Proton diffusion across biological membranes is a fundamental process in many biological systems, and much experimental and theoretical effort have been employed for deciphering it. Here we report on a new spectroscopic probe, which can be tightly tethered to the membrane, for following fast (ns) proton transfer events on the surface of membranes. Our probe is composed of a photoacid that serve as our light-induced proton source for the initiation of the proton diffusion process. We use our probe to follow this diffusion, and its pH-dependence, on the surface of lipid vesicles composed of either a zwitterionic headgroup, a negative headgroup, a headgroup that is composed only from the negative phosphate group or a positive headgroup without the phosphate group. We reveal that the kinetic parameters of proton diffusion are highly sensitive to the nature of the lipid headgroup, from a fast lateral diffusion at some membranes to the escape of protons from surface to bulk (and vice-versa) at others. By referring to existing theoretical models for the diffusion process of protons on the surface of membranes we found that while some of our results confirm the quasi-equilibrium model, other results are in line with the non-equilibrium model.ases for fuel cells.
Wood is a biological material with outstanding mechanical properties resulting from its hierarchical structure across different scales. While the cellular structure and the winding angle between the stiff cellulose fibrils and the wood cell axis have been reported to be key factors for its high stiffness and strength at light weight, the role of the molecular organization of its chemical components: cellulose, hemicellulose and lignin, is still to be fully understood. At the molecular scale, most of the hemicellulose molecules attack on the surface of the stiff crystalline cellulose fibrils, while lignin molecules fill the rest space. By applying a recently developed full atomistic model of the wood cell wall material, we studied how wood benefits from this intriguing molecular organization by intentionally varying the material distribution so that hemicellulose and lignin are randomly mixed or lignin molecules attach on the cellulose surface. It is found that better adhesion between the cellulose fibrils are achieved with the material distribution found in natural wood. Further detailed studies on individual molecules reveal that the hemicellulose show higher adhesion than lignin with cellulose and the three-dimensional structure of lignin originates its higher rigidity. Moreover, the covalent crosslinks between hemicellulose and lignin molecules enhance the load transferring between them. Therefore, the material distribution found in natural wood forms a pathway for load transferring that materials with stronger interactions are paired together. Our study reveals the molecular principles that wood adapts to achieve the outstanding mechanical properties at the macro-scale, which could shed light on the design of composite materials.

Bacterial Microcompartments (BMC) are roughly icosahedral shells found in bacteria that sequester enzymes involved in certain metabolic processes. Experiments suggest that some BMCs assemble by a pathway in which the enzymatic cargo first undergoes phase separation, after which the shell assemblies around the dense cargo droplet. Other types of BMCs assemble in a single step, with simultaneous cargo coalescence and shell assembly. Computational studies suggest that the strength of interactions between cargo particles are a key determinant of the assembly pathway. However, the physical origins of these interactions remain unclear; in particular, whether they result from direct attractions between enzymes or are mediated by scaffolding proteins.

In this presentation we describe coarse-grained computational and theoretical modeling to study the effect of cargo interactions and cargo topology on microcompartment assembly. We present results of dynamical simulations that compare shell assembly when cargo coalescence is driven by direct cargo-cargo attractions or scaffold-mediated attractions. We find that cargo properties can dramatically influence assembly pathways. Depending on conditions, the presence of cargo may increase or decrease shell size in comparison to the intrinsic protein curvature. This result may explain recent experiments on different BMC systems in which empty BMC shells were respectively smaller or larger than full shells. In comparison to direct cargo-cargo attractions, our simulations identify a richer set of assembly behaviors for scaffold-mediated cargo attractions, and suggest that there are experimentally distinguishable differences between the two classes of systems. Understanding factors that control encapsulation of cargo by self-assembling shells is the first step for reengineering BMCs to construct drug delivery vehicles or customizable nanoreactors that encapsulate a programmable set of enzymes.
Polyethylene (PE) is one of the widely used commercial polymers. Cross linking improve many properties of PE such as high dielectric strength, mechanical strength, low water permeability. Cross-linked PE (XLPE) has emerged as the insulator of choice for high-voltage direct current (HVDC) power transmission cables due to its favorable dielectric properties, low water permeability, structural integrity at high temperature and chemical resistance. Dicumyl Peroxide (DCP) has been used as an accelerating agent in cross linking PE. We investigated cross linking mechanisms and mechanical and electrical properties of XLPE systems using large scale molecular dynamics simulations. We first started with a non-reactive force field to understand diffusion of DCP molecules into the PE matrix with and without the influence of external electric field. Second, we employed eReaxFF to investigate cross linking mechanisms. ReaxFF reactive force fields first developed for hydrocarbons and later ported to different systems such as ceramics, metals and their oxides and provided precise results for those systems. eReaxFF is an extension to ReaxFF in which electrons are treated explicitly in a pseudo classical manner. We adopted a previous ReaxFF reactive force field and developed eReaxFF reactive force field to capture DCP-PE interactions, and investigated reaction mechanisms of crosslinking of PE via DCP under the external electric field using large scale molecular dynamics simulations. We investigated the effects of different parameters such as temperature, density, pressure and the ratio of peroxides to polyethylene on the formation of byproducts, distribution of functional groups and cross-linking. Furthermore we investigated mechanical ( tensile strength, bulk modulus) and electrical properties ( dielectric strength ) of the cross linked PE.

9:00 AM BM03.01.05
Modeling the Influence of Emergent Interactions Between Nascent Oligomers on the Sequences of Step-Grown Copolymers Kateri H. DuBay and Zhongmin Zhang; University of Virginia, Charlottesville, Virginia, United States.

The sequences of synthetic copolymers are notoriously difficult to control, and numerous complex protocols have been developed to help us do so. However, we lack a comprehensive understanding of what governs the sequential incorporation of different monomers into a chain for even the simplest of copolymerizations. To learn more, we performed coarse-grained modeling of a linear, step-growth copolymerization between two monomers. Our results demonstrate that transient associations and emergent self-organization among the reacting monomers and nascent oligomers can exert considerable influence over the sequential arrangement of monomers in the resulting chains, even when reaction barriers between the different monomer pairs are held constant. The magnitude of the effect we observe for differing co-monomer attractions can be explained by an emergent phase separation among the nascent oligomers – a phase separation that is both initiated and limited by the copolymerization.

9:15 AM BM03.01.06
Computational and Experimental Studies of Peptide: Silica Interactions Victor V. Volkov and Carole C. Perry; Nottingham Trent Univ, Nottingham, United Kingdom.

Structural properties of bioinorganic composites are of contemporary research interest in fields such as drug delivery, bone repair and biomimetics. While being a key material in bio-engineering applications, silica may be either hazardous or biocompatible depending on parameters such as particle size, shape or surface properties. Effective simulation at the quantum level of large silica-based bio-composites is necessary to gain a deeper insight into the properties of such materials. How to bridge between structural extraction from large scale classical simulation to predictions by quantum chemistry for silica based structures is the focus of our contribution. In this presentation we present MD and DFT simulation data, complemented by experimentally derived vibrational and optical spectroscopic data for the study of (a) 2nm silica nanoparticles, (b) the possible effects of local fields next to such nanoparticles and (c) the interaction of silica with 7-mer peptides.

9:30 AM BM03.01.07
Predicting Viscoelasticity, Strength and Fracture for Ideal Reversible Polymer Networks German A. Parada and Xuanhe Zhao; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Ideal Reversible Polymer Networks have well-controlled network structures similar to ideal covalent networks but exhibit transient properties due to the presence of reversible crosslinks. We have developed a theory to describe the mechanical properties of these ideal reversible polymer networks under small shear deformation, and have predicted that the networks behave as a single Maxwell element of a spring and a dashpot in series, with the instantaneous shear modulus and relaxation time determined by the concentration of elastically-active chains and the dynamics of reversible crosslinks, respectively. Due to the use of short polymer chains, we expected no contributions from polymer chain entanglements or chain relaxation, as the Rouse relaxation time is much shorter than the reversible crosslinks’ characteristic time. The theory also provided general methods to (i) independently control the instantaneous shear modulus and relaxation time of the networks, and to (ii) quantitatively measure kinetic parameters of the reversible crosslinks, including reaction rates and activation energies, from macroscopic viscoelastic measurements. The theory and methods were validated experimentally using a 4-Arm polyethylene glycol hydrogel system. We have also employed the theoretical and experimental system developed to characterize the fracture modalities and mechanical properties under large uniaxial deformation at varying loading rates.

Revisiting the Strong Stretching Theory for pH-Responsive Polyelectrolyte Brushes Harnoor S. Sachar and Siddhartha Das; Mechanical Engineering, University of Maryland, College Park, College Park, Maryland, United States.

Polyelectrolyte brushes grafted to a substrate attain a brush like configuration above a critical grafting density. Polyelectrolyte brushes (PE) have gained significant attention in the last few decades due to a myriad of applications like flow control, biosensing, current rectification, ion manipulation etc. We present a self-consistent model of backbone charged pH-responsive PE brushes using the Strong Stretching Theory (SST). State of the art theoretical model (we refer to it as model 1) for the pH-responsive PE brushes assume a Boltzmann distribution for hydrogen ions both inside and outside the PE layer. In other words, the effect of the coupling between the brush ionization and local hydrogen ion concentration is not considered. This is a major limitation of the existing theory that has been hitherto overlooked. We propose a new theory that self-consistently calculates the correct hydrogen ion distribution by accounting for the appropriate coupling between the brush ionization and local hydrogen ion concentration. We obtain a pair of coupled ordinary differential equations in electrostatic potential and hydrogen ion concentration that are solved numerically to obtain (a) the monomer profile, (b) the distribution of chain ends, (c) the electrostatic potential, and (d) the hydrogen ion distribution. Our results indicate a larger deviation from the results of model 1 at lower bulk salt concentrations and higher pH values. The self-consistent theory always predicts a smaller brush height in comparison to that predicted by model 1. In addition, we observe an enhanced biasness of the monomer concentration profile towards the base than the brush tip.

Multiscale Modeling of Polymer at Solid and Soft Interfaces

Paola Carbone; The University of Manchester, Manchester, United Kingdom.

The prediction of the adsorption and dynamics properties of polymers at solid and soft interfaces is an important technological and biological problem. Solid interfaces are indeed present in all polymer composites (where particles are dispersed into a polymeric matrix with the aim of improving its mechanical and rheological properties) but also relevant for many applications such as for coating. Polymers absorb also at liquid interfaces in many industrial processes, such as liquid/liquid extractions, solvent displacement methods, or emulsifications, and also when used for biological applications, such as drug nanocarriers, biocompatibilizers, or protective coatings.

In this talk we will present a set of multiscale approaches developed over the years to predict the adsorption properties of polymers at solid surfaces (specifically carbon black) and soft interfaces (liquid/liquid and lipid membrane).

The aim of the multiscale technique is to balance the need to retain important chemical details allowing long simulations and ultimately to identify design rules to predict the polymer-interface adhesion properties as a function of surface roughness and polymer composition.

M. Zaki, P. Carbone, Langmuir 2017,33, 13284

11:00 AM BM03.01.10
Effect of Structural and Material Heterogeneity on Failure in Fibrous Materials

Sai S. Deogekar, Mohammad R. Islam and Catalin Piciu; Rensselaer Polytechnic Institute, Troy, New York, United States.

Fiber networks occur abundantly at all length scales in the biological and non-living worlds. Various applications of such fibrous materials require them to maintain their structural integrity. Hence, an accurate understanding of the factors affecting failure at system subscale is important. Since these materials are structurally stochastic, heterogeneity plays a major role in determining the dominant failure mechanism and affects strength and toughness of the material. In addition, most of these networks naturally occur as composites (e.g. in various types of tissue). Previously, we studied the effect of heterogeneity in the strength of the inter-fiber bonds on the overall network strength. In this work we study the effect of structural heterogeneity and network architecture, on the macroscopic strength and strain-at-failure. We observe that increasing the structural heterogeneity increases the strain-at-failure while the strength remains unaffected. Thus, we propose to use structural disorder of these materials to control their toughness. Further, we investigate the behavior of network-based composites formed by embedding spherical inclusions, rigid or deformable, in a fibrous network. A small fraction of inclusions strongly affects the network deformation and alters drastically the microscopic deformation and failure mechanisms. This is due primarily to the confinement effect of inclusions on the deformation of the network.

11:15 AM BM03.01.11
Simulating Polymers with Reactive MD—Cross-Linking, Stress/Strain, Degradation, Solvation

Adri van Duin\(^1\), Nick Austin\(^1\) and Fedor Goumans\(^1\); Software for Chemistry & Materials (SCM), Amsterdam, Netherlands; \(^1\)Department of Mechanical & Nuclear Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States.

Reactive molecular dynamics techniques such as ReaxFF afford insight at the atomic level for complex chemical processes as well as for material properties which involve chemical bond breaking and formation. We will discuss recent developments in the ADF-ReaxFF software in the context of polymers.

A new bond boost method enables the atomistic simulation of cross-linking processes such as epoxy resin hardening at reasonable time scales. The cross-linking densities from these simulations are in good agreement with experiments.

Stress/strain properties and yield points can be obtained with ReaxFF while straining the system, including the underlying atomistic processes. Similarly, degradation rates and mechanisms under extreme conditions can be simulated with ReaxFF.

Finally we will discuss how the information from reactive MD runs, in particular the dynamic charges, may be used to refine our COSMO-RS thermodynamic predictions for solubilities and related properties.

11:30 AM *BM03.01.12
Diffusioosmotic and Thermoosmotic Transport in Nanochannels Grafted with End-Charged Polyelectrolyte Brushes—Continuum Calculations and Molecular Dynamics Simulations

Siddhartha Das, Raja Mahheedhara, Parth Rakesh Desai, Haoyuan Jing and Harnoor S. Sachar; University of Maryland, College Park, Maryland, United States.

Liquid flows in nanochannels grafted with polyelectrolyte brushes have been invariably retarded owing to the significant drag force imparted by the PE brushes. In a recent study, we proposed a paradigm shift in this understanding – we showed that for nanochannels grafted with end-charged brushes (having a charge density of $\sigma$), the electroosmotic (EOS) transport got massively augmented as compared to the brush free nanochannels having a wall charge density of $\sigma$. We argued that the presence of the end-charged brushes localized the charge density of the induced electric double layer (EDL) and hence localized the EOS body force away from the nanochannel wall, thereby ensuring a massive manifestation of the EOS body force eventually enforcing a larger EOS transport. Here we report our first Molecular Dynamics (MD) simulations based verification of this phenomenon. Furthermore, we carry out continuum calculations for the diffusioosmotic (DOS) and thermoosmotic (TOS) transport in such end-charged PE-brush-grafted nanochannels in presence of an axial concentration and an axial temperature gradient respectively to establish that these transports too get enhanced due to the corresponding enhancement in the induced EOS transport. Furthermore, MD simulations are carried out to validate the continuum findings.

*SESSION BM03.02: Multiscale Modeling of Soft Materials and Interfaces II

Effect of Solvent on the Molecular Structure and Electrical Conductivity of DNA

Busra Demir\(^1\), Sumeyye Gokce\(^1\), Hashem M. Mohammad\(^2\), Sunil R. Patil\(^1\), Yuanhui Li\(^1\), Josh Hihath\(^1\), M. P. Anantram\(^2\) and Ersin Emre Oren\(^1\); \(^1\)Department of Biomedical Engineering, TOBB University of Economics and
DNA is a promising molecule for molecular electronics due to its unique electronic and self-assembly properties. Understanding the nature of electrical conductance of DNA is essential for rational design and engineering of these soft materials for use in molecular electronics. The structure of double-stranded DNA (dsDNA) is known to be sensitive to solvent conditions and thus its electrical conductivity. Here, we first used Molecular Dynamics (MD) simulations to determine both the transformation path and the stable molecular conformations of DNA (CCCGGGCCC and TTATATTTT) in various solvent (water-ethanol mixtures) conditions. The MD trajectories revealed that there is a specific ethanol concentration, below which the B form DNA is stable. Above this threshold value, which also depends on the sequence, we observed that A form DNA is the stable form. These observations also validated by the circular dichroism experiments for the same DNA sequences. The MD simulations also revealed that for extremely high ethanol concentrations the DNA helix is destabilized and collapsed. We then selected representative structures along the transformation path using structural clustering algorithms, and calculate the wave functions near the HOMO-LUMO gap using Density Functional Theory (DFT). Finally, we used Green’s functions based transport modelling to analyze conductivity of DNA. Our calculations reveal that the solvent conditions is an important factor that determines the device characteristics because it can significantly change the conformation and conductance of the DNA.

1:45 PM BM03.02.02
Determining the Binding Mechanisms of All 20 Natural Amino Acids to (hkl) Facets of Hydroxyapatite as a Function of pH
Sam Hoff, Juan Liu and Hendrik Heinz; University of Colorado Boulder, Boulder, Colorado, United States.

Mineralization of hydroxyapatite is a complex and highly controlled process involving interactions of biological and mineral components. Understanding the basic interactions between individual amino acids and hydroxyapatite at the (001) and (020) surfaces at pH 7 and 5 is a crucial step in understanding the mineralization process and potentially aiding in designing peptides to direct and control bone growth and biomimetic materials. In our study, a combination of steered and unrestrained molecular dynamics simulations using the CHARMM36 and Interface force field parameters are used to study the dynamic nature of hydroxyapatite as well as the binding conformations of N and C capped amino acids. The results indicate that charged amino acids have a distinctly higher affinity to the mineral surface than non-charged amino acids. Binding site preferences, conformations, and the effects of pH and surface facet on the affinities are reported, and significant differences for Arginine, Glutamic Acid, Aspartic Acid, and Lysine quantified. The trends provide valuable insight into the affinity and binding mechanism of the building blocks of larger biological structures such peptides and proteins onto hydroxyapatite surfaces. The results will be useful in designing peptides to target specific bone facets for growth or suppression as well as potentially offering the ability to target specific bone sites where infections exist.

2:00 PM BM03.02.03
Elucidation of the Induced Chirality of Dansylglycine by Its Interaction with Human Serum Albumin
Aquinaldo R. Souza 1, Izabelle Amorin Ferreira Boza 1, Valdecir F. Ximenes 1, Mauricio L. Yoguiun 1, Nelson Morgon 2 and Ignace Caracelli 1; 1Chemistry, Sao Paulo State University - UNESP, Bauru, Brazil; 2Chemistry, Campinas State University, Campinas, Brazil; 3Physics, Federal University at Sao Carlos, Sao Carlos, Brazil.

Human serum albumin (HSA) plays an important role in the transport of substances with pharmacological properties due to their high plasma concentration and specificity, placing it as the fundamental protein responsible for the pharmacokinetic implication of the drugs. The dansylglycine amino acid derivative (DG) is a fluorescent marker specific for the II site on the HSA. In addition, when binding to the protein, DG acquires chirality, a feature that can also be used to characterize the binding site of new compounds in albumin. This work aimed to elucidate the induction of chirality in the DG by its binding to the HSA. Experimental Electronic Circular Dichroism (ECD) spectra of DG (100 μM) in the absence or presence of HSA (30 μM) in 50 mM sodium phosphate buffer pH 7.0 were obtained in a Jasco J-815 spectropolarimeter at 25 °C. The spectra were obtained with a resolution of 1 nm and a scanning speed of 50 nm/min. The theoretical ECDs were simulated using the Density Functional Theory (DFT) approach with the hybrid functional B3LYP and CAM-B3LYP in the base set 6-311 + + G (2d, p) and the implicit Solvation Model based on Density (SMD) for the solvents ethanol, methanol, acetonitrile, water and tetrahydrofuran; the calculations were performed with the Gaussian09 program. The DG-HSA complex formation in buffer resulted in the appearance of a positive ECD spectrum centered at 346 nm. Considering that the ECD signal should arise from a chiral conformation of the DG acquired by binding in the protein, calculations were initially performed to obtain the stable conformations focusing on the inversion of configuration centered on the nitrogen atom: alpha-amino group. However, both configurations: R and S showed similar and positive ECD signals. Calculations of the potential energy surface (PES) of the DG were performed, focusing on the dihedral angles formed by the bonding of the -N(CH3)2 group of the naphthalene ring. The analysis of the various conformations obtained and their respective theoretical ECDs revealed that the 150° dihedral (ECD positive centered at 320 nm) presented excellent similarity with the experimental spectrum. On the other hand, the 80° dihedral showed a signal of the ECD spectrum opposite to that observed experimentally. In addition, we observed that the nitrogen atom of the -N(CH3)2 group presented the greatest contribution to the HOMO-LUMO transition that gives rise to the n-p* electronic transition involved in the generation of the ECD signal. The molecular docking analysis, using the GOLD 5.5 program, of the complexation between DG and HSA revealed a conformation with a dihedral similar (150°) to that obtained theoretically (DFT) and whose ECD is in agreement with the experimental result. In conclusion, through the study of the possible conformations for dansylglycine and the calculation of its theoretical ECD, it was possible to identify the origin of the ECD signal obtained by the complexation between DG and HSA.

2:15 PM BM03.02.04
Understanding Malaria Pathogenesis Through Coarse-Grained Computational Modeling
Sulin Zhang, Yao Zhang, Leann Tilley, Ju Li and Subra Suresh; 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Northwestern University, Evanston, Illinois, United States; 4The University of Melbourne, Melbourne, Victoria, Australia; 5Nanyang Technological University, Singapore, Singapore.

A normal human red blood cell (RBC) is characterized by two distinct features: high deformability and discocyte shape, which underlie its biological functions, demonstrated by the repeated transit of RBCs (diameter ~8 mm) through narrow capillaries and in 1-2 mm interendothelial slits in the spleen. These two distinct features of RBCs can be comprised genetically or in a variety of pathological conditions, leading to severe RBC diseases. Here we present a coarse-grained RBC membrane model integrating an one-agent-thick lipid bilayer model and a string-of-bead spectrin network model to simulate the change of deformability of the infected RBCs by the malaria parasites (plasmodium falciparum). In particular, we show how malaria parasites harness several RBC membrane principles simultaneously to render the RBC losing its deformability during asexual stage (disease-causing stage) and how the parasites alter the entropy of the spelin network to enable the RBC regain the deformability during the sexual stage (disease-transmission stage). Our simulation results suggest potential targets for the development of new antimalarial therapies.

Behavior of Polyethylene Glycol in Bulk and in Water as Studied by Multi-Scale Simulations

Gokhan Kacar; Genetics and Bioengineering, Trakya University, Edirne, Turkey.

Polyethylene glycol (PEG) is an important polymer that has an enormous area of application especially in biomedical field such as drug carrier agent, hydrogel, and tissue engineering material. A thorough understanding of the molecular structure of PEG at different environments is important to devise better routes to develop materials with desired purposes. Although, PEG has been a widely studied material its molecular structure in bulk and in aqueous environment has been poorly investigated. In this work, we strive to perform multi-scale molecular simulations in order to study the physical behavior and molecular structure of PEG in dry environment and interacting with water. We initially perform Dissipative Particle Dynamics (DPD) simulations to create the structure of PEG. Later, we perform reverse-mapping of the atomistic coordinates to perform atomistic molecular dynamics simulations in order to observe the chain configurations and material properties of PEG.

DPD simulations result in successful prediction of the negative volume excess of PEG upon mixing with water. Here, we use a recent extension of the DPD method, where the non-bonded potential of DPD is modified by a Morse potential term to mimic the intermolecular attraction. The parameterization of the Morse potential is done by a mapping of the mixing energies of different hydrogen bonding bead pairs and from radial distribution functions (RDF) for the energy and equilibrium hydrogen bond length terms, respectively. DPD simulations yield preferential attraction of some chemical groups to water as quantified by radial distribution functions. Moreover, PEG chain structure is observed to deviate significantly from a random coil structure as a result of the end-to-end distances and radius of gyration values. Moreover, DPD simulations reveal that water plays a significant role in increasing the flexibility of PEG chains. The helical structures of PEG chains are quantified and a significant helicity of PEG chains is noted with a higher fraction in wet environment.

The reverse-mapped coordinates of DPD simulations of bulk PEG structure are used in atomistic simulations to compute the material properties such as coefficient of thermal expansion, elastic modulus and Poisson’s ratio. The computed values mainly reveal that PEG becomes more elastic and less compressible upon addition of water. In addition, the experimental coefficient of thermal expansion is in line with the experimental values of water. Moreover, PEG chain structure is observed to deviate significantly from a random coil structure as a result of the end-to-end distances and radius of gyration values. Moreover, DPD simulations reveal that water plays a significant role in increasing the flexibility of PEG chains. The helical structures of PEG chains are quantified and a significant helicity of PEG chains is noted with a higher fraction in wet environment.

Machine Learning Methods to Design Next-Generation Gas Separation Membranes

Sanat K. Kumar; Columbia University, New York, New York, United States.

Machine Learning (ML) has been used for quite some time in analyzing large sets of data in a variety of disciplines in order to make predictions on new data. Although gas permeability data has been collected for polymer membranes for decades, only hundreds of data points are available in the literature out of the thousands of possibilities. In order to address the intractability of running thousands of different gas permeability studies, we use ML to build a model on existing data and predict which untested polymers are most likely to achieve superior gas separation performance.

Using Gel Actuated Smart Capsules for Particle Capture

Svetoslav Nikolov1, Alberto Fernandez-Nieves2 and Alexander Alexeev1; Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Physics, Georgia Institute of Technology, Atlanta, Georgia, United States.

Advancements in nanotechnology over the last two decades have allowed researchers to tackle a number of critical biomedical problems on the microscale, like site-specific drug delivery and micro-sensing. Microgels which can selectively capture nanoparticles at a given rate are particularly interesting as they are critical for the development of enzymatic bioreactors which are used in many in vivo micro-sensing applications. These devices could also be used for origin of life studies, where the ability to bring in particles at predefined rates can be used to carry out complex chemical reactions. In our work, using dissipative particle dynamics, we leverage the large volume changes of microgels to design a novel microdevice which can be used for nanoparticle capture. Our device is made up of a perforated rigid spherical shell that is embedded with a spherical microgel. Upon application of an external stimulus the gel swells, expanding through the perforated holes and making contact with the external nanoparticle rich solution. After removal of the external stimulus the microgel collapses into the shell interior, bringing along with it nanoparticles from the external solution. The area around each of the perforations is functionalized with a polymer brush which is used to achieve chemical gating, when the gel is in the collapsed state. We study how the capture rate depends on the swelling period and gel-nanoparticle interactions and we quantify the optimal swelling period which maximizes capture rates.

Confinement Effect of Nanoscale Biological Systems
Arvand M. Navabi and Nima Rahbar; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

The nanoscale molecular dynamics of the confined organic matrix in the biological material, nacre and its contribution to the exceptional toughness of this biomaterial has been studied. While under stress, the dynamics of the nanoscale structure of nacre have significant influence on the energy dissipation of the system and ultimately on the fracture toughness of the material. For better understanding these mechanisms, a solution of the c-domain consensus of the protein, Lustrin A, was confined between two ceramic layers of aragonite by employing molecular dynamics computations. Then the aragonite walls were subjected to shear, and the polymeric system responded by unfolding. This study reports increase in the energy dissipated through unfolding mechanisms of the protein system as the confinement size decreases. The dominant energy dissipation method in larger systems transition from unfolding to polymeric interactions and entanglements.

BM03.03.02

2D Powerless Capillary Microchannel Device for Efficient Capture of Circulating Tumor Cells
Yiting Zheng; Northeastern University, Boston, Massachusetts, United States.

Introduction: Liquid biopsy of circulating tumor cells (CTCs) can help find cancer at an early stage and determine whether treatment is effective or not. Secondary microscale features such as micropillars, microstripes and silicon nanowires, microfluidic channels can be functionally modified with cell selective species such as anti-epithelial cell adhesion molecules (Anti-EpCAM) and aptamers to enhance efficacy of CTC capture. However, the surface bound cell adhesion molecules have less flexibility to interact with receptors over-expressed on the surfaces of flowing cancer cells, leading to low capture efficiency. Meanwhile, the microfluidic devices require sophisticated processes to make and accessory such as pumps and tubing to work, which makes microfluidic device not an ideal tool for point-of-care diagnosis and prognosis.

This work describes a method for efficient capture of CTCs from human whole blood using a two dimensional (2D) capillary microfluidic device modified with long chain polymers that have cell-adhesive terminals. The height of microchannel is designed to approximate the diameter of single cells. Given its low cost, easy operation, repeated usage, and zero-power consumption, this device would find its use at points-of-care.

Results: CEM cells solution with PBS was studied in channels with different heights and capture efficiency is inversely proportional to channel height to the second power which agrees well with the modeling of cell sedimentation in channels. Cells are injected in channels by flow and the flow filling time in our device is not long enough to let all the cell settling. The 30 μm channel can achieve 95% capture efficiency. This optimal parameter was applied in cell capture in human blood. Figure 2 shows fluorescence images of CEM cells captured on folic acid modified channel. The capture efficiency of the channel has calculated to be 88.3 ± 14.6% for CEM cells in spiked blood with concentration of 5×10^6 cell/ml and 90±4% with concentration of 5,000 cell/mL. CEM cells are found firmly attached on the substrate. The capture efficiency agrees well with the assumed theory of cell rolling and cell sedimentation.

Conclusions: Circulating tumor cells (CTCs) spiked in human blood can be captured efficiently with 2D capillary microchannel device which was modified with polymer brush. Blood or cell suspension can be sucked in the channel by capillary force. The kinetics of channel filling for buffer solution containing cells agreed with theoretical models. The capture efficiency decreases with increased height of channel due to cell rolling and tethering in microchannels. In high channel, less cells are captured by cell rolling and tethering while more cells have ligand receptor reaction by cell settling. The polymer brush modified glass can be easily disassembled for further analysis of captured cells. This non-sealing and pump-less device does not have blocking or leaking problems as normal fluidic device.

BM03.03.03

The Effect of Microenvironment Stiffness on Oligodendrocyte Differentiation
Alexander Evenchik; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Understanding how a cell senses its environment is key to understanding how it acts and responds to different stressors, such as changes of pH, temperature, or concentration of small molecules. Oligodendrocytes are a type of glial cell found in the central nervous system; they are responsible for wrapping axons in myelin, a sheath that allows neurons to effectively transmit electrical impulses in the brain. Oligodendrocyte dysfunction leads to debilitating diseases such as multiple sclerosis. Polystyrene petri dishes, which are currently used to culture and study these cells, are poor models of the brain (e.g. the Young’s Modulus of polystyrene is approximately 10^8 times larger than that of the brain). It is hypothesized that this lack of biomimicry may contribute to inaccurate or incomplete understandings of oligodendrocyte and myelin biology, as well as hinder the pace of therapeutic development. The goal of our research is to help bridge that gap of understanding by studying the effect of various mechanical cues on the differentiation and myelination of human oligodendrocyte cells. Here we fabricate and characterize various substrates that recapitulate key physical properties of the oligodendrocyte microenvironment. Human oligodendrocytes are derived from induced pluripotent stem cells and cultured in these engineered microenvironments. The extent of differentiation and myelination is assessed via immunocytochemistry and fluorescence microscopy. These results may help lead to more effective methods to culture human oligodendrocytes, and shed light on how these cells may respond to pathological mechanical changes in the in vivo environment.

BM03.03.04

Continuous Elasto-Capillary Clustering of Tilted Nano-Pillars
Sang Moon Kim, Junsoo Kim, Seongmin Kang, Daeshik Kang, Segeun Jang, Seung Eon Moon, Hong Nam Kim and Hyunsik Yoon; 1Harvard University, Massachusetts, Massachusetts, United States; 2Chungnam Univ., Daejeon, Korea (the Republic of); 3Ajou Univ., Seoul, Korea (the Republic of); 4Seoul National University of Science and Technology, Seoul, Korea (the Republic of); 5Incheon National University, Incheon, Korea (the Republic of); 6Analytics and Telecommunications Research Institute, Daedeo, Korea (the Republic of); 7Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Complex structures of clustered micro/nano pillars from the elastocapillarity have been extensively studied for the application of mechanical electrical micro system devices and sensors systems. Herein, we investigate the unidirectional clustering property of initially slanted nanopillars. The deionized water droplet was dispensed onto the slanted nanopillars fabricated by using of Faraday cages and was dried off to generate cluster formation of the patterns. We observed non-continuous clustering of the low-tilted (initial tilting angle of −0° and −15°) nanohairs and unidirectional clustering of the nanopillar arrays with tilting angles of −30° and −45°. We proposed theoretical model to analyze the unidirectional cluster formation and set a criterion for a unidirectionality. Furthermore, we predicted the shape of clustered pillars for the case of the non-continuous clustered pillars based on our proposed model.

BM03.03.05

Investigation of Self-Assembly of Polypeptoids in Aqueous Solution—From Atomistic to Coarse-Grained Simulations
Pu Du and Revati Kumar; Louisiana State University, Baton Rouge, Louisiana, United States.

Polypeptoids or poly N-substituted glycines are a type of peptide mimetic polymers that are highly tunable, and hence an ideal model system to study self-assembly as a function of chemical groups in aqueous soft matter systems. In this study, atomistic simulations were performed on sequence-defined ionic peptoid block copolymers consisting of a hydrophobic and a hydrophilic segment (with one singly charged and the remaining uncharged polar groups) in
aquous solution. These studies revealed that the placement of the charged moiety on the polymer chain affected the micellar structure and shape. However, the computational expense limits simulation times and system sizes to a hundred nanoseconds and tens of nanometers, respectively, necessitating the development of coarse-grained models to study more complex polypeptoids with multiple types of hydrophilic side groups. A coarse-grained (CG) model for N, N-dimethylacetamide (DMA), which represents the polypeptoid backbone, is developed as a step towards developing a CG model of the complex polypeptoid systems. The DMA CG model is parameterized to reproduce the structural properties of DMA liquid as well as a dilute aqueous solution of DMA using a reference all atom model, namely the OPLS-AA force-field. The intermolecular forces are represented by the Stillinger-Weber potential, which consists of both two- and three-body terms that are very short-ranged. The model is validated on thermodynamic properties of liquid and aqueous DMA, as well as the vapor-liquid interface of liquid DMA and the structure of a concentrated aqueous solution of DMA in water. Without long-ranged interactions and the absence of interaction sites on hydrogen atoms, the CG DMA model is an order of magnitude faster than the higher resolution all-atom (AA) model.

BM03.03.06
Artificial Exosomes—Tailored Conjugation of Fusogen to Lipid/Polymer Hybrid Vesicles for Enhanced Drug Delivery
Jeong Yi Kang1 and Jin Woong Kim1,2; 1Bionano Technology, Hanyang University, Ansan, Korea (the Republic of); 2Chemical and Molecular Engineering, Hanyang University, Ansan, Korea (the Republic of).

The development of a wide spectrum of nanoscale technologies is beginning to change the scientific landscape in terms of disease treatment. The small size, customized surface, improved solubility, and multi-functionality of nanoparticles will continue to open many doors and create new biomedical applications. Indeed, the novel properties of nanoparticles, including carbon nanotubes, nanofibers, self-assembling polymeric constructs, liposome, and nano-sized silicon chips, offer the ability to interact with complex cellular functions in new ways. Among them, recent technology pays attention to exosomes, nano-sized vesicles that are released from various types of cells into the extracellular space, since they are able to provide a practical means of intercellular communication and transmission of macromolecules between cells. Moreover, they are able to act as useful vectors for drugs because they are composed of cell membranes, rather than synthetic polymers, and as such are better tolerated by the host. In this study, we propose an exosome-analogous drug delivery system which is established by using lipid/polymer hybrid vesicles with fusogenic peptide conjugates. The lipid/polymer hybrid vesicles are fabricated by co-assembly of phosphatidylcholine and poly(ethylene oxide)-b-poly(caprolactone)-b-poly(ethylene oxide). Thanks to large size and slow dynamics of amphiphilic triblock copolymers at the bilayer membrane, the hybrid vesicles show long-circulating time and high drug loading efficiency. Fusogenic peptide, penetratin, induces vesicular interaction with cell membrane, thus enhancing cellular uptake. To evaluate the cell affinity of fusogenic exosomes, the interaction force between an exosome and a cell is characterized via microscale thermophoresis. Finally, in vitro cell-penetration study demonstrates the practical applicability of our artificial exosome as a remarkable cell delivery nanocarrier.

BM03.03.07
Systematic Control of Flory-Huggins Interaction Parameter of Block Copolymer Forming Sub-10 nm Perpendicular Lamellar Pattern
Seung Won Song, Voon Hyung Hur and Yoon Sik Jun; Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Directed self-assembly of block copolymer is one of the most promising candidates for sub-10 nm scale lithography due to its cost effectiveness and nanometer scale pattern resolution. However, further improvements of line edge fluctuation and pattern resolution to sub-10 nm region of Poly(styrene-b-methyl methacrylate) (PS-b-PMMA) block copolymer remain as critical challenges. To improve pattern resolution, higher Flory-Huggins parameter ($\chi$) is required. However, too high of $\chi$ value induces horizontal lamellar pattern which cannot be used in devices. Therefore, deliberate design of block copolymer with medium $\chi$ value is required so that $\chi$ value is high enough to achieve sub-10 nm pattern formation and small enough to prevent horizontal lamellar pattern. Here, we suggest a newly designed block copolymer that can form sub-10 nm sub-10 nm lamellar pattern which is aligned by graphoepitaxy template. The block copolymer was synthesized by reversible addition-fragmentation chain-transfer polymerization copolymerized with a fluorine containing monomer, which is hydrophobic. The modified block copolymer showed controlled $\chi$ value as the fraction of hydrophobic monomer changed. Block copolymer pattern with sub-10 nm feature size could be achieved due to a three times higher $\chi$ value than the conventional PS-b-PMMA. Even though the newly synthesized block copolymer has a high $\chi$ value, the polymer could form perpendicular lamellar morphology by short thermal annealing.

BM03.03.08
Theranostic Pluronic Nanoparticles for Glioblastoma Treatment—Synergic Application of Chemotherapy and Photodynamic Therapy
Diego S. Pellosi1, Leonardo B. de Paula2, Maryanne T. de Melo2, Danielle R. Mota2, Giovanni A. Lima2 and Antonio C. Tedesco2; 1Chemistry, Federal University of São Paulo, Diadema, Brazil; 2Chemistry, University of São Paulo, Ribeirão Preto, Brazil.

Despite advances in the fight against cancer, glioblastoma multiform treatment continues inefficient due inhibitory activity of brain-blood barrier (BBB) that causes low efficacy and selectivity for temozolomide (TMZ) chemotherapy. In order to improve therapeutic outcomes aiming side effects reductions the present work followed two strategies: (i) the use of theranostic pluronic nanoparticles and (ii) application of photodynamic therapy (PDT) as adjuvant treatment. Pluronic P85/F127 nanoparticles were engineered as multifunctional theranostic/targeted nanoparticles (m-NP) through the chemical functionalization of its surface with biotin (target moiety) and rhodamine-B (fluorescent probe). The chemical-modified pluronic copolymers self-assemble into m-NP that present the advantage of overcoming BBB and encapsulate multiple cargo for the application of multiple tumor treatment modalities with an optimized drug ratio. In addition, PDT characteristics such as its high selectivity upon light-driven activation and the non-development of cross-resistance mechanisms make it a valuable option as adjuvant for TMZ chemotherapy. m-NPs formulations were firstly optimized to obtain best drug loading conditions (for both TMZ and PDT agent) and formulation long-term stability. In these studies we demonstrated that lyophilization of formulation was the best methodology to obtain a longer shelf life for the proposed system. Due theranostic characteristics of m-NP and PDT agent, in vitro confocal microscopy studies on U87-MG, T98-G, U343 glioblastoma cells and NIH-3T3 fibroblast as control were evaluate in order to understand m-NPs role in uptake and intracellular drugs distribution. Uptake experiments demonstrated that the proposed nanoparticle possess higher affinity toward cancer cell lines in detriment of the non-tumor cell line NIH-3T3. In addition, confocal images revealed a broad intracellular distribution for both m-NP and encapsulated drugs at cells cytoplasm, but not in the nucleus. Blank formulations were not cytotoxic while formulations containing TMZ or PDT agent separately presented a reduced effect in cell viability. Nevertheless, PDT/TMZ concomitant treatment presented high efficiency due their synergic action even at low and safe drug concentrations. As demonstrated by flow cytometry experiments, this synergism is due to the different mechanisms of action of each proposed drug in the cell cycle arrest and their selective/controlled delivery at the intracellular level. In conclusion, these results point m-NP are a promising nanostructure to carry different drugs and selectively release encapsulated cargo in cancer cells.

BM03.03.09
Computational Design of Dendron-Grafted Soft Materials-Based Nanoparticles
Akash Banerjee and Meeakashi Dutt; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.
Many drug delivery strategies demand the need for the adsorption and transport of charged, therapeutic biomolecules. These requirements can be met by nanoparticles (NPs) encompassing multiple molecular species that endow electrostatically-induced interfacial binding of specific biomolecules. We are interested in understanding the role of the architecture and composition of the molecular species on the morphological characteristics of the NPs. We study multicomponent NPs encompassing phospholipids and lipids bearing hyper-branched polyelectrolytes (namely, polyamidoamine (PAMAM) dendrons) via the Molecular Dynamics simulation technique. The bonded and non-bonded interactions between the particles is captured by the Martini force field. We examine the impact of interfacial area, dendron generation and relative concentration on the NP morphology. Our studies can potentially guide the design of multicomponent amphiphile-based nanoparticles for applications in medicine and environmental sustainability.

BM03.03.10
A Multiscale Approach to Study Molecular and Interfacial Characteristics of Colloids Xiang Yu and Meenakshi Dutt; Chemical and Biochemical Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

The functions of colloidal particles are dictated by interfacial properties which are determined by an interplay of physical interactions and processes spanning multiple spatiotemporal scales. The multiscale characteristics of colloidal particles can be resolved by the hybrid Molecular Dynamics- Lattice Boltzmann technique. This technique enables the resolution of the particle dynamics along with long range electrostatic and hydrodynamic interactions. We have examined the feasibility of an implementation of the hybrid technique to capture the molecular and interfacial characteristics of colloidal particles, such as vesicles. For simplicity, we have examined two types of vesicles whose molecular components have different sustained interactions with the solvent. One of the vesicles encompassed phospholipids and the other vesicle was composed of phospholipids and polyethylene glycol (PEG)-grafted lipids. The molecular and interfacial characteristics of the phospholipid vesicle and PEGylated, or hairy, vesicles are found to be in good agreement with earlier experimental, computational and theoretical findings. These results demonstrate that the multiscale hybrid technique is suitable for capturing the molecular and interfacial characteristics of colloidal particles. The results of our investigations demonstrate the potential of the hybrid technique in capturing multiscale interfacial characteristics of intra- and inter-colloid interactions in suspensions under different flow conditions, and their relation to molecular properties.

BM03.03.11

The Rhesus D (RhD) as well as A and B antigens are important immunogenic epitopes on red blood cells (RBCs) which need type matching during blood transfusion, and mismatching will lead to fatal reactions. Producing antigen negative RBCs, which are universal for transfusion, are necessary especially in emergency situation. While the conversion of A and B antigens into immunity negative cells have been achieved, however, the transition of D-positive cells to D-negative is still problematic. To solve the problems in transfusion, we developed a rational approach to shield the antigens on the Rh D-positive RBCs for D-negative blood production by using the surface-anchored and cross-linked nanogel framework. A thin and uniform nanogel layer, which is consisted of algicin acid and tyramine, was constructed on individual RBCs catalyzed by surface-anchored enzyme. The physical and biological properties of modified RBCs were similar with native RBCs. More importantly, the D antigens on surface of engineered RBCs were shielded completely by the framework layer, preventing the recognition of immune system both in vitro and in vivo. The distribution of “the D-negative blood” in tissues including heart, liver, spleen and kidney was similar with native ones in blood circulation. The resulting stealthy effects achieve complete sheltering of blood group D antigens on RBCs membrane, providing a potential methodology of cell surface engineering for universal blood transfusion regardless of blood types.

BM03.03.12
Lipid Morphology in Solid Lipid Nanoparticles Demi L. Pink1, Jayne Lawrence2  and Christian D. Lorenz3; 1King’s College London, London, United Kingdom; 2University of Manchester, Manchester, United Kingdom.

Solid lipid nanoparticles (SLN) first came to attention in 1991 as they were considered promising particles to investigate with regards to potential applications in drug delivery. These nano-colloidal particles are typically spherical and are comprised of a solid lipid core. This solid lipid core is not perfectly crystalline and so it contains defects which can be used to trap and solubilise lipophilic and hydrophobic drug molecules. Surfactant molecules are then utilised to further stabilise the lipid core. The exact properties of SLN depend on their composition and preparation, with lipid and surfactant selection being key in the development of non-toxic, stable nanoparticles. Since SLN properties can be modified by using different lipids and surfactants, SLN can be optimised for encapsulation and delivery of specific molecules. Whilst the potential for their use in healthcare has been the dominant area of research, there are also options for the application of SLN in a range of other industries, including cosmetics and agriculture.

A significant challenge concerning the use of SLN in drug formulations is the tendency of the solid lipids to converge towards a perfectly crystalline lattice when stored over time. This is due to the increased thermodynamic stability this confers. However, the transition towards a perfect crystalline lattice removes the defects in which the drug molecules are stored. This can result in the expulsion of the drug molecules during storage or rapid expulsion of the drug upon administration, potentially rendering them ineffective. The triglycerides used in SLN can exist in 4 distinct conformations and by examining the conformations of triglyceride in the SLN we aim to better understand the mechanisms behind drug encapsulation and drug expulsion.

This work uses molecular dynamic simulations to investigate the overall morphology of the SLN as well as looking closely at the conformation of lipids in solid lipid nanoparticles. Through this we have gained a detailed understanding of the role of lipids within SLN. By modifying the temperature of our simulations we were able to compare the conformations of lipids in both liquid and solid lipid aggregate as well as in the SLN. This simulation worked is paired with experimental work in order to develop a multi-scale and experimentally relevant understanding of solid lipid nanoparticles.

Design Guidelines of Optoelectronics Devices Based Triboelectrification Abdelsalam Ahmed1, Islam M. Hassan1, Ali Radhi1 and Jean Zu2; 1University of Toronto, Toronto, Ontario, Canada; 2Stevens Institute of Technology, Hoboken, New Jersey, United States.

Triboelectric nanogenerators (TENGs) are a new power generation technology with high affinity to ambient energy harvesting from the surrounding media. This has driven many researchers towards coupling such technologies into numerous electronic devices, introducing the field of tribophototronics. An analytical framework has been established for practical evaluation of the multiphysics aspects of tribophototronics devices. The work shows the numerous operating modes of TENGs and their impact on the electrical performance from structural, material and ecological perspectives. Scalability, electrical regulatory systems, supply channel control features are presented. The attributed properties of lightweight, low-cost, high material selections will be shown to have a significant impact on tribophototronics devices.

BM03.03.15
MD Simulation and Cellular Potts Model for Neuronal Differentiation on Polymeric Nanoscaffolds

Over the past decades, a great progress has been made in the field of tissue engineering and regenerative medicine especially in the differentiation and proliferation of stem cells into desired lineages in vitro on 2D scaffolds. The purpose of this study is to simulate and design of nanofibrous Polycaprolactone-Graphene (PCL-G) scaffolds, for neuronal differentiation and investigate subcellular and cellular level interactions of cells with the scaffold using MD simulation and Cellular Potts Model (CPM). We explore the interactions between PCL, graphene, and F-actin towards better understanding of neuron cell mobility on PCL-G scaffold. F-actin protein is associated with controlling the mobility and influences the dendritic spines for neuronal cell. Here we use VMD (Visual Molecular Dynamics) for modeling and visualization, NAMD for Molecular Dynamics (MD) computations and Cellular Potts Model (CPM) for cell-cell, cell-scaffold interaction study. After 10ns of MD simulation data and trajectory visualized in VMD, we observed that PCL chains shows affinity towards graphene sheet and try to fit into the graphene sheet. Further, we plan to repeat MD simulations using different sizes of graphene sheet allowing further to investigate the interactions between F-actin and PCL-G. For the CPM simulation, the interactions such as cell-cell, cell-scaffold adhesion and cellular motility contribute to the system’s energy given by a function known as Hamiltonian which manages the lattice rearrangement using the stochastic Monte Carlo’s probabilistic model by minimizing the system’s total energy. In our simulation we set 1 pixel to correspond to 4µm and the time, which is given by Monte Carlo Steps (MCS), to corresponds to 2s of the real experimental time. One simulation is set for as long as 12h to also consider that cells can undergo duplication or apoptotic events. We found out that the cells are moving and changing their shapes, their mobility and growth. More investigations are underway on altering cell-cell and cell-scaffold adhesion energy that can be the key on achieving an alignment of cells on the scaffold and migration afterwards.

BM03.03.16
Superoiled DNA with Mismatched Base Pair—Probing the Role of Structural Defect on Plectoneme Pinning by Molecular Dynamics Simulation

Mismatched base pairs in DNA can result in mutations. Mismatched base pairs are recognized by the MutS enzyme, which initiates the mismatch repair pathway. MutS recognizes mismatches through a process that involves introducing a sharp bend and flipping out a DNA base at the mismatch site. Single-molecule magnetic tweezers-based DNA supercoiling measurements found that plectonemes nucleate, and are localized, at a mismatch. Localizing the mismatch at the end of the plectoneme loop may facilitate mismatch detection by MutS due to the stabilization of the bent and base-flipped out conformation. The plectoneme end loop containing a mismatch can kink more easily, which reduces the energy of the end loop. However, these experiments were limited to positively supercoiled DNA at salt concentrations of 0.5 M NaCl and higher. Theoretical studies predict that for positively supercoiled DNA under physiologically relevant conditions, i.e., at salt concentrations of 0.2 M NaCl, plectoneme nucleation at the mismatch becomes probabilistic rather than deterministic. Here, we use molecular dynamics simulations to study the effect of a mismatched base pair on DNA supercoiling. We employ the oxDNA model to simulate DNA under torsional stress. The oxDNA model is a coarse-grained model in which each nucleotide is treated as a rigid ellipsoid with three interaction sites. The oxDNA model has been shown to accurately reproduce the response of an intact DNA to both negative and positive torsional stress. To model a mismatched base-pair we eliminate hydrogen bonding between the two nucleotides. Using this modification of the oxDNA model, we first determine the effect of a mismatched base-pair on the bending free energy of a short 15 base-pair DNA and compare the results to atomistic simulations. We find that the bending free energy of a short DNA containing a G-T mismatch is close to the bending free energy predicted by atomistic simulations. We then perform simulations of a 600 base-pair DNA with 0, 2, 4 and 6 consecutive mismatched base pairs. We find that for positively supercoiled DNA at high salt, i.e., 1 M NaCl, the plectoneme always localizes at the mismatch, in good agreement with experiments. Extending this framework to study the case of both positively and negatively supercoiled DNA at 0.2 M NaCl, we find that plectoneme localization at the mismatch indeed becomes probabilistic. We will present the relation between the probability of plectoneme localization and the number of mismatches in addition to an analysis of the shape of the loop of the plectoneme for different mismatches.

BM03.03.17
Bioinspired Multifunctional Surfaces for Versatile Optical Applications

The capability of fabricating multifunctional polymeric structures has great advantages to satisfy the increasing demand for flexible and wearable energy conversion devices, electronics and displays. In this work, we have demonstrated a novel fabrication method for structuring bioinspired multifunctional moth-eye TiO2/PDMS pad by using conventional lithography, imprinting, and thin sacrificial layer. It is noted that the embedded TiO2 nanoparticles acted
as an effective UV-protector. As a result, the high energy UVB-light is perfectly blocked by the embedded TiO₂ nanoparticles and the UVA-light is partially penetrated though the surface. Also, the moth-eye inspired nanostructures on the surface show high transparency in a visible wavelength range as well as self-cleaning effect due to nano-roughness on the surface. Further, we successfully fabricated hierarchical structured surface, where we want, by controlling partially-cured region using the multifunctional polymeric pad with partial blocking property of UVA ray.

BM03.03.18
Temperature-Independent Zero-Birefringence Polymer and its Compensation Mechanism for Temperature Dependence of Birefringence Kenji Wada¹, Akihiro Tagaya¹ and Yasuhiro Koike¹,²; ¹Graduate School of Science and Technology, Keio University, Yokohama, Japan; ²Keio Photonics Research Institute, Kawasaki, Japan.

Optical polymers are used as key materials for liquid-crystal displays (LCDs) due to their ease of processing, high transparency, and low-cost. Most of polymers exhibit orientational birefringence because polymer chains tend to become oriented by processing. In LCDs, the birefringence in polarizer protecting films cause light leakage. This light leakage decreases the contrast ratio and increases color shift depending on the viewing angle. Therefore, orientational birefringence of the polymers is ideal to be zero for LCDs. Orientational birefringence is always zero no matter how much a polymer is orientated by processing if intrinsic birefringence Δn₀ which is a specific value of each polymer is zero. Our group proposed and synthesized zero-birefringence polymers (ZBPs) which exhibited almost no Δn₀ [1]. Recently, we found temperature dependence of Δn₀ of the polymers [2]. It becomes a problem for in-car LCDs which generally require no birefringence in the large temperature range from around −40 to 85°C, compared with the range for interior LCDs. However, the mechanism of temperature dependence of Δn₀ has not been clarified. For synthesis of temperature-independent zero-birefringence polymers (TIZBPs) which exhibited almost no Δn₀ in the wide temperature range, the detail clarification of the behaviors of polymer molecules is necessary. The purpose of this article is clarification of the mechanism of temperature dependence of Δn₀ for design and synthesis of TIZBP by the method of birefringence compensation.

Poly(methyl methacrylate (MMA)/benzyl methacrylate (BzMA)) and poly(MMA/phenyl methacrylate (PhMA)) in various composition ratios were synthesized. Then, uniaxial heat-drawn films of these copolymers were made. Absorbance spectrums in IR region of the copolymer films were measured from 25 to 65°C by FT-IR. The spectrums were analyzed to clarify the behavior of main chains and side chains of the polymer in the heating process. Also, Δn₀ of the films from 15 to 65°C were evaluated by automatic birefringence measurement system to calculate temperature dependence of Δn₀ of them. From the above, it suggested that increasing or decreasing of Δn₀ in heating process is related to the orientation behavior of a polymer molecule. Based on the results, the composition of monomers in a system of MMA, BzMA, and PhMA was calculated to compensate birefringence and its temperature dependence for designing a TIZBP. Moreover, poly(MMA/BzMA/PhMA) (39:38:23 wt.%) was synthesized and exhibited almost no intrinsic birefringence Δn₀ from 15 to 65°C.

All Atom and Coarse-Grained Molecular Dynamics Simulations of an Interdigitated Multilamellar Phase of a Mixed Surfactant System Arpita Srivastava and Ananya Deb Nath; Indian Institute of Technology, Jodhpur, Jodhpur, India.

A coarse-grained (CG) molecular dynamics simulation of a cationic surfactant behenyl trimethyl ammonium chloride (BTMAC), co-surfactant (SA) in presence of water is performed at a ratio of 2:1 at 283 K from an all atom (AA) simulation [1]. The CG bonded potentials are derived by the Boltzmann inversion of their respective AA distributions [2]. A good match in the CG and AA bonded distributions validate the bonded potentials derived for the model. The MARTINI non-bonded potentials [3] are used to obtain the interdigitated (L₃) multi-lamellar phase as in the AA simulation. The single chain conformational entropies of both BTMAC and SA reveal that around 4% of the molecules have relatively higher entropy than the rest of the molecules, indicating coexistence of both ordered and disordered phases in the bilayer. The molecules with higher entropy and low order parameter are confined to the upper monolayer of a bilayer without flipping to the other layer as evident from their cosine angles with respect to the bilayer normal. The coexistence between ordered and disordered phases is attributed to the oscillation between the bent and stretched conformers of disordered BTMAC molecules with an energy barrier of 5 kJ/mol whereas all ordered molecules stay stretched throughout the simulations. Our calculations show the suitability of MARTINI force field in predicting the phase behavior of interdigitated bilayer and reveal that the coexistence of two phases arise due to the strong interdigitation between two layers dictated by the chain length of shorter SA which do not allow longer BTMAC to flip-flop and traverse. Thus our analysis will be helpful in understanding the multi-component membrane dynamics with various applications in the field of biological membranes, pharmaceuticals or industry.

Mechanical Basis for the Morphology of Fibrillar Aggregates Thomas C. Michaels and I. Mahadevan; Harvard University, Cambridge, Massachusetts, United States.

The self-assembly of fibrillar aggregates is of importance in biology, biomedicine and materials science, yet understanding the range of possible shapes for these structures remains an open question. We propose a coarse-grained approach that averages over specific molecular details to suggest that the spatial complexity of self-assembling fibrillar structures is due to the competing effects of (the bending and twisting) elasticity of individual filaments and the adhesive interactions between them. We show that a theoretical framework accounting for this allows us to capture a number of diverse fibril morphologies observed in natural and synthetic systems, ranging from Filopodia to multi-walled carbon nanotubes, and leads to a phase diagram of possible fibril shapes. We also show how the extreme sensitivity of these morphologies can lead to spatially chaotic structures. Together, these results suggest a common mechanical basis for the microscale fibril morphology as a function of the nanoscale mechanical properties.

Crack Formation in Wet Colloidal Pillars

Justin Beroz, Alvin Tan, Ken Kamrin and A. John Hart; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

A basic and well-established assumption about solid materials is that they do not crack when subject to uniform compression. Intuitively, it is paradoxical to imagine how a solid material could conspire to split apart while being uniformly compressed together. In this talk, we present an example of such a case, wherein cracks appear during the drying of vertically freestanding water-saturated colloidal pillars we constructed using a direct-write technique. Paradoxically, the cracks form at the free end, far from the substrate, where the particle network is unconstrained in contracting its volume as it bears compression by a uniform capillary pressure acting at its outer surface. We first detail our experiment results and then provide a theoretical explanation for the cracks based on a dominant balance of wetting energy terms, from which follows a simple relationship between the colloidal particle size and pillar dimensions that captures the presence or absence of cracks. Our theoretical result agrees with experiment, and demonstrates that having an evaporating liquid exert the pressure is fundamentally different compared to the typical balance of surface energy and bulk stress considered for dry materials.

sasPDF—Pair Distribution Function (PDF) Analysis of Nanoparticle Assemblies

Chia-Hao Liu1, Ellie Buenning1, Eric M. Janke2, Igor Coropceanu2, Dmitri V. Talapin2, Sanat K. Kumar1 and Simon J. Billinge1,4; 1Chemical Engineering, Columbia University, New York, New York, United States; 2Chemistry, The University of Chicago, Chicago, Illinois, United States; 3Applied Physics and Applied Mathematics, Columbia University, New York, New York, United States; 4Condensed Matter Physics and Materials Science, Brookhaven National Laboratory, Upton, New York, United States.

Nanoparticle superlattice assemblies (NPSA) are being developed for their special properties in applications such as flat-panel displays. The properties of the resulting assemblies can be further engineered by controlling interparticle spacings and arrangements. It is therefore crucial to be able to determine the structure of these NPSAs as quantitatively and accurately as possible. In general, they may have only short-range (on the nanoparticle length-scale) structural correlations (though some assemblies are highly crystalline), making the quantitative determination of NPSA structure difficult. TEM is popular for visualizing mesoscopic structures. Small angle scattering (SAS) may also be applied. However, conventional analysis of SAS data as so far resulted only in semi-quantitative analyses and TEM images can be subjected to sample bias and are not suitable for sample-average measurements. Atomic pair distribution function (PDF) analysis of x-ray and neutron powder diffraction data is a powerful approach for studying non-periodic structural signals, for example from nanoparticles themselves. It yields local structural information from nanomaterials with high precision and quantitative accuracy. Here we describe how we have extended the PDF analysis to the SAS regime, where we can apply similar quantitative modelling methods that are proving powerful at the atomic scale, but to the extraction of structural information about superlattice assemblies. In this presentation, we will present PDF analysis in SAS regime (sasPDF) and we will also present applications of sasPDF techniques to systems with different levels of ordering, from highly crystalline assemblies to isotropic, amorphous polymer coated silica nanoparticles that have promise in gas separation membranes.

Synthesis of Metal and Polymer Nanoparticles for Hybrid Nanoassembling and Functional Properties

Nikunjkumar Visaveliya; The City College of New York, New York, New York, United States.

Nanoscale metal and polymer particles have captured broad attention and allowed enormous technological progress in various fields from biomedical and photonics to catalysis and sensing. In this work, surface-active polymer nanoparticles as well as polymer-polymer and polymer-metal nanoassembly particles are synthesized, and different parameters such as their size, morphologies and assembling strength have been studied. Nanoassembly particles are attractive because of the coupled properties with a large surface to volume ratio. A key challenge is to produce the core shell polymer nanoparticles via single-step processes. To address this concern, here, microfluidics approach and precise interfacial reaction strategies is highly promising, and hence different types of surface layered polymer nanoparticle systems were obtained in one-step processes. An inner core material is hydrophobic whereas a hydrophilic surface layer (in-situ formed during the polymerization process) swells in the aqueous environment. On other side, polymer-metal nanoassembly particles as well as metal catalyzed metal deposited four layered nanoassembly particles of tuned size and compositions were produced. It is shown that these particles can be used as nano-sensor particles for surface-enhanced Raman spectroscopy.

Toward Self-Healable Multifunctional Coatings Containing Catechol in Hybrid Polysilsesquioxane

Sohyeon Park, Sungwon Jung and Jinkee Hong; Chemical and Biomolecular Engineering, Yonsei University, Seoul, Korea (the Republic of).

The polysilsesquioxane (PSQ) is an organic/inorganic hybrid material and has excellent biocompatibility and mechanical properties. Thus, PSQ is regarded as a promising candidate for coating materials for various medical devices. From a medical device point, the ideal coating should have the ability to exert excellent biocompatibility, durability, antimicrobial effect and drug delivery capabilities. However, most of the developed coatings for medical devices were limited in exhibiting this simultaneous ability. Here, we fabricated catechol-functionalized PSQ hybrid coatings with various functions. First, well-defined PSQ matrices were synthesized by sol-gel reaction using hydrophilic precursors, and catechol groups were functionalized in carboxymethyl cellulose (CMC). Subsequently, the catechol-functionalized PSQ hybrid coatings were prepared by excellent compatibility of organic primers in PSQ to catechol-functionalized CMC. Synthesized PSQs were highly durable and exhibit superhydrophilic properties that contribute to the antimicrobial effect, through their morphological changes. On the other hand, the catechol residues of the coating were initiated and promoted by rapid and strong hydrogen bonding between them when cracks were formed in the coating, and their strong wet adhesive properties also contribute to the regeneration of the coating by generating other noncovalent interactions. We have attempted to introduce a drug delivery function into this self-healable antimicrobial coating. We have also applied this coating to a variety of medical devices and verified its versatility.

BM03.03.25

Diffusion Modeling for the Prediction of Bacterial Patterning on Vascularized Polymers

Kayla Marquis, Benjamin Chasse and Caitlin Howell; University of Maine, Orono, Maine, United States.

The creation of rationally designed and spatio-temporally controlled surfaces for cell culture is of great interest in the pursuit of the next generation of advanced biointerfaces. Here, we explore the use of COMSOL Multiphysics modeling to calculate the mass transport of antibiotic compounds through a bio-inspired vascularized polymer system, and use this model to predict the growth pattern of a bacterial biofilm on the surface of the polymer. The vascular system geometry, antibiotic concentration, and diffusion coefficients define the model, and are used in conjunction with known bacterial growth parameters such as minimum inhibitory concentration and critical time to determine the final arrangement of the biofilm on the surface. The theoretical models are then compared to an experimental validation. This approach may prove useful in applications such as compact methods for separation of bacterial multi-cultures based on antibiotic resistance or the creation of multiple spatially isolated colonies from a single culture sample for high-throughput diffusion studies.
BM03.03.26
Prediction of Surface Wettability of Fresh and Aged Graphite Surfaces from First-Principles Density Functional Theory Simulations Chun Yu Lu, Chia Yun Lai, Mariam S. Mansouri, Tuza Olukan, Harry Apostolierois, Ibrahim Almansouri and Matteo Chiesa; Khalifa University, Abu Dhabi, United Arab Emirates.

Elucidating the surface wettability of graphite has increased attracting much attention owing to its applications in several engineering fields, including the CMOS industry, energy storage technology and steel casting. However, despite the abundant information in literature, the underlying mechanism for the temporal surface property variations is still not fully elucidated yet, particularly the role played by water vapor. Prediction of the intrinsic surface wettability of graphite from first-principles density functional theory simulations offers an opportunity to clarify the overall evolution. In this study, by combining density functional theory (DFT)-predicted water contact angles and DFT-predicted AFM force-distance curves with experimental temporal observations, we provide conclusive evidence to demonstrate that water adsorption itself causes the graphite surface to be more hydrophobic. This finding helps to explain the variations of surface properties between fresh and aged graphite surfaces in ambient air. Moreover, in this study, we propose a methodology to predict the surface wettability at the nanoscale by linking the adhesive energy at the solid/liquid interface and cohesive energy at the liquid/liquid interface with the DFT AFM-predicted force of adhesion through the Young–Dupre equation.

BM03.03.27
Investigation on Micromechanical Behavior of Living Cell with FEM Simulation Guanlin Tang1, Massimiliano Galluzzi2, Yu-Lin Shen3 and Florian J. Stadler1; 1Shenzhen University, Shenzhen, China; 2The University of New Mexico, Albuquerque, New Mexico, United States.

Atomic force microscopy (AFM) indentation is a powerful technique to characterize micromechanical properties of soft materials including living cells, such as detecting alterations of single cell rigidity correlated to pathophysiological conditions. However, the mechanical data obtained from deep indentation measurements can be problematic to interpret due to heterogeneity of a cell, nonlinearity of indentation contact, and constitutive relations of hyperelastic soft material. In this work, living MDA-MB-231 cells were indented by spherical probes, and the morphological and mechanical data obtained were adopted to build an accurate finite element model (FEM) for a parametric study. Living cells can be considered as complex multi-layered systems comprising membrane, cytoskeleton layers (actin, tubulin, intermediate filaments), nucleus, and internal organelles. Initially, a 2D-axisymmetric numerical model was constructed with the main purpose of understanding the effect of geometrical and mechanical properties of constitutive parts such as cell body, nucleus, and lamellipodium. Then, a 3D finite element model was constructed to simulate indentation events with an asymmetric misalignment geometry. Deformation field from FEM simulations were directly compared with atomic force spectroscopy to resolve the mechanical convolution of heterogeneous parts and quantify Young’s modulus and geometry of nuclei. The results showed that nuclei of adherent MDA-MB-231 in standard conditions are 3-4 times stiffer than the surrounding cell body. 3D simulations demonstrated the nucleus shifting laterally during asymmetric indentation, underlining how a stiffer nucleus can prevent deformability (and therefore damage) caused by external force stimuli.

BM03.03.28
Preliminary Multiscale Studies of the Montmorillonite, Amylose, Fatty Acids and Water for Polymer-Clay Nanocomposite Modeling Felipe A. Azevedo Rios Silva1, 2, Elaine R. Maia1, Maria José A. Sales1, Latifa Chebil2 and Mohamed Ghoul2; 1Instituto de Química, Universidade de Brasília, Brasília, Brazil; 2Ecole Nationale Supérieure d’Agronomie et des Industries Alimentaires, Université de Lorraine, Vandœuvre lès Nancy, France; 3Escola de Exatas, Arquitetura e Meio Ambiente, Universidade Católica de Brasília, Brasília, Brazil.

More than ever, biodegradable polymers attract much attention in polymer science. Although, some biopolymers, such as starch, presents disadvantages such as poor processability. In order to circumvent those disadvantages, researchers mix those polymers with compounds such as clays. This work presents the final part of a theoretical study of a Polymer-Clay Nanocomposite (PCN) composed by: starch, Pequi vegetable oil and montmorillonite (MMT), a phyllosilicate. In the present study, amilose oligomers, oleic, palmitic and stearic acids in the proportion found in the vegetable oil, montmorillonite and water, acting as solvent involved in the experimental medium, were studied, as an simplified model, in order to simulate in multiscale their structural and behavioral correlations. The calculations were carried out by Molecular Mechanics, Dynamics (MM/MD) and Dissipative Particle Dynamics (DPD) methods at 363 K and variable dynamic times, using Materials Studio™ software. In the dynamic trajectories, the organic molecules organized near the MMT, strongly interacting with it. The MD simulations were used as a basis to calculate the interaction parameters for the DPD model, which showed similar characteristics. The organic material concentrated near the MMT surfaces, what correlated with the MD results, implying in the validity of the model. The new knowledge acquired about those molecular systems, works as a starting point to build more complex models and, if the theoretical work converge with the experimental findings, will encourage further studies in the design of PCNs with biopolymers.

Enhanced Icephobic Surface Using Porous Silica Particles Mi-jin Kim1, Beom Jin Yoon1, Jin Hwan Kim1, Byungsu Lee2, Daechul Kim2 and Younseok Kim1; 1Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of); 2Kangnam Jevisco Co., LTD., Gunpo, Korea (the Republic of).

Icephobicity is usually defined as the ability to delay and prevent ice nucleation and formation on surfaces induced either by pouring a supercooled water. Formation, adhesion, and accumulation of ice, snow, frost, glaze, rime, or their mixtures can cause severe problems for solar panels, wind turbines, aircrafts, heat pumps, power lines, telecommunication equipment, and submarines. Recently, extremely low ice adhesion was introduced by tailoring the cross-link density of different elastomeric coatings and by enabling interfacial slippage of surface. But, the icephobicity for such surfaces can be short-lived, as the oil may be displaced and removed by water droplets or frost, or during accreted ice removal. Here, we introduced oil-impregnated silica particles into modified hydrophobic polyurethane. The swelling capacity of oil was greatly increased by the lived, as the oil may be displaced and removed by water droplets or frost, or during accreted ice removal.

BM03.03.30
Solvent Induced Coil-to-Globule Conformation Change of a Single Poly(acrylic acid) Chain Yaxin An, Karteeek K. Bejagam and Sanket A. Deshmukh; Virginia Tech, Blacksburg, Virginia, United States.

Poly(acrylic acid) (PAA) is a polymer with carboxylic acid as pendant side-chains. The conformation of the PAA chains is sensitive to changes in the pH, salt concentration, and solvents, which makes it a good candidate as stimuli-responsive polymers. To investigate the effects of solvents on the structure of the PAA polymers at atomistic level, the all-atom (AA) PAA model was solvated in pure water, pure dimethylformamide (DMF), and mixtures of these two solvents of varying concentrations. Molecular dynamics (MD) simulations were performed to analyze the conformation of the PAA and the local solvent structure around the PAA chain. The radius of gyration (Rg) of the PAA chain in pure water and pure DMF were \( -10.0 \pm 1.0 \) Å and \( -14.0 \pm 1.0 \) Å at 300 K, representing its globule-like and coil-like state, respectively. The local structure of the solvents at the polymer-solvent interface was characterized by the radial distribution functions (RDFs) between polymer and solvents. The intra-molecular and inter-molecular hydrogen bonds of PAA, and the hydration free energy of the monomer of PAA in different solvents were calculated to probe the polymer-polymer interaction and the polymer-solvent interaction. This study of the AA model of PAA paves the way for developing coarse-grained PAA models.

Amino acids are important structural units of biomolecules and biomaterials such as peptides, proteins, and peptide amphiphiles (PAs). The focus of this study is on developing accurate transferable coarse-grained (CG) models of twenty standard amino acids. In CG models a group of a few or several atoms is represented by a bead, which can allow the modeling of processes like self-assembly of biomolecules and biomaterials. A 2:1 to 4:1 mapping scheme, where a CG bead is comprised of two to four heavy atoms and associated hydrogens, is employed to represent functional groups in amino acids. The amino acid backbone is comprised of two beads, while the side chains are comprised of one to five beads. The bonded parameters for the CG model are obtained from atomistic distributions of all-atom models of dipeptides. Nonbonded parameters are optimized using the particle swarm optimization (PSO) method to reproduce experimental properties (e.g. solvation free energy, surface tension, and density) of analogues of the side chains and backbone of the amino acids. In the near future, we plan to utilize these new CG models to construct PAs and simulate their self-assembly in the presence of explicit water models to elucidate the mechanism of their self-assembly. The knowledge gained from our study could then be used to aid the successful development of new PAs with potential applications in the field of drug delivery, regenerative medicine, tissue engineering, and stabilized photosynthetic complexes.

We report a new implicit-solvent simulation model for studying the self-assembly of surfactants, which the hydrophobic interactions were captured by calculating the relative changes of the solvent accessible surface area (SASA) of the hydrophobic domains. Using histogram-reweighting grand canonical Monte Carlo simulations, we demonstrated that this approach allowed us to match both the experimental critical micelle concentrations (cmc) and micellar aggregation numbers simultaneously with a single phenomenological surface tension \( \gamma_{\text{SASA}} \) for the poly(oxyethylene) monoalkyl ether (C\( _m \)E\( _n \)) surfactants in aqueous solutions. Very good transferability was observed that the same model can accurately predict the experimental cmc and aggregation numbers for the C\( _m \)E\( _n \) surfactants with alkyl lengths \( m \) between 6 and 12, and poly(oxyethylene) lengths \( n \) between 1 and 9. The implicit-solvent model with SASA calculations put forward in this study is general and may be applied to study the more complex amphiphilic systems such as the surfactants with branched alkyl chains, or the surfactant and hydrocarbon mixtures.

Proteins are one of the basic biopolymers that can be generally found in many different forms in the body of living organisms. A protein molecule is usually composed of one or several polypeptide chains that combine to form a certain folded three-dimensional protein structure. The protein structures are easily excited by external force causing vibration or structural transition. One efficient way to extract the natural frequency of a protein is normal mode analysis (NMA), which provides the frequency and normal modes of the most general motion of a protein structure. However, NMA can be difficult for large protein structures since it will be both compute and memory intensive to solve the eigenvector and eigenvalue of the Hessian matrix, which is a square matrix composed of second-order partial derivatives of the potential energy function of all the constituting atoms of the protein structure. Here, we developed a machine-learning algorithm that allows us to efficiently compute the vibrational spectra of a protein without solving the hessian matrix nor using any chemical force field. To build the algorithm, we wrote our own code to compute and build a database of the first 70 normal modes of over 100,000 protein structures available in the Protein Data Bank by using NMA in a consistent manner. We train our algorithm by randomly pick 80,000 proteins out of the database (80%) and explore the correlation between their natural frequency and the other structural features of the protein (size and secondary structure content) that are easier to be measured with a convolutional neural network. We test the performance of the machine-learning model by predicting the natural frequency of the rest 20,000 protein structures (20% of the database) by giving their structural features. We find the predictions given by our algorithm can largely explain the natural frequency of these protein structures, especially for their low-frequency region (<20 cm\(^{-1}\)). The correlation coefficient between the predicted frequency and the frequency given by NMA is over 0.9, demonstrating the reliability of this machine learning algorithm.

This method will be useful to obtain the natural frequencies of protein structures without knowing their detailed atomic geometry, which may be helpful for the analysis of a frequency spectrum and the quick recognition of the unknown chemical molecules. Besides frequency prediction, we conclude the presentation with the demonstration of a new musical instrument, the EigenProt, that creates complex sounds based on the vibrations of more than 100,000 protein structures.
Molecular dynamics (MD) simulations provide key insights into the microscopic behavior of materials and, as a predictive tool, allow theory-driven design of functional materials. However, because of the large temporal and spatial scales involved in thermodynamic and kinetic phenomena in materials, atomistic simulations are often computationally infeasible. Coarse graining methods are widely used to tackle the challenge of expensive atomistic simulations. Current coarse graining methods require intensive manual tuning to determine both the coarse graining rules and the force field parametrization [1]. Inspired by recent works that achieve deep learning based accelerated calculation in Density Functional Theory [2], molecular kinetics [3] and free energy landscape calculations [4], we propose an alternative data-driven framework utilizing auto-encoders to map the atomistic trajectory into a latent space of coarse grained “super-atoms”. By training on data from atomistic molecular dynamics trajectories or electronic structure calculations, this approach adopts stochastic gradient optimization of the coarse-graining rules, the force field parametrization and the up-resolution rules. Thus, it can provide parameters for large scale coarse-grained calculations and also map the coarse-grained trajectory back to dynamic information with atomistic details. Through this approach, systematic coarse graining pipelines can be built for fast molecular dynamics simulations and high-throughput predictions of the thermodynamics and kinetics of materials.

A Hierarchal Approach to Understand Kevlar Using Quantum and Classical Molecular Dynamics Subodh C. Tiwari, Sungwook Hong, Paulo S. Branicio, Rajiv Kalia, Aichiro Nakano and Priya Vashishtha; Univ of Southern California, Los Angeles, California, United States. The outstanding strength-to-weight ratio of para-aramid fibers, such as Kevlar and Twaron, can be largely attributed to their high content of p-phenylene terephthalamides (PPTA) crystals. Here, we perform non-adiabatic shock loading on large PPTA crystal models along different low-index crystallographic directions using quantum molecular-dynamics simulations. Results reveal an anisotropic shock response displaying elastic, plastic, and phase transformation from crystalline to para-crystalline configuration. A reactive forcefield is developed and verified based on the shock data obtained using quantum molecular dynamics. Further, we performed reactive forcefield simulation to include the effect of chain end in PPTA. The simulation results provide an atomistic view on the shock absorbing mechanism during shock in para-aramid synthetic fibers.

Using Particle Swarm Optimization to Develop Lennard-Jones Parameters Between Hexagonal Boron Nitride and Water Preeya F. Achari, Kartee K. Bejagam and Sanket A. Deshmukh; Chemical Engineering, Virginia Tech, Blacksburg, Virginia, United States.

Hexagonal boron nitride (BN) has shown great potential in lubrication, electronic devices, sensors, and as an additive for cosmetic products due to its light weight, thermodynamic and chemical stability, great strength-to-weight ratio, and increased resistance to oxidation. Its used in microfluidic and nano-fluidic applications at the molecular level demands accurate force-field parameters to describe the interactions between BN and water molecules. In this study, particle swarm optimization (PSO) and machine learning (ML) were coupled with molecular dynamics (MD) simulations to accelerate the development of Lennard-Jones (LJ) parameters, which are used to describe the non-bonded interactions between a water droplet and a sheet of hexagonal BN. Three commonly used water models, namely, SPC, SPC/Fw, and SPC/E were employed to describe water, while the BN sheet was modelled using REBO potential. The LJ parameters were optimized to reproduce the nanoscopic contact angle of water on the BN sheet.

9:30 AM BM03.04.07
Coupling Lattice Boltzmann and Molecular Dynamics—A Versatile Tool for the Study of Soft-Matter Hydrodynamics Burkhard Duenweg1, 2; 1Max Planck Institute for Polymer Research, Mainz, Germany; 2Department of Chemical Engineering, Monash University, Melbourne, Victoria, Australia. The talk outlines the methodology of Lattice Boltzmann (LB) simulations for hydrodynamics, and its stochastic version to include thermal fluctuations. To study colloidal dispersions, polymer solutions, and similar systems, a particle system is run by Molecular Dynamics, and coupled to the LB background by a Stokes friction force and a Langevin force. The method can be shown to represent both statistical mechanics and hydrodynamics fully consistently. A particularly successful application was the solution of the problem of hydrodynamic screening in semifluid polymer solutions. If time permits, the talk will also outline new (and so far not yet fully successful) attempts to base stochastic LB rigorously and approximation-free on the underlying Boltzmann entropy that governs the statistical mechanics of the system.

State of Trapped Matter Inside Graphene Nanobubble Petr Zhilyaev, Evgeny Iakovlev and Iskander Akhatov; Skolkovo Institute of Science and Technology, Moscow, Russian Federation. Graphene nanobubbles are formed when material is trapped between graphene and atomically flat substrate. Van der Waals interaction between graphene and the substrate results in the high pressures up to 1 GPa inside the graphene nanobubble. Such extreme pressures and confinement could lead to phase transition in trapped material. Here we present multiscale model that describes both the state of matter inside the graphene nanobubble and its mechanical properties. Adhesion energies and their dependence on the thermodynamics parameters is calculated on atomistic level, energy is evaluated in continuum. We apply developed model to the graphene nanobubble on the graphite substrate with argon inside. Super critical state of argon is predicted at room temperature for graphene nanobubbles with radius in range from 100 to 500 nm. Gas phase of argon is emerged inside graphene nanobubbles with radius greater than 500 nm.
Interfacial Effects on Free Volume, Mobility and Glassiness

Jane Lipson, Ronald White and Jeffrey DeFelice; Dartmouth College, Hanover, New Hampshire, United States.

Finite homogeneous materials are contained by interfaces, whose influence on bulk properties is typically unremarkable. However, as the interfacial presence begins to dominate, for example in an ultrathin film or a sample loaded with nanoparticles, significant perturbations in behaviour may result. While it is evidently the material in very close proximity to an interface - e.g. within several nanometers - that is directly affected, the consequences can extend tens of nanometers into the sample. As a result, sample averaged properties might be significantly different from those of the bulk.

This talk will focus on links between changes in local mobility and free volume as interfaces are introduced, and how those changes translate into altering dynamic relaxation and the glass transition. We have recently shown that the Cooperative Free Volume (CFV) theory can resolve bulk dynamic relaxation data over a broad temperature and pressure range, including the span from Arrhenius to non-Arrhenius behaviour. Most recently, we have turned to studying thin films, and found intriguing connections between interfacial confinement and pressure. Application of CFV analysis to experimental dielectric relaxation data will be described, as well as prediction of trends.

The work discussed will also include simulation results using our simple Limited Mobility (LM) model. Here the focus will be on predicting interfacial effects caused by introducing additives into a bulk sample. The LM data reveal connections between the unfavourability of short-range polymer-additive interactions and sample-wide changes in glassiness and local mobility. The LM predictions show good agreement when tested both against experimental data and relative to results from more detailed simulation treatments.

From Small to Large—Multi-Scale Modeling of Biomolecular Structures in Implicit Solvent

Alexey Onufriev; Virginia Tech, Blacksburg, Virginia, United States.

Water is as important to biomolecular simulations as it is to biology. However, accurate treatment of solvation effects explicitly, by representing solvent as discrete particles, can be computationally expensive. A popular alternative that can speed-up practical simulations is based on representing solvent as a continuum: solvent effects on the biomolecule in question are accounted for implicitly, at various levels of approximation. Molecular simulations within this so-called implicit solvent can speed up conformational search dramatically. Here I will discuss the foundations of the methodology and some of its new multi-scale variants. I will also discuss applications across many length scales: from atomistic simulations of the folding of small proteins to studies aimed at understanding chromatin compaction and dynamics at the level of the entire cell nucleus.

Understanding the Thermomechanical Response of Polymer Nanocomposites via Predictive Coarse-Grained Modeling

Wenjie Xie; North Dakota State University, Fargo, North Dakota, United States.

Understanding and predicting the thermomechanical responses of polymer materials are challenging as their responses are greatly influenced by many factors, such as interfacial energy and filler volume fraction, giving rise to the presence of nanoscale interfaces. To overcome the spatiotemporal limitations of atomistic modeling, we have recently established an atomistically informed coarse-graining technique, called energy-renormalization approach, to achieve temperature transferability for coarse-grained (CG) modeling. Here, we employ our CG models to investigate how the nanoscale interface and free surface influence the mechanical and glass transition properties of polymer films and nanocomposites. Taking cellulose nanocrystal and poly(methyl methacrylate) (PMMA) nanocomposites as a relevant model system, we present a multi-scale framework built upon our CG approach and machine learning algorithms to allow the prediction of thermomechanical properties of nanocomposite as a function of interfacial energy and filler volume fractions. Our established multi-scale framework is validated by recent experiments and breaks new ground in predicting key structure-property relationships for polymer nanomaterials.

Nanostructure and Interfacial Characterisation Using Image Classification and Machine Learning

Baichuan Sun and Amanda S. Barnard; CSIRO, Parkville, Victoria, Australia.

Restricting materials informatics to the numerical parameters output from conventional materials modelling software restricts us to a subset of machine learning methods capable of uncovering structure/property relationships and driving materials discovery and design. Presented here is a simple way of converting materials structures in to unique image-based fingerprints suitable for image processing methods that does not require subjective pre-assessment of the data and selection of descriptors by the user. This combination of methods is shown to classify the morphologies of in a meaningful way, and predict the correlation with the functional properties in agreement with other machine learning methods that required user intervention. This image-based, rather than feature list-based, description of nanoparticle surfaces can be extended to more complex interfaces including macromolecules.

A Multiscale Model for Solute Diffusion in Hydrogels

Eneco Aspe1, Giovanni Offeddu3, Yin Chang4, Doreen Chan2, David Merida4 and Eric A. Appel1; 1Materials Science and Engineering, Stanford University, Stanford, California, United States; 2Chemistry, Stanford University, Stanford, California, United States; 3Biological Engineering, Massachusetts Institute of Technology, Boston, Massachusetts, United States; 4Engineering, University of Cambridge, Cambridge, United Kingdom; 5Electricity and Electronics, University of the Basque Country, UPV/EHU, Bilbao, Spain.

Currently, solute diffusion in hydrogels is modeled by at least one of three main theories (hydrodynamics, free volume and obstruction theory), proceeding from distinct diffusion mechanisms. However, a comprehensive predictive model is lacking, so that time and capital intensive trial-and-error procedures are used to test the viability of hydrogel applications. In this presentation, a model for the diffusivity of solutes in hydrogels that combines the three main theories will be introduced. The model is verified by a combination of (i) positron annihilation lifetime spectroscopy (PALS) to measure the sub-nanoscopic free volume, (ii) instrumental indentation to quantify mesh size, and (iii) fluorescence recovery after photobleaching (FRAP) to quantify the diffusivity of dextran solutes of different sizes in poly(ethylene glycol) hydrogels with various mesh sizes. The model presented here outperforms

Multiscale Modeling Framework with Application to the Facet Capsule Ligament and Podocytes Jacob Merson, Sai S. Doogekar, William R. Tobin, Catalin Picu and Mark S. Shephard; Rensselaer Polytechnic Institute, Troy, New York, United States.

A multiscale strategy is presented which is used to model various types of biological structures such as the cervical facet capsular ligament (FCL), and the podocyte; a cell responsible for filtration in the kidney. This strategy allows the micromechanical representation of the biological tissues as collagen networks, and the direct use of the detailed geometry obtained through various microscopy techniques.

In the FCL we start from the observation that the volume of the ligament is divided in a patchwork of sub-domains, each having a different direction of preferential fiber orientation. Such preferential orientation produces hydrostatic stress amplification and increased fluctuations. We construct a model based on the FCL geometry and perform a parametric study to determine the effect of the preferential orientation on the overall mechanical properties, and microscale fiber reorientation. This study is pertinent because the microscale fiber reorientation has been linked to FCL damage and pain. The multiscale method is also applied to study the deformation of podocytes due to capillary distention. This study is relevant for podocyte degeneration which is associated with degradation of renal function. We determine the threshold strain beyond which such degradation is expected.

Rheology and Relaxation of Entangled Polymers in Strongly Nonlinear Extensional Flows Thomas C. O'Connor1, Austin Hopkins1, Nicolas Alvarez2 and Mark O. Robbins1; 1Johns Hopkins Univ, Baltimore, Maryland, United States; 2Drexel University, Dept Chemical Engineering, Philadelphia, Pennsylvania, United States.

Nonlinear extensional flows are common in polymer processing but remain challenging theoretically because dramatic stretching of chains deforms the entanglement network far from equilibrium. Tube and slip-link models that describe flow of melts near equilibrium must be enriched to describe these states, but it is not clear what physics is missing. Here, we address this problem by performing coarse-grained simulations of extensional flows in entangled polymer melts for Rouse-Weissenberg numbers Wi=0.06-52 and Hencky strains ->6. Simulations reproduce experimental trends in extensional viscosity with time, rate and molecular weight. Studies of molecular structure reveal an elongation and thinning of the confining tube with increasing Wi. The rising stress is quantitatively consistent with the decreasing entropy of chains at the equilibrium entanglement length. Molecular weight dependent trends in viscosity are related to a crossover from the Newtonian limit to a high rate limit that scales differently with chain length. Stress relaxations from steady state reveal chains rapidly retract and recover their equilibrium tube diameter even when chain primitive paths are fully aligned and do not intersect. Contrary to some geometric models of entanglement, our results suggest the degree of chain confinement is independent of the orientation of the entanglement network. The results are used to test and constrain generalizations of tube and slip-link models to strongly nonlinear flows.

Integral Equation Coarse-Graining Simulation Approaches for the Mixtures of Polymer Melts—Composition-Dependent Effective Potentials Mohammad Hasan Dinpaech and Marina Guenza; University of Oregon, Eugene, Oregon, United States.

Mixtures of polymers with different compositions are of great importance for many technological and industrial applications because as the composition of polymers change, the mixture structure and dynamics can change significantly. Molecular simulations may be used to study polymer mixtures but their properties develop on such an extended range of time and length-scale that they cannot be investigated by atomistic simulations. In this regard, the integral equation coarse-graining (IECG) approach has been developed in which the polymers are either represented as soft spheres or multi coarse-graining (CG) sites, where each CG site consists of a large enough number of monomers to use Gaussian statistics to obtain the intramolecular correlations. The IECG method is based on the liquid state theory and solves the Ornstein-Zernike equation to obtain the intermolecular correlations, and consequently the effective CG potentials. Representing melts with a given degree of polymerization at various resolutions, we use the IECG theory and/or perform the IECG simulations to investigate the properties of the same polymer melt represented by mixtures of CG models at various resolutions. We show that the structural and thermodynamical properties, such as pressure and pair correlation functions, for such mixtures are consistent with pure CG liquids as well as the underlying atomistic simulations. We also address the compositional dependence of the effective IECG potential, along with its range for various types of mixtures.

Replica Exchange Enhanced Self Assembly of Ultrashort Peptides Srinivasan Mushnoori2, Vivek Balasubramanian1, Doaa Altarawy4, Benjamin Pritchard2, Shanthu Jha1 and Meenakshi Dutt5; 1Electrical and Computer Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Chemical and Biochemical Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 3Electrical and Computer Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 4Molecular Sciences Software Institute, Virginia Tech, Blacksburg, Virginia, United States.

Replica-Exchange (RE) is a class of simulation techniques used to enhance sampling and comprehensively explore phase space of simulations. Originally proposed using Monte Carlo methods, RE techniques have since found their way into Molecular Dynamics (MD) methods, particularly for addressing problems of large, complex biomolecular systems. RE simulations are generally used for exploring single proteins or peptides, but seldom to explore assembly. Assembly of biomolecules constitutes a class of physical processes which are especially susceptible to kinetic traps. RE provides enhanced sampling that aids the systems in overcoming these kinetic traps. In this study, we apply the REMD technique to the assembly of ultrashort peptides and explore the morphological diversity of the supramolecular structures.

Bridging Time Scales with Variationally Enhanced Sampling Omar Valsson; Max Planck Institute for Polymer Research, Mainz, Germany.

The usefulness of atomistic simulations is generally hampered by the presence of several metastable states separated by high barriers leading to kinetic bottlenecks. Transitions between metastable states thus occur on much longer time scales than one can simulate. Numerous enhanced sampling methods have been introduced to alleviate this time scale problem, including methods based on identifying a few crucial order parameters corresponding to the relevant slow degrees of freedom and enhancing their sampling through the introduction of an external biasing potential [1].

Here we will discuss Variationally Enhanced Sampling [2], a generally applicable enhanced sampling method where an external bias potential is constructed by minimizing a convex functional. We present numerous examples from physics, chemistry, and materials science which show the flexibility
Two SWNT(5,5)- and SWNT(10,10)-containing nanocomposite systems, as well as a control PAN, were constructed. Higher stresses were observed in both polyacrylonitrile–single-wall carbon nanotube (PAN-SWNT) nanocomposites, to a draw ratio of two, which mimics fiber-spinning and drawing processes. The most studied polymeric system because it strongly interacts with CNTs and is the most common source of high-performance carbon fibers. In order to exploit the anisotropies and structures of CNTs. Among various types of polymer-CNT nanocomposite fiber, polyacrylonitrile (PAN) has been among the most studied polymeric systems because it strongly interacts with CNTs and is the most common source of high-performance carbon fibers.

Bone displays structural hierarchy spanning from the molecular scale to the macroscale, beginning with well-organized arrays of collagen molecules and nanoscale hydroxyapatite which in turn form the fibrils followed by concentric lamella and the osteon and finally the macroscopic bone. The role of molecular interactions between the nanosized hydroxyapatite and collagen on the mechanics of collagen is evaluated using molecular dynamics simulations. In addition, detailed steered molecular dynamics studies on the mechanics of full length collagen of 300nm size, are conducted and the impact of inter-chain molecular interactions on the structure of collagen and mechanics on the collagen are mechanistically evaluated. The mechanical response obtained from molecular scale studies are incorporated into a 3D finite element model of fibril using a hierarchical multiscale modeling approach. Simulations using the finite element models of collagen fibril are conducted to study the elastic and inelastic response of the fibril. These simulations provide an insight into key mechanisms that influence the mechanics of fibril and indicate that the molecular scale interactions at collagen-mineral interfaces have a significant impact on the mechanics of the fibril. Further, we report the role of crosslink densities in collagen fibrils on the mechanics of the fibril. These studies are vital towards understanding ageing and diseases in bone.

**Hiking on the Energy Landscape—All-Atom Computational Understanding of the Universality of Long Timescale Phenomena and Rare Events in Non-Equilibrium Matter—Metal, Water and Protein Yong Zhang**

In the last few years, we have developed an all-atom metadynamics method, which allows intelligently sampling statistically rare events in complex materials, and a Relaxation-Excitation Mode Analysis (REMA) theoretical framework, which links the computationally sampled statistics of the energy landscape to experimentally measurable two-point correlation functions. This synergistically integrated experimental and computational approach opened the way for qualitatively examining a range of non-equilibrium matter and the associated complex processes that occur over a very long timescale, such as the viscous flow of supercooled liquids and glasses, nucleation and crystal growth, the folding of polypeptide chains into structured proteins, the self-assembly of micro-units into functional objects, and aging and degradation of materials. In this talk, first I will show the intriguing energy landscape characteristics of three apparently-different systems: glass-forming metallic liquids, water, and protein; then, I will describe our quantitative investigations of how confinement blocks the transition pathways on the energy landscape of proteins and thus prevents their thermal unfolding/denaturation.

**Structural Evolution in Polymer Nanocomposite Fibers—A Molecular Dynamics Simulation Approach**

Sojeong Hoo1, Jeong-Eun Lee1, Seunggeol Lee2 and Han Gi Chae1; 1UNIST, Ulsan, Korea (the Republic of), 2Pusan National University, Busan, Korea (the Republic of).

Carbon nanotube (CNT)-based polymer nanocomposites have often been processed into fibers because fibrous shapes are one of the best methods of fully exploiting the anisotropies and structures of CNTs. Among various types of polymer-CNT nanocomposite fiber, polyacrylonitrile (PAN) has been among the most studied polymeric system because it strongly interacts with CNTs and is the most common source of high-performance carbon fibers. In order to understand the structural evolution and related mechanical properties under extensional flow, molecular dynamics (MD) simulations were performed on polycrylonitrile–single-wall carbon nanotube (PAN-SWNT) nanocomposites, to a draw ratio of two, which mimics fiber-spinning and drawing processes. Two SWNT(5,5) and SWNT(10,10)-containing nanocomposite systems, as well as a control PAN, were constructed. Higher stresses were observed in both nanocomposite systems. In addition, higher Young’s (4.76 GPa) and bulk (4.09 GPa) moduli were observed when the smaller-diameter SWNT(5,5) was used, compared to those of PAN-SWNT(10,10) (4.41 GPa and 3.96 GPa, respectively), suggesting that SWNT(5,5) resists stress better. Furthermore, we also observed the formation of void structures at both ends of the SWNTs, especially for the large-diameter SWNT(10,10); these voids became larger in the drawing direction with increasing draw ratio and may adversely affect the mechanical properties of the nanocomposite fibers.
Uptake in Microspheres from Crystalline Nanocellulose—Modelling Diffusion and Kinetics Junqi Wu and Mark P. Andrews; Department of Chemistry, McGill University, Montreal, Quebec, Canada.

Crystalline nanocellulose (CNC) is a crystalline rod-like particle, derived from sustainable forests and biomass. CNC has emerged as a leading "platform" material with potential for broad spectrum applications in technology, including microarrays for intelligent drug delivery and microreactors. In the present work, CNC nanorods are kinetically assembled into microspheres by spray drying. The transport properties of these micro-object are investigated by measuring methylene blue dye uptake. Methylene blue dye adsorption kinetics are predicted using both pseudo-first, pseudo-second kinetics and film-pore diffusion models. The film-pore diffusion model equations were solved numerically by the method of lines, and the initial estimates of external-film transport coefficients were obtained using single resistance models. Dye uptake Isotherms were investigated for large range of initial concentrations (from 5mg/L to 100mg/L) and isotherm type (Langmuir, Freundlich, and Temkin). The thermodynamics of dye adsorption were evaluated based on the kinetic data at different temperatures. The Gibbs free energy was estimated using both chemisorption kinetic models and diffusion kinetic models. Knowledge of CNC dye adsorption mechanisms and uptake is important to extract microstructural information of CNC microspheres. This can be used to further understand how small molecules can be delivered in and out of the micro-particles, and therefore to provide insight into how to control small molecule delivery using CNC micro-vehicles.

Bridging Scales of Diverse and Complex Crystal Structures from Atoms to Colloids Julia Dshemuchadse1, Michael Engel1,4, Pablo F. Damasceno2,5, Carolyn L. Phillips1, Matthew Spellings1 and Sharon C. Glotzer1,2,3; 1Department of Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States; 2Applied Physics Department, University of Michigan, Ann Arbor, Michigan, United States; 3Department of Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States; 4Department of Chemical and Biological Engineering, Friedrich-Alexander-University Erlangen-Nuremberg, Erlangen, Germany; 5Department of Cellular and Molecular Pharmacology, University of California, San Francisco, California, United States; 6Argonne National Laboratory, Argonne, Illinois, United States.

Soft condensed matter research has led to the discovery of increasingly intricate crystal structures over the last 15 years: systems of dendrimer or block copolymer micelles, colloids, and polymer- or DNA-grafted nanoparticles are found to crystallize in structure types that are known from atomic compounds (e.g., [1–5]). Examples for these crystal structure types are Laves phases (e.g., Fe24-MgCu2, hP12-MgZn3), Frank-Kasper phases and quasicrystal approximants (e.g., cP8-CrSi, cP30- CrFe), or clathrates (e.g., cP54-KrSi4). Some of these building blocks can be tuned smoothly and span entire phase diagrams of structural behavior that can be likened to that of a multicomponent atomic system [6].

In this study, we simulate the self-assembly of one- and two-component systems of attractive particles that interact via short-ranged, isotropic pair potentials. Previous exploratory work had found these simple systems to be capable of forming highly complex structures, such as an icosahedral quasicrystal [7]. Here, we inspect large areas in such parameter spaces and find a variety of crystal structures with varying degrees of complexity, including structures with super-large unit cells. We systematically screen two phase spaces of one-component systems, and we explore the higher-dimensional design spaces of the two-component systems by incorporating machine-learning methods into our simulation scheme.

Although our model is short-ranged and fairly simple, we observe many geometric equivalents to atomic-scale structures. The continuous variation of the simulated interaction potentials results in a breadth of structures that spans the entire range of chemical interactions, from low-coordinated, covalent-like environments to highly-coordinated, metallic-like dense sphere packings. Our agnostic phase space exploration grants us a design flexibility beyond that of the periodic table and allows us to engineer new crystal structures to be synthesized in the future under exotic growth conditions or on the mesoscale.

8:30 AM BM03.06.03
Interface-Mediated Assembly of Nanoparticles into Anisotropic Structures Tsung-Yeh Tang1 and Gaurav Arya2; 1Materials Science and Engineering, University of California, San Diego, La Jolla, California, United States; 2Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina, United States.

A significant challenge in the bottom-up fabrication of nanomaterials is assembling spherical or near-spherical nanoparticles into anisotropic architectures. One promising strategy is to use the interfacial tension between two immiscible solvents to trap particles at the interface; however, this approach is typically limited to producing two-dimensional assemblies. Here we demonstrate through molecular dynamics simulations that the interfacial tension across two immiscible polymers combined with the grafting of nanoparticles with polymer chains can be used to assemble spherical nanoparticles into unique anisotropic clusters, such as dimers with a tunable tilt angle at the interface, and more complex three-dimensional architectures, such as chiral ribbons with tunable curvature. We show that this approach can also be used to tune the orientation, and subsequent assembly, of shaped nanoparticles at the interface. Our results suggest that such interfacial assembly of nanoparticles could be a promising approach for fabricating next-generation polymer nanocomposites, where precise spatial and orientational organization of nanoparticles is required for proper function.

8:45 AM BM03.06.04
Multiscale Modeling of Polymer-Colloid Interactions in Waterbased Coatings Alyssa Travitz1, Wenlin Zhang2 and Ronald G. Larson2; 1Macromolecular Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States; 2Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Formulations containing rheology-modifying polymers and nanometer-sized colloids have widespread use in pharmaceuticals, personal care products, and water-based coatings. A typical rheology-modifying polymer consists of a hydrophobic backbone that associates with the hydrophobic surface of the colloids. These hydrophobic interactions drive the polymer to form either a loop on a single colloid or a bridge between adjacent colloids. The continual breakage and formation of loops and bridges results in a transient network with relaxation times that span several orders of magnitude. Because it is computationally infeasible to capture the full range of relaxation times while maintaining atomistic resolution, our group has developed a highly efficient hybrid population balance-Brownian dynamics model (Pop-BD). The Pop-BD model reduces the system to pairwise colloidal interactions with attractive contributions from bridging and repulsive contributions from the layer of loops on the colloid’s surface. Currently, the Pop-BD model approximates the interactions between polymer-coated colloids as a steep, short-range repulsion. However, experimental data suggest that the layer
of polymer loops is often a brush with much longer-range interactions. In this work, we use molecular dynamics simulations to study pairwise interactions of polymer-coated colloids with experimentally relevant coverage fractions. We compare the polymer density profiles from these simulations with small angle neutron scattering data and analytical calculations. Our results are in good agreement with self-consistent field theory and show repulsive potentials with ranges several times longer than previously assumed. In future studies, these repulsive pair potentials will allow us to study equilibrium phase behavior as well as to inform current models that capture the dynamics of these transient networks to ultimately predict and design the rheology of such systems.

9:00 AM BM03.06.05
Inverse Design of Pressure-Induced Solid—Solid Transitions in Colloids Using the Alchemical Ensemble

Chris Yixiu Du1, 2, Greg v. Anders1, Julia Dshemuchadse1, Paul Dodd1 and Sharon C. Glotzer1; 1University of Michigan, Ann Arbor, Michigan, United States; 2School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

Recent developments in anisotropic particle synthesis have shown promise for using these particles as building blocks for functional materials. However, due to the large design spaces that are available to us, it can be challenging to find appropriate building blocks for target behaviors. Here, instead of mapping out the phase behavior for a range of particle shapes, we present a new, alternative computational statistical mechanical approach that couples together multiple systems within the “alchemical ensemble”—a generalized, statistical mechanical framework in which model attributes are allowed to fluctuate along with thermodynamic variables. The alchemical ensemble has application to a wide variety of design problems within statistical mechanics and this modeling and simulation approach bridges multiple scales by linking bulk properties to molecular simulations through design. Here, we demonstrate its use in the design of particle shapes for target materials properties, and present examples of candidate colloidal-and nano-particles designed within the alchemical ensemble specifically for structurally reconfigurable colloidal crystals.

9:15 AM BM03.06.06
Twisted Domains Get Edgy—Microrafts in Colloidal Membranes of Length-Asymmetric Rod Mixtures

Douglas M. Hall1, Joia Miller3, Johanna Robaszkiewski3, Prema Sharma1, Michael Hagan1, Zvonimir Dogic1, 2 and Gregory M. Grason1; 1Polymer Science and Engineering, Univ of Massachusetts-Amherst, Amherst, Massachusetts, United States; 2Physics, University of California, Santa Barbara, Santa Barbara, California, United States; 3Physics, Brandeis University, Waltham, Massachusetts, United States; 4Physics, Indian Institute of Science, Bangalore, India.

Osmotically-condensed colloidal membranes of rod-like, chiral filaments offer an experimental platform for directly probing intra-membrane microstructure formation processes that would be far more difficult, if not impossible, to observe at the nanometer scales of phospholipid membranes. In particular, membranes formed by two component mixtures of rods (either wild-type or mutant fd-virus particles) exhibit a remarkably rich set of intra-domain phase-separated morphologies, most notably the formation of raft domens whose lateral dimensions are self-limiting in equilibrium yet much larger than the range of rod-rod interactions. The prevailing theoretical model to explain this phenomenon focuses on the asymmetry in the chirality—a distinct preference for right- vs. left-handed intra-membrane twist for different species—as the stabilizing factor in raft formation. Notwithstanding its successes to capture the raft formation at a qualitative level, several recent experimental observations are not captured by this chirality-driven phase separation (CDPS) model. In particular, the degree of raft twist is shown to be a non-monotonic function of its radius, and there is a pronounced asymmetric behavior of rafts of tall vs. small rods, independent of their chirality. Small rods in background membrane of tall rods form finite size, twisted rafts. In contrast, tall rod domains in a background membrane of short rounds refuse to twist at their outer edge, and instead, become unstable to invaginated or annular morphologies that enclose stable, twisted small-rod rafts.

To understand these observations with develop a model to predict the microstructure and thermodynamic effects of the intra-rod domain edge. We show that geometrical constraints imposed by the twisting of (rigid) rods require splay of the mid-plane of the raft that has important consequences for the shape of the inter-domain edge. Our model predicts the existence of a thermodynamic coupling between domain edge curvature and rod-tilt through the dependence of membrane excluded volume to the 3D geometry of rod packing. We show that the thermodynamics of this the curvature/tilt coupling not only captures the asymmetric dependence of raft behavior on their height (i.e. tilted domain edges generically favor bending towards the shorter rod domain) their effects are quite distinct from the CDPS model (i.e. they lead to free energy terms that are achiral and proportion to domain edge curvature). We argue further, based on symmetry principles, that this curvature/tilt coupling is generic, and as such should exist in any model of phase-separating membranes as a coupling between in-plane tilt and second-derivatives of (scalar) composition.

9:30 AM BM03.06.07
Clustering and Collective Dynamics of Microwimmers—Effects of Shape and Hydrodynamics

Roland G. Winkler and Gerhard Gompper; Institute for Advanced Simulation, Forschungszentrum Jülich GmbH, Jülich, Germany.

Structure formation of active colloidal particles is governed by their shape and hydrodynamic interactions [1], but the effective dimensionality of the system, i.e., three-dimensional bulk fluid versus thin film, plays also a major role. In order to address these various aspects, we have studied structure formation of active dry and wet colloidal systems. Dry matter is modeled by active Brownian particles (ABPs), whereas in the presence of fluid, the active agent is described by a recently developed spheroidal squirmer [2]. The fluid is explicitly modeled by the multiparticle collision dynamics (MPC) approach, a mesoscale hydrodynamic simulation technique [3].

We have studied the swimming behavior, cooperative motion, and motility-induced phase separation (MIPS) of spheroidal squirmers in a narrow slit. For two squirmers, we find a strong influence of confinement on their cooperative motion caused by surface hydrodynamic interactions [2]. Considering the phase behavior of many squirmers, we find that hydrodynamic interactions suppress MIPS for spherical squirmers, but motility-induced clustering (MIC) is present. This is in agreement with results in strictly two-dimensional systems [4], but disagrees with other simulation results for slits [5]. In contrast, hydrodynamic interactions enhance MIPS for elongated squirmers. Moreover, the swimmer type, characterized by the hydrodynamic multipole expansion of its flow field, i.e., puller, pusher, and neutral squirmer, strongly affects the phase behavior. A negative active-stress parameter (puller) is advantageous for MIPS, while a positive value (pusher) is disadvantageous.

The observed clustering of spheroidal squirmers is in contrast to the behavior of motile bacteria, e.g., *E. coli*, in suspensions, which display active turbulence [6]. At the moment, there is no detailed understanding of the different behavior and the underlying mechanisms. Possible hydrodynamic mechanisms will be discussed in the presentation.

References:
Materials adopting the diamond structure possess useful properties in atomic and colloidal systems and are a popular target for synthesis in colloids where a photonic band gap is possible. The desirable photonic properties of the diamond structure pose an interesting opportunity for reconfigurable matter: can we create a crystalline material to switch reversibly to and from the diamond structure with a photonic band gap in the visible light range? Drawing inspiration from high-pressure transitions of diamond-forming atomic systems, we design a system of polyhedrally-shaped colloidal particles that transitions from diamond to a tetragonal diamond derivative upon a small pressure change. The transition can alternatively be triggered by changing the shape of the colloidal particles in-situ. Additionally, our modeling and simulation approach bridges multiple length-scales by linking bulk property calculations to molecular simulations. We propose that the transition provides a reversible reconfiguration process for a potential new colloidal material and draw parallels between this transition and phase behavior of the atomic transitions from which we take inspiration.

Structure-Property Relationships of the Crystal-Amorphous Interface During Deformation of High-Density Polyethylene by Molecular Dynamics Simulations
Andrew L. Bowman1,2, Sungkwang Mun2, Steven Gwaltney3, Mei Chandler4, Michael Baskes5 and M F. Horstemeyer1,2; 1Mechanical Engineering, Mississippi State University, Mississippi State, Mississippi, United States; 2Center for Advanced Vehicular Systems (CAVS), Mississippi State University, Mississippi State, Mississippi, United States; 3Chemistry, Mississippi State University, Mississippi State, Mississippi, United States; 4U.S. Army Engineer Research and Development Center, Vicksburg, Mississippi, United States; 5Aerospace Engineering, Mississippi State University, Mississippi State, Mississippi, United States.

Molecular Dynamic (MD) simulations using a Modified Embedded Atom Method (MEAM) for saturated hydrocarbons is used to investigate the complex crystal-amorphous interface of High-Density Polyethylene (HDPE) at various applied strain rates (1e7 – 1e9) and stress states (tension and shear). A random walk algorithm is developed to model the crystalline-amorphous interface through the insertion of four types of amorphous chains within a crystalline domain: 1) tie chains connecting separate crystalline surface, 2) loop chains connecting separate points on the same crystalline surface, 3) chains originating from a crystalline domain and terminating within the amorphous region, 4) chains both originating and terminating within the amorphous region. To better understand the complex structure-property relations of the various polymer chains emanating and terminating within the crystalline and amorphous domains, a Design of Experiments (DOE) methodology is implemented to independently investigate the influence of eight parameters (number and length of each of the four chain types) concerning the crystalline-amorphous interface in uniaxial tension and simple shear boundary conditions. The relative volume fractions of amorphous to crystalline regions are studied in order to bridge the stress-strain behavior of a completely amorphous polymer and a completely crystalline polymer system. The addition of a small number of amorphous segments is shown to drastically lower the ultimate stress of the further investigation of the crystalline-amorphous interface under more mechanically and chemically complex boundary conditions.

A Theoretical Framework for Raft Interactions in Ternary Colloidal Membranes
Chaitanya Joshi1, Joia Miller1, Douglas M. Hall2, Arvind Baskaran2, Gregory M. Grason3, Zvonimir Dogic3, Michael Hagan1 and Aparna Baskaran1; 1Brandeis University, Waltham, Massachusetts, United States; 2University of Massachusetts, Amherst, Massachusetts, United States; 3University of California, Santa Barbara, California, United States.

Colloidal membranes are a recently developed experimental system of rod-like chiral particles that self-assemble into one rod-length-thick mono-layers under the influence of a tunable depletion interaction. Despite being monolayers that are 1 micron thick, colloidal membranes are described by the same continuum theory as lipid bilayers, and their colloidal scale enables study of behaviors that cannot be visualized in lipid bilayers. Forming membranes from a mixture of short right-handed rods and long left-handed rods results in a rich phase behavior, including microphase separation, wherein one species forms finite-sized domains, or rafts, floating in the background of the other species. This talk will discuss the theoretical analysis of colloidal membranes comprised of three rod species: one with a shorter length and right-handed chirality, the other two with longer lengths and respectively right- and left-handed chirality. Controlling the composition of a mixture of rod lengths allows tuning the chirality of the background. Experiments have shown that making the long rod mixture effectively achiral leads to complex, non-pairwise interactions between the short rod rafts. We employ a Ginzburg-Landau description of the system to understand how this behavior arises from a combination of chirality, rod length mismatches, and the depletion interactions. In particular, we find that raft interactions and their non-pairwise-additivity can be explained from the deformations of the background membrane. We also theoretically examine the experimental observation that there is an asymmetry between rafts of short rods in a background of long rods, or rafts of long rods in a short rod background --- the two systems lead to very different ensembles of raft morphologies.

Computational Design of Multi-Component Superstructures with Multi-Element Colloidal Building Blocks Using a Genetic Algorithm-Based Framework
Mehdi Zanjani1 and Dhananjai Rao2; 1Mechanical and Manufacturing Engineering, Miami University, Oxford, Ohio, United States; 2Computer Science and Software Engineering, Miami University, Oxford, Ohio, United States.

Engineering micro/nanoscale structures and interfaces through self-assembly of colloidal particles is a powerful approach in material design and processing. Colloidal building blocks, with a variety of shapes, sizes, and compositions, can self-assemble into different structures with desirable electronic, photonic, and phononic properties. Recent advances in synthesis and characterization of complex colloidal units, such as colloidal clusters and patchy particles, has provided a library of multi-element building blocks that can significantly expand the current scope of metamaterial self-assembly. However, the complexity of these building blocks makes it significantly harder to predict the resulting structures and their transport properties. Therefore, developing predictive tools based on computational and machine learning approaches becomes a necessity for successful implementation of new material design procedures with multi-element colloidal units.

In this study, we establish a computational framework to help identify feasible multi-component supercrystals of multi-element colloidal building blocks. Specifically, we investigate various designs for multi-component crystalline structures of four or more elements and map out feasible supercrystal phases. We also develop a computational framework to predict transport properties of the target multi-component supercrystals. Band structure calculations are performed to capture the influence of key parameters such as structural features and building block size/shape on the photonic and phononic properties of various proposed metamaterial designs. Finally, we present a Genetic Algorithm (GA) that is established based on the computational analysis of structural...
The Multi-Facetted Nature of Nanocrystal Growth Revealed by Multi-Scale Simulations

We develop a computational model to describe the behavior of active, flexible sheets in solution that can undergo spontaneous self-sustained motion. The active sheets are uniformly coated with a catalyst that decomposes the reagent in the surrounding fluid. The resulting variations in the fluid density give rise to a convective flow around the catalyst-coated sheets. The chemically-generated fluid flow, in turn, dynamically “sculpts” the shape of the sheet and thereby enables it to perform a range of functions. For example, with a periodic influx of reagent, an initially flat, rectangular sheet undergoes repeated shape transformations and thereby exhibits directed crawling along the wall. We also consider a petal-shaped sheet that is anchored to the surface of the solution-filled microchamber. When all four petals are coated with the same catalyst, the generated flow propels the petals to bend and unbend, allowing the sheet to wrap and unwrap a particle localized on its surface. Finally, we examine how four-petal sheets that are coated with different catalysts, and thereby respond to different reagents, can be used to construct logic gates. The findings provide guidelines for creating autonomously moving active fabrics that can be made to crawl, envelop particles in solution or perform simple logic operations in a microfluidic device.

Design of Nanomaterials for Gene Delivery Using Molecular Modeling

The design of ligand functionalized inorganic nanoparticles (NPs) that can induce specific structural transitions in nucleic acids (NA) is important for nanotechnology applications including gene delivery and nanoelectronics. However, comprehensive understanding of ligand design principles lies in the cost associated with synthesizing and characterizing diverse ligand chemistries and ability to carefully assess the structural integrity of biomolecules upon interactions with NPs. It is known that the interaction of nucleic acids and nanoparticles may be tuned through changes in nanoparticle size, charge, polarity, or shape. However, the factors that affect structural transitions are not fully understood. We performed atomistic molecular dynamics simulations of the binding of nucleic acids to monolayer-protected gold nanoparticles to elucidate structural changes that take place for nanoparticles and DNA upon binding. Results from these simulations were analyzed to determine modes of DNA and RNA bending with nanoparticles. Our simulations show that highly charged nanoparticles cause DNA to bend with little damage to the helix structure, similar to DNA in the nucleosome. Nanoparticle shape as well as charge is shown to affect the wrapping of nucleic acids with the nanoparticle. Low salt concentrations and high nanoparticle charge cause greater disruptions to DNA structure. We find that the roll parameter is the most important base-pair parameter for DNA bending. Requirements for bending differed significantly between DNA and dsDNA. The degree of DNA bending is controlled by the charge of the NPs, but ligand flexibility played a more significant role in dsRNA bending. These results allowed us to determine the training data for machine learning algorithms and design a novel ligands capable of controlling wrapping of NA around NP. We have shown that the designer gold NPs are capable of wrapping NAs with fine control of binding strength through NP charge and ligand stiffness. These findings are useful for designing gene delivery systems with enhanced biocompatibility and selectivity.

Predictive Engineering of High-Density Lipoprotein-Mimetic Nanomaterials—Structural and Functional Analysis on Paraoxonase-1

Incorporation, Jiae Young Kim, Yoshitaka J. Sei, Michael Toth, Sang Eun Jee, Seung Soon Jang and Yong Tae Kim; Georgia Institute of Technology,

and transport features of the multi-component supercrystals. This GA uses Machine Learning techniques to define material design rules with respect to structure and transport properties of the desired multi-component supercrystals.
Recent studies have introduced that compositional alteration of HDLs in patient with CVD or chronic kidney disease (CKD) lead to HDL functional heterogeneity. The resulting dysfunction of HDL may lead to the failure to demonstrate that raising plasma high-density lipoprotein (HDL) levels are associated with reducing cardiovascular disease (CVD). This challenge highlights the importance of better understanding of HDL functional heterogeneity. Paraoxonase-1 (PON1) is a major anti-inflammatory and anti-atherosclerotic component of HDL. However, our understanding of the mechanism with which PON1 interacts with HDL relies on the results from bare measurement of plasma HDL levels. Here, we present a new combined approach that leverages both molecular dynamics simulation and microfluidic synthesis of engineered HDL-mimetic nanoparticles (eHNPs) to predict and validate PON1 interactions with or incorporations into eHNPs (apolipoprotein A1 based eHNPs). We found that PON1 binds to both discoidal and spherical eHNPs, both of which have the double-belt apoA1 structure while spherical eHNPs have cholesterol in the core, but not to apoA1-free micelle structure nor to trefoil model structure for spherical eHNPs, which are composed of three apoA1’s. Energy analysis of MD simulation confirmed that PON1 binds to the apoA1 helix 7 of a discoidal eHNPs, while adhering to the apoA1 helix 17 and helix 18 of a spherical eHNPs. More interestingly, we found that the hydrophilic N-terminal domain of PON1 (PON1-H1) serves as a binding area of PON1 to a spherical eHNPs, whereas it has nothing to do with a discoidal eHNPs. Furthermore, we explored possible incorporation of multiple PON1’s into a single eHNPs, resulting in distinct helix interaction from the single PON1 cases. Our integrated approach will bring a new ground-breaking approach to the analysis and development of engineered nanomaterials as well as analysis of natural nanocomposites, addressing the current challenge of costly and vague experimental approaches to the measurement and quantification of complex nanomaterials.

Determining of the Structure of Rosette Nanotubes Using Multi-Scale Molecular Modeling—Ring Stack vs Helical Tube

Arthur A. Gonzales2,1, Hector Grande1, Takeshi Yamazaki3 and Hicham Fenniri1; 1Chemical Engineering, Northeastern University, Boston, Massachusetts, United States; 2Chemical Engineering, University of the Philippines, Quezon City, Philippines; 3Vancouver Prostate Centre, Vancouver, British Columbia, Canada.

Rosette Nanotubes (RNTs) are tubular soft materials self-assembled from guanine-cytosine (GAC) hybrid molecules, which can be covalently functionalized for use in various applications. They have been shown to be effective assemblies in regenerative medicine, drug display and delivery, and catalysis.

Previous spectroscopic studies suggest they have a structure which is formed by hexamer rings, maintained by self-complementary hydrogen bonds, that are further stacked and supported by π-π interactions, which form the ring-stacked RNTs. While this mode of association maximizes the hydrogen bonding interactions and results in efficient π-π stacking, it is also possible to envision that the GAC modules assume a helical organization defining a tubular core. We investigated this possibility by using the lysine-functionalized RNT (K1-RNT) and applying multi-scale molecular modeling methods, which include Monte-Carlo conformational search, molecular dynamics, and the statistical mechanical theory of molecular liquids, 3D-RISM theory. We considered three structures of the K1-RNT: stacked arrangement (ST), left-handed helical coil (LHT), and right-handed helical coil (RHT). Our results suggest that the formation of ST, LHT, and RHT K1-RNTs in water are favorable and are enthalpically driven. Moreover, 3D-RISM analysis suggests that the RHT conformation is more probable than the ST and LHT RNTs and this is due to a more favorable solute-solvent interaction energy. Using the 3D distribution of solvent sites around the RNTs (from 3D-RISM calculations), we were also able to determine the solvation structure and estimate the free energy of binding of each water molecule in the RNT channel. The results also corroborate the higher probability of occurring for the RHT nanotubes. Further experimental studies are underway to verify these findings.

Specific Adhesion and Non-Specific Adhesion of Nanoparticles Influenced by the Surface Charge of Plasma Membranes

Shayandev Sinha, Haoyuan Jing, Harmoo S. Sachar and Siddhartha Das; University of Maryland, College Park, Maryland, United States.

Nanoparticle (NP) driven drug delivery is preferred for its target specificity and effectiveness. But it is a well-known problem that this technique cannot eliminate the non-specific adhesion (NSA) to healthy cell, which in turn leads to cytotoxicity. Specific adhesion can only occur when the NP can adhere to the surface of the plasma membrane through the receptor-ligand (R-L) bond formation. The surface charge of plasma membrane and the presence of the Electric Double Layer (EDL) around the cells can change this scenario in such a way that the electrostatic repulsion of the negatively charged plasma membrane and the negative charge induced on the NP might not be enough to overcome the van der Waals attraction and the thermal fluctuations. In those cases, the surface effects will play a role in engulfing the NP and cause the NSA. Here we propose an electrostatically motivated design of NPs and also propose to cover the NPs with a lipid bilayer thus making them biomimetic. We show that doing so we will have a condition where we can resist NSA and increase the chances of specific adhesion. On the other hand, a bare NP in specific cases can be of use to deliver drugs to cells that have stiffer membranes—a very common case in cholesterol rich systems. We show that tuning the ionic environment can lead to adhesion of NPs on cells with stiffer membranes. We would discuss about the membrane surface charge and salt concentration phase-space where such situations are possible.

Nanoparticles Organization Controls Their Potency as Universal Glues for Polymer Interfaces

Nicola Molinarį2,1 and Stefano Angioletti-Uberti1,2; 1Imperial College London, London, United Kingdom; 2SEAS, Harvard University, Cambridge, Massachusetts, United States; 3Vancouver Prostate Centre, Vancouver, British Columbia, Canada.

In recent years, nanoparticles (NP) have been shown to have the potential to answer the centuries-old question of how to mechanically strengthen an interface between soft materials. The wide range of tunable parameters and properties make glues composed of nano-sized particles appealing to a variety of fields and applications. Despite the simplicity of the idea, the design of novel and universal adhesives based on NPs would benefit from a deeper understanding of the parameters that concur to determine the final adhesion strength.

Using a molecular-simulations-based approach we investigate the trends in, and the fundamental drivers of, the mechanical reinforcement of NP-reinforced interfaces between polymer melts. A coarse-grained model is adopted to describe both the polymer melt and the nanoparticles, and the systems are uni-axially strained and stress-strain curve constructed. We shine light on the interplay of three key properties: size of the NPs, strength of the NP-polymer interaction, and NP density. Our main result shows a non-monotonous strengthening of the mechanical response depending on the layering of the nanoparticles at the polymer interface, which we are able to identify and quantify thanks to the molecular resolution of the computer experiments. Our results confirm recent experimental speculations made to justify the existence of a maximum reinforcement at different NPs’ density. Furthermore, our findings are in good qualitative agreement with a simple analytical model of the melt adhesive energy that we adapted from the literature. The results from this investigation help disentangling the contributions to the strengthening of the interface and can be used as a guide to experimental design of nanoparticles-based adhesives.
Using kinetic Monte Carlo simulations of a simple coarse-grained model, we demonstrate that the self-assembly of oppositely charged nanoparticles is a promising approach to design efficient bulk heterojunction (BHJ) solar cells. Simulations are performed starting from a random configuration of oppositely charged nanoparticles in solution for a range of concentrations. Interconnected percolated morphologies form at high nanoparticle concentrations, when the aggregate growth ceases after certain time. If only Coulombic interactions are present, the observed morphologies have very high interfacial area but too small domain size, whereas optimum values of both the interfacial area and domain size are desired for BHJ. We therefore propose and establish that an additional hydrophobic attraction between nanoparticles of same type is desired to obtain the ideal BHJ morphology. We also discuss the effects of solvent dielectric constant and the size- and charge-asymmetry of nanoparticles, which may provide additional means to control the BHJ morphology.

SESSION BM03.08: Multiscale Modeling of Soft Materials and Interfaces VII
Session Chairs: Siddhartha Das and Meenakshi Dutt
Thursday Morning, November 29, 2018
Sheraton, 2nd Floor, Back Bay B

8:15 AM BM03.08.01
The Molecular Sciences Software Institute Jessica Nash: The Molecular Sciences Software Institute, Virginia Tech, Blacksburg, Virginia, United States.

The Molecular Sciences Software Institute (MolSSI) is a nexus for research, education, and cooperation serving the worldwide community of computational molecular scientists - a broad field including of biomolecular simulation, quantum chemistry, and materials science. The Institute focuses on the software infrastructure, education, standards, and best-practices that are needed to enable the molecular science community to open new windows on the next generation of scientific Grand Challenges, ranging from the simulation of intrinsically disordered proteins associated with a range of diseases to the design of new catalysts vital to the global chemical industry and climate change. The MolSSI is working to enable the computational molecular sciences community to work together to leverage its diverse capabilities that will reduce or eliminate the gulf that currently delays by years the practical realization of theoretical innovations. Ultimately, the Institute will enable computational scientists to tackle problems that are orders of magnitude larger and more complex than those currently within our grasp. This lecture will provide an overview of the Institute’s activities, goals, and vision.

Hybrid Simulations of Gas Permeability of Carbon Nanotube Network Materials Alexey N. Volkov, Omid A. Ranjbar and Md Abu Horaira Banna; University of Alabama, Tuscaloosa, Alabama, United States.

Carbon nanotube (CNT) network material, including buckypaper, films, vertically aligned arrays, and aerogels, are microporous materials that can be used for gas separation, purification, and storage. Scaffolds of CNTs can be also used as reinforcement in nanocomposite materials, fabricated by chemical vapor deposition, chemical vapor infiltration, or atomic layer deposition of inorganic materials on networks of carbon nanotubes. Utilization of the potential of CNT materials in these applications requires understanding of relationship between structural properties of random CNT networks and their gas permeability. The goal of this work is to develop a hybrid computational approach for simulations of gas flows through networks of CNTs, as well as deposition from the gas phase on CNT surface. Our computational model includes (1) a mesoscopic model of CNT materials, (2) an atomistic-mesoscopic model of molecular motion through a random network of nanotubes, and (3) a gas kinetic model of gaseous flow through CNT materials. In the mesoscopic model, every nanotube is represented by a chain of cylindrical segments. This model is used to generate samples of CNT films and aerogels with well-defined structural properties, including bundle and porous size distributions, in dynamic simulations of self-assembly of dispersed nanotubes into networks of bundles. In the atomistic-mesoscopic model, gas flows through generated CNT networks are simulated using molecular dynamics-type approach based on
direct solution of equations of motion of individual gas molecules. In this model, gas molecules interact with a fixed CNT network through a specially designed mesoscopic force field that accounts for the absorption of molecules at the CNT surfaces. The gas kinetic model is used to study the diffusion process at larger length scales that are not accessible in mesoscopic simulations. In this case, the material sample is modelled by a regular two- or three-dimensional arrays of straight CNT bundles with structural parameters that resemble the average structural parameters of in silico generated material samples. The gas kinetic model is implemented in the form of the Direct Simulation Monte-Carlo method, where interaction of gas molecules with CNTs is described by the model of diffuse scattering. This hybrid approach allows us to study gas permeability of CNT materials and material deposition in a broad range of length scales, from nanometers to millimeters. The simulations of gas permeability are performed in a range of pressure from 1000 Pa to 1 MPa and for density of CNT films and aerogels varying from 0.01 g/cm³ to 0.4 g/cm³. The simulations reveal the strong effect of porous structure and density of the CNT materials on self-diffusivity of gases, effective permeability, and homogeneity of deposition of materials inside CNT networks. This work is supported by the NSF CAREER award CMMI-1554859 and NASA Early Stage Innovations program (project NNX16AD99G).

Bio-Inspired Structural Coloration Obtained from Micro-Kirigami Photonic Structures—A Computational Study
Amina Matt,1,2 Fabien Sorin1 and Craig Carter;1 Institute of Materials, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Structural coloration is a macroscopic phenomenon resulting from the interaction of light with microscopic, i.e. sub-wavelength, structure features. It is naturally observed in diverse applications, notably the vivid blue color of certain butterfly wings, due to a combination of elementary optical processes such as thin-film interference and diffraction gratings. Recently, the dynamical effects of such artificial structures under stresses and deformations have received a great deal of attention, hinting towards tunable bio-inspired materials. Simple photonic structures have succeeded in replicating bright and vivid structural colors observed in nature, while more complicated structures address the issue of angle-dependent reflectivity, achieving a stable color across wide viewing angles with the introduction of irregularity but at the cost of manufacturing complexity.

Here, we suggest and illustrate an alternative approach using micro-kirigami photonic crystals, which achieves bright and vivid colors across wide viewing angles and allows tunability of the obtained color. Micro-kirigami are three dimensional buckled structures, obtained from the deformation of two dimensional materials with patterned microscopic cuts. Recent advances in the field have extended such techniques to the obtention of mesoscale structures from micro/nanomembranes with complex shapes resulting upon buckling from the wide variety of cut patterns [1]. The demonstration of micro-kirigami structures could lead the way further in the miniaturization of such assemblies. Numerical calculations on periodic arrays of simple polymeric ribbons with parallel cuts and more complex micro-kirigami structures, exhibit the required design objectives. The introduction of irregularity, facilitated by the notch patterning, helps stabilize the obtained color across a range of viewing angles while tunability is inherent in the buckling process. The large parameter space is efficiently optimized using a combination of Finite Element and Finite Difference Time-Domain modelling to produce various structures with bright and stable colors.

Using Simulations of Rare Earth Elements in Aqueous Solution, in Organic Acid Complexes and at Interfaces to Suggest Improved Processing Routes
Aaron Finney,1 Sebastien Lecet,2 Linghan Kong,1 Colin L. Freeman1, Stephen Stackhouse2 and John H. Harding;1 1Materials Science and Engineering, The University of Sheffield, Sheffield, United Kingdom; 2School of Earth and Environment, University of Leeds, Leeds, United Kingdom.

Researchers are searching for more efficient and environmentally-friendly extraction and processing methods. This is particularly true in the case of rare earth elements (REEs), the security of supply of which has been identified as ‘critical’. [1] New and sustainable extraction, processing and recycling methods for REEs are urgently needed. Since REEs can be mobilised and concentrated in hydrothermal fluids [2] and from easily leachable clays [3], fractionating REEs from solution offers a cheap way to increase their yield from deposits. Biologically active molecules, such as organic acids can accumulate specific groups of REEs from solution, [4] and so understanding their action should help to design better additives for materials processing. In the present study, density functional theory and classical force field molecular dynamics have been applied to investigate Nd³⁺, Gd³⁺ and Er³⁺ REEs in solution. The solvation structure, energetics and mobility of REEs compared well with experimental measurements. Ligand binding simulations were performed with common anions, e.g. chloride, and organic acids using advanced sampling methods—including Umbrella Sampling and metadynamics—and complex stability constants were calculated. Ligand exchange mechanisms and preferential organic acid binding to REEs were characterised by analysis of free energy surfaces. Our results show that ion size is crucial for the type of ligand exchange mechanism.

Simulations were performed to understand the sorption of REEs onto kaolinite clays where they are often found in nature. By studying reversible exchange reactions for REE binding at the kaolinite–solution interface we can quantify the strength of interaction and identify barriers to REE release for processing. Furthermore, the simulations, by spanning light to heavy REEs (Nd to Er), allow us to investigate why REE clay deposits are a good source for heavy REEs. Combined, these simulations at the nanoscopic level provide new information to aid in the design of REE processing methods from unconventional deposits in the search for economical, environmentally friendly ways to secure REE supply.

9:15 AM BM03.08.05
Active Micromechanics of Blood Clot Contraction
Alexander Alexeev; Georgia Institute of Technology, Atlanta, Georgia, United States.

Blood clotting is the final step in hemostasis resulting in the sealing of an injured blood vessel and the bleeding arrest. Clotting is a highly complex multi-stage and multi-scale process involving platelet activation, polymerization of fibrin networks, and development of a platelet-fibrin hemostatic plug in the damaged vessel that retracts to restore normal blood flow. Blood clotting disorders may result in a variety of life threatening conditions, including excessive bleeding, stroke, and heart attack. Understanding of the physics underlying the clotting process is critical for effective treatment of these and other blood disorders.

We develop an experimentally-informed mesoscopic model to obtain fundamental insights into the active process of blood clot contraction. We employ the model to examine how the clot size and microstructure evolve in time due to the fibrin-platelet interactions and to explore the role of the platelet activation pattern in the clot contraction kinetics. Our results pinpoint the critical role platelet heterogeneity plays in the effective clot contraction.

9:45 AM BREAK
A liquid drop on a soft elastic surface equilibrates by selecting a contact angle demonstrated by Neumann’s law. A hydrophobic drop itself deforms and causes a deformation in the substrate. Studying this phenomenon necessitates a combination of macroscopic and microscopic description of the contact angles. We develop new scaling theory to quantify the interplay of the two effects of drop wetting, i.e. the drop compressing the polymer brush and the polymer brush repelling the drop. Our scaling theory predicts that for a case of low stiffness the polymer compression is independent of stiffness and for high stiffness there is a monotonous decrease of polymer compression due to its interaction with the droplet. To verify this scaling theory, we perform molecular dynamics simulation of a 2-D LJ droplet wetting a flat polymer brush grafted plate. We simulate a case where the polymer brush is solvophobic. We find that the drop causes a deformation in the polymer brush that agrees quantitatively with the scaling theory we develop. We also find that the stiffness of the polymer brush influences the motion of the drop on the surface of the polymer grafted plate. Our theory, which is verified by MD simulations, predicts that the stiffness of polymer brush will cause the transition of the equilibrium contact angle from Young’s law (rigid limit) to Neumann’s law (soft limit). Our scaling theory will be useful in development of self-cleaning surfaces, and in the development of new nanofluidic devices.

The stress wave dissipation in sinusoidal patterned interfaces that were inspired by biological sutures was investigated using Finite Element (FE) analysis. Although man-made shock absorbers such as car bumpers or guardrails are designed to absorb impact energy through plastic deformation, biological materials do not use this strategy as severe plastic deformation may cause fatal damage. Biological materials use elastic and viscoelastic responses effectively to dampen impacts and absorb energy in an effort to maintain structural integrity. In nature, suture joints are found where two stiff components interlock each other and where dynamic impacts are needed to be dissipated. For example, in mammalian skulls, turtle shells, woodpecker beaks, and ammonoid shells, a wavy sinusoidal interface was observed. An idealized bar with a sutured interface (i.e., sutured bar) and an idealized bar with a flat interface (i.e., unsutured bar) were created and analyzed from two-dimensional FE analysis in Abaqus/Explicit under dynamic conditions. FE results from this study show that a sutured interface decreased the pressure 37% more than an unsutured interface did, which arose from wave scattering and energy dissipation via interaction between the viscoelastic material in the gap and sinusoidal boundaries. Wave scattering is an interaction of waves with a boundary resulting in wave reflection, transmission, or refraction. Since the compressive incidence impinged the sinusoidal interfaces, stress wave scattering resulted in converting compressive waves (S11) into flexural waves (S22) and shear waves (S12). This decreased both the peak pressure (attenuation) and wave speed (dispersion). Also, higher strain energy occurring at sutured interfaces brought energy loss within the viscoelastic gap. Several variables related to the suture interfaces for their influence on stress wave mitigation were also parameterized. The following seven parameters were examined in this study: 1. waviness of suture (ratio of suture height to suture period), 2. ratio of the suture height over the entire structure thickness, 3. gap thickness, 4. elastic modulus, 5. type of the boundary, 6. impact amplitude and 7. impact duration. The results of the parametric study revealed that wave attenuation increased by the following three factors: a higher ratio of the suture over the entire structure thickness, shorter impact duration, and a lower elastic modulus. Wave dispersion was caused by the following two factors: a higher ratio of the suture over the entire bar thickness and a lower elastic modulus. If the material properties and impact duration cannot be controlled in the engineering design of a structural component or system, then making the suture height greater becomes the only controllable design variable that matters. These findings can be applied to design structures that resist impact yet maintain structural integrity by optimizing sutures designs for impact scenarios.

Anti-agglomerant (AA) molecules are chemical inhibitors that help prevent the blockage of oil and gas transmission pipelines due to the aggregation of gas hydrate crystals. However, the effectiveness of these inhibitors is reduced at high water content, which makes it critical to design molecules tailored for water-dominated environments. Furthermore, salinity has been shown to improve the performance of most industrially-deployed anti-agglomerant molecules, including simple quaternary ammonium salts. Understanding the energetics and mechanisms of AA-hydrate interactions in aqueous water-dominated environments of varying salinity can help production chemists and flow assurance engineers design better AA molecules with reduced experimental trial- and-error. We used molecular dynamics simulations to examine the surface adsorption of a model anti-agglomerant (AA) molecule binding to a sII methane-propane hydrate in environments of different salinity. From our simulation data, we identified the preferred binding sites on the hydrate surface and characterized the equilibrium binding configurations. In addition, for a subset of these binding configurations, we calculated the standard binding free energy in different concentrations of brine using potential of mean force free energy calculations. We demonstrated that in higher salinity environments, the surface adsorption of the AAs is enhanced through two distinct mechanisms. First, the salt decreases the solubility of the AA in the solution, which increases the thermodynamic driving force for surface adsorption. Second, the salt ions create a negatively charged interfacial layer close to the hydrate surface that effectively solvates the cationic head of the AA molecule. Quantitatively, we found that the presence of 3.5 wt% and 10 wt% NaCl decreases the standard binding free energy of the long hydrocarbon tail binding configuration by 0.8 and 1.4 kcal/mol, decreases the standard binding free energy of the catonic head binding by 1.5 and 3.3 kcal/mol, and decreases the standard binding free energy of simultaneous head and tail binding by 1.9 and 4.3 kcal/mol, respectively.

In this talk, a “good”, a “bad” and an “ugly” stories will be telling around the behaviour of water at nanoscale solid-liquid interfaces. The understanding of water transport in nanoconfined configurations has revealed a prominent significance to predict the performance of biomedical phenomena and to guide the rational design of other engineering devices. First, molecular dynamics simulations are used to compute the self-diffusion coefficient of water within nanopores, around nanoparticles, carbon nanotubes and proteins. For almost 60 different cases, the diffusion coefficient is found to scale linearly with a dimensionless parameter which represents the confinement degree of the water molecules [1]. Such relationship, coupled with the “good” understanding of water transport behaviour, has shown to accurately predict the response of contrast agent for magnetic resonance imaging [1]. Later on, this relationship has been experimentally and
individually validated by the Oak Ridge National Laboratory, beyond biomedical applications [2].

Second, experiments and atomistic simulations are used to elucidate the non-trivial interplay between nanopore hydrophilicity and the overall water transport through zeolite crystals. A poor correspondence between the experiments and simulations has suggested the presence of a “bad” surface diffusion resistance at the interface between the zeolite porous matrix and water [3]. This suggests future experimental works to address these surface imperfections, as an essential prerequisite for improving water permeability of such membranes.

Finally, the complexity of water-solid interfaces will be fully revealed by “ugly” surfactants wrapping nanoparticle (NP) in aqueous solutions. Despite the large use of nanoparticle suspensions, tuning NP interactions and identifying desired NP assembly processes, in presence of surfactants, still represent a challenge for the design of nano-suspensions. We present a multiscale model for investigating nanoscale interfacial phenomena, stability, and aggregation of nanoparticles in aqueous solutions, including the dynamics of realistic surfactants [4]. In addition, the developed multiscale model is able to predict thermal properties of NP suspensions in reasonable agreement with the relevant experimental data from the literature, overcoming limitations of traditional theories obtained by coupling the DLVO (Debye-Hückel-Overbeek) theory with the kinetic theory of aggregation. Our results will enable the formulation of design rules for engineering NP aqueous suspensions suitable for a wide range of applications.

11:30 AM BM03.08.10
How Graphene Inclusions Increase Mechanical Toughness of Epoxy Resins Maxime Vassaux, Robert Sinclair, Robin Richardson, James Suter and Peter Coveney, University College London, London, United Kingdom.

Adding graphene to an epoxy matrix is experimentally known to improve its mechanical properties [1], most specifically enhancing toughness. The mechanisms responsible for this increase of dissipated energy at failure are far from clear [2]. By means of molecular dynamics simulations, we have explored the interactions between pure small graphene sheets (~10 Nm) and a crosslinked epoxy network, but the 2D nanoparticles do not appear to enhance the properties of the original polymer. Conversely, in the case of previously studied clay and linear polymer nanocomposites [3], the strength of the resulting nanocomposite is reduced and the interaction energy between the sheet and the network remains relatively low. The difference in behaviour is due to the high degree of crosslinking found in epoxy resins.

It appears that the benefits of adding graphene arise at larger scales, in particular at the continuum level. At the atomic scale the toughening is not observed because the single defect doesn’t induce diffuse cracking but merely the fatal crack. In order to investigate mechanisms emerging in the transition from atomistic to continuum descriptions, we have implemented a concurrent multiscale model based on the heterogeneous multiscale method [4]. Using this method we can in turn explore how an isotropic distribution of nanoparticles influence the fracture processes.

Furthermore, due to processing limitations, pure graphene is rarely employed in nanocomposites and is often replaced by oxidized graphene. Hence our proposed methodology is also applied to provide insights on the influences of bonded and non-bonded interactions between the polymer and the sheets on emerging mechanical properties.

We present a model to investigate the formation of two-length scale surface patterns in biological and synthetic anisotropic soft matter materials through the high order interaction of anisotropic interfacial tension and capillarity at their free surfaces. The unique pattern-formation mechanism emerging from the presented model is based on the interaction between lower and higher order anchoring modes. Analytical and numerical solutions are used to shed light on why and how simple anisotropic anchoring generates two-lengthscale wrinkles whose amplitudes are given in terms of anchoring coefficients. The novel finding is that the surface energy landscape with its maxima and minima can be imprinted onto the surface geometric landscape. Symmetry relations and scaling laws are used to provide the explicit relations between the anchoring constants and surface profile of the two length scale wrinkles. These new findings establish a new paradigm for characterizing surface wrinkling in biological liquid crystals, and inspire the design of novel functional surface structures.

Fuel cells have attracted enormous interest due to their high efficiency to convert chemical energy into electrical energy with very low emission. It can be used in stationary, portable, and transport power generation. It also reduces the CO₂ emission when compared with the conventional hydrocarbon fuels, therefore considered as environmentally clean energy source. Fuel cells are classified based on the electrolyte/electrode material and operating temperature range. Solid oxide electrolyte based fuel cells operate at high temperature and are the most efficient fuel cells. They can handle variety of fuels such as H₂, CO and various hydrocarbons CH₄. [1-2]

Perovskite is a family of compound having ABX₃ type crystal structure, where A and B are cations whereas X is an anion. They exhibit variety of properties due to ferroelectric, dielectric, pyroelectric, and piezoelectric behaviours. There is paramount interest to replace conventional Ni-YSZ cermet electrode with doped perovskite in solid oxide fuel cell [3]. SrTiO₃, a member of perovskite family, is a well-known band insulator. Doping of La significantly enhance the electronic conductivity of SrTiO₃. Experimentally, perovskite (LaTiO₃), pyrochlore oxide (La₂Ti₂O₇) and lanthanide (La₂TiO₅) phase can coexist at higher temperatures (∼1500 °C) [5]. Thus, it is essential to investigate the effect of doping in these phases of La and Sr. To satisfy the valency, O vacancy is created in pyrochlore oxide and lanthanide phase after Sr doping.

In the present study, we have used GGA-DFT to investigate the various La doped structures of SrTiO₃, Sr doped structures of La₂Ti₂O₇ and La₂TiO₅ and O vacancy in Sr doped structures of La₂Ti₂O₇ and La₂TiO₅. The concentration of dopant is varied between 0-100 ‰ considering all possible configurational structures. We have varied the concentration of dopant to establish its dependence on electronic energy, band gap, fermi level and formation enthalpy. We have also estimated the elastic properties of these phases. We observed a band insulator to a metallic behaviour by doping La in SrTiO₃. It became band insulator again after 100% La replacement in SrTiO₃. Such behaviour is not observed in the pyrochlore oxide phase. At the end, we shall report the preferential doping among these phases in a mixture where they all can coexist.

It is widely anticipated that many future materials will be engineered at the nano-scale, be comprised of dissimilar materials, and possess multi-functional properties and behaviour. In coming decades, in silico prediction and testing – that is, R&D performed on a computer – will be commonplace for these materials, in both academia and industry, given the increasing capabilities and diminishing costs of high performance computing.

We are working towards a multiscale computing environment to seamlessly simulate the properties of functional multicomponent 2-d materials. This is designed to encompass electronic, classical and coarse-grained molecular dynamics and continuum methods with correctly designed and implemented coupling between the levels. We aim to produce high fidelity and actionable predictions, subjected to full verification, validation and uncertainty quantification. Ultimately, the aim is to construct between the key properties of 2-d and other nanocomposites that are linked to the underlying chemical building blocks. [1,2,3]

Membraneless organelles are aggregates of disordered proteins that form spontaneously to promote specific cellular functions in vivo. The possibility of
synthesizing membraneless organelles out of cells will therefore enable fabrication of protein-based materials with functions inherent to biological matter. Scattered copolymers contain various reactants of both amphiphilic and solvophilic groups, they are expected to function in non-biological media similarly to a set of disordered proteins in membraneless organelles. Interestingly, the internal environment of these organelles has been noted to behave more like an organic solvent than like water. Therefore, an adsorbed layer of random copolymers that mimics the function of disordered proteins could in principle protect and enhance the proteins’ enzymatic activity even in organic solvents, which are ideal when the products and/or the reactants have limited solubility in aqueous media. Here we demonstrate via multiscale simulations that random copolymers efficiently incorporate proteins into different solvents with the potential to optimize their enzymatic activity. We investigate the key factors that govern the ability of random copolymers to encapsulate proteins including the adsorption energy, copolymer average composition and solvent selectivity. The adsorbed polymer chains have remarkably similar sequences, indicating that the proteins are able to select certain sequences that best reduce their exposure to the solvent. We also find that the protein surface coverage decreases when the fluctuation in the average distance between the protein adsorption sites increases. The results herein set the stage for computational design of random copolymers for stabilizing and delivering proteins across multiple media.

Miscibility and Nanoparticle Diffusion in Ionic Nanocomposites Argyrios Karatrantos1, Yao Koutsawa2, Philippe Dubois3, Nigel Clarke4 and Martin Kröger5; 1Physics, Univ of Sheffield, Sheffield, United Kingdom; 2Materials, Luxembourg Institute of Science and Technology, Esch-sur-Alzette, Luxembourg; 3University of Mons, Mons, Belgium; 4Materials, ETH Zürich, Zürich, Switzerland.

We investigate the effect of various spherical nanoparticles on dispersion, chain dimensions and entanglements in ionic nanocomposites for dilute and high nanoparticle loading, by means of molecular dynamics simulations. The nanoparticle dispersion can be achieved, due to the presence of ionic bonding, in oligomer matrices, in contrast to conventional nanocomposites where the electrostatic interaction is absent. We show that the overall configuration, as characterized by the radius of gyration, of ionic oligomer chains is unperturbed by the presence of charged nanoparticles. In addition, nanoparticle diffusion is reduced due to the electrostatic interaction and deviates from the predictions of the Stokes Einstein relation.

High-Speed Contact Mechanics Between Amorphous Carbon Nanoparticles Weifu Sun and Pengwan Chen; Beijing Institute of Technology, Beijing, China.

The contact mechanics plays an important role in describing behaviours of granular matter, such as packing, flow of particles. With the development of precision processing, the high-speed motions (including translation, rolling, sliding) between nanosized building blocks are often experienced in nanodevices, such as nano-electro-mechanical system (NEMS). However, the contact behaviours between amorphous nanoparticles have seldom been explored, in particular, whether the contact models still hold or not at the nanoscale remains unknown. In this work, the dynamic behaviours between amorphous carbon nanoparticles will be studied using molecular dynamics simulations during the head-on impact and the validity of conventional continuum contact models will be tested.

A Coarse-Grained Molecular Dynamics Model of Single-Stranded DNA-Functionalized, Shaped Nanoparticles Benjamin E. Swedlow1, Fang Lu2, Matthew Spellings3, Julia Dhemuchade4, Oleg Gang5,6, and Sharon C. Glotzer3,4; 1Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States; 2Center for Functional Nanomaterials, Energy & Photon Sciences Directorate, Brookhaven National Laboratory, Upton, New York, United States; 3Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States; 4Biointerfaces Institute, University of Michigan, Ann Arbor, Michigan, United States; 5Chemical Engineering, Columbia University, New York, New York, United States; 6Applied Physics and Applied Mathematics, Columbia University, New York, New York, United States.

Typical materials science follows a top-down approach: processing conditions influence the formed structure, dictating the key material properties. Conventional processing often limits fine control over structure-property relationships. However, advances in nanotechnology, such as DNA nanoparticle (NP) functionalization, enable a bottom-up approach for materials design. By coating NP surfaces with DNA strands that terminate in unpaired bases, specifically engineered DNA sequencing can programmatically enforce NP binding. Yet this enthalpic basis alone is insufficient to explain all aspects of NP self-assembly: entropic parameters such as particle size and shape, as well as DNA flexibility and length, all contribute to the observed equilibrium structures. Computer simulations of these systems allow us to screen candidate building blocks and probe the effects of interactions between nanoparticles more easily and efficiently via computational rather than experimental exploration. Previously, a coarse-grained molecular dynamics model using the Discrete Element Method implemented in HOOMD-blue was used to simulate structures assembled in one-component double-stranded DNA (dsDNA) NP systems. Here we expand this implementation to replicate experimental results for assembly of two-component flexible single-stranded DNA (ssDNA) NPs and to predict the assembly behavior of new systems of binary shapes, where we find unique phase behavior. Our experimental studies on binary mixtures of DNA coated shaped NP are in agreement with computational results. We find that core NP shape and ssDNA flexibility are critical to self-assembly in these systems.

Stable Frank-Kasper Phases of Self-Assembled, Soft Matter Spheres Abhiram Reddy1, Michael Buckley2, Akash Arora1, Frank Bates1, Kevin Dorfman1 and Gregory Grason; 1University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; 2University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Self-assembly of soft-molecules into spherical domains adopting Frank Kasper lattices have been observed in a variety of systems, including liquid-crystalline dendrimers, charged surfactants and block copolymers (BCPs). The formation of these complex phases has been previously attributed to optimal self-assembly of soft-molecules into spherical domains adopting Frank-Kasper lattices have been observed in a variety of systems, including liquid-crystalline dendrimers, charged surfactants and block copolymers (BCPs). The formation of these complex phases has been previously attributed to optimal assembly and/or volume asymmetry (polydispersity or Voronoi partition of cells) leading to the question: What selects volume asymmetry in these assemblies and how does this impact surface area of the partitions? We will address these in the context of BCPs by drawing comparisons between Diblock Foam Model (DFM) that captures the Polyhedral Interface Limit (PIL) and SCFT for diblock melts. DFM describes thermodynamics of sphere phases in terms of competing geometric quantities: surface area and dimensionless stretching (or radius of gyration) of cellular volumes enclosing domains. DFM correctly predicts not only which of these lattices is favored in equilibrium (the sigma phase) but also their relative ranking in terms of entropy and enthalpy, and their equilibrium volume distribution among spheres. Comparison to SCFT results show that increasing conformational asymmetry between blocks drives a transition to radial-chain stretching and towards the PIL described by DFM calculations. We further show that the degree of polyhedral “warping” of the spherical domains is directly correlated with the dimensionless stretching-moment of distinct cells.

A Computational Study on Thermo-Mechanical Characterization of Carbon Nanotube Reinforced Natural Rubber Manish Dhawan and Raj
A computational study based on molecular dynamics simulation technique has been used to predict the mechanical and thermal behavior of carbon nanotube (CNT) reinforced natural rubber (NR) composites. A single-walled 5,5 armchair type CNT has been used for this purpose. In this study, a comparison has been made between pristine and functionalized CNTs. The functionalization groups used in this study were carboxylic (COOH), ester (COOCH3) and hydroxyl (OH). The studies show the improvement in elastic properties of developed composites in the presence of functionalization group. In addition, the effect of volume fraction and 1-25% addition of functionalization group has been studied. The obtained simulation results show the better load-transfer capacity in developed polymer system and improved elastic modulus. Thermal properties of developed composite systems were studied by non-equilibrium molecular dynamics method (NEMD). The addition of functionalized CNTs shows enhanced mechanical and thermal properties.

**Bioresorbable Electronic Materials for Wireless Neuroregenerative Therapy** John A. Rogers; Northwestern University, Evanston, Illinois, United States.

Peripheral nerve injuries commonly result in lifelong disability. Even the most advanced surgical procedures and pharmaceutical treatments have limited ability to improve clinical outcomes. Intraoperative electrical stimulation performed at the site of nerve repair is a well-established treatment that can accelerate and improve overall rates of functional recovery. Clinical utilization of electrical stimulation has, however, been limited to the intraoperative period, wherein injured tissue is physically accessible. This talk describes bioresorbable electronic materials and devices that allow for non-pharmacologic neuroregenerative therapy via prolonged post-operative electrical stimulation throughout the healing process, enabling substantially improved outcomes in nerve regeneration and functional recovery compared to the existing intraoperative mode. An essential characteristic of these implantable systems is that they undergo complete dissolution and elimination from the body via natural biochemical processes over timescales matched to operational requirements and without adverse biological effects. The result thereby eliminates the need for secondary surgical extraction and associated risks to the patient and to site of the nerve repair. This type of bioresorbable technology represents a new vehicle for the delivery of non-pharmacologic bioelectric and neuroregenerative therapies in a variety of clinical settings, and a significant paradigm shift in the treatment of critical nerve injuries with limited potential for sensorimotor recovery.

**Elastomeric Polymers for Microfabrication of Organs-on-a-Chip** Milica Radisic; Univ of Toronto, Toronto, Ontario, Canada.

Recent advances in human pluripotent stem cell (hPSC) biology enable derivation of essentially any cell type in the human body. However, limitations related to cell maturation, vascularization, cellular fidelity and inter-organ communication still remain. Here, biological wire (Biowire) technology will be described, developed to specifically enhance maturation levels of hPSC based cardiac tissues, by controlling tissue geometry and electrical field simulation regime (Nunes et al Nature Methods 2013). We will describe new applications of the Biowire technology in engineering a specifically atrial and specifically ventricular cardiac tissues, safety testing of small molecule kinase inhibitors, potential new cancer drugs, and modelling of left ventricular hypertrophy using patient derived cells.

For probing of more complex physiological questions, dependent on the flow of culture media or blood, incorporation of vasculature is required, most commonly performed in organ-on-a-chip devices. Current organ-on-a-chip devices are limited by the presence of non-physiological materials such as glass and drug-absorbing PDMS as well as the necessity for specialized equipment such as vacuum lines and fluid pumps that inherently limit their throughput.
An overview of two new technologies, AngioChip (Zhang et al Nature Materials 2016) and inVADE (Lai et al Advanced Functional Materials 2017) will be presented, that overcome the noted limitations and enable engineering of vascularized liver, vascularized heart tissues and studies of cancer metastasis. These platforms enable facile operation and imaging in a set-up resembling a 96-well plate. Using polymer engineering, we were able to marry two seemingly opposing criteria in these platforms, permeability and mechanical stability, to engineer vasculature suitable for biological discovery and direct surgical anastomosis to the host vasculature. Finally, to enable minimally invasive delivery of engineered tissues into the body, a new shape-memory scaffold was developed that enables delivery of fully functional tissues on the heart, liver and aorta through a keyhole surgery (Montgomery et al Nature Materials 2017).

Acellular PCL Scaffolds Laden with Fibroblast/Endothelial Cell-Derived Extracellular Matrix for Bone Regeneration Radoslaw Junka and Xiaojun Yu; Stevens Institute of Technology, Hoboken, New Jersey, United States.

Biological scaffolds derived from decellularized tissues function as tissue remodeling templates during bone regeneration. This isolated extracellular matrix (ECM) provides a structural framework that regulates adherence, migration, proliferation, and differentiation of bone residing cells and those in surrounding tissues. Nonetheless, decellularization protocols, like the ones used in isolation of demineralized bone matrix (DBM), require use of acids and other harsh chemicals that render osteoinductive proteins in DBM denatured. Also, lack of vascular cues in DBM presents another impediment to bone healing, and results in non-unions from poor vascularization of the regenerating tissue. To address these limitations, we used tissue engineering approach and tested the regenerative capacity of decellularized ECMs derived from sequential cultures of fibroblasts and endothelial cells grown on polycaprolactone (PCL) fibers. We hypothesized that this vascular ECM would enhance osteoblast proliferation, differentiation, and matrix deposition in vitro. The bottom-up strategy eliminated competition between cell types with varying proliferation rates and allowed for ECM remodeling. ECMs from decellularized cultures were evaluated via methylene and Coomassie blue stains, and their protein and DNA content was quantified. Staining also revealed that endothelial cells grown on fibroblast ECM (Fibro/Endo) form networks resembling capillaries. These structures stained positively for endothelial markers CD31 and vWF. Analysis of SEM images indicated changes in morphology and preferential attachment of endothelial cells to PCL fibers laden with fibroblast ECM. Osteoblasts grown on this Fibro/Endo ECM yielded higher proliferation rates at each time point during 28 day culture. Significantly higher ALP activity in these cultures suggest better capacity of osteoblasts to form bone tissue and higher degree of differentiation. The color area and intensity of Alizarin Red staining of Fibro/Endo cultures revealed uniform and greater calcium deposits than in cultures with only single type of ECM. Relative expression of osteoclacin and osteopontin between culture conditions was compared via immunostaining. Successive culture/decellularization cycles enriched the ECM product, which in turn significantly enhanced proliferation and differentiation of osteoblasts in vitro. Thus, addition of vascular ECM cues to biological scaffolds might lead to improved bone healing rate in vivo. The use of this hybrid ECM can expanded to other combinations with additional cell types, which might further improve regeneration of tissues.

Influence of Cerium Oxide Nanoparticles on the Properties of Gelatin-Alginate Scaffold for Bone Tissue Engineering Shiv D. Purohit1, Rakesh Bhaskar2, Hemant Singh1, Indu Yadav1, Mukesh K. Gupta2 and Narayan C. Mishra1; 1Polymer and Process Engineering, Indian Institute of Technology Roorkee, Roorkee, India; 2Biotechnology and Medical Engineering, National Institute of Technology Rourkela, Rourkela, India.

It has been observed that polymeric scaffolds loaded with cerium oxide nanoparticles (CeONP) hold great potential for tissue engineering applications. In this study, nanocomposite scaffolds (NCS) have been fabricated by freeze drying of aqueous mixture of the CeONP, gelatin and alginate, with a goal of obtaining CeONP incorporated porous biocompatible scaffolds for bone tissue engineering applications. Further, influence of varying concentration of CeONP, on the scaffold properties, was evaluated in terms of mechanical, biodegradation, cell attachment and cell proliferation properties of the scaffold. Field emission scanning electron microscopy images of the NCS revealed presence of interconnected pores. The NCS was highly porous with porosity ranging from 82-89%. The CeONP covered the surface of the composite matrix and made the surface of the NCS rougher. Compressive strength of the NCS was found to be significantly higher than the gelatin/alginate scaffolds which are not having any CeONP. This may be due to the CeONP present in the NCS. High % swelling (~640%) of the NCS indicates its hydrophilicity. Slow biodegradation (~26% in 30 days) indicates its suitability for bone regeneration. In vitro cell culture studies, by seeding MG-63 osteoblast-like cells on NCS and performing cell attachment studies, MTT assay, Environmental Scanning Electron Microscopy of cell-scaffold construct and Giensta staining, showed an enhancement in cell attachment, proliferation and adhesion as compared to the gelatin/alginate scaffold which are not having any CeONP: this indicates the influence of the CeONP of such enhancement in the scaffold properties which, in turn, can enhance bone regeneration process ultimately. Thus, it could be stated that the incorporation of CeONP to gelatin-algininate, or in other words, the CeONP incorporated composite scaffold has vital importance for applications in bone tissue-engineering in future regenerative therapies.

9:30 AM OPEN DISCUSSION

9:45 AM BM04.01.06

In Vivo Bioreosorbability and Tissue Reaction of Hydroxyapatite/Collagen–(3-Glycidoxypropyl)Trimethoxysilane Injectable Bone Paste Taira Sato1, Yuki Shroska2, Sho Oshimai3, Yoshishia Koyama2, Mamoru Aizawa2 and Masanori Kikuchi4; 1Department of Applied Chemistry, Meiji University, Kawasaki, Japan; 2Department of Materials Science, Kyushu Institute of Technology, Kitakyushu, Japan; 3National Institute for Materials Science, Tsukuba, Japan; 4Major in Industrial Science, Ibaraki University, Hitachi, Japan.

Injectable self-setting bone pastes are a user-friendly bone void filler in comparison to dense, porous and granular ones, because pastes are applied for minimal invasive surgeries and are shaped easily to fit bone defects. However, surgeons desire biodegradable bone paste strongly because present bone pastes are very slow biodegradable and brittle and a risk to be a cause of secondary bone fracture. Presently available biodegradable bone void fillers in Japan are β-tricalcium phosphates, carbonated apatite and hydroxyapatite/collagen bone-like nanocomposite (HAp/Col). The HAp/Col demonstrates good viscoelasticity and excellent bioreosorbability with bone formation ability by incorporating into bone remodeling process. We focused on the HAp/Col as a base material for novel injectable bone cement. In the previous report, the HAp/Col biodegradable self-setting pastes were prepared by a mixing of the HAp/Col powder and aqueous solution of (3-glycidoxypropyl)trimethoxysilane (GPTMS), which is a setting agent by cross-linking of collagen and forming siloxane network by self-condensation. The HAp/Col-GPTMS bone pastes implanted into porcine tibia were resorbed and replaced by newly formed bone within 12 weeks. In this study, the pastes were implanted in the rat tibia and the biological tissue reaction and the absorption behavior of the pastes up to 4 weeks after transplantation were investigated in detail.
The HAp/Col (80/20 in mass ratio) powder at 100 μm or less in particle size was prepared by ball-milling of the HAp/Col compact prepared by a uniaxial pressing after synthesis by the melt-casting/crystallization method. The de novo bone formation when seeded with adipose-derived stromal/stem cells and stromal vascular fraction (SVF) and implanted in murine critical-sized cranial defects. Murine models of critical-sized bone defects due to disease, degeneration, trauma, and aging, bone loss occurs in the body. Although there have been remarkable improvements in development of functional bone scaffolds, it remains difficult to fabricate porous and biocompatible constructs in physiologically relevant sizes (cm-scale). Herein we developed biomineralized origami-inspired paper scaffolds in three-dimensions (3D). To our knowledge, this work is the first demonstration that paper can be used as a 3D construct to induce template-guided mineralization by osteoblasts. In this work, we used the principles of origami to fabricate free-standing paper scaffolds in cm-scale. Because paper is an extremely flexible material that can easily be cut, creased, and folded to form 3D structures, the scaffolds were easily fabricated in a variety of different geometries. This feature can potentially be useful in generation of constructs for patient-specific applications especially for patients who have defects of irregular sizes and shapes. After sterilizing the constructs, they were seeded with osteoblasts in a collagen matrix. The samples were cultured up to 21 days and mineralization was monitored using alizarin red S staining and X-ray micro-computed tomography. We have demonstrated the osteoinductive properties of PCL-DCB scaffolds by assessing the de novo bone formation when seeded with adipose-derived stromal/stem cells and stromal vascular fraction (SVF) and implanted in murine critical-sized cranial defects. Murine models of critical-sized bone defects due to disease, degeneration, trauma, and aging, bone loss occurs in the body. Although there have been remarkable improvements in development of functional bone scaffolds, it remains difficult to fabricate porous and biocompatible constructs in physiologically relevant sizes (cm-scale). Herein we developed biomineralized origami-inspired paper scaffolds in three-dimensions (3D). To our knowledge, this work is the first demonstration that paper can be used as a 3D construct to induce template-guided mineralization by osteoblasts. After sterilizing the constructs, they were seeded with osteoblasts in a collagen matrix. The samples were cultured up to 21 days and mineralization was observed for the paste with 10-2% GPTMS, it is expected to be substituted completely with newly formed bone deduced from the results of pig test. In addition, the results of histological observations will be presented on a podium.
Cryogenically Electrosprun Fibrous Sponge Scaffolds as Stromal Extracellular Matrix for Salivary Gland Regeneration

A Multicellular Tissue Model for Vascularized Osteogenesis

A close correlation between vascularization and bone formation in endochondral ossification as maximum extent of bone formation follows maximum levels of VEGF expression. This suggests that osteogenesis and vascularization are coupled by spatiotemporal regulation of paracrine signaling in which the invading vascular endothelial cells secrete osteogenic morphogens to stimulate cell differentiation and bone formation. The objective of this work was to develop a tissue model to investigate the effect of spatial patterning of mesenchymal stem cells and endothelial progenitor cells and spatiotemporal delivery of osteogenic and vasogenic morphogens on vascularized osteogenesis in a 3D culture system. To achieve the objective, a 3D co-culture system was developed consisting of a cell-adhesive, degradable polyethylene glycol matrix with gelatin methacrylate-filled microchannels for patterning of human mesenchymal stem cells (MSC) and endothelial progenitor cells (EPC). MSC were encapsulated in the matrix and a combination of MSC+EPC were encapsulated in the microchannels. Self-assembled polyethylene glycol nanogels (PEG NG) were synthesized for timed delivery of BMP-2 and VEGF morphogens. The osteogenic BMP-2 was conjugated to 1-day release NG and added to the MSC-laden matrix. The vascularogenic VEGF was conjugated to 5-day release NG and added to the MSC+EPC-laden microchannels. The 3D tissue model was cultured in osteogenic-vasogenic medium. At each time point, the tissue model was evaluated for osteogenesis and vasogenesis by biochemical, mRNA, and protein analysis.

Groups included MSC/EPC patterned tissue model without BMP-2/VEGF (None), with dissolved BMP-2/VEGF, and with BMP2-NG/VEGF-NG. Osteogenic control group was MSC encapsulated in degradable PEG gel with BMP-2 or BMP2-NG. Vasogenic control group was MSC+EPC encapsulated in gelatin methacrylate with VEGF or VEGF-NG. Based on the results, the extent of vascularized osteogenesis was higher in patterned constructs compared to un-patterned controls. Further, time-release of VEGF and BMP-2 in the patterned cellular constructs significantly enhanced the extent of vascularized osteogenesis compared to the direct addition of VEGF and BMP-2. We further discovered that the spatial patterning of MSC and EPC and the spatiotemporal of BMP-2 and VEGF sharply increased the expression of vasogenic factors bFGF and PDGF and osteogenic factor TGF-β in the tissue constructs. The results suggest that osteogenesis and vasogenesis are coupled by localized secretion of paracrine signaling factors during bone formation.
Dentinogenic Peptide Hydrogels for Pulpal Regeneration

Endodontic root canal therapy is one of the most common clinical procedures to treat infected dental pulp. This non-regenerative treatment removes the dental pulp as well as the vascular and nerve tissues and replaces them with elastomeric composites, such as gutta-percha. The resulting tooth is devitalized and fragile, which may require additional intervention within 3 years. Our self-assembling peptide hydrogels (SAPHs) aim to establish a regenerative solution to this problem by replacing the inert material used in endodontic therapy with materials that promote dental pulp regeneration. In this work, we have used solid-phase peptide synthesis to create dentinogenic self-assembling peptides that form hydrogels under physiological pH and ionic strength.

Physical characterization of these hydrogels, using circular dichroism, atomic force microscopy, and scanning electron microscopy, revealed that our peptides formed β sheet nanofibers, which in turn are non-covalently crosslinked to create robust hydrogels. We demonstrated the thixotropic nature of these hydrogels through oscillatory rheometry, and further verified their injectability and in situ reassembly into strong hydrogels through in vivo subcutaneous injection studies. In both in vitro and in vivo studies, we were able to show the efficacy of our SAPHs to support and promote the proliferation of dental pulp stem cells. Additionally, in our in vivo studies we observed the infiltration of blood vessels into our hydrogels, suggesting their ability to provide a suitable environment for dental pulp regeneration. The goal of these SAPHs is to provide an improved regenerative alternative to conventional endodontic therapy.

2:15 PM BM04.02.03
3D Self-Foldable Silk-Based Nanoladder Scaffold for Directional Axonal Outgrowth and Functional Regeneration After Spinal Cord Injuries

Neurons are naturally encompassed by a network in a highly aligned manner. After spinal cord injury (SCI) in the central nerve system (CNS), the organized extracellular matrix (ECM) within the spinal cord is profoundly disrupted, which causes axonal regeneration over injury sites challenging due to the lack of orientational guidance. Because of the nature of the spinal cord, bioengineered scaffold in a three-dimensional (3D) format is of great importance for the functional recoveries after injuries. Herein, we report a self-foldable 3D silk-based nanoladder scaffold to mimic the hierarchic structure of the spinal cord with no spatial constraints, comparable mechanical properties, controllable biodegradation rate and sustainable growth factor release. In this study, we fabricated a silk-based nanoladder film with the integration of two scales, micron-meter fibers, and nanoprotrusions. We have proved that micron-meter fibers can provide directional guidance to the regenerated axons, while nanoscale protrusions can serve as mechanical cues to stimulate neurite outgrowth and synapse formation. We further developed the 3D self-foldable nanoladder by coupling the hydrophobic silk nanoladder film with a hydrophilic thermal expanding hydrogel layer. By controlling the biodegradation rate of the 3D nanoladder, a sustainable release of growth factors embedded in the silk film was achieved to trigger the axonal regeneration after injuries. We further applied organotypic spinal cord tissue slices as the ex vivo injured model to demonstrate an enhanced axonal regeneration and functional connection between two slices placed in a distance of 2-3 mm. In all, we suggest that 3D silk-based nanoladder can serve as a grafting bridge to guide axonal regenerations to desired targets for functional reconnections after SCI.

Citrate Chemistry and Biology for Orthopedic Engineering

Citric acid, historically known as an intermediate in the Krebs cycle, is a multifunctional, nontoxic, readily available, and inexpensive cornerstone monomer used in the design of citrate-based biomaterials. In addition to the convenient citrate chemistry for the synthesis of a number of versatile polymers that may be elastomeric, mechanically strong and tough, injectable, photocrosslinkable, tissue adhesive, bioimaging/biosensing-enabled, and/or electrically conductive, citric acid also presents inherent anti-bacterial, anti-clotting, angiogenic characteristics and modulates cellular energy levels leading to facilitated stem cell differentiation, which make citrate biomaterials ideal for a number of medical applications. We have attained a comprehensive new understanding of the citrate roles on osteo-phenotype progression and identified a new mechanism pertaining to the metabolic regulation of citrate to elevate cell energy status for bone formation, referred to as citrate metabolic regulation. This previously unexplored citrate metabolic regulation has allowed us to design new biomaterials to meet the dynamic biological, biochemical, and biophysical needs in bone regeneration. In this presentation, we methodology for the design of biomimetic citrate biomaterials and their applications in regenerative engineering, drug delivery, bioimaging and biosensing will be discussed with a focus on orthopedic engineering.

Multifunctional Biomaterials Containing Amino Acid Based Segments for Tissue Regeneration and Efficient Transfection of Primary Human Cells

Modern medicine requires biomaterials combining multiple functions such as degradability, stimuli-responsivity, cell instructivity or carrier capabilities for bioactive molecules. Complex polymer network architectures are a versatile molecular design for integrating different functions in one material system. Such networks often contain physical netpoints for adjusting mechanical properties or implementing stimuli-sensitivities. For this purpose macromolecules are potentially equipped with chain segments being able to exhibit strong physical interactions. Here amino acid based oligomeric segments are built either from L-lysine disocyanate or from morpholinoacids. Pure oligodepsipeptides, alternating copolymers of an α-amino acid and an α-hydroxy acid, have been selected as a hydrophobic block in segmented polymers in order to achieve strong physical interactions for stabilizing nanoparticles during their formation [1] or for providing high formstability to thermoplastic elastomers. Degradable triblock copolymers having a central oligodepsipeptide block have shown great potential as transfection agent combining high transfection capability with low toxicity [1]. Depsipeptide based multiblock copolymers are suitable for creating soft actuators with excellent performance in shape stability and reversible strain [2]. L-lysine-based oligoacids are incorporated as dangling side chains or crosslinking segments in gelatine based polymer networks. In architectural gelatin-based hydrogels (ArcGel) the local elastic modulus was adjustable independently from the macroscopic compression modulus by the molar ratio of L-lysine disocyanate to freely available amino groups in gelatin. The dynamic alteration of cellular microenvironments accommodating mesenchymal stem cells is studied during degradation. Along with the degradation-related pore growth cell migration and differentiation were followed. The potential of ArcGels for a purely material-induced regeneration was demonstrated in a critical femur defect [3] and a cranial defect [4] in rat models.
properties of the resulting 3D PLA/apatite composite scaffolds are then determined. Second, GelMA photopolymer is synthesized from porcine gelatin and potassium phosphate dibasic to form a precipitate that is mineralized into apatite at physiological pH. The architectural, microstructural, and mechanical

**Nanofibrous Scaffolds with Both MSC-Laden Cell Fibers and Growth Factor-Loaded Fibers for Tissue Regeneration**

Huihua Li, Haoran Sun and Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong.

Tissue engineering scaffolds with biomimetic nanofibrous topography can facilitate the regeneration of tendon and ligament which are fibrous connective tissues composed of specific fibroblasts and aligned nanofibrous extracellular matrix (ECM). As a versatile and effective method to produce nanofibers, electrospinning has been extensively investigated to make nanofibrous scaffolds. Apart from physical cues, biological signaling molecules such as growth factors, are also often used in tissue engineering. Meanwhile, using mesenchymal stem cells (MSCs) for tissue regeneration has many advantages. Among various types of growth factors, basic fibroblast growth factor (bFGF) is a typical biomolecule that upregulate gene expression of tendon and ligament-specific ECM proteins and hence promote the proliferation and differentiation of MSCs toward fibroblasts. Therefore, the combination of incorporating MSCs in a scaffold and having controlled delivery of bFGF in the scaffold should provide a good strategy for tendon/ligament regeneration. MSCs can be encapsulated in fibers via cell electrospinning developed in our group and the fibers can be aligned parallelly in scaffolds to simulate the cell distribution in native tendon/ligament tissue. In this study, multilayered scaffolds consisting of cell fibers and bFGF-containing nanofibrous membranes were fabricated. Bone marrow-derived MSCs were encapsulated in cell fibers while bFGF was incorporated in nanofibrous membranes for its controlled delivery to promote MSC differentiation. Medical grade poly(lactic-co-glycolic acid) (PLGA) was employed for fabricating bFGF-containing fibers in scaffolds. Cell fibers were made from Na-alginate solutions and contained MSCs. The Na-alginate was crosslinked into Ca-alginate using a CaCl2 solution. In in vitro experiments, the constructs with bFGF-containing PLGA nanofibers and MSC-laden cell fibers were cultured for up to 21 days. In day 1, a sodium citrate solution was dripped onto scaffolds to disrupt the crosslinked Ca-alginate cell fibers to release to MSCs. The viability and proliferation of MSCs were studied using LIVE/DEAD assay and MTT assay. On Day 1 and Day 3, the cell viability was all above 90%. MSCs proliferated well during the culture period up to 21 days. The MSCs in scaffolds with encapsulated bFGF proliferated faster than the control group and elongated notably, indicating that MSCs cultured under bFGF release had fibroblasts-like differentiation. The morphology and structure of scaffolds before and after different culture periods were investigated using SEM. Mechanical properties of the constructs were also examined.

**Growth Factor-Laden Microparticles Incorporated into Polyactic Acid/Apatite Composite Scaffolds for Tooth Regeneration**

Growth factors such as bone morphogenetic protein 2 (BMP2) have been found to stimulate the odontogenic differentiation of mesenchymal stem cells (MSCs) of the dental pulp. This is particularly important for the regeneration of the dentin tissue of the tooth. However, the short half-life and poor distribution of growth factors like BMP2 may present problems with high cost and inconvenience due to the need for repeated dose injections to sustain tissue regeneration and healing. Consequently, strategies that combine slow, sustained release of BMP2 with three dimensional (3D) bioactive scaffolds are important for the differentiation of the MSCs into the odontoblast lineage to accelerate dentinogenesis. Herein, we present the results of in vitro studies of the controlled release of BMP2 from gelatin methacrylate (GelMA) microparticles to human dental pulp stem cells (hDPSCs) growing on 3D polyactic acid (PLA)/apatite composite scaffolds. First, 3D printing is utilized to fabricate PLA scaffolds, which are then surface-coated with biomineralized apatite particles synthesized via a bioinspired mineralization process. This involves alternate immersion of the PLA scaffolds in solutions of calcium nitrate and potassium phosphate dibasic to form a precipitate that is mineralized into apatite at physiological pH. The architectural, microstructural, and mechanical properties of the resulting 3D PLA/apatite composite scaffolds are then determined. Second, GelMA photopolymer is synthesized from porcine gelatin and methacrylyc anhydride. After that, BMP2-laden GelMA microparticles are fabricated using an oil-in-water emulsion technique and ultraviolet photor crosslinking. Subsequently, a scaffold/microparticle hybrid construct is produced by the attachment of the BMP2-laden microparticles to the 3D PLA/apatite composite scaffolds. The microstructure of the GelMA microparticles and the release profiles of BMP2 from the microparticles are characterized prior to and following attachment to the PLA/apatite scaffolds and the differences are highlighted. Finally, the effect of the controlled release of BMP2 on hDPSC cells growing on the PLA/apatite scaffolds is investigated. This is done by assessing hDPSC cell proliferation, odontogenic differentiation, and extracellular matrix production and mineralization. The implications of the results for tooth regeneration are then discussed.
Oxygenating Bioinks for Organ-Like Cell Density Constructs

In tissue engineering and bioplotting, the major limitation to building large constructs with physiological cell densities is the poor diffusion of oxygen and nutrients. Organs and many tissues have cell densities in the range 1-5x10^8 cells/ml, yet bioinks can only sustain up to 25x10^6 cells/ml. Oxygen concentration in culture medium is one of the major limiting factors for cell survival and its concentration is about 30 times lower than glucose. This limits the tissue models that can be printed. Furthermore, upon implantation cell survival is dependent on revascularization rate and limit the potential applications in vivo.

Using oxygen releasing microparticles we designed a bioink system capable of prolonging cell survival at high cell density (2x10^7 cells/ml), mimicking physiological organ cell densities.

Oxygen releasing microparticles (OµP) were produced by phase separation method using poly caprolactone (Mw 80000, Aldrich, USA) and calcium peroxide (Aldrich, USA). Particle size measurement was confirmed using field emission scanning electron microscope (FE-SEM, FEI Inspect F-50, USA). The bioink was prepared by mixing 10% (w/v) of OµP in a 1% alginate solution. Oxygen release was measured in 250µL of bioink coinkersed with 0.1M calcium chloride solution and immersed in 1ml PBS at 37°C using an AL300 oxygen sensor (OceanOptics via Gamble Technologies, Canada). Organ-like high density cell culture was performed by seeding a high density (4x10^7 cells/ml) by combining 125µL CHO cells and 125µL of 2% alginate solution alone or containing 20% OµP. The mixture was then extruded through a 20G needle in a 0.1M calcium chloride solution to form 20µL beads. Cells were then cultured for 48h. Cell viability was assessed using MTT.

Scanning electron microscopy revealed that the size of the microparticles ranged from 200µm to 5µm. Oxygen measurements indicated that the dissolved oxygen content of the bioink was kept at 41 ± 5% for 72h. Bioinks with organ-like cell densities without OµP had a cell viability of 27 ± 19% and 13 ± 4.8% at 24 and 48h respectively, whereas with OµP viability was significantly higher at both times; 87 ± 18% and 63 ± 20% at 24 and 48h respectively (N=9, p<0.001).

Lack of oxygen can be detrimental to cell function and survival. In tissues the diffusion of oxygen around a capillary is reported to be around 200µm. By incorporating OµP to a bioink it was possible to create organ-like density construct (2mm thick) with a high viability. This new approach to bioinks may enable printing of more complex and physiologically relevant tissue models.
The extra-cellular matrix (ECM) conveys different biochemical, mechanical and structural cues to cells. These signals are highly orchestrated in space and time. Precise instructions from the ECM dictate cell fate processes, such as proliferation, differentiation and migration. The ECM exerts mechanical forces on cells, which are sensed by cells through different mechanisms, and are translated into biological outcomes. However, these mechanisms are not well understood. One of the main limitations in deciphering this language of forces on cells has been the lack of in vitro systems, which can generate forces on cells that mimic natural stresses.

The present-day methods, which attempt to apply such forces on cells, include single cell manipulation techniques that are highly invasive and although very cell-selective, do not mimic natural stresses. Other techniques rely on the use of flexible elastomers, which better replicate natural stretches, but do not provide user-defined cell selectivity. Therefore, it remains a challenge to develop a system for manipulating cells with mechanical forces, which are precisely controlled in space and time domains.

Here we demonstrate a novel hydrogel system, which can reversibly apply precise, user-defined mechanical forces on selected cells in a cell population. Our approach comprises a smart ECM-mimic hydrogel system, which responds to a light trigger. This causes reversible local deformations of the cell growth substrate and leads to the generation of mechanical forces on cells. These forces are transient and can be controlled at a sub cellular and sub-population scale, in a wide range of time scales (up to ms), with pre-defined directionality.

Such a system for opto-mechanical stimulation of cells is an effective tool for investigating how repeated actuation of a soft hydrogel affects cells. This is experimentally demonstrated in a case study using fibroblast cells to show the proof-of-principle of the concept.

The dynamic hydrogel swelling/shrinking closely replicates the stretches experienced by soft tissues in the body during activities, such as movement, growth etc. We believe that this system bridges the gap between single cell manipulation techniques and cell sheet deformation techniques. This system shows great potential in fields of 'mechano-diseases' and in understanding cell-ECM interactions.

**Improved Antibacterial Properties of Titanium Implants After Acid Etching and Atomic Layer Deposition**  
Paria Ghannadian, James W. Moxley and Thomas Webster; Northeastern University, Boston, Massachusetts, United States.

Despite the progress tissue engineering has made in the development of improved biomaterials, inhibiting bacterial infection has not been a central focus to date. Infection is a leading cause of implant failures with many agencies (such as the Centers for Disease Control) predicting more deaths from bacteria than all cancers combined by 2050. Gram-negative bacteria are naturally resistant to numerous treatments and are difficult to kill due to their robust and hydrophobic outer lipopolysaccharide membrane which helps to prevent the flow of antibiotics or drugs into the cell. Moreover, due to extensive antibiotic use, gram-positive Staphylococcus aureus has evolved to a methicillin-resistant strain, which can overcome other classes of antibiotic treatments. The development of an implant capable of reducing bacterial growth (without resorting to the use of antibiotics which causes antibiotic resistant bacteria) would be an effective way to improve implant success. Recently, scientists have been investigating novel materials and techniques to meet growing orthopedic tissue engineering needs. The first step in implant infection is bacterial adhesion, which can potentially result in the formation of antibiotic resistant biofilms for some species. Bacterial adhesion, growth, and subsequent biofilm formation on surfaces are particularly resistant towards the body’s defense mechanisms and antibiotic treatments, which can cause implant rejection. Multiple substrate properties, including chemical composition, hydrophobicity, and surface roughness, are believed to be of significance in the bacterial attachment process. In this study, multiple titanium samples were etched with different concentrations of nitric acid (10N or 12N) for varying durations (60 or 90 minutes), followed by a consistent and extended heat treatment (400 for one hour) for all samples. As a comparison to these samples, which were modified through conventional acidic etching treatment, another group of titanium samples were prepared by coating with 25 nm of titanium dioxide at 200 for approximately 4 hours through an atomic layer deposition (ALD) technique. To assess the potential effect of both approaches on inhibiting bacterial adhesion, and thus conferring antibacterial properties, samples were cultured with Staphylococcus aureus and colony forming unit (CFU) assays were conducted. ALD treatment, in comparison to conventional acidic etching treatment, demonstrated reduced bacterial density. As such, ALD treatment may pose a promising way to inhibit the growth of infectious bacterial populations, on a vast variety of surfaces and materials, without the need for antibiotics.

**Bio-Plotting Facial Cartilage Replacements**  
Raymond Oliver¹, Michelle Griffin², Peter Butler² and Chawisa Deesomboon¹; ¹School of Design, Northumbria University, Newcastle upon Tyne, United Kingdom; ²Division of Surgery and Interventional Science, Centre for Nanoscience and Technology, London, United Kingdom.

Several diseases include cancer, skin diseases, inflammatory conditions, trauma and congenital deformalities cause ear and nose defects that require reconstruction. Due to the wide patient population that this affects, nose reconstruction creates a huge social and economic burden. Each year, 1/6000 children are born with a small or missing ear, a condition called microtia. This devastating facial disfigurement causes high physical, social and mental burden for both the child and parent. Current surgical reconstruction involves harvesting tissue from elsewhere in the body, to recreate the cartilage framework of the ear and the nose. As such, this is not only painful and time consuming, it is also limited by tissue availability. As such, bio-printing could be an effective way to improve implant success. Recently, scientists have been investigating novel materials and techniques to meet growing orthopedic tissue engineering needs. The first step in implant infection is bacterial adhesion, which can potentially result in the formation of antibiotic resistant biofilms for some species. Bacterial adhesion, growth, and subsequent biofilm formation on surfaces are particularly resistant towards the body’s defense mechanisms and antibiotic treatments, which can cause implant rejection. Several synthetic and biological hydrogels and synthetic polysaccharide composite materials to act as the replacement for the cartilage framework of the ear and the nose. We describe the concepts being developed from 3D to 4D biofabrication using a high precision Bioplotter robot (Envisiontec) to ensure we are creating accurate patient focused auricular and nasal relacements. The bioplotter has proven capable of printing several materials sequentially in very precise locations with and without cells incorporated in the material. Now, in the second stage of our current programme, we are exploring suitable combinations of synthetic and biological material for nose and ear reconstruction, printing of the patient's own cells within the biological component of the material will be optimised. The ability of the cells to survive, grow and support tissue formation is driven by novel laminar(low shear) flow mixing to ensure maximum stem cell survival.

**Peptide-Based Polyelectrolyte for Neural Tissue Engineering**  
Wei-Fang W; Su, Chia-Yu Lin, Jia-Shing Yu and Shy-Chyang Luo; National Taiwan Univ, Taipei, Taiwan.

Neural tissue engineering has emerged as a potential technology to cure neural damages. Although various synthetic polymers with good biocompatibility
and biodegradability are adopted as candidate materials for scaffolds, most of them require incorporation of biomolecules or conductive materials to promote the growth of long axon. Here we propose a peptide-based polyelectrolyte which is conductive and contains neurotransmitter of glutamic acid. The designed copolymer of poly(γ-benzyl-L-glutamate) and poly(L-glutamic acid) sodium salt (PGBA/Na+) is electrosprun into 3D scaffold with aligned fibers. Neuron-like rat pheochromocytoma (PC12) cells are cultured on the scaffolds to evaluate cell proliferation and differentiation. The results show with both electrical and biochemical chemicals, the polyelectrolyte PGBA/Na+ gives longer axon outgrowth and higher differentiation ratio compared with the neutral copolymer of poly(γ-benzyl-L-glutamate) and poly(L-glutamic acid) (PGBA).

**Graphene Oxide as a Drug Carrier for Delivery of Zoledronate in Metabolic Bone Disease and Secondary Bone Cancer Treatment**

Sepideh Takavoli and Duygu Ege, Bogaziçi University, Istanbul, Turkey.

In this study, Zoledronic acid (ZOL), a type of nitrogen containing bisphosphonate, was loaded on graphene oxide (GO) particles to increase the particle size of the drug-nano-carrier complex which reduces drug filtration by the kidney and consequently, increases drug circulation time and its tumor uptake. The conjugation between ZOL and GO occurs via π-π stacking and hydrogen bonding interactions, and therefore, the drug may be gradually released from GO in physiological conditions which eliminates the need to apply high doses of the drug. Loading and release profile of ZOL on GO particles was investigated by using UV-Vis spectroscopy. Samples with different concentrations of 0.025-1.25 mg/ml of ZOL were loaded on 0.2 mg/ml GO. UV analysis showed that the maximum loading happens at ZOL to GO ratio of 1.0:2. This loading was obtained when 1 mg/ml of ZOL was initially loaded on 0.2 mg/ml of GO nanoparticles. The drug and drug carrier complexes were characterized using FTIR, AFM, and UV-Vis spectroscopy. Cell culture studies were carried out with MCF-7 breast cancer cells for three dosages of ZOL, ZOL-GO and GO. Cell migration was assessed using Bio-Coat cell migration chambers and cell proliferation was investigated by alamarBlue assay. Cell viability was evaluated by staining dead cells with propidium iodide (PI) and live cells with acridine orange (AO). Overall, the characterization results confirm loading of ZOL on GO nanoparticles and cell studies results show that GO conjugated ZOL complexes are promising to reduce MCF-7 breast cancer cells migration, proliferation and viability.

**Bioinspired Mineral-Organic Bioreorbable Bone Adhesive**

Alina Kirillova, Cambre N. Kelly, Natalia von Windheim and Ken Gall; Department of Mechanical Engineering and Materials Science, Duke University, Durham, North Carolina, United States.

Bioreorbable bone adhesives have potential to revolutionize the clinical treatment of the human skeletal system, ranging from the fixation and osseointegration of permanent implants to the direct healing and fusion of bones without permanent fixation hardware[1]. With sufficient strength bioreorbable bone adhesives could ultimately become an ideal means for fixing bone fractures instead of conventional plates, nails, pins and screws used today. [2] Despite the evident clinical need, there are currently no bioreorbable bone adhesives in clinical use that can form a bond to bone in a wet environment strong enough to bear clinical loads and sustainable enough to allow fracture healing.[1] Inspired by the sandcastle worm that creates a protective tubular shell around its body by gluing together sand grains and shell fragments underwater using a proteinaceous adhesive, we introduce a novel mineral-organic bone adhesive (aka Tetranite®) that cures in minutes in an aqueous environment and provides high bone-to-bone adhesive strength. The new bioreorbable material is measured to be more adhesive than both bioreorbable calcium phosphate and poly(methyl methacrylate) bone cements, which are standards of care in the clinic today. Osteointegration and bioreosorbability of the bone adhesive are demonstrated over a 25-week period in a critically sized distal femur defect in rabbits. Based on its unique capabilities, Tetranite is the first in a new class of biomaterials, which may spark innovative clinical treatments and revolutionize procedures in which bone regeneration or fixation is critical for treatment.

**Silicon-Based Nanoneedles to Guide and Regulate Stem Cell Behaviour**

Hyejeong Seong1, Stuart G. Higgins1,2,3, Spencer W. Crowder1, Julia Sero2, Jelle Penders1, Charlotte Lee-Reeves1, James Armstrong1 and Molly Stevens1,2,3; 1Department of Materials, Imperial College London, London, United Kingdom; 2Department of Bioengineering, Imperial College London, London, United Kingdom; 3Institute of Biomedical Engineering, Imperial College London, London, United Kingdom.

In recent years, surfaces with nano/micronscale topography have been widely used to control stem cell behaviour. These patterned substrates possess fascinating qualities that render them more valuable than conventional flat surfaces in many bio-applications, such as neuronal differentiation, biosensing, tissue engineering and DNA analysis. Among these, nanopillar and nanoneedle structures have been extensively investigated because they are beneficial in terms of increasing enhancing cell adhesion and growth, and ability to penetrate cells for facilitating drug/biomolecules delivery. We have co-developed high-aspect ratio, porous silicon nanoneedles made by electrochemical wet etching for in vitro and in vivo manipulation of cell behaviour1,2. These structures are highly biocompatible and can be used to directly interact with the cell membrane, cytoskeleton, and nucleus of primary human cells, generating distinct responses at each of these cellular compartments.

Moreover, we have recently developed a new generation of non-porous nanoneedles using a deep reactive ion etching process. Our new system provides high chemical stability in cell culture media, making it suitable for the long-term investigation of stem cell fates and differentiation at a nanoneedle interface. Furthermore, by systematically tuning the sharpness of the nanoneedles, we could precisely probe their effect on cellular mechanotransduction. The structural effect on cell morphology, alignment, and gene-level expression was observed with scanning electron microscopy, immunofluorescence, and real-time polymerase chain reaction. Our findings provide an ideal framework for manipulating and exploiting stem cell behaviour for longer periods, as a means for understanding cell-material interfaces and differentiation capacity of stem cells. Moreover, we used focused ion beam scanning electron microscopy to determine the critical sharpness required to achieve close interaction between the surface and the cell membrane. We expect elucidating the interfaces between nanoneedles and cells to enable new applications in bioengineering, especially in the sensing and monitoring of live cell cultures via 3D-structured electronic devices.

2. C. Chiappini et al., Nat. Mater. 2015, 14, 532-539
Early detection of cancer plays an important role in successful treatment. Therefore, there is an urgent need for more effective and less toxic biomarkers to detect cancer. Cancer cells use exosomes to survive and metastasize to other tissues. Exosomes are small vesicles released to blood by cells, and they can deliver proteomic and genetic information unique to each cell. Therefore, isolating the exosomes secreted by cancer cells can provide us valuable information about the state of a tumor. Since every cell in the body releases exosomes, separating those coming from cancer cells can be a cumbersome task. Current techniques to isolate exosomes are time consuming and costly. Hence, our aim in this study is to use magnetic nanowires (MNWs) to magnetically isolate cancer cells’ exosomes in an efficient way through a simple blood biopsy and a magnetic stand.

In this work, we have used Fe/Au segmented MNWs to separate exosomes released by osteosarcoma cancer cells. These MNWs have been functionalized with PEG, and their concentration has been optimized in order to improve their capture and internalization by the cancer cells. We have observed by TEM that most of the MNWs end up inside the lysosomes in cancer cells. Once inside the cells, these MNWs tend to be broken into smaller pieces that can be released inside the exosomes. This way, by using a magnetic stand, we can easily and efficiently separate only the cancer cells’ exosomes, since they contain segments of magnetic nanowires.

In addition, our Fe/Au segmented MNWs can also be used as customized radio frequency identification (cRFID) labels. MNWs have magnetic (Fe) and nonmagnetic (Au) segments which resemble barcodes, and their structure can be engineered (e.g., by changing the length of each segment) to produce different cRFID signatures. Hence, distinct nanowires can be attached to different types of cancer cells in order to distinguish between the exosomes derived from each type, thereby further improving the efficacy of our blood biopsies.

Electrospun fibrous scaffolds have shown great promise in promoting axon regeneration to improve repair of peripheral nerve defect. Especially, when the fibers are collected as uniaxially aligned arrays, the growth of neurites can be guided and accelerated. Despite the progress, it remains a challenge to place temporally and spatially controlled delivery of biological effectors such as growth factors from the electrospun fibrous scaffold. Such a requirement can be met by integrating electrospun fibers with a controlled release system based upon a stimuli-responsive material. We have developed a temperature-regulated system for the on-demand release of nerve growth factor to promote neurite outgrowth. The system was based upon microparticles fabricated using co-axial electrospray, with the outer solution comprised of a phase-change material (PCM) and the inner solution containing the payloads. When the temperature was kept below the melting point of the PCM, there was no release due to the extremely slow diffusion through a solid matrix. Upon increasing the temperature to slightly pass the melting point, the encapsulated payloads could be readily released from the melted PCM. By leveraging the reversibility of phase transition, the payloads were released in a pulsatile mode through on/off heating cycles. When the PCM microparticles (co-loaded with nerve growth factor and a near-infrared dye) were sandwiched between two layers of electrospun fibers, the nerve growth factor could be released on-demand upon photothermal heating with a near-infrared laser. The nerve growth factor was released with well-preserved bioactivity and stimulated the extension of neurites from spheroids of PC12 cells. By choosing different combinations of PCM, biofactor, and scaffolding material, this controlled release system can be applied to a wide variety of biomedical applications.

Reprogramming cellular functions through the design, fabrication and use of engineered platforms that mimic the physiological cellular environment is a major goal of cell engineering. Indeed, it has been widely demonstrated that the use of 3D systems, compared to 2D, is crucial for a more physiological relevant study of cellular systems, since the third dimension could differently and strongly affect diverse cell functions. However, the precise engineering of 3D systems often results challenging, consequently limiting the control over cellular fate. Here, we report the fabrication of 3D instructive platforms that modulate cellular behaviour in terms of cellular polarization, membrane curvature and uptake capability. By means of two-photon polymerization (2PP) technology, we processed a commercial biocompatible photosensitive to fabricating a cage-like 3D structure capable to entrap cells. We then investigated the cell-material interaction and the effect of different micro-topographies (grooves) on cellular response. To evaluate the effect of such topographies on cellular membrane curvature, we took advantage of the SEM/FIB technology and ultra-thin plasticization (UTP) of cells, which gives the opportunity to directly observe cell-material sections with nanometric resolution. We thus gathered
important information on the relations between membrane curvature and caveola formation, known to be fundamental in endocytosis processes. Moreover, by functionalizing our structures with fluorescent nanoparticles (NPs) we were able to observe how different topographies modulate the cellular uptake by evaluating NPs internalization with confocal microscopy. Our results clearly show that by modulating cellular membrane curvature through specific topographical micro-features, it is possible to tune cellular membrane curvature and, thus, the cellular uptake capabilities. Such results could then give new guidelines for the design of innovative and more efficient delivery systems based on 3D scaffold-like devices.

BM04.03.16 Tunable Visible Light Polymerization of Poly(Ethylene Glycol) Hydrogels for Post-Polymerization Modulation of Material Properties Katherine Wiley, Elisa Ovadia and April Kloxin; University of Delaware, Newark, Delaware, United States.

Synthetic hydrogels, such as those formed with multifunctional poly(ethylene glycol) (PEG) or poly(vinyl alcohol) (PVA) macromers, are of great interest for a variety of biological applications. The high degree of property control that these materials afford, including mimicking the elasticity or ‘stiffness’ of tissues in the human body, makes them particularly useful as biomimetic, multidimensional culture environments for hypothesis testing in studies of disease and regeneration. Traditionally, control of synthetic hydrogel mechanical properties has been achieved with polymer concentration, molecular weight, or reactive group stoichiometry. Recently, the rate of hydrogel formation also was demonstrated as an effective handle for controlling mechanical properties. For example, the rate of hydrogel formation by oxime chemistry was controlled using pH, where the resulting differences in mechanical properties were determined to arise from differences in network heterogeneity (e.g., defects) that depended on the rate of gelation (Zander et al, Advanced Materials, 2015). Inspired by this, in this work we investigated if a rate-based approach for controlling mechanical properties could be used with photoinitiated (lithium acrylphosphate, LAP) synthetic thiol-ene hydrogels (PEG-8-norbornene, PEG-2-thiol) and the resulting defects exploited for temporal property modulation. Specifically, we established a system for hydrogel formation using different doses of visible light (455nm LED, 70-90 mW/cm², 1-10 min) to tune the mechanical properties. We confirmed dependence of hydrogel mechanical properties on factors beyond polymer concentration, including light intensity and exposure time. Elasticity, measured by dynamic mechanical analysis (DMA), indicated that, for precursor solution of the same composition, elasticity increased with both increasing light intensity and exposure time. To better understand the source of defects contributing to differences in hydrogel mechanical properties, end group conversion during hydrogel formation was monitored with magic angle spinning (MAS-NMR) and correlated with mechanical properties over the polymerization time. Through these comparisons, both reduced end group conversion and looping were determined to contribute to differences in mechanical properties observed at different rates of hydrogel formation. Control of end group conversion subsequently was exploited to stiffen hydrogels post-polymerization by covalent incorporation of a secondary thiol-ene network using photopolymerization (365nm, 10 mW/cm²). In sum, we have demonstrated the high level of property control afforded by this visible light polymerization system and the potential utility of this approach for post-polymerization modulation of material properties. This method of modulating properties is promising for studying cell response to dynamic stiffness in three-dimensional culture, with applications in the study of cancer progression and wound healing.

BM04.03.17 Microcapsule Sensors for In Situ Monitoring of pH in Microenvironment Sangmin Lee, Chan Ho Park and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

In-situ monitoring of pH is of great importance in biomedical fields as pH affects activities of enzyme and drug and is a symptom of certain diseases. It is known that the microenvironment of cancer cells is weakly acidic due to the secretion of lactic acid through anaerobic respiration. Therefore, pH can be an effective indicator for cancers. However, it is very difficult to use conventional litmus papers or pH-meters for measurement of local pH in cellular environments. To provide an injectable, implantable, suspendable platform of pH sensors, we suggest a microcapsule-type sensor that is composed of the pH-responsive optical sensor in the core and semipermeable polymer in the shell. As a template to produce microcapsules, monodisperse water-in-oil-in-water (W/O/W) double-emulsion droplets are prepared using a capillary microfluidic device. The innermost water phase water contains molybdenum disulfide (MoS₂) nanosheets whose surfaces are grafted by pH-responsive polymers with a fluorescent group at the distal end. As the middle oil phase, a photocurable resin of polysiloxanes modified with methacrylate is used. The double-emulsion drops are irradiated by ultraviolet, which leads to the polymerization of the resin, forming a semipermeable solid shell. The pH-responsive polymer that links the MoS₂ nanosheets and fluorescent groups are designed to show a drastic conformation change in the range of pH 6.0-7.4. At physiological condition of pH 7.4, the pH-responsive polymer is collapsed so that the fluorescent groups are brought to the optical quencher of MoS₂, yielding a weak fluorescence due to the Förster resonance energy transfer (FRET). By contrast, at cancer microenvironment with pH 6.3, the pH-responsive polymer is highly extended, increasing fluorescent intensity. As the pH sensors are encapsulated by a semipermeable shell, they are free from dilution with physiological fluids and adhesion of proteins and lipids, thereby maintaining the sensing performance in a physiological environment. The microcapsule sensors can be injected, implanted, and suspended in any target volumes, which enables the in-situ monitoring of pH in the microenvironment where the microcapsules are located.

BM04.03.18 Piezoelectric Performance and Biocompatibility of (Ba,Ca)(Zr,Ti)O₃ Ceramics for Biomedical Applications Kara K. Poon¹, Matthias Wurm², Mari-Ann Einsarsh¹, Rainer Lutz² and Julia Glaum¹; ¹Department of Materials Science and Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway; ²Department of Oral and Maxillofacial Surgery, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany.

The replacement of bone tissue in surgical interventions with artificial materials is a standard procedure in current clinical practice, however, it is a substantial surgery with high patient morbidity and high healthcare costs. It is therefore desirable to develop artificial bone materials which induce controlled, guided and rapid healing to improve patient recuperation and which allow for a stable fixation between bone and implant for immediate loading.

Interest in piezoelectric ceramics for biomedical applications has risen in recent years, due to the need for biocompatible materials with active functionalities. Several studies have proposed that osteogenic regeneration may be improved with the application of electrical stimuli. Barium titanate doped with calcium and zirconium, (Ba,Ca)(Zr,Ti)O₃, are a class of lead-free piezoelectric ceramics which generate electric surface potentials under a mechanical load due to its non-centrosymmetric crystal structure. This class of piezoelectric ceramics may serve as bioactive bone replacement materials.

However, the biocompatibility of BCZT is not well established.

In the present study, we investigate the suitability of BCZT as an artificial bone replacement material. Several compositions of bulk BCZT ceramics were synthesised via solid-state synthesis, including a morphotrophic phase boundary composition (MPB) and several other tetragonal compositions. The MPB composition was chosen for its expected high piezoelectric performance, and the tetragonal compositions for the different stabilities in piezoelectric...
BM04.03.19
Adhesion Effect of Elastin-Like Polypeptide-Supplemented Composite Cement on the Tooth Sun-Young Kim1 and Hyun-Jung Kim2; 1Seoul National University, Seoul, Korea (the Republic of); 2Kyung Hee University, Seoul, Korea (the Republic of).

I. Objectives

Elastin-like polypeptide (ELP) has a variety of application in biomedical field. ELPs are composed of repeats of the pentapeptide Val-Pro-Gly-Xaa-Gly; the guest residue Xaa can be any amino acid except Pro. We have tried to improve the mechanical property of dental cement by ELP supplementation in previous studies. Specially, we found the supplementation of ELP increased the adhesion ability of composite cement to tooth. Here, the objective of this study was to investigate the adhesion effect of ELP supplementation on the tooth between the ELP-supplemented dental cement and tooth surface.

II. Materials & Methods

ELP genes either with or without octaglutamic acid termination were genetically engineered: V125 and V125-E8. Pure ELPs were gathered through a series of protein synthesis process using E.coli through gene transformation, expression, protein purification. 10 wt% ELP solutions were then prepared. The crown of human third molar without caries and restorations was horizontally sectioned to have 2mm thickness by high-speed sawing machine (Buehler). Two holes in tooth specimen were made 4.1 mm in height and 1.4 mm in diameter. 0.3 ratio in liquid/powder were prepared: cement + 60mL of either DW, V125, or V125-E8. Mixed cements as given ratio, were loaded at tooth cavities (20 cavities x 3 subgroup) and set in 37°C incubator for 7 days under 100% humidity. Push-out strength of samples were measured in universal testing machine (SHIMADZU, Japan) at a cross-head speed of 1mm/min with compressive mode. Data were analyzed using Two-way ANOVA and Bonferroni’s post-hoc test at 95% significance level.

III. Results

V125-E8 group showed the highest push out strength significantly (p<0.001). V125 group showed lower strength than V125-E8 group, but higher push-out strength than DW group (p<0.001). V125-E8 groups showed significantly less viscosity and high flow compared to other groups. V125-E8 group showed a narrower gap between composite cement and dentin and composite tag in dentinal tubule while other group showed wider gap and no tag inserted in dentinal tubule.

IV. Conclusion

ELP-supplemented dental cement has higher push-out strength than DW-mixed MTA. V125-E8 showed the highest adhesion ability to tooth. The increased adhesion ability might be due to rheologic property through low viscosity and high flowability.

BM04.03.20

Type I collagen forms fibrous viscoelastic networks that comprise a dominant fraction of the extracellular matrix (ECM). Through interactions with single cells and tissues, networks of type I collagen can be remodeled to form anisotropic networks, which are observed in biological processes as diverse as branching morphogenesis and metastatic invasion. However, replicating the structure of anisotropic collagen networks ex vivo is challenging because current collagen fiber alignment techniques are often limited to unidirectional alignment over small mm-scale areas or in thin films. Here, we adapt three-dimensional (3D) microextrusion printing as a technique to fabricate anisotropic networks of type I collagen with tunable fiber alignment and geometry.

Changing the concentration of Matrigel in the collagen-Matrigel ink allowed the geometry of collagen fibers to be tuned. By modifying the aforementioned parameters, we 3D-printed complex patterns of collagen fiber alignment and geometry that were separated by sharp interfaces. 3D-printed networks of type I collagen have great potential for studies that assess the role of collagen fiber alignment in developmental biology and tissue engineering.

Rational Design of Antimicrobial Peptide Nanofibers Bijlal Sarkar1, Steven Park2, Peter Nguyen1, Zain Siddiqui1, Michael McGowan1, David Perlin2 and Vivek Kumar1; 1New Jersey Institute of Technology, Newark, New Jersey, United States; 2Public Health Research Institute, Rutgers, The State University of New Jersey, Newark, New Jersey, United States.

Natural antimicrobial peptides are crucial components of the innate immune system against invading pathogens. Inspired by these natural peptides, we designed a set of cationic amphipathic peptides that can self-assemble into injectable hydrogels. Our self-assembled system employs non-covalent forces to yield hierarchical assembly of these materials capable of disrupting cell membranes of pathogens, such as bacteria (e.g. Pseudomonas aeruginosa) and fungi (e.g. Fusarium solani). The self-assembly of the nanofibrous hydrogel was characterized with spectroscopic techniques as well as high-resolution microscopy techniques such as atomic force microscopy and scanning electron microscopy. We tested the self-assembling peptide hydrogels were tested for compatibility with stromal cells with in vitro cell culture. Moreover, we subcutaneously implanted the hydrogels and observed no systemic toxicity. We screened the antimicrobial platforms against a spectrum of pathogens that were associated with nosocomial infections. In addition, we determined the mechanism through which the nanofibers disrupt the pathogen colonies. The hydrogel can be either be applied as a topical antibiotic or can be integrated into medical devices, such as catheters and grafts. In addition, due to their shear-thinning viscoelastic properties, these hydrogels can be syringe aspirated and injected directly onto or into a target site. The rational design of the nanofiber should provide researchers and clinicians a viable platform to build therapies against multi-drug resistant pathogens that threaten to complicate even the most routine surgical procedures.

BM04.03.22
Biodegradable pH-Activated Polymeric Nanoparticle Modulate Lysosomal Acidification and Autophagy in Parkinson's Disease Jialiu Zeng1,
We have developed a novel polymeric pH-activable, acidifying nanoparticle (acNP) that restores the pH of compromised lysosomes to rescue autophagic flux and cellular function in neurons (PC-12 cells) under exposure to either 1-methyl-4-phenylpyridinium (MPP+) or 6-hydroxydopamine (6-OHDA). Parkinson’s disease (PD) occurs in 13 per 100,000 people in the population, and about 60,000 new cases are identified each year. It is characterized by the accumulation of alpha synuclein (a-syn) within Lewy bodies and neurites of the nervous system in the form of amyloid fibrils. Recent studies have indicated that perturbations in the autophagy-lysosome pathway, especially impaired lysosomal acidification that mediate the degradation of a-syn may play a role in its pathogenesis. Therefore, targeting lysosomal acidity represent a new target for therapeutic development. Although some studies have demonstrated that genetic restoration of autophagy can inhibit the development of PD, to date no effective therapeutic approach has been developed. In this study, we designed an acidic nanoparticle (acNP) that contains caged acid which can be released upon moderate pH changes to enable controlled acidification of the impaired lysosomes under lipotoxicity. The non-cytotoxic acNPs are taken up into the lysosomes of PC-12 cells, rescue cell death caused by MPP+ and 6-OHDA neuro-toxins, restore lysosomal acidity, and decrease the accumulation of autophagic proteins LC3II and p62 expression levels, indicating an overall rescue of autophagic flux. The acNPs also decreased a-syn accumulation in the PC-12 cells, effectively improving the function of PC-12 cell lines. These results established a primary causative role of impaired lysosomal acidification on the de-regulation of autophagic flux and cellular materials that are biocompatible. Towards this aim, we have screened several hundred acrylamide copolymer hydrogels by studying their non-fouling properties to identify top-performing materials that resist protein absorption and blood platelet adhesion. Further, we have examined the biocompatibility of poly(meth)acrylates; however, these coatings suffer from instability and short lifetimes. In contrast, polyacrylamides exhibit remarkable stability and thus are a broad class of polymers, but have been poorly studied as non-fouling coatings, driving the need for the development of novel ultra-low fouling surfaces transferred YAP into the nucleus. These results indicate that the YAP activity can be regulated by the molecular mobility independently of the initial adhesiveness. It had reported that the YAP nuclear localization led to dedifferentiate hepatocytes and impaired hepatic functions [3]. Highly mobile growth factor-tethered PRX surfaces. Previously, we have succeeded in tethering growth factor tethered surfaces. In recent years, we clarified the relationship between the cell differentiation of mesenchymal stem cells (MSCs) and the molecular mobility on PRX coated surfaces (PRX surfaces). The highly mobile surfaces were preferable to adiogenic differentiation, whereas the less mobile surfaces induced their osteogenic differentiation [1]. For the further advancement of the control of cellular behaviors, we designed growth factor tethered surfaces. Previously, we have succeeded in tethering positively charged heparin-binding growth factors onto sulfonated PRX surfaces via electrostatic interaction. The surfaces enhanced osteoblast differentiation by the mobility of PRX and tethering of growth factors [2]. Based on the surface design, we attempted to improve hepatic functions in vitro of hepatic-derived cells (HepG2) in the present study. In particular, a sulfonated PRX triblock copolymer, which consists of a sulfated PRX as a middle block segment and poly(benzyl methacrylate) as both terminal segments, was coated to a polystyrene substrate by a simple casting method. Subsequently, alpha heparin-binding epidermal growth factor-like growth factor (HB-EGF) as a survival factor for hepatic function was bonded to a sulfonated PRX surface. As a control surface, HB-EGF was adhered on a non-sulfonated PRX surface by hydrophobic interactions. For assessing mechanical signalings by the molecular mobility, initial adhesion and subcellular localization of Yes associated protein (YAP) which is an essential transducer of mechanical signals was analyzed by microscopic observation. After 24 h in culture, the number of adhered cells on sulfonated surfaces was almost the same as that on non-sulfonated PRX surfaces, regardless of the molecular mobility. Although highly mobile surfaces suppressed nuclear localization of YAP, less mobile surfaces transferred YAP into the nucleus. These results indicate that the YAP activity can be regulated by the molecular mobility independently of the initial adhesiveness. It had reported that the YAP nuclear localization led to dedifferentiate hepatocytes and impaired hepatic functions [3]. Highly mobile growth factor-tethered PRX surfaces. Previously, we have succeeded in tethering growth factor tethered surfaces. In recent years, we clarified the relationship between the cell differentiation of mesenchymal stem cells (MSCs) and the molecular mobility on PRX coated surfaces (PRX surfaces). The highly mobile surfaces were preferable to adiogenic differentiation, whereas the less mobile surfaces induced their osteogenic differentiation [1]. For the further advancement of the control of cellular behaviors, we designed growth factor tethered surfaces. Previously, we have succeeded in tethering positively charged heparin-binding growth factors onto sulfonated PRX surfaces via electrostatic interaction. The surfaces enhanced osteoblast differentiation by the mobility of PRX and tethering of growth factors [2]. The highly mobile surfaces were preferable to adiogenic differentiation, whereas the less mobile surfaces induced their osteogenic differentiation [1]. For the further advancement of the control of cellular behaviors, we designed growth factor tethered surfaces. Previous
surfaces would be suitable to maintain or enhance the functions. In order to evaluate the functions, albumin secretion from HepG2 on surfaces was quantified. Highly mobile sulfonated PRX surfaces with tethered HB-EGF induced the highest secretion of albumin among all culture conditions. These results strongly suggest the synergistic effect of the mobility of PRX and tethering of HB-EGF via electrostatic interactions.

Synthesis of Selenium-Incorporated Alpha-Tricalcium Phosphate and Evaluation of Its Cement-Type Reactivity
Bersu Bastagiul1, 2 and Caner Durukan1, 2
1Metallurgical and Materials Engineering, Middle East Technical University, Ankara, Turkey; 2BIOMATEN Center of Excellence in Biomaterials and Tissue Engineering, Middle East Technical University, Ankara, Turkey.

Alpha-tricalcium phosphate (α-TCP) is a promising hard tissue analog due to its cement-type hydraulic conversion to the mineral component (calcium deficient hydroxyapatite, CDHAp) of natural bone tissue. A variety of different inorganic and organic agents can be incorporated to α-TCP in order to enhance its regenerative and regenerative properties. In this study, an ionic incorporation - selenium (Se) - was accomplished to impart anti-carcinogenic property to α-TCP. Se-incorporated α-TCP (α-TCP:Se) was obtained by a solid-state reaction of custom synthesized Se-incorporated mononette (CaHPO₄:Se) and calcium carbonate (CaCO₃) precursors at 1200 °C for 2 h. The effect of Se-incorporation on crystal structure of α-TCP and on its cement type hydraulic reactivity at 37 °C was investigated in detail by crystallographic analysis (Rietveld refinement) and by isothermal calorimetry, respectively. At low amount of Se-incorporation (< 5 wt%), α-TCP remains phase pure, however relatively higher amount of Se addition (10 wt%) leads to formation of β-polymorph of TCP lacking the cement-type setting behavior. The SEM examinations showed that the morphological properties of α-TCP remain unaffected after doping with Se. However, Se-incorporation occurs at a limited extent, lower than the theoretically expected values as revealed by spectroscopical analyses. Se-incorporation does not change the reticulated needle/plate like morphology of the CDHAp, which is characteristic to cement-type hydration and hardening. Se-incorporated TCPs fully convert to CDHAp, but Se-incorporation changes the reaction kinetics and mechanic path for α-TCP to CDHAp cement conversion and higher amount of Se addition slows down the reaction kinetics. The results imply that an optimal Se amount is critical to preserve intrinsic cement nature/behavior of α-TCP.

BM04.03.27
NanoComposite for Wound Dressing Applications Obtained by 3D Printing

Infection in exposed wounds is one of the most important factors affecting wound healing. Thus, antimicrobial engineered biomaterials have been addressed in clinical applications for regenerative medicine [1]. Wound dressings used in the treatment of diabetic foot ulcers, affliction causing 85 % of non traumatic lower limb amputations, may prevent infections and possible amputations providing an environment to improve wound healing [2]. Herein, a 3D printed novel nanocomposite with tissue regeneration and antimicrobial properties constituted by a bacterial cellulose (BC) membrane and a biocompatible polymer matrix was produced. BC presents attractive applications, especially in the medical area due to its high degree of crystallinity, purity, reticulated conformation, biodegradability and biocompatibility [3]. For this research, BC was obtained from mango pulp, an industrial waste used in the formulation of alternative culture media. In addition, BC membrane was supported by biocompatible polymers (polycaprolactone and poly(vinyl alcohol)) at varying ratios and functionalized with grapefruit seed extract to enhance antimicrobial properties and durability. Physico chemical properties of the nanocomposite were analyzed by SEM, TGA, FTIR, tensile testing and water holding capacity techniques. In vitro assays consisted of evaluating biocompatibility, viability, antimicrobial and antifungal activity. In vivo studies comprised the analysis of intracutaneous reactivity, cytotoxicity, and mutagenic activity. As BC membranes exhibit biocompatibility properties, high mechanical resistance in wet conditions, high capacity for hydration and permeability of liquids and gases; in addition to the null or low irritation that causes to the skin, these membranes are a useful material in the care and regeneration of cutaneous wounds [4]; complementing the BC membrane with biopolymers and an antimicrobial agent to create a nanocomposite suggests the biocompatibility and bioactivity behavior may increase. Hence, the developed nanocomposite may be used in diverse regenerative engineering applications such as wound dressings.

Integrated Design Scheme Based on Mechno-Biology and Level Set Based Topology Optimization for Bone Scaffolds
Mehmet S. Aydin1, 2, Busra Kaloglu1, Caipa Sipahi1, Berkay Cayir1 and Guliu Kiziltas1, 2; 1Sabanci University, Istanbul, Turkey; 2Sabanci University Nanotechnology Research and Application Center, Istanbul, Turkey.

One of the key requirements of scaffolds is the balance between mechanical function and mass transport to aid biological delivery and tissue regeneration. Computational topology design and Solid Free-Form Optimization methods can overcome this challenge. In this work, we developed a computational design tool based on the integration of the level set method and mechano-regulatory models for optimizing scaffolds based on desired multi-functionality including elasticity, diffusivity, and permeability as well as tissue differentiation. First, for the level set method, computational models are implemented using COMSOL Multiphysics which provides the opportunity to build an FEA (Finite Element Analysis) model where various boundary value problems are coupled and studied at the same time to reach an optimally performing tissue. Response of the scaffold is analyzed using solid mechanics, general form PDE and fluid flow modules. These modules are integrated to resolve respective governing equations simultaneously. Level-set method is performed by utilizing Hamilton-Jacobi equation in the general form PDE module. A initial level-set surface is updated according to the sensitivity of the desired metrics with respect to material parameters. The change in the level-set surface is automatically reflected on the scaffold structure and an optimum structure with desired stiffness, porosity and diffusivity is obtained by finding an optimum level-set surface. As a second capability, the level set based topology scheme is integrated to a self-healing simulation capability, via a mechano-regulatory model developed to mimic tissue regeneration. For the topology optimization design method the level-set method is employed, where the design process starts with an initial geometry that satisfies physical constraints. At each time step, this geometry is improved based on sensitivity analysis results until convergence is reached. Results of both the mechneregulatory and the topology optimization methods validate well-known benchmark design problems in literature. One design that resulted from the integrated framework on both is successfully fabricated using non-solvent-induced phase separation and 3D printing. Characterization studies using micro-CT and mechanical testing are underway. Finite element method integrated to the level-set based topology optimization is proven to be among the most computationally efficient and generic design tool for solving non-intuitive tissue engineering problems. Hence, the proposed design framework,
Brain pathologies often arise from the dysfunction of specific neural circuit nodes. Interrogation of these nodes is a primary goal of neuroscience research. Reliable targeting of these microstructures can be difficult, however. Nodes are often small (sub-mm) and irregularly shaped. Current approaches employ stereotactic mapping and rely on large (>300μm) guide cannulas to ensure minimal deflection of probes during insertion. Such techniques can result in extensive glial scarring. This can substantially modify the local microenvironment to be investigated and limit chronic viability of implants. This is especially the case for fluidic targeting and drug delivery. Acutely inserted needles used for drug microinfusions (100nl-2μl) are large (23-25G), causing insertion trauma and backflow of infusate.

We present a toolkit for manufacturing multimodal neural probes (termed Miniaturized Neural drug Delivery systems (MiNDs)) for use in both small and large animal models. Probes can be customized according to desired functionalities. Here we show in vivo functionality of MiNDs containing fluidic and electrical functionalities and an MRI-compatible MiNDs with 2 fluidic channels in a 200μm footprint. We also report the ability to independently insert and steer individual 60μm fibers of various materials, allowing access to multiple brain sites from a single burr hole. We characterize the mechanical insertion properties of different probe sizes and materials, elucidating the various advantages of each. The microinvasive footprint of the probes limits gliosis and enhances neural regeneration, allowing for chronic viability and functionality up to 1 year post-implantation.

High sensitivity MicroPET was used to characterize distinct infusion dynamics of nanoliter fluid infusions through chronic implants, emphasizing the ability to finely tune volume to target brain microstructures. We supported this by inducing volume-dependent behavior modulation in rodents with unilateral stimulation of GABA circuitry in the substantia nigra. These techniques are readily transferable to other laboratories seeking to develop custom neural probes for multimodal chronic neural interfacing. MiNDs is a powerful tool for the dissection of deep brain microstructures in small and large preclinical models.

Cancer is an uncontrolled disease affecting millions of patients a year. To overcome the critical drawback of conventional therapies, targeted-therapy has gained attention as next generation strategy to cure cancer patients with less toxicity. Among many designs, biological material based nucleic acid as drug agent was demonstrated by numerous groups from early 2000s. Small interfering RNA, or siRNA, is non-coding short RNA molecules capable of regulating protein expression using RNA interference machinery. Utilizing siRNA as biological drug to repair cancerous metabolism caused by mutated protein has resulted in positive outcome with anti-cancer effects in pre-clinical experiments and clinical trials. In fact, siRNA therapeutics by Alnylam Pharmaceuticals is FDA-approved for clinical use for respiratory syncytial virus infections. However, the delivery of siRNA has been major hurdle in translating the efficacy in various cancer patients. Here, we incorporated nanoparticle to enhance the delivery of siRNA to target tumor sites under systemic administration. Bio-compatible and bio-degradable glycol chitosan was self-assembled with polymerized siRNA to form stable delivery complex to tumor sites to downregulate oncogenic expression. Phosphoinositide 3-kinase (Pi3K) and Ras are the most commonly activated oncogenic pathways in solid malignancies and have interdependent relationship via feedback loop system. Many previous reports have shown that dual-inhibition of Pi3K and Ras pathway has therapeutic effects in various cancer models. Though use of multi-drug achieves simultaneous inhibition of specific pathways, undesired side-effects and resistance occasionally occur from collision of pharmacokinetics of small molecule inhibitors. In addition, currently none of Ras inhibitor is potent enough for pathway inhibition, instead secondary inhibitor on downstream protein, MEK, is more commonly used. Here, we used siRNA therapeutics in collaboration with pan-Pi3k inhibitor to demonstrate anti-tumor effects in ovarian cancer. Ovarian cancer cell line with PTEN deficiency and Kras(G12D) mutation were obtained from spontaneous tumor model to examine synergistic effect of Pi3k and Ras inhibition. In cellular level, GDC and siKRAS impeded the activity of Pi3k activity and expression of Ras, respectively. When both pathways were simultaneously inhibited, cell proliferation and migration significantly delayed. In allograft ovarian cancer model, tumor sizes were critically reduced when both Pi3k and Ras were inhibited together. The immunoblot and immunohistochemistry results verified that that dual-inhibition impeded tumor growth and induced apoptosis. Here, we demonstrate that combination inhibition of Pi3k and Ras using different treatment strategies is an exceeding alternative over conventional single-agent treatments.
Conclusions: Nanoparticles or 3D-printed constructs releasing drugs could constitute a therapeutic promise to combat metastatic spine tumors. Nanoparticles can be integrated into commercial bone cements to develop a bioactive bone graft following bone tumor resection to deliver localized drug facilitating bone stability and healing while preventing tumor recurrence. Likewise, 3D printed scaffolds can be made to perfectly fit patients’ defect sites while at the same time be loaded with chemotherapeutics to block cancer recurrence and promote bone repair.

BM04.03.32
Development of Biodegradable Polyurethane Elastomers with Chain Regulators for Bone Tissue Engineering Retul S. Yasar1 and Eda Ayse Aksoy1, 2; 1Faculty of Pharmacy, Department of Basic Pharmaceutical Sciences, Hacettepe University, Ankara, Turkey, 2 Institute of Science, Department of Polymer Science and Technology, Hacettepe University, Ankara, Turkey.

Bone injuries necessitate the use of scaffold-based tissue engineering approaches and development of hard tissue supports and innovative biomaterials are important. In this study it is aimed to develop novel biodegradable polyurethane elastomers as based bone regenerative films. For this purpose, firstly synthesis of polyurethane prepolymer were studied and condensation polymerization between polycapro lactone diol and hexamethylene diisocyanate monomers were carried out. Monomer ratios, catalyst amount, synthesis time and temperature were changed and obtained prepolymer were characterized according to their chemical properties, average molecular weights and solubility in solvent systems. During the second step of polymerization with chain regulators were integrated in to diisocyanate-terminated polyurethane prepolymer via their difunctional groups. As chain regulator agent organic and inorganic compounds and an amino acid molecule were used. The chemical, thermal, viscoelastic and surface free energy of chain regulated polyurethane films were investigated by FTIR, DSC, TGA, DMA and goniometer, respectively. The bioactive chain regulator containing polyurethanes had shown of urethane, urea hydrogen bonds and provided all the transitions of viscoelastic behavior. Biodegradation behaviors were examined in enzymatic and oxidative media in 75 days period. The bioactive chain regulator containing polyurethanes have showed surface erosion type of biodegradation and over 20 % and 60 % weight loss were recorded gravimetrically in oxidative and enzymatic medias respectively. Significant and positive findings were obtained for the developed biodegradable polyurethane elastomers as bone regenerative film.

Nano- and Microfabricated Hydrogels for Regenerative Engineering Ali Khademhosseini; Department of Bioengineering, Chemical Engineering, Radiology, University of California, Los Angeles, Los Angeles, California, United States.

Engineered materials that integrate advances in polymer chemistry, nanotechnology, and biological sciences have the potential to create powerful medical therapies. Our group aims to engineer tissue regenerative therapies using water-containing polymer networks, called hydrogels, that can regulate cell behavior. Specifically, we have developed photocrosslinkable hybrid hydrogels that combine natural biomolecules with nanoparticles to regulate the chemical, biological, mechanical and electrical properties of gels. These functional scaffolds induce the differentiation of stem cells to desired cell types and direct the formation of vascularized heart or bone tissues. Since tissue function is highly dependent on architecture, we have also used microfabrication methods, such as microfluidics, photolithography, bioprinting, and molding, to regulate the architecture of these materials. We have employed these strategies to generate miniaturized tissues. To create tissue complexity, we have also developed directed assembly techniques to compile small tissue modules into larger constructs. It is anticipated that such approaches will lead to the development of next-generation regenerative therapeutics and biomedical devices.

8:30 AM *BM04.04.02
Decellularized Extracellular Matrix Based Hydrogels for Regenerative Engineering Karen L. Christman; University of California, San Diego, La Jolla, California, United States.

The extracellular matrix (ECM) is nature’s scaffold, and in recent years, researchers have isolated these scaffolds for tissue engineering applications by removing all of the cellular components, a process called decellularization. These scaffolds are known to promote cell influx, regeneration, and healing in a variety of tissues, and their degradation products have angiogenic, chemoattractant, and antimicrobial properties, as well as promote cell proliferation. By removal of the cellular antigens, these scaffolds are considered biocompatible, and xenogeneic sources can be used. While these scaffolds retain the native ECM structure, they are not amenable to minimally invasive, injectable procedures. We have developed a variety of injectable ECM derived hydrogels that self-assemble to form porous, nanofibrous scaffolds once injected in vivo or brought to physiological conditions in vitro. These ECM based scaffolds have been shown to increase tissue specific differentiation and maturation of a variety of progenitor and stem cells in vitro, and are showing promise in vivo in several tissues including the myocardium and skeletal muscle. This talk will cover the recent progress with these materials.

Self-Assembling Peptide Hydrogel for Enhanced Cholesterol Uptake Biplob Sarkar, Peter Nguyen, Zain Siddiqui and Vivek Kumar; New Jersey Institute of Technology, Newark, New Jersey, United States.

Blocking proprotein convertase subtilisin/kexin type 9 (PCSK9) is an important therapeutic target for lowering circulation of low density lipoprotein (LDL) particles, which can improve cardiovascular health. We have developed a self-assembling peptide hydrogel that can bind PCSK9, leading to increased uptake of LDL particles in the liver cells. The cholesterol-lowering therapeutic hydrogel may be locally applied/implanted for sustained release. The
The cultivation is expected to be useful for studying in vitro model of nerve injury and regeneration. Local damage was observed at the illuminated spot. The developed method that can manipulate neurite outgrowth by photothermal stimulation even during damage by applying photothermal stimulation to neurites directly. NIR beam was focused on the neurites that grew along the melted agarose channel and hydrogel was successfully melted by localized heat of GNRs under NIR illumination. Through the micro-sized channel produced by the melted agarose, the neurites grew in contact with the gold-coated substrate following by photodeposition of Ppy using a current density of 0.3-0.9 mA/cm² for 60-240 sec. The resultant gradients are characterized by fluorescence microscopy and Energy Dispersive X-ray Spectroscopy (EDS) analysis and are compared to theoretical model of diffusion. The fluorescence imaging of both the hydrogel stamp and the corresponding deposited CP film demonstrate that the profile of molecular gradient within the hydrogel is time-dependent. These results are further confirmed using EDS analysis. The present approach can be effectively applied to generate CP films of various geometries with controlled molecular gradients for guiding cellular behavior for tissue engineering purposes.

Photoclickable thiol:norbornene poly(ethylene glycol) (PEG) hydrogels are promising for in situ delivery of chondrocytes to promote tissue regeneration in focal cartilage defects. This platform offers a high degree of tunability through the introduction of thiolated matrix components and growth factors, achieving a range of mechanical properties and degradation behaviors with spatiotemporal control offered by photo-polymerization. In particular, degradation is critical for allowing the transition from hydrogel to neo-tissue as cells secrete new extracellular matrix (ECM) molecules. Using a combined experimental and computational approach to design degradable hydrogels, we have identified two mechanisms that facilitate the transition from gel to neo-tissue: 1) interactions between the cell and polymer precursors, which reduce crosslinking near the cell and 2) cell clusters, which enable early localized tissue growth and eventual connection to form neo-tissue. This work aimed to identify the interplay of cell clusters and heterogeneous crosslink density and its influence on neo-cartilage growth in PEG hydrogels.

We defined three parameters: \( R_x \), the distance over which the crosslink density varies from the cell membrane to the bulk gel; \( F \), the volume fraction of clusters relative to the total construct volume; and \( c_z \), the ratio of cluster cell density to the background cell density. Computationally, we identified that gels with high \( F \) and \( c_z \) led to interconnected ECM prior to reaching reverse gelation due to an overlapping \( R_x \). Experimentally, we developed methods to induce cell clusters via agitation pre-encapsulation. The ratio of clusters to single cells was controlled pre-encapsulation in hydrolytically degradable gels enabling the cluster size to be varied while holding \( F \) and \( c_z \) constant. When cultured for 4 weeks, there was no difference in ECM deposition measured by sulfated glycosaminoglycans (sGAGs) and collagen as a function of cluster size. Moreover, the modulus decreased from ~20 kPa to ~5 kPa indicating an overall loss in gel without sufficient matrix production. However, the gel was expected to reach reverse gelation prior to 4 weeks indicating that the little ECM produced had formed enough of a connected network to maintain the construct, which was supported by histology imaging for collagen and sGAGs. The clinical viability of the constructs was tested over longer times in in vivo experiments by placing cellular gels subcutaneously in nu/nu mice. TGFβ3 was immobilized in gels to help support and maintain the chondrogenic phenotype. With a 9 week culture there was a ~2x increase in the modulus of the gels compared to a 25% decrease in in vitro gels.

To conclude, we combined experimental and computational methods to identify that heterogeneous distribution of cells and crosslinks contribute to the transition from hydrogel to neo-tissue. We are able to induce clusters and design gels that promote tissue formation.

To control the position of neurons and connection of their neurites on culture substrates, various cell-attractive or cell-repellent materials have been used for micropatterning techniques. However, when neurons are cultured on an engineered substrate fabricated by conventional patterning methods, it is difficult to change their patterned distribution again during the cultivation. In this study, we utilized gold nanorods (GNRs) that has the property of photothermal effect in the near-infrared (NIR) region to fabricate thermoplasmonic interface on a culture substrates. By integrating this interface with a micropatterning method using thermosensitive agarose hydrogel, we demonstrate the manipulation of neurite outgrowth even after the neuronal cultures formed confined networks. GNRs, which was synthesized by seed-mediated method, were immobilized on glass culture substrates through the electrostatic binding. Following by poly-D-lysine coating on the thermoplasmonic interface for neuron attachment, agarose hydrogel was patterned using micro-molding in capillary method to fabricate micro-sized square wells. On the patterned substrate, E18 hippocampal neurons were seeded and they connected each other only within individual agarose wells because of the repellency of the hydrogel for cell adhesion. At one or two weeks after cell seeding, agarose hydrogel was successfully melted by localized heat of GNRs under NIR illumination. Through the micro-sized channel produced by the melted agarose, the neurites extended from neuronal networks in agarose wells. We also show that the heat generated from GNRs can be used for inducing localized neurite damage by applying photothermal stimulation to neurites directly. NIR beam was focused on the neurites that grew along the melted agarose channel and local damage was observed at the illuminated spot. The developed method that can manipulate neurite outgrowth by photothermal stimulation even during the cultivation is expected to be useful for studying in vitro model of nerve injury and regeneration.
Hydrogels are attractive matrices for delivering mesenchymal stem cells (hMSCs) for cartilage repair given its injectability and tunable properties. However, conventional hydrogels often result in slow cartilage formation due to the time needed to degrade and remodel the original hydrogel network. Our group has recently reported sliding hydrogels with molecular mobility as a novel 3D cell niche, which is characterized by mobile crosslinks and biochemical ligands, and enable cells to reorganize biochemical ligands and protrude in 3D hydrogels. The goal of this study is to develop sliding hydrogels with tunable mobility and biochemical ligands to evaluate the effect of introducing molecular mobility and varying biochemical ligand types on modulating cartilage formation by MSCs in 3D. Previous studies show that HyA hydrogels support vascular network formation via optimized ligand density, heparin-mediated growth factor tunable mechanical and biological properties. Accordingly, we have developed HyA hydrogels to assess the effects of adhesion ligand presentation, matrix microdroplets of the pre-gel solution. The ejected microdroplets were solidified into hydrogel microparticles by crosslinking using ionic reaction, culture and tissue encapsulation for in vivo implantation. Here I introduce recent progress on simple centrifuge-based techniques for synthesizing 3D. While previous study has suggested that HAVDI incorporation into hyaluronic acid-based hydrogels enhanced chondrogenic differentiation and cartilage matrix production and deposition by MSC in 3D, MSCs were encapsulated in sliding hydrogels crosslinked by MβCDNecleopatide (COPGQIGWGC) to allow cell-mediated degradation. To assess the effect of varying ligand types in sliding hydrogels on MSC chondrogenesis, two types of biochemical ligands (1 mM) were incorporated into sliding hydrogels including CRGDS and N-cadherin mimicking peptide HAVDGGGC. Molecular mobility in non-degradable sliding hydrogels substantially accelerated and enhanced cartilage matrix deposition by MSCs in 3D. Incorporation of cell-mediated degradation synergized with molecular mobility, and further enhanced neo-cartilage formation throughout the hydrogels. Compared to no ligand control, CRGDS significantly inhibited the chondrogenesis of hMSCs, as shown by downregulations of cartilage markers as well as decreased SaGAG deposition in 3D. Our results validate sliding hydrogels as promising matrices for enhancing stem cell-mediated cartilage regeneration, and provide a materials tool to uncover the novel role of molecular mobility in modulating stem cell differentiation and tissue formation in 3D. Our group has recently reported sliding hydrogels with molecular mobility as a novel 3D cell niche, which is characterized by mobile crosslinks and biochemical ligands, and enable cells to reorganize biochemical ligands and protrude in 3D hydrogels. The goal of this study is to develop sliding hydrogels with tunable mobility and biochemical ligands to evaluate the effect of introducing molecular mobility and varying biochemical ligand types on modulating cartilage formation by MSCs in 3D. Future studies will further examine the effects of varying the types and density of mobile ligands on modulating chondrogenesis in 3D. Our results validate sliding hydrogels as promising matrices for enhancing stem cell-mediated cartilage regeneration, and provide a materials tool to uncover the novel role of molecular mobility in modulating stem cell differentiation and tissue formation in 3D. Long-Term Maintenance of an Mesenchymal Stem Cell Niche Through Self-Assembly of Injected Monodisperse Hydrogel Particles into a Microporous Scaffold

Jaekyung Koh1, Donald Griffin2, An-Chieh Feng3, Thomas Horn1, Michael Margolis1, Hamed Haddadi1, Tatiana Segura5, Philip Scumpia1 and Dino Di Carlo1, 2; 1Department of Bioengineering, University of California, Los Angeles, Los Angeles, California, United States; 2Department of Biomedical Engineering, University of Virginia, Charlottesville, Virginia, United States; 3David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, California, United States; 4Jonsson Comprehensive Cancer Center, University of California, Los Angeles, Los Angeles, California, United States; 5Biomedical Engineering, Duke University, Durham, North Carolina, United States. Rate of migration and proliferation of BMSCs into microporous scaffolds could be modulated by adjusting mechanical properties. The scaffold made from these monodisperse (CV < 5%) particles yielded increased expansion and retention of embedded MSCs. Therefore, this new class of injectable microporous biomaterial should accelerate the development of stem cell therapies by creating an injectable microenvironment for self-renewal and expansion.

Mesenchymal stem cell (MSC) therapies hold promise for numerous intractable diseases arising from their immunosuppressive and tissue repair properties. However, systemic administration, the most common delivery method in clinical settings, suffers from poor survival and engraftment of transplanted stem cells. Moreover, loss of stem cell properties of the engrafted cells due to the unique environment in regenerating tissue can decrease therapeutic effects. Local delivery of MSCs using biomaterial has shown promising results. Ideal materials should deliver cells in a minimally invasive manner, enhance viability during and after transplantation as well as creating a microenvironment that stimulates self-renewal and expansion. Naturally-derived extracellular matrix (ECM) components, including Matrigel, have been applied but their high variability potentially impacts the reproducibility of the therapy. Artificial hydrogels with a high degree of tunability enable reliable and precise control of biophysical properties. However, the nanoscale porosity confines cells, thus interfering with migration, proliferation and cell-cell communication. Introduction of microscale porosity (e.g. through introduction of porogens) often compromises the ability to modulate mechanical properties and injectability of the hydrogel scaffold independently.

Here, we describe the development of an injectable microporous stem cell niche using microfluidically-generated monodisperse modular hydrogel particles. Delivered with MSCs, these particles are enzymatically assembled in situ, generating a highly-controlled interconnected microscale pore space, where cells can easily migrate and proliferate, leading to enhanced survival of transplanted cells. Moreover, the properties of the particles, including stiffness, degradability and cell binding motif concentration, can be modulated independently. By modulating these properties, the microporous scaffold can mimic the natural ECM for high maintenance of stem cell properties.

The scaffold made from these monodisperse (CV < 5%) particles yielded increased expansion and retention of embedded MSCs in vitro and in vivo. The diffusivity through the scaffolds for small molecules (0.3kDa) and large proteins (70kDa) was 70% and 40% respectively of that through pure buffer. Bone-marrow-derived C57BL/6 mouse MSCs incorporated in the scaffold expanded at a rate 7-fold faster than cells in the nanoporous scaffolds over the course of two weeks. The retention of subcutaneously injected MSCS in vivo was 4-8 times higher than with the nanoporous scaffold or PBS over a two-week period. We also demonstrated that scaffolds with 2.5kPa modulus and 2.5mM RGD concentration particles showed the highest retention of stemness of MSCS. Therefore, this new class of injectable microporous biomaterial should accelerate the development of stem cell therapies by creating an injectable microporous niche that enhances function.

SESSION BM04.05: Polymeric Biomaterials for Regenerative Engineering I

Nanoengineered Biomaterials for Regenerative Medicine

Akhilesh K. Gaharwar; Texas A&M University, College Station, Texas, United States.

Two-dimensional (2D) nanomaterials have gained unprecedented attention due to their unique atomically thin, layered, and well-defined structure. As the dimensions of 2D nanomaterials are only a few nanometers thick, they interact with biological moieties in a unique way and have raised exciting questions about their interactions with cellular components. We have used next-generation sequencing technology (RNA-seq) to understand the effect of a synthetic 2D nanomaterials (nanosilicates) on human stem cells at the whole transcriptome level. Our results identify more than 4,000 genes that are significantly affected, and several biophysical and biochemical pathways that are triggered by nanosilicates treatment. This approach in understanding nanosilicates-cell interactions, illustrates how change in transcriptomic profile can predict downstream effects following nanomaterial treatment. Based on our transcriptomic data, we will demonstrate the application of nanosilicates towards bone and cartilage tissue engineering. The high surface area and charged characteristics of 2D nanomaterials is leveraged for sustained and prolonged delivery of pro-angiogenic molecules to stimulate angiogenesis. We have also evaluated the application of nanosilicates in the emerging field of 3D bioprinting to print complex organ and tissue.

Hybrid Nanogels with Self-Integrated Plasmonic Nanoparticles for Light-Induced Molecular Delivery

Seungki Lee, Jung A Kwon, Yunjeong Lee, Hyo Sil Kim, Chang Min Jin and Inhee Choi; University of Seoul, Seoul, Korea (the Republic of).

Nanoscaled hydrogel (nanogels) have drawn much attention as one of the promising materials in developing drug delivery system. Owing to superior water swelling property, nanogels are profitable to load large amounts of molecules including drugs, growth factors, and genes. Recently, many efforts have been made to develop hybrid nanogels which exhibit multi-functions and stimuli-responsive characteristics as well as encapsulation of the molecules. Herein, we present a novel method for synthesizing light (or heat)-responsive hybrid nanogels composed of biocompatible polymers, plasmonic gold nanoparticles, and thermo-responsive linkers (e.g., N-isopropyl acrylamide or N-vinylcaprolactam). We systemically characterize the physicochemical properties including size, shape, surface functionality, and light and thermo-responsive properties. By using the optimized hybrid nanogels, we demonstrate light-induced releases of the encapsulated molecules via photothermal-conversion effect of the embedded gold nanoparticles. Furthermore, we achieve the successful light-induced molecular delivery into the live cells. We envision that the proposed light-responsive hybrid nanogels would be beneficial materials in developing new drug delivery systems and further applying to regenerative engineering.

Optical Cell Manipulation Using Biomaterial-Based Photodegradable Hydrogels

Shinji Sugiuira; Biotechnology Research Institute for Drug Recovery,

States; 2Department of Biomedical Engineering, University of Virginia, Charlottesville, Virginia, United States; 3David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, California, United States; 4Jonsson Comprehensive Cancer Center, University of California, Los Angeles, Los Angeles, California, United States; 5Biomedical Engineering, Duke University, Durham, North Carolina, United States.

Here, we describe the development of an injectable microporous stem cell niche using microfluidically-generated monodisperse modular hydrogel particles. Delivered with MSCs, these particles are enzymatically assembled in situ, generating a highly-controlled interconnected microscale pore space, where cells can easily migrate and proliferate, leading to enhanced survival of transplanted cells. Moreover, the properties of the particles, including stiffness, degradability and cell binding motif concentration, can be modulated independently. By modulating these properties, the microporous scaffold can mimic the natural ECM for high maintenance of stem cell properties.

The scaffold made from these monodisperse (CV < 5%) particles yielded increased expansion and retention of embedded MSCs. Therefore, this new class of injectable microporous biomaterial should accelerate the development of stem cell therapies by creating an injectable microporous niche that enhances function.
We have developed a photocleavable crosslinker for preparing photodegradable hydrogels by means of a one-step mixing reaction between the crosslinker and biocompatible polymers. We could control the chemical property of the photodegradable hydrogel by choosing the base polymer. We could prepare the biomaterial-based photodegradable hydrogels, on which cells adhered, and in which cells were encapsulated. So far, we have demonstrated cell separation from three-dimensional culture environment, cell micropatterning, and perfusion culture in the microfluidic devices. These studies will create new opportunities as novel the cell manipulation technologies in science and industry.

4:00 PM *BM04.05.05
Promoting Endogenous Tissue Repair with Materials Tatiaba Segura, Duke University, Durham, North Carolina, United States.

We believe that all tissues in the body have the capacity to repair through local stem or progenitor cells, but that due to unfavorable environmental conditions during the normal healing process they are not able to do so. We investigate the engineering of materials to “unlock” the regenerative capacity of damaged or diseased tissue to promote repair. Our general strategy is to combine our biomaterials engineering with designing materials that promote the formation of a space filling vascular plexus that could serve as part of a reparative niche directly at the wound site. In addition, our materials are engineered to modulate the immune system to decrease scarring and remove inhibitors to regeneration. The idea is that this vascular plexus would lay the groundwork for the recruitment of endogenous stem cells located in the local tissue surrounding the damaged area and immune modulation would generate an environment that would foster repair rather than scarring.

Stress/Strain and Degradation Tests on Nanofibrous Scaffold for Cardiovascular Regeneration Amanda Kennell, Anthony Brayer and Andrei Stanishevsky, University of Alabama in Birmingham, Birmingham, Alabama, United States.

Cardiovascular disease-related mortalities are predicted to rise to 23.3 million per year worldwide by 2030 [1] with the main cause being cardiovascular diseases (CVD) [2]. The current procedures to correct CVD are time consuming, because a surgeon needs a healthy artery to perform bypass surgery which is not readily accessible. However, if hospitals had a healthy blood vessel scaffold in storage the patient’s recovery time would decrease. Such a scaffold must be biodegradable, easily manufactured, and environmentally safe. To make this scaffold, AC electrospinning is used to create nanofibrous sheets (NFs) from a base polymer solution (fish skin gelatin, FSG). Additions of polysaccharides (Chitosan and Cellulose) are added in to strengthen the scaffold. These NFs are then thermally crosslinked and placed in synthetic body fluid (SBF). In increments, over a period of 3 weeks, the NFs sheets are removed to test their degradation and strength. Preliminary data has shown these NFs to last for two weeks in SBF at 37°C. These NFs were able to withstand a range of applied forces from 30 to 70mN at 80%-100% elastic deformation which translates into 0.15-0.85MPa. To increase the NFs strength a larger percentage of polysaccharides is being used. These NFs will further be seeded with endothelial cells. These NFs meet the requirements for the blood vessel scaffold. They are a “green” scaffold (made from an aqueous solution), easily manufactured (AC electrospinning is a “high yield” technique, 15-30g/h productivity), and “biodegradable”. It is expected that these nanofibrous tubular scaffolds will help reduce the mortality rate, patient recovery time, and need for organs at a lower price and higher acceptance rate. Further studies in vitro and in vivo are planned to evaluate the feasibility of the approach.

4:45 PM BM04.05.07
Short-Term Evaluation of Antithrombogenicity of a PMPC-Grafted PEEK Mechanical Heart Valve in a Porcine Aortic Valve Replacement Model Yusuke Kambe1, Atsushi Mahara1, Kyoko Fukazawa2, Yihua Liu3, Kazuhiko Ishiha2 and Tetsuji Yamaoka1; 1Department of Biomedical Engineering, National Cerebral and Cardiovascular Center Research Institute, Suita, Japan; 2Department of Materials Engineering, School of Engineering, The University of Tokyo, Bunkyo-ku, Japan.

Improved antithrombogenicity of mechanical valves is desired to decrease the risk of thromboembolism and thrombosis and to reduce the dosage of anticoagulation with a vitamin K antagonist (e.g., warfarin). For several mechanical valves, design-derived features are responsible for their improved antithrombogenicity. However, it remains unclear whether material-derived features provide a practical level of antithrombogenicity of mechanical valves. Here we studied the effect of a bileaflet valve made of poly(ether ether ketone) (PEEK) with a poly(2-methacryloyloxyethyl phosphorylcholine) (PMPC)–grafted surface (PEEK-g-PMPC). PEEK has a benzophenone-like structure in its unit, where radicals can be generated by photoirradiations. Thus, PMPC, which is a well-known antithrombogenic polymeric material, was directly graft-polymerized on the PEEK valve surface by a 27-mN/cm² ultraviolet light irradiation at 60°C for 30 min. Surface characterization, such as Fourier-transform infrared analysis, X-ray photoelectron spectroscopy, and transmission electron microscopy, showed the existence of a 250-300-nm thick PMPC layer on the PEEK-g-PMPC valve surface. Porcine aortic valve replacements were conducted using neither an anticoagulant nor an antiplatelet agent and the animals were observed up to 26 h. It was shown that the PEEK-g-PMPC valve opened and closed normally with an allowable transvalvular pressure gradient. Unlike an untreated PEEK valve, no thrombus formed on the PEEK-g-PMPC valve because fibrous fouling was still observed on the leaflet. The authors thank Prof. Hiroshi Tanaka, Prof. Kenji Minatoya, Dr. Sachiro Kakinoki, and Dr. Masayuki Kyomoto for their assistance.

BM04.04.06.01
Enhanced Cell Adhesion on N-Cadherin Modified Graphene Oxide Stimulates Neuronal Growth and Intracellular Transport Ellen Qin1, Mikhail
In the nervous system, cell-cell contacts are predominantly mediated via the homophilic interactions between N-cadherins on adjacent cells. Recombinant N-cadherin molecules are often attached to cell culture substrates via physical adsorption to recapitulate the neural environment. However, those methods typically involve more complicated surface chemistries or result in poor cell adhesion. To address this issue, we hypothesized that the additional noncovalent interactions of graphene derivatives with proteins would enhance the specific activity of immobilized recombinant N-cadherin. Results showed a substantial enhancement of neural cell adhesion on recombinant N-cadherin physisorbed on graphene oxide (GO) and reduced graphene oxide (rGO) relative to N-cadherin on glass, with improvements in the microstructure and physiological activity of neural networks. Biophysical measurements showed the mean adhesive force between AFM tips and N-cadherin coated GO or rGO flakes was ten times higher than that measured with N-cadherin physisorbed to uncoated glass. The latter behavior correlated with increased dendritic arborization and neural network formation on the GO- or rGO substrates, relative to cells on glass. Furthermore, intracellular mass transport was higher along the neurites on N-cadherin coupled to GO- or rGO-coated glass, as visualized using spatial light interference microscopy. The results of this study will be broadly useful for recreating active neural tissues in vitro and for improving our understanding of the development, homeostasis, and physiology of neural networks.

BM04.06.02
Proliferation Acceleration of Mesenchymal Stem Cells on Nanostructured Surfaces Hyeji Park and Jin Seok Lee; Sookmyung Women’s University, Seoul, Korea (the Republic of).

Biophysical properties of the microenvironment, such as nanotopography, modulate proliferation and differentiation of stem cells. Cells directly probe and respond to the physicochemical properties of their extracellular environment through adhesion complexes. Many previous studies have been investigated cell behavior such as cell adhesion, spreading area, cell proliferation, and migration using various topographical cues and the results have indicated topographical confinement by nanostructured architecture affects cellular behavior significantly. Up to date, overall control of cellular response has been carried out by cell isolation in the structure through geometry. However, there is little research about the effect of surface topography on cellular behavior. It is essential to study the surface topography by controlling the size, shape and density of the nanostructure.

In this study, we investigated the effects of the nanostructured silica bead arrays on cellular behavior, particularly proliferation. Human mesenchymal stem cells (hMSCs) were selected to investigate the nanotopological effects on cell proliferation. In the first step, the silica beads were synthesized by Stöber Method by controlling the amount of reagents or injection rates. The silica bead arrays can be achieved by utilizing a rubbing method, which is simple and fast, to obtain a monolayer of silica beads with various diameter sizes from 200 nm to 1900 nm. In the second step, the hMSCs were seeded onto the flat glass and silica bead arrays and then cultured for 24 hours to figure out the nanotopological effect on the cellular behavior. The results have shown that the cell spreading areas and proliferation on the different nanotopological substrates were significantly different. This paper will discuss how the silica bead arrays influence hMSC cellular behavior and optimize cell proliferation within the system. This study could be extended to serve as a model for stem cell therapy in terms of cell proliferation.

BM04.06.03
Skin-Penetrating Peptide-Based Micelle for Transdermal Drug Delivery Do Hyun Bae1, Yong Ho Kim2,3, Jin-Chul Kim2 and Ki Sung Kang4; 1Department of Biomedical Engineering, Sungkyunkwan University, Suwon-si, Korea (the Republic of); 2SKKU Advanced Institute of Nano Technology (SAINT), Sungkyunkwan University, Suwon-si, Korea (the Republic of); 3Natural Products Research Institute, Korea Institute of Science and Technology, Gangneung-si, Korea (the Republic of); 4College of Korean Medicine, Gachon University, Seongnam-si, Korea (the Republic of).

Transdermal drug delivery has been extensively studied to overcome the enzymatic degradation of drugs delivered via oral administration because it not only passes metabolic digestion passage, but also has a possibility to sustain the release of drugs. However, low permeability of stratum corneum inhibits deep penetration of drugs into target area and reduces percutaneous adsorption of drugs. Therefore, a new carrier system that can efficiently transport drugs into the stratum corneum would greatly enhance transdermal drug administration. Here, we demonstrated a formation of skin-penetrating peptide-based micelle for efficient transdermal drug delivery. Skin-penetrating peptides (SPPs) can be used as an excellent transdermal drug transporter due to its biocompatibility and exceptional cell-penetrating ability. We examined various cell-penetrating peptides (CPP) that adapt adsorptive-mediated transcytosis to verify their skin-cell permeability and identified one CPP that showed high cellular uptake inside the dermal papillae cells. The newly discovered SPP was further modified by conjugating an aliphatic chain at the N-terminal of the peptide to induce self-assembly for lipopeptide-based micelle formation. The micelle was found to achieve enhanced thermodynamic stability compared to SPPs only, which suggests that it can maintain its conformation in biological condition. The self-assembled micelle could securely encapsulate the minoxidil, a drug for hair regeneration, and increased cellular uptake of the drug into the dermal papillae cells. We believe that our new transdermal drug delivery system can be applied in the field of cosmetics and pharmaceuticals to increase skin administration efficiency of functional components.

BM04.06.04
RF Coupling of Interdigitated Electrode Array on Aerogels for In Vivo Nerve Guidance Applications Jacob Hadley, Jack Hirschman, Bashir Morshed and Firozeh Sabri; University of Memphis, Memphis, Tennessee, United States.

Aerogels are light-weight porous materials that can tolerate the processing steps required for designing and creating an interdigitated electrode (IDE) array using sputter coating with a shadow mask where the aerogel can be utilized as a substrate. Previous studies have shown the biostability and biocompatibility of polyurea crosslinked silica aerogels both in vivo and in vitro and have demonstrated the potential use of aerogels in biomedical applications. In vitro studies have shown that in the presence of an applied electric field neurites regeneration rate was greater on crosslinked silica aerogels than on tissue culture petri dishes that served as control. Currently, Epineural suturing and nerve grafting are the gold standards for surgical reconstruction of severed nerves. However, because these techniques rely on passive mechanisms for reapproximating the distal and proximal terminals they often lead to partial or limited recovery leaving room for improvement. The present study investigates the feasibility of a wireless aerogel –based electrically-stimulating implant intended for nerve repair applications. Here the authors report on a transcutaneous RF coupling between a primary coil (external) and a secondary coil (internal) connected to an IDE array consisting of eleven interdigitated fingers, created on a silica aerogel substrate. The coupling strength was tested using sputter coating with a shadow mask where the aerogel can be utilized as a substrate. Previous studies have shown the biostability and

BM04.06.05
Nanostructured Biomaterials for Functional Neurons Debika Debnath1, Krishnan Gopal Jain1, Manu Dalela1, Sonali Rawat1, Amtoj Kaur1, Neha Kaushik1, Ankarao Kalluri1, Bhushan Dharmadhikari1, Prabir Patra1 and Sujata Mohanty1; 1Stem Cell Facility, All India Institutes of Medical Sciences, New Delhi, India; 2Biomedical Engineering, University of Bridgeport, Bridgeport, Connecticut, United States; 3Electrical Engineering, University of Bridgeport, Bridgeport, Connecticut, United States.
We fabricated Polycaprolactone-graphene (PCL-G) biomaterials scaffolds by stretching graphene dispersed viscoelastic PCL solution uniaxially under an applied voltage with an aim to provide microenvironment in vitro for differentiation and proliferation of functional neurons from mesenchymal stem cells (MSCs). Varied amount of graphene (0.05 - 0.5 wt percentage of graphene) was dispersed in PCL matrix for scaffold formation. We induced MSCs to differentiate into neurons by taking advantages of topological and electrical effect of scaffold, and biochemical effect of FGF2 and Oxyester. SEM images of PCL-G scaffolds were taken to study the effect of the scaffolds on cell morphology. We performed confocal imaging to confirm differentiation of MSCs into neurons. Confocal images of Vinculin and FAK on MSC grown on scaffolds were observed. We measured Contact angle of water on scaffolds to determine hydrophobicity and hydrophilicity of scaffold. Calcium ions being the most important ions for regulating biological processes we did the Ca2+ ion imaging. Cell culture and in vitro cell adhesion studies showed that PCL-G scaffolds was most effective for promoting stem cells adhesion and spreading. Microscopic images show that the PCL-G fibers are structurally similar to ECM proteins like collagen, laminin and fibrils. This work also demonstrates the key role of graphene in aligning neurons. With its optimum dose as 0.05 wt percentage as filler in composite scaffolds significantly provides permissive surfaces for protein and cell adhesion as well as electrically stimulate axon growth that increases over all biological responses. Thus, we envisaged that such a platform could serve as a powerful tool for developing future therapies for any diseases and injuries of the spinal cord.

BM04.06.06
Pulsed Laser Deposition and Biocompatibility of Titanium Nitride Coatings Meenakshi Singh1 and Svitlana Fialkova2; 1STEM Early College at NC A&T, Greensboro, North Carolina, United States; 2Mechanical Engineering, North Carolina Agricultural and Technical State University, Greensboro, North Carolina, United States.

The purpose of this study is to evaluate the effect of Titanium Nitride (TiN) thin films deposited on magnesium substrates using a pulsed laser deposition method. The application of a TiN coating on magnesium implants has the potential to remove the necessity for a second surgery for patients undergoing the process of healing. The coating developed has been shown to help reduce the degradation rate of the magnesium implant such that the Mg would remain stable for the time required for healing before beginning to degrade. Magnesium was chosen as a substrate due to its biocompatible and biodegradable properties. TiN was chosen due to its stellar properties of high hardness, good diffusion barrier, high hardness and good electrical conductivity, and scattered reports in the literature about its biocompatibility. The crystallographic orientation and surface morphology of the films were studied using X-ray diffraction (XRD) and scanning electron microscope (SEM). The hydrophilic nature of the films was investigated using contact angle measurements. Preliminary results on the biological behavior of the TiN coated Mg substrates suggest that TiN is a biocompatible material and has great promises in biological applications.

BM04.06.07
Magnetic Nanoparticles as a Therapeutic Biomaterial in Magneto-Ultrasonic Hyperthermia Arkadiusz Jozefczak, Katarzyna Kaczmarek and Tomasz Hornowski; Institute of Acoustics, Adam Mickiewicz University, Poznan, Poland.

In medicine, a controlled increase in temperature up to 41–45°C is called hyperthermia. It induces heat in cancer cells which leads to their weakening. Weakened cells are therefore more susceptible to radiotherapy or chemotherapy. The heating can be induced by means of ultrasonic waves or magnetic field. The effectiveness of ultrasound therapy can be significantly improved by using so-called sonosensitizers, for example, magnetic nanoparticles that locally increase the attenuation of the ultrasonic wave [1]. Magnetic particles can also be used for selective induction of heat by an externally applied alternating magnetic field (AC) [2]. Recently, there has been a great interest in the application of multimodal thermal treatments. Magnetic and ultrasonic hyperthermia may work synergistically to produce a more efficient treatment. This sonomagnetic therapy is a promising new technique based on the synergistic interactions of ultrasound and AC magnetic field. The presence of magnetic nanoparticles also improves contrast in both ultrasonic and magnetic resonance imaging, which facilitates control of temperature during hyperthermia therapy. Magnetic nanoparticles can act as theranostic nanoparticles.

In the study, we have focused on evaluating the influence of magneto-ultrasonic heating on phantom temperature in the presence of superparamagnetic iron oxide nanoparticles (SPION). The experiments are performed with the use of agar tissue mimicking phantoms doped with magnetic sonosensitizers. Integrated treatment by means of simultaneous application of a focused ultrasound wave and alternating magnetic field (bimodal sonomagnetic hyperthermia) leads to a higher temperature increase, which enables more precise control over the heating process. Magneto-ultrasonic heating creates very innovative, promising approach which has an application potential to treat cancer at a lower SPION concentration. We demonstrate that bimodal stimulation of nanoparticles provides better heating efficiency.

Antibacterial Coating on Contact Lens Using Polyethyleneimine Based Polymers Suresh Kumar Raman Pillai, Yogesh Shankar Vikhe, Zheng Hou, Sheethal Reghu and M. B. Chan-Park; Nanyang Technological University, (NTU) Singapore, Singapore.

Microorganisms such as bacteria that grow on the surface of contact lenses cause irritation to the eyes. These infections that are difficult to treat and can cause to vision loss. Besides the availability of new contact lens materials and better cleaning solutions, the risks of the above conditions remains the same for many years. Silver coating have been commonly studied, but the material can leach out of the lenses and their antimicrobial effect fades over time. In this report, we have synthesized PEI-PEGMA polymer and used for the application of an antimicrobial coating on contact lenses in order to prevent bacterial infection and reduce the risk of extended wear. Different types of failures such as (1) reduction of coating adherence to the substrate of contact lens and (2) disintegration of interface between coating and substrate of contact lens exists. To improve coating formulations to resist failures caused by the applied normal load with fingers of users, monomer (3-Acrylamidopropyl) trimethyl ammonium chloride (AMPTMA) or [2-(Methacryloyloxy) ethyl] dimethyl-(3-sulphopropyl) ammonium hydroxide (SBMA) was added to the antimicrobial polymer PEI-PEGMA.

Two different coating strategies were adopted to form PEI-PEGMA-AMPTMA or PEI-PEGMA-SBMA polymeric film on the surface of the contact lens. In the first method, the silicone contact lenses were treated with ozone to activate the surface and form the peroxide groups. Vanadate solutions of PEI-PEGMA and AMPTMA/SBMA dissolved in DI water and degassed the solution using Argon for 45 min. The contact lenses were immersed into the solution and the radical initiation polymerization reaction was activated by the addition of Ammonium iron(II)sulfate. The polymerization reaction was carried out at 37°C for 24 hrs. The lenses were thoroughly washed with DI water and isopropanol (IPA) before doing the antibacterial testing. Antimicrobial activity of the coated lenses were tested with 1x 10^6 CFU of Methicillin-resistant Staphylococcus aureus (MRSA). The coated contact lenses were found to be effective for antibacterial activity with killing rate > 99.9 % and log reduction of 3.20. Cell viability for the coated lenses were found to be 80 % using MTT assay protocol. In the second method, the radical initiation was activated thermally. The lenses were treated with ozone to form peroxide group on the
Sub-Compartmentalized Microreactors as Cell Implants for Conducting Enzymatic Cascade Reactions

Could regenerate the arterial vascular tissue in three months. and αSMA positive cells existed as same as the results for three month transplantation. Although the cell density in media layer was sparse as compared and Flk-1. For evaluation of the medium layer, the tissue was stained with antibody against α-smooth muscle actin (αSMA)

Graft was extirpated. Luminal surface was evaluated by histological staining using HE, vWE, as well as primary antibody against CD31, CD34, CD105, and CD105, and Flk-1. For evaluation of the medium layer, the tissue was stained with antibody against α-smooth muscle actin (αSMA).

Thus, herein, with the aim to design a highly-sophisticated artificial organelle we present a carrier containing multiple compartments consisting of polymeric capsules entrapping thousands of liposomes and gold nanoclusters. Liposomes are chosen as the subcompartments since, by means of their lipid bilayer which makes them biomimetic, are ideal candidates to encapsulate fragile biomolecules such as enzymes protecting them from misfolding or degradation in the bloodstream and then from the intracellular degrading contents, will greatly diminish current limitations of enzyme replacement therapy. However, the delivery of enzymes has been proven so far very challenging and, thus, so far it has shown very limited success. The reason being that enzymes are very fragile entities prone to degradation in the bloodstream. This fact makes them difficult to reach the target site, which is usually a diseased cell, and remain active for a reasonable amount of time. Thus, the creation of artificial organelles encapsulating enzymes that will protect them first from degradation in the bloodstream and then from the intracellular degrading contents, will greatly diminish current limitations of enzyme replacement therapy. Biological organelles operate by conducting multiple sets of (enzymatic) reactions with high specificity and accuracy without cross-contamination. They can separate multiple functions while protecting internal contents thanks to compartmentalization. This compartmentalization can be clearly seen in the Golgi apparatus or the mitochondria, where several enzymes for the citric acid cycle are situated in the intermembrane space. Thus, herein, with the aim to design a highly-sophisticated artificial organelle we present a carrier containing multiple compartments consisting of polymeric capsules entrapping thousands of liposomes and gold nanoclusters. Liposomes are chosen as the subcompartments since, by means of their lipid bilayer which makes them biomimetic, are ideal candidates to encapsulate fragile biomolecules such as enzymes protecting them from misfolding or denaturation. The polymer carrier shell possesses the structural integrity and it is able to protect the liposomes from degradation and the gold nanoclusters, thanks to their fluorescent properties, allow us to detect and tract the artificial organelles inside the host cell. We demonstrate preservation of functionality of our artificial organelles by encapsulating two different enzymes within different liposomes and conducting an enzymatic cascade reaction inside the cell. In particular, artificial organelles loaded with the enzymes glucose oxidase (GOx) and horseradish peroxidase (HRP) are internalized by macrophages. Next, upon incubation with D-glucose, it gets converted by GOx into D-glucuronolactone and hydrogen peroxide. The latter is utilized by HRP to convert the Amplex Red probe into the fluorescent product resorufin which is detected by fluorescent spectroscopy to confirm that the enzymatic cascade reaction has successfully taken place.

In-Flow Preparation of Collagen Sheets with Tunable Fibril Alignment for the Engineering of Arterial Substitutes That Recapitulate Blood Vessel Microstructure

David Miranda-Nieves1, 2, Shashi Malladi3, Daniel Wong1, Constantine Tarabaris1, Carolyn Hailer3, Axel Gruenther4 and Elliot Chaikoff1, 2; 1Massachusetts Institute of Technology, Boston, Massachusetts, United States; 2University of Toronto, Toronto, Ontario, Canada; 3Harvard University, Boston, Massachusetts, United States.

Lower extremity peripheral arterial disease (PAD) affects up to 15% of the population over 65 years old. The number of endovascular and bypass operations has doubled in the past decade, yet outcomes after surgical and catheter-based interventions remain compromised with low complication rates. Tissue-engineering strategies have been explored as alternatives; however, no clinically available graft exists. The main limitation of most approaches is failure to recapitulate the blood vessel microstructure, and, as a consequence, native physiological properties. Considering that the arterial wall is a circumferentially aligned fibrous matrix, the capacity to create highly structured, oriented structures is critical for the generation of physiologically responsive arterial substitutes. Over the years, various methods have been designed to influence the organization of self-assembling collagen fibrils, including the use of magnetic fields and fiber spinning. However, none of these approaches represent a one-step, scalable technique for the generation of collagen films with precise control over fibril orientation. Here, we present a solution that leverages molecular crowding and hydrodynamic focusing to fabricate ultrathin collagen sheets with tunable fibril alignment and mechanical properties, and our initial attempts to engineer arterial substitutes using these sheets.
Monomeric rat-tail tendon collagen was dissolved in 10 mM HCl, and injected into the middle layer of a multilayered, PDMS-based microfluidic device at varying flow rates. As shear flow, a polyethylene glycol (PEG) solution was used. The presence of PEG caused molecular crowding, which triggered the gelation of the collagen solution. Hydrodynamic focusing was achieved by modifying the flow rates of the two solutions.

Extruded collagen sheets had thicknesses of 3-8μm and widths of 15-30 mm. The degree of alignment and compaction of the collagen fibrils was controlled, with up to 40% of fibers aligned within ± 5° of one another, and up to 95.5% of compaction. As a result, ultimate tensile strengths of 1.25-13MPa, Young’s moduli of 1.3-130MPa, and strains to failure of 15-55% were achieved. Molecular alignment of the collagen sheets induced preferential alignment of vascular smooth muscle cells (VSMC), maintained cellular expression of phenotype markers, and guided active film contraction.

Efforts involving the controlled assembly of the ultra-thin, robust, anisotropic collagen sheets seeded with VSMC have yield arterial constructs with circumferential collagen fibrils and high density of VSMC that closely recapitulate native blood vessel microstructure. Biomechanical characterization has revealed that the constructs can withstand high pressures and tensile strengths. Ultimately, we believe that these biological and mechanical properties will translate to the mimicry of physiologic responses in vivo.

DMD Printed Scaffold for Vascularized Tissue Roya Samanipour1-3 and Mina Hoorfar; 1 Harvard-MIT Division of Health Sciences and Technology, Massachusetts Institute of Technology, Boston, Massachusetts, United States; 2 University of British Columbia, Vancouver, British Columbia, Canada.

In this paper, we developed a high resolution stereolithography-based bioprinter (DMD printing) to fabricate micron size of vasculature using CT images. The development of in-vitro highly organized-vascularized three-dimensional (3D) complex constructs is of great importance in tissue engineering. While several microfabrication strategies (ranging in micromolding, photolithography, stereolithography, and bioprinting,) have been used, these technologies lack the spatial control for the formation of complex vascular networks. Current 3D bioprinting techniques cannot provide the required printing resolution, throughput, and complex and biomimetic microarchitectural features. Here, we developed a DMD (Digital Mirror Device) 3D printing technology platform capable of rapidly fabricating tissue constructs with smooth features and high cell viability. DMD 3D printing was developed to fabricate variety of microscale resolution vascularized tissue. Blended prepolymer solutions consisting of varying ratios of GelMA (synthesized by the method described by Cha et al [3]) and polyethylene glycol diacrylate (PEGDA, M₄₇00, Sigma Aldrich) with LAP photoinitiator (Sigma Aldrich) were tested to optimize the polymer composition for printing. To ensure proper material properties needed to withstand subsequent perfusion, mechanical testing of the different prepolymer formulations was performed using a CellScale MicroSquisher system (Waterloo, ON, Canada). The optimized optimized polymer composition of 7.5 wt % GelMA+10 wt % PEGDA 700+25 LAP was used to 3D print 310 um microchannels with fine structural features. Afterwards, Human umbilical vein endothelial cells (HUVECs, Lonza, Portsmouth, NH) were injected into microchannel to create entheselial microchannel construct. To create a uniform monolayer of cells, the whole construct was manually rotated every 1.5 hours after the HUVECs-laden polymer solution was injected into the channel. The seeded cells into the printed structure were cultured for 14 days. The F-actin-Dapi was performed on the cultured samples on days 7 and 14. The CD31/Dapi was performed on the cultured samples on days 7 and 14. The results show that the endothelial cells proliferated and uniformly covered the microchannel. PrestoBlue assay was performed to assess proliferation on days 1, 3, 7, 10 and 14.

Block Copolymer Nanoparticles Remove Biofilms of Drug-Resistant Gram-Positive Bacteria by Nanoscale Bacterial Debridement M. B. Chan-Park; Nanyang Technological Univ, Singapore, Singapore.

Bacterial biofilms are the main cause of chronic infections and typically 1000-fold more resistant to conventional antibiotics and/or antimicrobial agents. Hence, many antibiotics, natural antimicrobial substances and synthetic antimicrobial agents fail to eradicate biofilms. Besides, various antibiofilm agents such as metallic or inorganic nanoparticles have shown the ability to remove biofilm, but they are usually suffered from the problem of toxicity and limited life span. In this paper, we developed a novel antibiofilm polymer nanoparticles which showed excellent preformed antibiofilm dispersal ability with non-hemolytic in vitro and low in vivo cytotoxicity. This polysaccharide-based polymer can self-assemble into nanoparticles which can effectively remove biofilms of multi-drug resistant clinically relevant Gram-positive bacteria (i.e. Methicillin-resistant Staphylococcus aureus (MRSA), Vancomycin-resistant Enterococcus (VRE) and Enterococcus faecalis (OG1RF)), with efficacy superior or comparable to that of current standard antibiotics. Interestingly, the antibiofilm property of these nanoparticles is not come from the antibacterial effect, but a new mechanism which we term “nanoscale bacterial debridement”. The nanoparticles can diffuse into biofilms and complex with bacterial surface. Further, its hydrophilic polysaccharide corona enhances the solvation of the bacteria/nanoparticle complex leading to detachment of bacteria from biofilm. Our in vitro data also shows the nanoparticles can remove the MRSA biofilm by 3.7 order of log reduction, compared to 2.1 order achieved by vancomycin antibiotic. Overall, this novel biofilm removal approach provides exciting opportunities for eradication of multi-drug resistant biofilm and which further may have widespread applications.

BM04.06.14
Short Aromatic Peptide Carriers for the Targeted Delivery of Cranberry Extracts Yasaman Hamedani, Elvira Lou Evangelista, Catherine Neto and Milana Vasudev; University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States.

In recent years, drug delivery using nanoparticles has gained attention due to their ease of synthesis, high effectiveness due to ease of uptake in cells, increased half-life in systemic circulation and the ability to target certain organs or group of cells. Such nanoparticles can be fabricated from natural or synthetic biopolymers, and lipids. Peptide-based nanoparticles are potential candidates as nanocarriers for the enclosure of various drugs. Peptides have complex structures and biological recognition abilities. Hydrophobic interactions, hydrogen bonding and p-p stacking all lead to formation of stable structures via self-assembly. Depending on the conditions for synthesis, peptides can self-assemble into various structures such as nanotubes, nanofibers and nanospheres. In this study, we have demonstrated the self-assembly of tripeptides to form nanospheres through a process called electrospraying. By optimizing the electrospraying conditions, we were successfully able to form hollow peptide nanospheres which are suitable candidate for delivery of various drugs. Moreover, cationic amphiphilic peptide sequences were designed to form peptide-based micelles for encapsulating various therapeutic drugs. Scanning electron microscopy (SEM) as well as Transmission Electron Microscopy (TEM) techniques have been utilized to investigate the morphology of the fabricated spheres/micelles. Chemical characterization of the samples were performed using Fourier transform Infrared (FT-IR) and Raman spectroscopy. Cranberry extracted compounds such as flavonoids/polyphenols and triterpenoids are amongst the natural therapeutic compounds which recently have gained considerable attentions due to their effectiveness in prevention of cardiovascular, carcinogenic, neurodegenerative and immune
Bicontinuous interfacially jammed emulsion gels (“bijels”) can be used as templates to fabricate bijels-derived structures, which maintain the bicontinuous internal structure of bijels and hence possess unique properties for various applications. Bijels-derived structures are potential delivery vehicles for the controlled release of growth factors (GFs) in tissue engineering. To apply bijels-derived structures in tissue engineering, the biocompatibility requirement must be met but most existing bijels-derived structures are not biocompatible. Using biocompatible materials such as hydrogels may provide solutions for solving the problems. Bioactive molecules, particularly GFs, have been used in tissue regeneration. Vascular endothelial growth factor (VEGF) and platelet derived growth factor (PDGF) are often used in the regeneration of tissues such as skin and gastrointestinal tract. Controlled delivery of GFs through appropriate vehicles can promote tissue regeneration. This study investigated the fabrication and characteristics of hybrid hydrogels consisting of biocompatible materials made via bijels for VEGF and PDGF delivery. A modified solvent induced phase separation process was used to fabricate bijels-derived hybrid hydrogel membranes. A ternary liquid mixture was made by adding pure ethanol, hexadecylidocylcetate (HDA), 2-hydroxy-2-methylpropioophenone (HMP), deionized water, Ludox TMA (silica nanoparticle suspension) and CTAB in ethanol. A glass plate was immersed in the ternary mixture for forming a mixture film on its surface. It was taken out and then immersed in a water bath to form bijels membranes through phase transition. A high-intensity UV light was applied to cure HDA and harden the bijels structure. Then bijels films were immersed in VEGF- or PDGF-containing Na-alginate solutions, taken out and immersed in CaCl₂ solution for crosslinking, forming GF-containing bijels-derived hybrid hydrogel membranes. The bicontinuous microstructure in membranes could be clearly seen under SEM. UV-cured HDA polymer and crosslinked CA-alginate hydrogel formed two continuous phases in the membrane. The diameter of the bicontinuous structure (channel size) could be adjusted by UV-curing time and other parameters. In vitro experiments of as-fabricated hybrid hydrogel membranes, human dermal fibroblasts (HDF) were cultured on membranes whose biocompatibility was assessed using LIVE/DEAD assay. At Day 3, fibroblasts proliferated on membranes and nearly no cell death was observed. MTT assay was used to evaluate cell proliferation on membranes. Results showed good cell proliferation after 1, 2, 3-day culture. Following the established test protocol, the in vitro release behavior of VEGF and PDGF for bijels-derived membranes was studied. Steady and sustained releases of VEGF and PDGF were both seen within test durations. This study demonstrates the high potential of bijels technology in the tissue engineering field.

BM04.06.15
Delivery of Growth Factors via Bijels-Derived Hybrid Hydrogels
Haoran Sun and Min Wang; Department of Mechanical Engineering, The University of Hong Kong, Hong Kong, Hong Kong.

In the present study, we demonstrate a rapid and low-cost method to prepare biomaterials with anisotropic, gradient micro-ridge/groove arrays having variable local pattern width. It was anticipated this study will demonstrate the ability of gradient micro-topographies to influence preferential neuronal adhesion and maturation, dendritic tree expansion, and synaptic network formation, providing a comprehensive understanding of the neuron-microenvironment interaction for the design of neuroregenerative devices.

The surface topography of biomaterials with specific spatial structure mimic the physical microenvironment of neurons, regulating their orientation and neurite outgrowth. However, most topographical structures used in neuron culture are fabricated with simple geometries. This necessitates bulk fabrication, which is both inefficient and laborious, while also increasing potential contamination. A single gradient micro-topographical device with variable geometries of a single orientation begins to ameliorate these issues, although few studies have examined the influence of linear micro-ridge/groove structures on synaptic network formation and dendritic tree structure.

The physicochemical properties of the prepared gradient micro-ridge/groove array were characterized by analyzing the surface morphology and wettability. The patterning structure and dimensions were confirmed to be intact through scanning electron microscopy and viable for cell contact. Additionally, cell adhesion was increased through surface treatment with poly-L-lysine and laminin. The chemical composition of the surface modification was verified through FTIR-ATR spectroscopy. Uniformity of the surface treatment was verified through fluorescent intensity of FITC-poly-L-lysine. Cell experiments were subsequently carried out using primary rat hippocampal neurons.

Immunofluorescent images of neurons in culture for 14 days revealed smaller pattern widths regulate neuron growth and increase orientation along the microtopography direction. Neurons cultured on these substrates demonstrate a preference to attach in areas of smaller pattern width. Additionally, cell somas located within a 5μm groove demonstrate heightened aspect ratios. Dendrites of these neurons extended less when introduced to a linear topography, decreasing their coverage area with respect to decreasing geometry. Preferential axon maturation was found to grow more within the groove as opposed to on top of each ridge. Finally, the density of synapses formed and relative protein expression significantly decreased in the presence of topography, with large increases when the geometry becomes smaller than the neuron soma. Thus, the effect of gradient micro-topography on neuron behavior was achieved and systematically understood by a one-step screening on a single integrated chip, lending itself to potential advances in the design of neuroregenerative micro-devices.

Gradient Micro-Topography for Morphological Control and Synapse Formation
Ryan McNaughton, Yuda Huo, Guicai Li, Hengye Man and Xin Zhang; Boston University, Boston, Massachusetts, United States.

Stem cells are sensitive to both chemical and mechanical changes in the environment, which proliferation and differentiation depend on three main factors: the type of stem cell, the underlying scaffold, and the signaling molecules added. It has been shown that stem cells isolated from the dental pulp (dental pulp stem cells (DPSCs)) can differentiate and express markers of odontoblasts, osteoblasts, adipocytes or neuronal cells when they are grown in specific inducing media. However, the external chemical inducers such as steroids can cause adverse side effects such as hyperglycemia and a weakened immune system in clinical studies. Therefore, we focus on engineering the underlying substrates to induce DPSCs differentiate along the desired pathway without external chemical inducers added. Titanium, a material used as dental implant, has shown to promote its osseointegration with specific surface treatment to manipulate its surface roughness and topography. Herein, we introduce a new method to fabricate titanium substrate by atomic layer deposition (ALD), which deposits a homogeneous 2~3nm thickness of titanium on silicon wafer substrates. Due to surface chemistry changed, DPSCs have shown to proliferate well on ALD titanium substrates compared to bare silicon surface. At week 4, mineralization were characterized by SEM/EDS and Raman microscopy.
spectroscopy. RT-PCR was also used to identify odontogenic and osteogenic differentiation markers. The results showed that biomineralized deposits (Ca/P) along with collagen fibers were observed on ALD titanium substrates, and RT-PCR results showed that osteocalcin (OCN) was upregulated from week 2 to week 4 but Dentin Sialophosphoprotein (DSPP) expression remained low over 4 weeks. It suggests that DPSCs growing on ALD titanium surface might induce them to differentiate along osteogenic pathway. The ALD method provides a fast and easy process to coat a homogeneous thin layer of titanium on the substrate, where only surface chemistry changes but which roughness and topography remain the same. This method could be a potential application to coat a thin layer on titanium on any biomaterial to further promote stem cells differentiation and proliferation.

We would like to thank the NSF-INSPIRE program (Grant #1344267.)

BM04.06.18
Substrate Mechanics in Combination with Nanoparticles Effects on Dental Pulp Stem Cells Proliferation and Differentiation Ya-Chen Chuang1,2, Chung-Chueh Chang2, Marcia Simon3, Miriam Rafaelovich1, Samantha Ying4 and Mindy Li5; 1Materials Science and Engineering, Stony Brook University, Stony Brook, New York, United States; 2ThINC Facility, Advanced Energy Center, Stony Brook, New York, United States; 3Oral Biology & Pathology, Stony Brook University, The State University of New York, Stony Brook, New York, United States; 4South Side High School, Hempstead, New York, United States; 5Princeton High School, Princeton, New Jersey, United States.

Stem cells are sensitive to both chemical and mechanical changes in the environment, which proliferation and differentiation depend on three main factors: the type of stem cell, the underlying scaffold, and the signaling molecules added. It has been shown that stem cells isolated from the dental pulp (dental pulp stem cells (DPSCs)) can differentiate and express markers of odontoblasts, osteoblasts, adipocytes or neuronal cells when they are grown in specific inducing media. In our previous study, we have shown that monodisperse polybutadiene (PB) can be used to produce biocompatible flat thin films with different surface mechanics by simply altering the film thicknesses where surface chemistry remains the same. We have also shown that DPSCs can sense and adjust their cell mechanics accordingly to the underlying substrate mechanics. In addition, without the addition of inducing media, dexamethasone, biomineralized deposits and up-regulation of osteocalcin (OCN) gene marker were observed on hard PB surfaces. In contrast, extremely low level of biomineralized deposits and OCN were observed on the softer PB surfaces. On the other hand, the rise of nanotechnology also promotes the study on the effects of nanoparticles (NPs) on stem cell and shows that nanoparticles can also offer a means of regulating cell function. However, stem cells are extremely sensitive to the extracellular signals where the stimuli from substrate mechanics and NPs should be studied simultaneously. Hence, in this study, we want to investigate how DPSCs proliferate and differentiate when both substrates mechanics and NPs cues were involved. Briefly, TiO2 NPs (0.1 mg/mL) were added post-plating onto soft and hard PB substrates after DPSCs fully attached. Cell proliferation and cell mechanics were measured at week 1 by hemocytometer and shear modulation force microscopy (SMFM). At week 4, biomineralized deposits were characterized by SEM/EDS and Raman spectroscopy. RT-PCR was also used to identify odontogenic and osteogenic differentiation markers. The results showed that with TiO2 NPs added, collagen fibers along with biomineralization were deposited on the substrates, and it showed up-regulation of OCN gene at the later stage of differentiation process no matter the substrate is soft or hard. The results suggest that TiO2 NPs override substrate mechanics effect and dominate DPSCs differentiation in this system, which could be a potential application for nanoparticles using as stem cell differentiation inducer.

We would like to thank the NSF-INSPIRE program (Grant #1344267.)

BM04.06.20
Non-Invasive Transdermal Photomedicine Using Hyaluronic Acid Derivatives Ki Sa Kim; Department of Organic Materials Science and Engineering, Pusan National University, Busan, Korea (the Republic of).

A variety of drug delivery systems have been investigated for high therapeutic efficacy via easy administration. Among them, transdermal delivery is presented as an attractive alternative to needle-based drug delivery because of patient preferences. Although transdermal microneedles are less invasive promising alternatives, needle-free topical delivery without involving physical damage to the natural skin barrier is still sought after as it can further reduce needle-induced anxiety and is simple to administer. However, this long-standing goal has been elusive since the intact skin is impermeable to most macromolecules. Also, the depth of light penetration in skin in photomedicine is a serious constraint on clinical applications. Here, we show an efficient, noninvasive transdermal delivery using Hyaluronic acid (HA) derivatives as carrier. For vaccine delivery, following topical administration in the skin, a model vaccine ovalbumin (OVA) and HA (HA–OVA conjugates) penetrated into the epidermis and dermis in murine and porcine skins, as revealed by intravital microscopy and fluorescence assay. Topical administration of HA–OVA conjugates significantly elevated both humoral and mucosal antibodies, with peak levels at four weeks. An OVA challenge at week eight elicited strong immune-recall responses. With pretreatment of the skin using non-ablative fractional laser beams as adjuvant, strong immunization was achieved with much reduced doses of HA–OVA.

In addition, we also developed implantable light-delivery devices using HA. With this light delivery system, we successfully demonstrated the facilitated photochemical tissue bonding (PTB) using hyaluronic acid (HA)–rose bengal (RB) conjugate and upconversion nanoparticle (UCNP). The UCNP emitting red and green light in the skin tissue by skin-penetrating near infrared (NIR) laser illumination could activate the RB dye and crosslink the collagen, inducing skin repair and deep tissue wound healing. Furthermore, hyaluronate–hollow gold nanosphere–adipocyte–targeting peptide (HA–HAuNS–ATP) conjugates will be presented for the photothermal ablation of adipose tissues.

BM04.06.21
Enhancing Biocompatibility of Tantalum via Anodization for Orthopedic Applications Ece Ush1,2 and Batur Ercan1,2; 1Metallurgical and Materials Engineering, Middle East Technical University, Ankara, Turkey; 2BIOMATEN, Middle East Technical University, Center of Excellence in Biomaterials and Tissue Engineering, Ankara, Turkey.

Tantalum and its alloys have been investigated as the next generation of orthopedic implant materials in the last decade. Being a valve metal, tantalum forms a naturally occurring stable oxide layer approximately 3-5 nm on its surface at ambient conditions and this layer both prevents heavy ion release from the metal and provides a natural barrier for implant corrosion. In fact, due to its chemically inert nature, tantalum has the highest corrosion resistance of all metals used in orthopedic applications. Tantalum also exhibits higher fatigue properties compared to the currently-used implant materials. Despite having ideal properties for orthopedic applications, bioinert nature of tantalum surfaces, which limits osseointegration with the juxtaposed tissue, is the leading problem to be addressed before its widespread use in implants. To overcome this problem, surface modification of tantalum within nanoscale could be a potential remedy to enhance its bioactivity.

Anodization is an electrochemical process which produces oxide based nanofeatured surfaces on various metals. It gained popularity in the last decade due to its versatility in controlling biomaterial surface topology. In literature, it was shown that anodized nanostructured surfaces having different morphologies, topographies and feature sizes enhanced bone cell adhesion, proliferation and cellular functions in orthopedic applications. Specifically, anodized titanium and its alloys were well characterized to enhance cellular functions in vitro. However, there is very limited data on the anodization of
tantalum for orthopedic applications. In this study, tantalum samples were anodized using 1M H₂SO₄, 3.3 wt % NH₄F, 1:9 (v/v) concentrated and aqueous HF/H₂SO₄ solutions to obtain oxide based nanofeatures on its surface. Upon anodization, 4 different surface morphologies, namely nanodimple, nanotubular, nanoporous and nanocoral, were successfully obtained on tantalum surfaces. Furthermore, anodization duration (1min-4hr) and voltages (10-80V) were fine-tuned to control feature sizes between 25 to 140 nm for the nanodimple, nanocoral and nanoporous morphologies. Topographical investigations indicated higher nanophase surface roughness on anodized surfaces compared to as-received tantalum. Anodized samples also expressed enhanced surface hydrophilicity independent of the morphology and feature size. To investigate biocompatibility of the samples, osteoblast (ATCC CRL-11372) adhesion and proliferation were examined up to 7 days of culture. Results indicated enhanced cellular functions on nanodimple, nanocoral and nanoporous morphologies compared to non-anodized surfaces. Furthermore, immersing these samples into simulated body fluid up to 1 month showed enhanced bioactivity of these surfaces compared to non-anodized tantalum. In conclusion, surface modification of tantalum via anodization could be a potential way to enhance biocompatibility of tantalum for orthopedic applications.

Suppression of Platelet Adhesion on Decellularized Vascular Graft by High Density REDV Peptide Immobilization

Kentaro Kojima1, Atsushi Mahara2, Yoshiki Hirota3 and Tetsuji Yamaoka4;1 Department of Biomedical Engineering, Kansai University, Suita, Osaka, Japan; 2 Department of Biomedical Engineering, National Cerebral and Cardiovascular Center Research Institute, Suita, Osaka, Japan.

**[Purpose]** Suppression of thrombus formation is required for graft patency of small caliber blood vessels. In our previous work, we succeeded in proving the good patency of the small diameter long bypass graft by modifying the luminal surface with a bioactive peptide [1]. The peptide consists of REDV and POG repetitive sequence which are the integrin α4β1, ligand and collagen binding sequence, respectively. We found that the REDV modified surface captured endothelial progenitor cells and inhibited the blood coagulation during initial contact with the heparinized blood. However, platelets were adhered on the REDV modified surface when platelet-rich plasma (PRP) was statically incubated with the surface. The REDV density was 8.4×10⁶ molecules/mm² when the REDV was immobilized via POG binding sequence. Therefore, the surface would not be fully covered by the peptide, and we assumed that the platelet adsorption was caused by exposed collagen. In this study, we developed the REDV peptide-conjugated silane coupling agents (PCSi) for high density REDV immobilization to decellularized vascular graft. The platelet adhesion on the PSCI modified surface and EPC binding affinity were evaluated.

**[Method]** REDV peptide was conjugated with the 3-(triethoxysilyl) propyl isocyanate (PCSi). The 0.02 - 10.0% PCSi solution was dropped into decellularized ostrich carotid artery and incubated under evacuation condition. The modification was evaluated by EDS and FT-IR. The density was quantified with ¹²⁵I-labeled PCSi. PRP was isolated from mini-pig arterial blood, and the tissues were incubated with the PRP for 1 hour. Human EPCs were seeded on the surface, and cell binding was evaluated by WST-8 assay.

**[Results]** Si signal and Si-O-Si band around 1020 cm⁻¹ in EDS and FT-IR were observed after PCSi treatment, and the REDV immobilized density was 8.4×10⁶ molecules/mm², which is almost 1000 times higher than that immobilized by the previous method using POG sequence. Platelets scarcely adhered on the PCSi treated tissue, but EPCs were adhered and spread out on the surface. These results suggested that the REDV was immobilized at a high density via PCSi, and the surface suppressed platelet adsorption and promoted the EPCs adhesion.

Biodegradable Hollow Capsules for the Efficient Delivery of Therapeutic Molecules and Nanoparticles

Isabel Gessner, Eva Krakor, Sven Santernik and Sanjay Mathur; University of Cologne, Cologne, Germany.

For the interconnection between a synthetic material and living matter, hollow mesoporous silica capsules (HMSC) have recently gained intense attention as drug delivery vehicles due to their biocompatibility, high loading capacity and sufficient stability in biological milieu. Compared to most of the published data, which mainly focus on the formation of spherical mesoporous silica particles, in this work, a simple and reproducible synthesis of ellipsoid-shaped HMSC (aspect ratio – 2) via a hematite template assisted route is presented. Hollow structures were formed through, coating of solid templates with a silica sol followed by acidic leaching of the core material. The porosity of prepared capsules was demonstrated by gas sorption studies, revealing mesoscopic pores around 4 nm and a high surface area of 308.8 m²/g. Both, cell uptake studies as well as cell viability assays, revealed the high biocompatibility of HMSC. Moreover, the successful cellular internalization was proven by confocal microscopy using human cervical cancer (HeLa) cells. The morphology of HMSC for drug delivery and nanoparticle applications was tested by loading antibiotic (ciprofloxacin) and anticancer (curcumin) compounds. A pH dependent drug release over several days under physiological conditions at 37°C was demonstrated (UV-vis spectroscopy) in both cases, which showed the versatility of HMSC in transporting hydrophilic as well as hydrophobic drugs. Ciprofloxacin-loaded HMSC were additionally evaluated towards gram negative (E.coli) bacteria to clearly demonstrate a complete bacterial growth inhibition over 18 hours using particle concentrations of 10 µg/ml. Besides the delivery of therapeutic molecules, metallic nanoparticles such as Cu or Ag were incorporated whereby a controlled leaching of metal ions demonstrated their usefulness for antibacterial applications. Additionally, hollow capsules slowly degraded into non-toxic molecules which is of crucial importance considering their application as biocompatible and clearable drug transporter.

Bacterial Cellulose Growth in Three-Dimensional Micrometric Molds—Production, Characterization and Biomedical Applications

Prospects Adriano J. Ottaka1, Rafael R. Domengeuzzi2, Mollizia Santos1, Sidney Ribeiro1 and Cleber Mendonça1; 1 Photonics Group, São Carlos Institute of Physics, University of São Paulo - USP, São Carlos, Brazil; 2 Laboratory of Photonic Materials, Institute of Chemistry, São Paulo State University - UNESP, Araraquara, Brazil.

Bacterial cellulose (BC) has emerged as an interesting candidate to fabricate advanced biomaterials, aiming applications in the tissue engineering, such as, artificial skin for burns treatment and wound healing. This biopolymer exhibits a nanofibrous porous network highly moldable, with high strength, low density, high biocompatibility, and which can be easily functionalized with drugs or other biological agents for selective applications. In this work, we fabricate several polymeric microenvironments with distinct geometries, to evaluate and study the growth dynamics of bacterial cellulose. The microenvironments were produced by two-photon polymerization using a Ti:Sapphire laser oscillator, centered at 780 nm, operating at a repetition rate of 86 MHz and delivering 100 fs pulses. The polymeric resin used in the microenvironments is composed by two acrylate monomers, tri(2-hydroxyethyl) isocyanurate triacrylate and dipentaerythritol pentaacrylate, which are combined to provide hardness to the structure and a smoothed surface after the polymerization, preventing deformations on the final structure. These monomers are mixed with an acrylpholine oxide photoinitiator, ethyl-2,4,6-trimethylbenzoyl phenylphosphinate, an organic compound responsible to generate free radicals after laser pulse irradiation. The laser beam is focused through a microscope objective (10X, NA=0.25) into the sample and scanned in the x-y direction by a pair of movable mirrors, while the sample's axial (z) positioning is performed by a motorized stage. The photopolymerization experiment can be monitored in real time, by an illumination source and a CCD camera. After complete fabrication of the molds and sterilization, bacteria Gluconacetobacter xylinus (ATCC 23760) are inoculated into the microenvironments, receiving all the necessary conditions for their development. We evaluate the bacterial cellulose growth for one week, monitoring the...
samples in specific times (hourly and daily). The formed biofilms were characterized morphologically and structurally by scanning electron microscopy (SEM), infrared spectroscopy (IRS) and Raman spectroscopy (RS). The structure and composition of growth bacterial cellulose in the microenvironments are similar to those grown in macro systems. The results obtained in this work open new opportunities for tissue regenerative engineering studies, as well as, show other possibilities to evaluate drug delivery mechanisms due to selective permeability of the formed biofilms.

BM04.06.25
Brain HDL-Mimetic Nanomaterials Designed to Mitigate Microglia-Mediated Neuroinflammation in Alzheimer’s Disease Jin-hwan Kim, Song Ih Ahn and Yong-Tae Kim; Department of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Microglia are the innate immune cells of the brain that mediate opposing deleterious pro-inflammatory and protective anti-inflammatory functions in Alzheimer’s Disease (AD). Multiple evidences showed microglia-mediated neuroinflammation has been recognized as a prominent manifestation of the AD brain. As disease-modifying treatments for AD are lacking, specific inhibitors of pro-inflammatory microglial functions with high brain bioavailability are needed. Kv1.3 is a microglial potential and pro-inflammatory functions and is highly expressed by amyloid beta plaque-associated microglia in human AD brains. However, the delivery of the inhibitor into the brain remains ineffective due to the blood brain barrier (BBB) that limits the bioavailability of therapeutic molecules. One possible route to deliver drug molecules across the BBB is to leverage physiologically relevant BBB-on-a-chip device.

We engineered apoE3-based HDL-mimetic nanoparticles (eHNP-E3) in a controllable and reproducible manner using a microfluidic synthesis technology. Lipids derived from 1,2-dimyristoyl-sn-glycero-3-phosphocholine (DMPC) were mixed through a series of microvortices in defined ratios with human recombinant apoE3. A ShK223 peptide (ShK3), an effective Kv1.3 blocker, was conjugated with cholesterol to anchor the peptide on the surface of eHNP-E3. Our microfluidic platform creates a series of controlled microvortices that enabled the rapid assembly of precursors (DMPC and apoE3) into discoidal structures of eHNP-E3 at a Reynolds number (Re ~ 50), followed by the incorporation of ShK into the nanoparticle (eHNP-E3-ShK). The size of eHNP-E3-ShK was approximately 18 ~ 20 nm as demonstrated by DLS and TEM. Successful cellular internalization of eHNP-E3-ShK was also monitored in microglia, suggesting the biological potential function as Kv1.3 channel blocker of this nanoparticle at the subcellular level. We are currently examining the biological function of eHNP-E3-ShK both in our microengineered human BBB-on-a-chip model and in the 5XFAD model.

In summary, we demonstrated successful synthesis and physicochemical characterization of eHNP-E3-ShK and are testing the biological functions for the delivery of a therapeutic molecule into the brain. We are evaluating the biological activities of our nanoparticle targeting anti-inflammatory effects on microglia in vitro and in vivo.

BM04.06.26

In the field of neuronal transplantation therapy, there has been a strong demand for a neuron-electrode interface to make it possible to monitor the process by which a graft is integrated into a host neuronal circuit. Since cell migration and glial scar formation lead to a loss of contact between an electrode and a graft, it is technically difficult to monitor the sequential changes in the circuit between the graft and the host tissue. Fabricating a graft by encapsulating neurons with a self-foldable and biocompatible electrode is a potent strategy for the maintenance of electrode-graft contact, because the graft can be enclosed and fixed by the folded electrode. The encapsulation of neurons with self-foldable metal films has been intensively studied, and close contact between encapsulated neurons and film has been achieved. However, conventional metal films are not applicable with this approach because 1) metal film has insufficient biocompatibility and optical transparency, and 2) the enclosed structure only allows partial connections between the encapsulated graft and the host tissue. In this study, we developed a self-foldable graphene film that has high biocompatibility, optical transparency and permeability with high electro-conductivity. Micro-pores patterned on the film allowed axonal passage, thus providing connections between the graft and host tissue.

The self-foldable graphene film with micro-pores was composed of monolayer graphene and parylene thin film laminated on a sacrificial layer of calcium alginate. Following the dissociation of the sacrificial layer, the graphene-parylene bilayer film was spontaneously rolled up to form a tubular structure by the π-π stacking interaction between these layers. To keep neurons (φ > 10 mm) inside the micro-roll and allow only their axons (φ < 2 mm) passage, an array of 8 mm micro-pores was photo-lithographically formed. We seeded primary hippocampal neurons and induced self-folding. The neurons were successfully kept inside the micro-roll. Furthermore, we confirmed that the micro-pores allowed the passage of axons outside the pore-patterned tube, unlike the plane tube. Time-lapse images of the micro-roll showed that encapsulated neurons extend neurites through the pore-patterned tube onto the bottom of the dish, while neurites grow only from the end of a plane tube. In addition, staining results indicate that Tau-1-positive axons grow more extensively from the pore-patterned tube than from the plane tube. MAP2-positive dendrites and cell bodies were localized within both types of tube, indicating that neurons were kept within the tubes. These results show that the self-folding of our graphene film can be applied to neuron encapsulation and that micro-pores pass axons selectively, providing a pathway for connections between the graft and host tissue. This encapsulation technique with self-foldable graphene film is promising as a tool for realizing a reliable neuronal graft-electrode interface.

Inert Metal/Degradable Metal Hybrid Stent Enabling Sustainable and Controllable H2O2 Generation for Antirestenotic Functionality Hyunseon Seo, Jinmin Park, Yu-Chan Kim and Myoung-Ryul Ok; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Significant advances in design of biocompatible metals allowed development of bare metallic stents (BMSs) utilizing these metals for the treatment of vascular diseases. However, restenosis, caused by abnormal accumulation of smooth muscle cells (SMCs) near BMSs, has hindered BMSs to have practical clinical use. Therefore, a different strategy to selectively inhibit the endothelial cells (VECs).

In our previous studies, we investigated delamination phenomenon of Mg thin film coated on the NiTi stent by using both experimental and simulational (finite element analysis) stretching test, we optimized coating pattern of Mg that can stably maintain the adhesion with NiTi stent even under highly deformed condition. Our
achieve offers a new insight on development of metallic stents by proposing a simple but novel approach to solve restenosis, which has been a major constraint on clinical application of the stent.

A New Hydrogel System Encapsulated Single Red Blood Cell for Transfusion

Mingjie Fan, Yueqi Zhao, Ruikang Tang and Ben Wang; Zhejiang University, Hangzhou, China.

The blood groups severely restrict blood transfusion owing to the antigens on red blood cells (RBCs) recognized by the immune system, which result in vast loss of mismatching blood or shortage of matching blood, sometimes occurrence of significant influence following transfusion in emergency. The red blood cell (RBC) membrane is architecturally complex and is characterized by significant biochemical diversity. The glycoprotein on the surface of RBC determined the blood type, while the different blood type lead to huge obstacle during clinical blood transfusion, especially in natural hazard, terrorist attack and warfare acute transfusion. Here we constructed a cell surface engineering system for hydrogel encapsulated single RBC, which based on the hydrogel formation by enzymatic crosslinking. Using biocompatible anchors for membrane, enzyme which could catalyze for the formation of a layer of hydrogel shell was introduced onto cell surface, and encapsulation of a single RBC by hydrogel shell was produced. We made a system of mTG-gelation hydrogel system which can shield cell surface antigen, more importantly, the physical properties, biological functions, tissue distributions and in vivo biocompatibility of the encapsulated RBCs were similar to those of the native RBCs, indicating a promising application for development using an enzyme catalyzed hydrogel system. These results may provide a new feasible solution for related research and applications for emergency blood transfusion.

A Robust Thin Film with a Selective Antibacterial Property for Infection-Resistant Medical Application

Goro Choi, Eunjung Lee and Sung Gap Im; Chemical and Biomolecular Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Rapid advances in medical and healthcare system brought about a great attention in antibacterial surface coating since bacterial infection of biomedical device are emerging as an urgent issue. Device-associated infections (DAI) have become a serious issue due to the increased risk of infectious diseases requiring hospitalization. Changing the surface properties of medical devices is a simple and direct approach to prevent DAI and intense research efforts have been focused on this aspect. Several surface modification methods such as non-adhesive, antibiotic releasing, silver-coated, or direct killing have been developed and evaluated to prevent bacterial infection on implant surfaces. However, these methods contain inherent limitations such as complicated, laborious procedures, the lack of controllability, cytotoxicity, and leaching problem. Herein, we propose a new strategy for anti-infective surfaces made of a cross-linked ionic polymer film to achieve dual functionality that kill the bacteria while at the same time favor the survival of mammalian cells. A one-step polymerization process, termed initiated chemical vapor deposition (iCVD) process could generate a cross-linked ionic polymer film from 4-vinylbenzyl chloride (VBC) and 2-(dimethylamino) ethyl methacrylate (DMAEMA) monomers in vapor phase. Especially, the deposition process produced a polymer network with quaternary ammonium crosslinking sites, providing the surface with ionic moieties with excellent contact-killing antibacterial property. This method possesses substrate compatibility, which enable the ionic polymer film coating on various materials of medical implants. Moreover, the ionic polymer-deposited surfaces supported the healthy growth of mammalian cells while selectively inhibited the bacterial growth in co-culture models without any detectable cytotoxicity. Thus, the cross-linked ionic polymer-based antibacterial surface developed in this study can serve as an ideal platform for biomedical application requiring highly sterile environment.

Labeling and Specifying the Magnetically Aligned Collagen Fibrils for Hyperthermia Cancer Treatment

Mohammad Reza Zamani Kouhpainji, Daniel Shore, Joseph Um, Yali Zhang, Rhonda Franklin and Bethanie J. Studler; University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

Collagen is the major component of connective tissues and accounts for one-third of all proteins in the human body. The fibril nature of the collagen, especially collagen type I, provides advantages in biological studies, such as imaging and cancer treatment, such as hyperthermia and drug delivery. In these applications and many others, labeling and identifying the cells in order to distinguish and separate the healthy and unhealthy cells is a crucial task to not damage healthy cells while treating the unhealthy ones.

In this work, different ferromagnetic nanowires were electrodeposited, characterized and incorporated into collagen fibrils. The nanowires were crosslinked with the collagen fibrils to achieve one-step bi-directional alignment of the collagen fibrils as verified using optical microscopy techniques. A new technique for radio-frequency identification (RFID) was demonstrated by placing the aligned collagen matrix onto a coplanar waveguide under a fixed microwave frequency while sweeping the magnetic field. The ferromagnetic resonance (FMR) of the nanowires provided distinct signatures for each collagen matrix. Finally, an alternating magnetic field was applied to control and manipulate the temperature of the matrices and investigate the possibility of hyperthermia cancer treatment.

Specifically, variation in the trends of FMR absorption vs. applied field at 240GHz were successfully measured. Engineered effective fields included shape anisotropy of the nanowires/matrix and the dipole moments that the nanowires apply to each other. Minimum detectable concentration of the nanowires in aligned collagen fibrils was quantified to be within a few percent, resulting in optimization of the magnetic properties of aligned collagen fibrils as well as labeling process. Furthermore, the hyperthermia experiments showed that aligned nanowires can prove specific absorption rates up to 1600W/g of ferromagnetic metal. These values are sufficient for both cryowarming of preserved tissues and cancer treatment using aligned collagen fibrils prior to denaturation of the collagen fibrils.

Effect of Microporous Structure on the Mechanics and Permeability of Polymer Films

Angelica Rose Galvan, Kendell M. Pawelec and Jeff Sakamoto; Mechanical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

There are approximately 700,000 peripheral nerve injuries per year, yet there are few technologies to repair damage to nerve tracts > 3cm. Porous poly ε-caprolactone (PCL) multi-channeled scaffolds are a technology that demonstrates nerve regeneration following traumatic nerve injury. However, further enhancing nerve regeneration requires tuning the microstructure within the scaffold architecture to improve nerve regeneration.

The size, shape and interconnectedness of pores in the scaffold walls affect the mechanics and permeability, which are important for suturability, patient mobility, nutrient diffusion and cell adhesion. The ideal scaffold is robust enough to maintain structural integrity during implantation, but also compliant enough to prevent microchannels from collapsing. The scaffold’s porous microstructure is determined by the type of porogen (e.g., NaCl), or the soluble particle that acts as a template for pores.

In order to investigate how microstructure affects scaffold mechanics, characterization was conducted on PCL films with 70 vol% porosity fabricated with porogen (NaCl), with particle sizes ranging from (10 – 60 μm), obtained via ball-milling and roller-milling. The tensile elastic modulus of the films were analyzed and compared. It was found that the elastic modulus decreases as the particle size decreases from 2.40 ± 0.34 to 1.06 ± 0.15 MPa for 62.2 and 9.2
μm particles, respectively. This correlation is likely due to better packing with smaller porogen size.

Permeability tests were also performed to characterize how the varying porogen sizes affected pore interconnectivity, which in turn influences cell adhesion and diffusion. The permeability decreases as the particle size decreases, from 9.91 x 10^{-13} m² at 62.2 µm to 2.53 x 10^{-13} m² at 9.2 µm, due to a reduction in the size of the pore interconnections and increased tortuosity in films with smaller porogen.

Characterizing the effect of scaffold microstructure on mechanics and permeability can help us predict how these properties will affect cell proliferation and adhesion, leading to improved scaffolds for nerve repair.

Enhancing Biocompatibility of Calcium Carbonate Particles for Biomedical Applications

Açıkgöz Mert Oral1, 2, Derya Kapusuz3 and Batur Ercan1 3; 1Middle East Technical University, Ankara, Turkey; 2Metallurgical and Materials Engineering, Gaziantep University, Gaziantep, Turkey; 3BİOMATEN, Middle East Technical University, Center of Excellence in Biomaterials and Tissue Engineering, Ankara, Turkey.

Calcium carbonate (CaCO₃) is a widely occurring biomineral synthesized by marine creatures. In nature, CaCO₃ mainly exists in its anhydrous forms, namely vaterite (unstable), aragonite (metastable) and calcite (stable). Though it is possible to synthesize these anhydrous polymorphs for biomedical applications, it still remains a challenge to fine-tune physical and chemical properties of CaCO₃ particles due to different stabilities of anhydrous polymorphs and their complex crystallization behavior. This situation is especially critical for vaterite particles, which have been proposed for bone cement and drug delivery applications, because of their unstable characteristics.

In our study, pH values and [Ca²⁺]/[CO₃²⁻] ratios of precursor solutions were altered and their effects on the polymorph, morphology and size of CaCO₃ particles were investigated. At low pH values, spherical and ellipsoidal vaterite particles were synthesized, whereas cuboidal and flower-like calcite particles were obtained at high pH values. Importantly, transformations from vaterite to calcite were observed at different pH values depending on [Ca²⁺]/[CO₃²⁻] ratio of the precursor solutions. In addition, average particle size was constantly decreased from micron to submicron sizes with decreasing pH values. Since ethylene glycol concentration was considered as one of the critical factors determining CaCO₃ particle properties, control experiments were performed to distinguish the effects of ethylene glycol concentration and pH values of precursor solutions. pH was observed as the dominating factor controlling CaCO₃ particle properties as opposed to findings in literature, although ethylene glycol concentration was also influential on some of the CaCO₃ particle properties. Since bone cell functions differ depending on physical and chemical properties of particles they interact with, the synthesized CaCO₃ particles were also investigated in vitro using human osteoblasts (bone cells). Results showed that none of the synthesized CaCO₃ particles exhibited any toxic effect upon their interaction with osteoblasts up to 5 days of culture, while polymorph morphology altered bone cell functions.

To conclude, pH and [Ca²⁺]/[CO₃²⁻] ratio of precursor solutions were shown as effective variables on polymorph, morphology and size of CaCO₃ particles without affecting their biocompatible characteristics. In contrast to findings in literature, pH, an ignored variable in most CaCO₃ particles synthesis protocols, was found to be the dominating factor as opposed to ethylene glycol concentration of the precursor solutions. In vitro tests also showed that bone cells performed their cellular functions without any compromise to their viability.

Exploiting Inherent Instability of 2D Black Phosphorus for Controlled Phosphate Release from PLGA/BP Composite Nanofibres

Negin Kamyar1; Ryan D. Greenhalgh2, Tatiana R. Nascimento2, Eliton S. Medeiros2, Peter D. Matthews3, Liebert P. Nogueira4, David J. Lewis1 and Jonny J. Blaker1; 1School of Materials, University of Manchester, Manchester, United Kingdom; 2Department of Materials Engineering, Federal University of Paraíba, João Pessoa, Brazil; 3School of Chemical & Physical Science, Keele University, Newcastle, United Kingdom; 4Department of Biomaterials, University of Oslo, Oslo, Norway; 5Department of Physics, Cambridge University, Cambridge, United Kingdom.

Black phosphorus (BP) is a two-dimensional (2-D) semiconductor with a tunable direct band gap and highly anisotropic properties. It is inherently unstable and degrades into phosphate ions in aqueous media via oxidation 1. Whilst the current paradigm with 2D materials leans toward stabilization, in this study, we do the opposite and explore the use of 2D BP as a source of phosphate ions by exploiting its inherent instability for controlled phosphate ion release. Liquid exfoliated BP 2 was incorporated into degradable poly (lactide-co-glycolide) (PLGA) fibres via solution blow spinning 3, forming a flexible 3-D nanocomposite with a continuous open-fibre structure. With increasing BP concentration, the average fibre diameter increased by 43%, which we attribute to changes in the precursor solution properties including surface tension and viscosity. Raman spectroscopy along with ICP-AES confirmed the incorporation of BP into the nanocomposite. By increasing the initial loading of BP there was an increase in the BP optical phonon mode intensity in Raman spectra. ICP-AES was used to quantify exact BP loading and demonstrated that modifying the initial loading of BP in the PLGA fibres permitted tuneable release rates of phosphate ions over 8 weeks in vitro. Hence, the release rate of phosphate ions from PLGA-BP nanocomposite fibres can be controlled by compositional tuning of brittle and lactide to glycolide ratio in the PLGA. Such nanocomposites have advantages over conventional bioactive glasses as they do not exhibit brittle behaviour which imparts great potential for non-load-bearing bone tissue applications and flexible therapeutic implants.

Hybrid Mats for Wound Dressing Applications from “Green” Renewable Resources

Adnan Memiçi; Tuerdemimaiti Abudula; Lassaad Gzara1, Giovanna Simonetti2, Ahmed Al-Shahrani, Numan Salah1, Pierfrancesco Morganti1, Angelo Chiamenti3, Afsoon Fahlahi1, Ali Tamayol3 and Sidi Benchere1; 1King Abdullah1 University, Jeddah, Saudi Arabia; 2Northeastern University, Boston, Massachusetts, United States; 3University of Nebraska-Lincoln, Lincoln, Nebraska, United States; 4University of Rome, Sapienza, Rome, Italy; 5Nanoscience Centre, MAVI Sud, Aprilia, Italy.

In the local treatment of both chronic and acute wounds it is crucial to prevent infections, control the removal of exudates and create a moist environment to allow for skin healing. To address these challenges it is necessary to develop the next generation of wound dressings. Chitin and lignin are bio-waste resulting from byproducts of crustacean crusts and plant biomass that have recently been proposed for bioengineering applications. However, their weak mechanical properties need to be accomplished this we fabricated hybrid mats composed of a chitin–lignin (CL)-based sol–gel mixture and elastomeric poly
Degradable Polyphosphazenes—Development of First, Second and Third Generational Polymers

Kenneth S. Ogueri, Harry R. Albeck and Cato T. Laurencin

The design of advanced biomaterials with a wide range of properties has been fueled by new fields such as regenerative engineering, defined as the convergence of advanced materials science, stem cell science, physics, developmental biology and clinical translation for the regeneration of complex tissues. The complexity and demands of this innovative approach have inspired the synthesis of new polymeric materials that can be tailored to meet application-specific needs. Polyphosphazenes are composed of an inorganic backbone with alternating phosphorus and nitrogen atoms. Each phosphorus atom bears two substituents, with a wide variety of side groups available for property optimization. Polyphosphazenes have been investigated as potential biomaterials for regenerative engineering. The polymers have received a great deal of attention due to their outstanding synthetic flexibility and their ability to exhibit properties.

Polyphosphazenes for use in biomedical tissue regeneration applications have evolved as a class to include different generations of degradable polymers. The 1st generation of polyphosphazenes for tissue regeneration entailed the incorporation of hydrolytically active side groups such as imidazole, lactate, glycolate, glucosyl, or glycerryl groups. These side groups were selected based on their ability to sensitize the polymer backbone to hydrolysis, which allowed them to break down into non-toxic small molecules that could be metabolized or excreted. The 2nd generation of polyphosphazenes developed for regenerative applications consisted of polymers with amino acid ester side groups. When blended with PLAGA, it showed the feasibility of neutralizing the acidic degradation products of PLAGA but formed mostly partially miscible blends. To overcome the miscibility issue, third generation degradable polyphosphazenes have been designed by incorporating dipeptide side groups which impart significant hydrogen bonding capability on the polymer for the formation of completely miscible polyphosphazene-PLAGA blends. The 3rd generation exhibits a unique degradation behavior by which the polymer is allowed to break down into non-toxic small molecules that could be metabolized or excreted.
study, we have shown that monodispersed polybutadiene forms a convenient biocompatible scaffold, to which the cells can adhere without additional coating. Furthermore, we have verified that the film modulus can be continuously tuned while maintaining the same functional form over a wide range of film thicknesses. The films were then coated with a continuous thin film material which was able to be varied by more than an order of magnitude simply by changing the film thickness. DPSC plated on these PB substrates were able to adjust their moduli in response to the film thickness, obeying the same functional form as the PB films. Yet, despite the continual change in cell hardness, an abrupt change occurred for substrates moduli greater than 2.3 MPa when large amounts of biomineralized deposits were observed after 28 days. RT-PCR analysis indicated that the substrate mechanics induced differentiation of the cells without any additional chemical inducers. Florescent immunohistochemically staining indicated that all the cells in the tissue that formed expressed OCN, a protein necessary for biomineralization and an indicator for osteogenic differentiation, on thin, hard PB films, while no OCN was found in cells on the softer, thick PB films. Hence direct contact with the hard substrate was only required for one of the layers, and the effect was propagated further into the scaffolds. Scaffolds with mechanical patterns surface patterns were then produced with length scales ranging from the macro to the nanoscale. The patterns were produced simply by imprinting on the substrate and adjusting the film thickness, without chemical cross linkers introduced into the PB films. Hence the influence of purely mechanical heterogeneity could be probed. In the case of microscale patterns, the results indicate that the influence of the substrate mechanics is communicated within the tissue via cell-cell contact. In this study, where both hard and soft patterns were present, in a manner with enabled cell-cell contacts to form between patterns, no biomineralization was observed. If cell-cell contacts were prevented, differentiation and non-differentiated cells were able to coexist within a single culture, where the phenotype was governed by the substrate mechanics. This study is important when applying printed scaffolds as dentin/tooth regenerative biomaterials, which surface is rough and the mechanics is not homogeneous.

8:45 AM BM04.07.03
Bioactive Aligned Conducting Polymer Nanofibers Using Laminin-Derived Biomolecules for Neuritogenesis Milad Khorrani, Zhihui Guo, Mohammad Reza Abidian and Anthony M. Kisselev; University of Houston, Houston, Texas, United States.

Peripheral nerve transaction occurs commonly in traumatic injury, causing deficit distal to the injury sites. Many studies have been devoted to promote nerve conduits for nerve injury repair including fabrication of hollow tubes or fibers. However they often fail due to short and slow regeneration over long gap. An ideal nerve conduit for regeneration should provide physical and/or biochemical guidance cue to direct the neural axons. To that end, conducting polymer have been widely used for neural applications due to 1) facile functionalization process with biomolecules to tune biological response, 2) soft mechanical properties that mimics the tissue properties and 3) the ability to transduce mixed ionic and electronic conductivity.

In this research, we investigated the fabrication of bioactive aligned conducting polymer nanofibers (CPN) to potentially directly the extension of neural processes. The fabrication process includes (1) electrospinning of poly(l-lactic acid) (PLLA) template nanofibers from homogeneous solutions of 3% (w/w) PLLA and 2% BTEAC (w/w) dissolved in chloroform at 100 kV/m electrical field and rotation rate of 1500 RPM, (2) electrochemical polymerization of laminin-doped poly(3,4-ethylenedioxythiophene) (PEDOT) from 0.02M PEDOT and 6.17µM laminin-derived peptide ((DEDEDYFQRYLI) in water/acetonitrile (1:1) solution with charge density of 600mC/cm². Scanning electron microscopy showed that the size of PLLA fibers was 302.6±101.66 nm diameter (n=100). The X-ray photoelectron spectroscopy results have proved the presence of laminin-derived peptide on the surface of CPN. We characterized the electrical properties (i.e. impedance and capacity of charge transfer) of the bioactive CPN. We will use rat dorsal ganglia to study the effect of laminin-doped aligned CPN on growth of neuronal cells and neurite outgrowth. Future study will also focus on creating a gradient of human lamin on the surface of aligned CPN as guidance for axonal growth.

9:00 AM BM04.07.04
Enhancing Osteointegration on Biodegradable Polymer Scaffolds with ALD Deposition of Titania Kuan-Che Feng1, Adriana Pinkas-Sarafova1, Likun Wang1, Ya-Chen Chuang1, Linxi Zhang1, Chung-Chueh Chang1,2,3, Marcia Simon1 and Miriam Rafailovich1; 1Stony Brook University, Stony Brook, New York, United States; 2Advanced Energy Center, ThINN Facility, Stony Brook, New York, United States.

Fused deposition modeling (FDM) is a rapidly growing method for device fabrication. The technique is inexpensive and the product, such as bone inserts, dental devices, can be printed directly from CT scans or impressions, and hence specifically tailored for the individual. However, from the former study shows that the cell did not attach well on the FDM printed surface due to the roughness of FDM printed surface and hydrophobicity of the polyactic acid (PLA).

In this study we produced FDM printed scaffolds that were then coated with titanium dioxide via the atomic layer deposition (ALD) method. TiO2has been shown in numerous studies to enhance osseointegration. Hence by this technique one can produce scaffolds that are at once biodegradable, and yet support osteogenic or odontogenic differentiation. In order to probe this concept we plated dental pulp stem cells on these scaffolds, incubated for 28 days, in media with glycerol phosphate, but without the commonly used induction factor, dexamethasone. The culture was then harvested for qRT-PCR and the surfaces were imaged with scanning electron microscopy. Cell mobility, proliferation, and differentiation were studied and significant differences in both biomimeralization and differentiation were observed between coated and uncoated surfaces.

9:15 AM BM04.07.05
Mechanical Perfromances of Engineered Polymer Scaffolds Ozlem Yasar1 and Ozgul Yasar-Inceoglu2; 1City University of New York, Brooklyn, New York, United States; 2Mechanical Engineering, California State University, Chico, Chico, California, United States.

There are more than 114,000 people are waiting in the waiting list for an organ transplantation and on average 20 people die each day waiting for a transplant. In recent years, tissue engineering has brought to the attention to do organ/tissue regeneration as an alternative way to the organ transplantation. Success rate of tissue regeneration strongly depend on the accurate scaffold fabrication. In this research, scaffolds were fabricated with Poly(ethylene glycol) diacrylate (PEGDA) and 2,2-dimethoxy-2-phenylacetophenone (DMPA). PEGDA is a biocompatible polymer that can be easily cured in the room temperature. DMPA is used as a photoinitiator, which starts the polymerization reaction when it interacts with the UV light. The mechanical characterization of PEGDA and DMPA mixture have been considered in some range in tissue engineering field. However, it is not fully studied.

In this research, firstly, PEGDA was diluted with water to prepare 20% and 40% PEGDA and 80% PEGDA. With these different PEGDA concentrations, cylindrical samples were prepared with photolithography process. On the other hand, 0.02% (w/v), 0.06% (w/v), and 0.1% (w/v) photoinitiator-solvent mixtures were prepared to alter the DMPA concentration. Then, cylindrical samples with altered DMPA concentrations were also prepared with photolithography process. After that, compression tests for all the cylindrical samples that were prepared with different PEGDA and DMPA concentrations performed with the Instron 3369 universal testing machine. Our results indicate that, as the PEGDA concentrations increased, compressive strength of the hydrogels also increased and PEGDA concentration had significant effects on elastic modulus and ultimate strength. Average ultimate strengths for 20%, 40% and 80% PEGDA concentrations were in the order of 1 MPa, 1.5 MPa, and 4.5 MPa, respectively. Our results related to the effect of photo-initiator on mechanical properties of engineered scaffolds showed that as the DMPA concentration was increased, ultimate strengths were decreased. For 0.02% (w/v),
While silver salts are frequently used as a source of antimicrobial silver ions (Ag\(^+\)), their elution in commercial external wound care products is immediate and therefore their solubility is used to control Ag\(^+\) availability, often leading to exposure to unnecessarily high and cytotoxic levels. In approach (1), silver nitrate (AgNO\(_3\)) is dissolved into the PLGA/PEG blowspinning solution, establishing consistent loading and elution profiles: The PLGA/PEG:Ag fibers release Ag\(^+\) quickly in a controlled manner over 24 hours, and they continue to release Ag\(^+\) over 30 days. AgNO\(_3\) concentration was tuned to 1 mg/mL to produce a dressing that inhibits microbial growth but does not affect cell viability. In a porcine burn graft donor model, PLGA/PEG:Ag can be applied once and requires few, if any, reapplications during the course of healing, and produces no delay in healing compared to a conventional polyurethane dressing. Because it is biodegradable, the polymer is incorporated into the scab and can be removed after the wound bed is reepithelialized and no longer requires a dressing.

Polymers can also be used internally as surgical sealants to prevent fluid leaks and promote hemostasis by occlusion of blood flow. However, uncharged synthetic polymers lack a mechanism to trigger the coagulation cascade. Approach (2) incorporates silica particles into PLGA/PEG to trigger the coagulation cascade via the “glass effect”, which takes advantage of the strongly negative charge present on bare silica. Composite sealants cause citrated blood to clot in scenarios where PLGA/PEG alone does not. The effect is also size-dependent: composites containing 20 nm silica particles cause blood to clot 25% faster with coexisting 600 nm particles. The composite sealant was tested in a liver laceration model, and achieved near-complete hemostasis within 15 minutes, while PLGA/PEG did not. Additionally, silica particles increase adhesion and can be used to modify the stiffness and extensibility of the sealant.

Delivery of therapeutic cargo to hematopoietic stem cells (HSCs) is a challenging problem whose solution could transform the treatment of many diseases, ranging from autoimmune disorders to hematological malignancies [1]. HSCs are multipotent cells that can differentiate into all blood cell types in the body, so delivering agents that promote lineage-specific differentiation of HSCs could transform medical practice. However, delivering therapeutic cargo to HSCs in vivo is extremely difficult given that HSCs reside in bone marrow and are notoriously difficult to transfect. To overcome this challenge, we have developed a biomimetic nanoparticle (NP) platform that enables targeted cargo delivery to HSCs.

We hypothesized that polymeric poly(lactic-co-glycolic acid) (PLGA) NPs coated with membranes derived from megakaryocytes (Mks) could enable specific recognition of HSCs for targeted cargo delivery. This hypothesis was based on prior work that showed megakaryocytic microparticles (extracellular vesicles that bud off Mk cells) could specifically bind and enter HSCs in vitro [2,3]. Here, we provide the results of our in vitro studies, which demonstrate the synthesis of Mk membrane-wrapped PLGA NPs (MkNPs) and validate that these MkNPs can effectively bind and enter HSCs to deliver their cargo.

To create MkNPs, ~100 nm diameter DiD-loaded PLGA NPs were co-extruded with empty membrane vesicles derived from Mk cells, which were labeled with PKH26, using an Avanti Mini Extruder. DLS and TEM measurements showed that MkNPs were monodisperse and spherical, with wrapped NPs having a diameter 10-20 nm larger than bare NPs. Bare NPs had a zeta potential of -48.55 mV, and the charge of MkNPs (-19.18 mV) was similar to that of membrane vesicles (-20.93 mV), indicating successful wrapping. Successful wrapping was further confirmed by stability in PBS, as MkNPs placed in PBS at 4°C did not swell, while bare NPs swelled from 120 nm to 600 nm in <1 h. Flow cytometric analysis of CD41, an outer membrane marker, on MkNPs versus membrane vesicles confirmed through similar expression levels that the membranes were right-side out on the MkNPs. Confocal imaging showed that CD41+ HSCs take up MkNPs within 24 hours of incubation, and super-resolution microscopy confirmed that PKH26 and DiD signals colocalize within HSCs. The MkNPs preferentially interact with the uropod region of HSCs, similar to what has been reported for megakaryocytic microparticles [2,3].

In summary, PLGA NPs can be wrapped with Mk-derived membranes, allowing the resultant MkNPs to bind HSCs to deliver their cargo. These data support continued development of MkNPs for HSC manipulation.

10:00 AM BREAK
Cellulose materials have shown great potential for biomedical applications owing to their intrinsic characteristics, such as biocompatibility, hydrophilicity, porosity, and tunable mechanical properties[1]. Wood-derived nanocellulose, coming from the most abundant biomass on earth, is naturally low cost and suitable for mass production. Compared to widely studied and commercially developed bacterial nanocellulose[2], wood-derived nanocellulose supports easy post-polymerization processing, both mechanically and chemically, making it a favorite candidate for applications such as 3D bioprinting[3].

In this study, we used cellulose nanofibrils (CNF) prepared from bleached birch kraft pulp, chemically oxidized using 2,2,6,6-Tetramethylpiperidinyloxy or 2,2,6,6-Tetramethylpiperidin-1-oxyl (TEMPO) and mechanically treated[4]. This CNF consisted of fibers with a dimension of ca. 5 nm in width and hundreds of nanometers in length and had a consistency of 1 w%/v with 1.14 mmol/g negative charge attributed to carboxylic acid groups from TEMPO-oxidization. The prepared CNF demonstrated excellent rheological properties in demand for 3D printing, in terms of high yield stress and shear thinning properties. Herein, we report for the first time 3D printed scaffolds with high resolution features printed using a single CNF component.

A secondary cross-linking approach was also investigated to further enhance and adjust the stability and mechanical properties of the 3D printed CNF scaffolds. CNF scaffolds were first cross-linked through ionic interaction between Ca²⁺ and carboxylic groups on the fiber surface of CNF, which provided a fast and in situ mechanism for 3D printing. The printed CNF scaffolds were then chemically cross-linked by 1,4-butandiol diglycidyl ether (BDDE) to form irreversible covalent bonds.

A series of characterizations were performed on the biofabricated CNF scaffolds, including rheology, swelling ratio, mechanical tests and cell culture, etc. The CNF scaffolds had demonstrated long term stability in PBS and a high ratio for water re-adsorption after freeze-drying. The compressive Young’s modulus and shear modulus were in the suitable range for skin wound healing and the cell studies showed positive results in supporting human dermal fibroblast cells adhesion and proliferation.

Aligned Conducting Polymer Nanotubes for Precisely Triggered Release of Proteins
Mohammadjavad Eslamian and Mohammad Reza Abidian;
University of Houston, Houston, Texas, United States.

Conducting polymers actuators are one of the most promising materials for development of controlled drug delivery systems, owing to their outstanding capability to reversibly change their volume during electrochemical process. We previously demonstrated the precise release of drugs such as dexamethasone from conducting polymer nanotubes. The fabrication process involved electrospinning of drug-loaded biodegradable nanofibers on microfabricated electrodes, followed by electrochemical deposition of conducting polymers on microelectrodes and around the electrospun nanofibers. Poly(3,4-ethylenedioxythiophene) (PEDOT) is one of the most versatile conducting polymers employed in the field of polymer electronics, owing to its superior electrical conductivity and chemical stability. Soluble growth molecules such as nerve growth factor (NGF) provide trophic support for neurons and are vital for axonal growth. The goal of this research is to develop a nanoscale device for precise delivery of NGF. To accomplish this task, NGF is encapsulated in aligned poly (lactic-co-glycolic acid) (PLGA) nanofibers via emulsion electrospinning process on gold coated silicon-based electrodes. Then, a thin layer of PEDOT is galvanostatically deposited on the electrodes and around the electrospun nanofibers at the current density of 1 mA/cm² for 1 min to form NGF-loaded aligned PEDOT nanotubes. The outer diameter of PEDOT nanotubes is 440±91 nm. The release behavior of NGF from PEDOT nanotubes is investigated by electrical actuation of PEDOT nanotubes in phosphate-buffered saline (PBS) using enzyme-linked immunosorbent assay (ELISA). The electrical actuation will be performed using cyclic voltammetry (CV) at the potential range of -0.8 V to +0.4 V at different scan rates, including 10, 50, 100, and 200 mV/s, and for different numbers of CV cycles (up to 100 cycles). Finally, the NGF release rate will be assessed as a function of scan rates and CV cycles. The results of this study may have impact for development of NGF delivery platforms for modular growth of axons in both central and peripheral nervous systems.

Solvent-Free Preparation of Porous Poly(L-Lactide) Microcarriers for Cell Culture and Bone Tissue Engineering
Mirasbek Kuterbekov1, 2, Paul Machillo2, Pierre Lhuissier3, Catherine Picart4, Alain M. Jonas1 and Karine Glinel1; 1BSMA, IMCN, Université catholique de Louvain, Louvain-la-Neuve, Belgium; 2IMBM, LMGP, Communauté Université Grenoble Alpes, Grenoble INP, CNRS, Grenoble, France; 3SIMAP, Communauté Université Grenoble Alpes, Grenoble INP, CNRS, Saint Martin d'Heres, France.

One of the main challenges in regenerative medicine is the development of appropriate biomaterial constructs that can guide cell behavior. Microcarriers are particularly attractive in this regard due to their small size. This feature allows them to circumvent many of the issues facing more traditional monobloc constructs such as low nutrient-metabolite exchanges and uneven cell infiltration into the bulk while still being suitable for dynamic culturing and engineering of large-scale tissue grafts [Declercq et al. Biomaterials 2013]. Porous microcarriers made of synthetic biodegradable polymers have the added advantage of a larger surface area, improved mass transfer and the tunability of their bioactive properties.

Currently, most methods for the production of porous polymeric microcarriers rely on creating emulsions, which require potentially toxic organic solvents and relatively complex setups [Silva et al. J. Tissue Eng. Regen. Med. 2007]. Alternatives limiting the use of organic solvents have been proposed; however, such methods often fail to replicate the tunable microcarrier morphologies that can be obtained with the emulsion-based methods. This in turn hinders the wider adoption of microcarriers due to concerns over safety to human health and potential limits in large-scale production.

To address this issue, we developed a novel organic-solvent-free approach for the production of porous poly(L-lactide) (PLLA) microcarriers. The method is based on the isothermal spherulitic crystallization of PLLA in its blend with polyethylene glycol (PEG). Resulting PLLA spherulites are easily recovered as microcarriers by simple removal of water-soluble PEG. Independent control and tunability of microcarrier size and porosity were demonstrated, with high crystalization temperatures leading to larger sizes and higher PLLA content resulting in lower levels of porosity. Moreover, microcarriers were shown to support not only the long-term proliferation of murine myoblast and human adipose stromal/stem cells (hASC) but also differentiation of hASCs towards osseous tissues. Furthermore, while no significant differences were observed during cell proliferation on microcarriers of two different porosities, microcarriers of lower porosity induced a stronger hASC osteogenic differentiation, as evidenced by higher alkaline phosphatase enzymatic activity and matrix mineralization. Consequently, the proposed organic-solvent-free method for the fabrication of biocompatible porous PLLA microcarriers represents an innovative methodology for ex vivo cell expansion and its application in stem cell therapy and tissue engineering.

In this study, we show that by combining physical reversible soft bonds with stiff covalent bonds in p(HEMA-co-EGDMA) based hydrogels, different properties were screened successfully. The principal finding is that fucoidan favours islet survival inside hydrogels and is effective in reducing the immune response, suggesting that fucoidan hydrogels can be used for regeneration (GBR). GBR consists of applying a barrier membrane to separate inflamed gingival tissue from bone, restricting invasion and allowing regeneration of osteoblasts. Current barrier membranes, however, do not fulfill all the desired properties of high biocompatibility, cell impermeability, and, in particular, high mechanical strength. As such, the following study synthesized novel Gelatin-Pluronic F127 hybrid hydrogels, thoroughly analyzing their in vitro viability as potential cell barrier membranes for use in GBR. Rheological analysis demonstrated high mechanical strength as hybrid hydrogels’ elastic moduli drastically increased with increasing percentages of the chemical cross-linker microbial transglutaminase (mTG). The surface of the hybrid gels was visualized with laser microscopy to show topographic changes among different crosslinking density. Cytotoxicity tests were first conducted to show the biocompatibility of hybrid gels. To investigate levels of cell adherence, confocal microscopy was performed on hybrid hydrogels plated with human dermal fibroblasts, which demonstrated significantly reduced cell attachment as compared to pure gelatin. Cell impermeability was further investigated by observing cell migration from gelatin gel to hybrid gel compared with from gelatin to gelatin, with a control setup consisting of Gelatin / Gelatin / Gelatin and an experimental setup of Gelatin / Hybrid / Gelatin. Human dermal fibroblasts plated on gelatin gels migrated through the middle gelatin, but, particularly at the highest mTG concentration, were unable to migrate through middle hybrid gels, showing hybrid hydrogels’ impermeability to cells. Our findings, identifying in vitro high mechanical strength, cell impermeability, and biocompatibility, point to novel Gelatin-Pluronic F127 hybrid hydrogels as promising biomaterials for use as GBR cell barrier membranes in treatment of periodontitis.

Type-1 diabetes is an autoimmune disease affecting ~90,000 children each year. Destruction of the insulin-producing islets by the autoactivated immune system leads to type-1 diabetes. Implantation of cells from other sources cannot reverse the condition owing to the immune response as the cells remain in contact with an activated immune system. In previous works, encapsulation of islets inside a hydrogel has shown promise but the cells were not protected from small inflammatory cytokines. Therefore, advanced functionality in a carrier with immunomodulatory capacity is a strategic goal for islet implantation. Marine-sulphated polysaccharides possess unique features that are shared among the extracellular matrix polysaccharides and have immunomodulatory properties. In the present work, fucoidan and three carrageenans (with different numbers of sulphate groups) were functionalised with methacrylate groups for photopolymerisation; the number of functional group in the polysaccharide chain was controlled precisely. The toxicity of the polysaccharides was evaluated by the cell growth inhibition assay on fibroblast L929 cells and all of them were found noncytotoxic. Fucoidan treatment resulted in a significant decrease in the LPS-stimulated expression of CD86, a costimulatory molecule essential to exert a full immune response to implanted islets, on PMA-differentiated THP1 cells; this response was comparable to that of IL-10, an anti-inflammatory cytokine. Fucoidan had a protective effect on THP1 cells from LPS- and IFN-mediated growth inhibition. Fucoidan also decreased the LPS-stimulated production of nitric oxide. For islet encapsulation, methacrylated polyvinyl alcohol (PVA) was synthesised and used as the base polymer and the marine polysaccharides were incorporated in order to support cell survival and impart immunomodulatory properties. Mouse insulinoma cell line, MIN6 cells were encapsulated in hydrogels (20 wt%) by UV photopolymerisation. Cell viability was assessed over a period of 28 days by live/dead assay, revealing a positive correlation between the number of sulphate groups in the disaccharide units and cell survival. Cell viability was found to be maximal in the fucoidan hydrogels that remained stable over this period. The protective effect of the hydrogels from inflammatory cytokines was evaluated by incubating the encapsulated islets in a medium containing inflammatory cytokines (IL-1β, TNF-α, & IFN-γ) for 48 h. Cell viability in the fucoidan hydrogels remained unaffected, which indicates the protective role of fucoidan, whereas decreased cell viability was observed in other hydrogels. The results show that marine polysaccharides with immunomodulatory properties were screened successfully. The principal finding is that fucoidan favours islet survival inside hydrogels and is effective in reducing the immune response, suggesting that fucoidan hydrogels can be used for in vivo islet implantation for the treatment of type-1 diabetes.
SESSION BM04.08: Polymeric Biomaterials for Regenerative Engineering III

1:30 PM BM04.08.01
Photo-Responsive Peptide Hydrogels for Tailorable Epitope Presentation Zain Siddiqui1, Peter Nguyen1, Biplob Sarkar1, David Sabatino2 and Vivek Kumar1; 1New Jersey Institute of Technology, Newark, New Jersey, United States; 2Seton Hall University, South Orange, New Jersey, United States.

Self-assembling peptides can form nanoporous hydrogels that can deliver cells, small-molecule drugs, and growth factors to potentiate phenotypic modulation. Here we show a modification of this platform that may tailor the in vitro and in vivo phenotype of a cellular niche via caged short pro-apoptotic sequences. We demonstrate the dose-dependent cell viability in vitro and show sequence dependent cellular infiltration in vivo. Although cytocompatible cellular carriers are promising delivery vehicles, potential for maladaptive responses, such as teratoma formation, are potential roadblocks for clinical translation. We designed and assembled sacrificial scaffolds that can be tuned on-demand. Peptides with cell adhesive RGD or pro-apoptotic WEWT moieties were introduced to create cell-adhesive and cell-arresting hydrogels. Culture of fibroblasts and stem cells demonstrated signaling efficacy of the hybrid peptides. Photobleaching caging of adhesive and arresting groups show remarkable potential for triggerable adhesion, proliferation, or apoptosis. “Caging/uncaging” of cellular signaling domains can act as an “on/off” switch in cell-loaded 3D hydrogels. Photo-patterning of cell-loaded gels yielded well-resolved niches of specific cells. Subcutaneous implants of the hydrogel showed biocompatibility through cellular infiltration and lack of a fibrous capsule around the implant. Light-activated switching of cellular behavior and phenotype could be broadly useful for construction of new photo-responsive scaffolds with encoded signals for controlling cellular outcome. Multicomponent tissue-engineered scaffolds based on this technology may be crucial next steps for our design paradigm.

1:45 PM BM04.08.02
Self-Expanding and Biodegradable Porous Scaffolds Based on Magnesium-Hydroxide and Hydrocolloids for Bone Tissue Engineering Domenic T. Cipollone1, Cerasela Dinu2 and Konstantinos Sierros1; 1Mechanical and Aerospace Engineering, West Virginia University, Morgantown, West Virginia, United States; 2Chemical and Biomedical Engineering, West Virginia University, Morgantown, West Virginia, United States.

The repairing and regeneration of large bone defects is a significant clinical challenge and has garnered considerable research attention over the past few decades. Typical methods for bone regeneration include allografts (from patient to patient), autografts (from one site to another), or metal implants. While useful, these practices limit availability, donor site morbidity, and the risk of disease transfer. Moreover, metal scaffolds may require a secondary surgery for removal of the implant. Therefore, the controlled engineering of biodegradable, biocompatible, porous, and mechanically robust scaffolds is crucial.

This work reports on the fabrication and characterization of self-expanding, biodegradable, porous magnesium-hydroxide-hydrocolloid scaffolds for use in bone tissue regeneration. In particular, the proposed interconnected porous network is engineered through in-situ hydrogen gas generation, thus providing the framework for a biodegradable and osteoconductive scaffold, while offering control over the pore size distribution and the resulting mechanical properties. The engineered foam is shown to be self-expanding in confined spaces, thus able to fill irregular and complex geometries. Furthermore, the use of magnesium-hydroxide, in combination with cross-linked hydrocolloids, aims to provide a solution to the high corrosion rates typical of magnesium scaffolds currently utilized. Surface morphology and porosity of the scaffolds are characterized though micro-computed tomography, scanning electron microscopy, and porosimetry, while uniaxial compression tests are used to study the resulting mechanical properties. In vitro studies are then used to determine cell viability and bioactivity of the scaffolds. It is found that the total porosity and pore size distribution of the scaffolds may be tailored through control of the magnesium-solvent reaction and resultant hydrogen generation. Moreover, this leads to control over the scaffold’s relative density and compressive modulus. It is believed that this work may hold the key for the development of next generation - low-cost, highly porous, biodegradable, and self-expanding - scaffolds for use in bone tissue engineering and regeneration.

2:00 PM BM04.08.03
Biodegradable Nitric Oxide (NO) Storage and Delivery Hyaluronic Acid-Based Nanofibers—Potent Applications for Tissue Engineering and Regenerative Medicine Kihak Gwon and Jae Ho Shin; Department of Chemistry, Kwangwoon University, Seoul, Korea (the Republic of).

Nitric oxide (NO) is one of the smallest pharmaceutical gas molecules, which mediates versatile physiological processes including stem cell regulation, angiogenesis, immune response, vasodilation, blood pressure regulation, antibacterial property, and wound healing. These several physiological functions have motivated researchers to develop various NO delivery systems for therapeutic applications. Recently, electrospun nanofibers as a NO carrier have received a great interest because of their facile functionalization, tunable mechanical properties, and large effective surface areas. In our previous studies, we have developed a series of polymethylmethacrylate (PMMA)-based NO-releasing nanofibers where NO donor N-diazienumidolate-modified aminoalkoxysilane and silyl-modified PMMA are covalently bound via sol-gel chemistry, displaying tunable NO storage amount and release kinetics. However, PMMA-based NO-releasing nanofibers are difficult to be degraded in the physiological milieu, restricting its potential in vivo applications. Our recent work has thus, aimed to develop biodegradable, NO-releasing hyaluronic acid (HA)-based nanofibers. The NO donor N-diazienumidolates are covalently bound to the HA backbone via use of appropriate conjugate chemistry. Various chemical compositions (e.g., HA concentration and NO donor amount) and electrospinning conditions (e.g., applied potential and flow rate) are tuned to control fiber diameter, degradability, and NO release properties (e.g., maximum flux, total NO release amount, and half-life time). In addition, cell proliferation and migration controlled by such NO-releasing nanofibers and its cytotoxicity are evaluated.

2:15 PM BM04.08.04
Fabrication of 3D Scaffolds Based on Nano-Biomimetic Collagen Hybrid Constructs for Skin Tissue Engineering Abolfazl Akbarzadeh1, Soodabeh Dovaran2, Ebrahim Mostafavi1 and Azizeh Rahmani Del Bakhshayesh1; 1Northeastern University, Boston, Massachusetts, United States; 2Tabriz University, Tabriz, Iran (the Islamic Republic of).

Three dimensional (3D) biodegradable and biomimetic porous scaffolds are ideal frameworks for skin tissue engineering. In this study hybrid constructs of 3D scaffolds were successfully fabricated by freeze-drying method from combinations of the type I collagen (Col), and synthetic poly (lactic acid) (PLLA) or polycaprolactone (PCL). Four different groups of 3D porous scaffolds including PCL, PCL-Col, PCL-PLLA, PCL-PLLA-Col were fabricated and systematically characterized by HNMR, FT-IR and SEM. Adipose tissue derived mesenchymal stem cells (AT-MSCs) were seeded in all scaffolds and the
viability, proliferation and adhesion of the cells were investigated using MTT assay and scanning electron microscopy (SEM). The results showed that scaffolds containing Col, particularly PCL-PLLA-Col scaffold, with pore sizes close to 400nm and sufficiently interconnected, have significantly greater potential (p<0.01) for encouraging AT-MSCs adhesion and growth. The PCL-PLLA provided a mechanically stronger mesh support and the type I Col microsponges encouraged excellent cell adhesion and tissue formation. The scaffold with the best properties could be an appropriate functional candidate for preparation of artificial skin constructs.

Hydrogels with Tunable Degradability for Tissue Engineering Applications—Characterization of Morphological Changes Using Cryo-SEM
Bonhye Koo1, Soyon Kim2, Jiwen Zheng3 and Min Lee3; 1U.S. Food and Drug Administration, Silver Spring, Maryland, United States; 2University of California, Los Angeles, Los Angeles, California, United States.

Photopolymerizable hydrogels are commonly used as tissue engineering scaffolds. Under visible blue light irradiation (VBL), methacrylated glycol chitosan (MeGC) can be photopolymerized with riboflavin (RF, vitamin B2 derivative) and applied to support the encapsulated cell proliferation and deposition of extracellular matrix. MeGC alone, however, is not a perfect candidate for a scaffold due to its relatively slow degradation rate. This is critical for a tissue engineering scaffold since it might hinder cell recruitment and delay tissue regeneration. Thus, there is strong impetus to develop a degradable tissue engineering scaffold to allow subsequent tissue regeneration and/or the release of encapsulated bioactive molecules.

In this report, we designed hydrogels with tunable degradation by incorporating lysozyme (Lys) with various concentrations (0, 0.1, and 1 mg/mL) in MeGC, based on its ability to degrade chitosan by cleaving the polysaccharide backbone. A suitable characterization technique is required to demonstrate the degree of hydrogel degradation. Cryogenic scanning electron microscopy (cryo-SEM) allowed to preserve the native structure of hydrogels in a frozen hydrate state and enabled direct imaging of the mesh structure of hydrogels degraded at atmosphere at 37 °C at a nanometer resolution. Our cryo-SEM micrographs of three hydrogels clearly showed differences in size of the mesh structure and the size change from day 0 to day 10. At day 0, the average pore size of the mesh structure was 38.6, 36.7, and 37.9 nm respectively for MeGC, Lys0.1 and Lys1. Their size changed to 67.6, 86.4, and 408.6 nm respectively for MeGC, Lys0.1 and Lys1 after 10 days. In addition, the maximum pore size increased up to 1,200 nm for Lys1 at day 10. This supported that MeGC hydrogel became degradable with lysozyme and the degree of degradation was controllable by adjusting the amount of lysozyme.

3:15 PM BM04.08.06
Fabrication of Composite Bone Scaffolds with Controlled Multi-Scale Porosity Using Non-Solvent Induced Phase Separation Based 3D Printing
Mehtemt S. Axdin1, Gullu Kiziltas1, 2 and Busra Kologlu1; 1Sabanci University, Istanbul, Turkey; 2Sabanci University Nanotechnology Research and Application Center, Istanbul, Turkey.

Bone fracture is a widespread injury associated with individual disability and loss of social productivity resulting in very high treatment costs. Well-designed scaffold implants are good alternatives in bone tissue engineering known to result in effective healing. An ideal bone scaffold should be biocompatible, porous, interconnected and strong, i.e. multi-functional. Therefore, composite materials stand out as desired material candidates. Advances in the design and production of porous composite scaffolds took place owing to solid free-form fabrication (SFF) techniques with mechanical and biological functions tailorable to specific bone defects. Aim of this study is to develop an effective SFF based technique capable of printing composites with well controlled macro-micro porosities making primarily use of commercial 3D printers. Similar features are displayed by novel designs obtained via topology optimization. Poly(ε-caprolactone) (PCL) was chosen as the scaffold polymer, which is FDA approved. A variety of SFF techniques have been developed to produce controlled porous PCL scaffolds. Also, incorporation of bioactive, stiff inorganic materials into PCL polymer led to significant enhancements in mechanical properties, bioactivity, and bone regeneration ability. However, only a few attempts have been made to create scaffolds with macro-micro porosity, despite their potential to more closely mimic the hierarchical architecture of native bones. Recently, non-solvent-induced phase separation (NIPS) seems capable of producing these scaffolds with multi-scale porosity if integrated into the 3D printing based process. Using this method, here we develop scaffolds with multi-scale porosity (~10 μm and ~100 μm) where, PCL pellets are dissolved in the THF solvent and mixed with various amounts of HA powders. Resulting solution is extruded and deposited in ethanol bath at RT. Microporous PCL/HA composite filaments are created via exchange of the solvent and the non-solvent (EtOH). Printing parameters were optimized in order to match the designed scaffold geometry. Morphological parameters such as porosity and connectivity of scaffolds were analyzed via micro-CT and SEM. FTIR, TGA and mechanical testing for tensile and compressive strength were carried out. Biological in-vitro tests for cytocompatibility and osteo-forming ability are underway to measure cell attachment, proliferation and growth. Initial results show that using NIPS and commercial printing, scaffolds displaying both macro and micro-porosity (%10-20) were successfully fabricated. Further characterization should prove that these scaffolds are bio-compatible, strong and well-designed. The capability to directly manufacture novel designs should open up new possibilities for other applications demanding multi-functional scaffolds, thereby allowing effective patient specific treatment.

3:30 PM BM04.08.07
3D Woven Metallic Lattices as Bio-Scaffolds with Hydroxyapatite Coatings
Ju Xue1, Ashley Farris2, Yunfei Wang3, Cristina Romany1, James Guest3, Warren Grayson3, Shoji Hall1 and Timothy P. Weihs1; 1Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 2Biomedical Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 3Civil Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

Fabrication of composite bone scaffolds with controlled multi-scale porosity using non-solvent induced phase separation based 3D printing of mehtemt s. axdin1, gullu kiziltas1, 2 and busra kologlu1; sabanci university, istanbul, turkey; sabanci university nanotechnology research and application center, istanbul, turkey.

Bone fracture is a widespread injury associated with individual disability and loss of social productivity resulting in very high treatment costs. Well-designed scaffold implants are good alternatives in bone tissue engineering known to result in effective healing. An ideal bone scaffold should be biocompatible, porous, interconnected and strong, i.e. multi-functional. Therefore, composite materials stand out as desired material candidates. Advances in the design and production of porous composite scaffolds took place owing to solid free-form fabrication (SFF) techniques with mechanical and biological functions tailorable to specific bone defects. Aim of this study is to develop an effective SFF based technique capable of printing composites with well controlled macro-micro porosities making primarily use of commercial 3D printers. Similar features are displayed by novel designs obtained via topology optimization (Hollister, S. J., Nature Materials, 2003; Aslan, O. S. and Kizilitas, G., Proc. of TERMIS-EU, 2013). Poly(ε-caprolactone) (PCL) was chosen as the scaffold polymer, which is FDA approved. A variety of SFF techniques have been developed to produce controlled porous PCL scaffolds. Also, incorporation of bioactive, stiff inorganic materials into PCL polymer led to significant enhancements in mechanical properties, bioactivity, and bone regeneration ability. However, only a few attempts have been made to create scaffolds with macro-micro porosity, despite their potential to more closely mimic the hierarchical architecture of native bones. Recently, non-solvent-induced phase separation (NIPS) seems capable of producing these scaffolds with multi-scale porosity if integrated into the 3D printing based process. 3D Woven Metallic Lattices as Bio-Scaffolds with Hydroxyapatite Coatings
Ju Xue1, Ashley Farris2, Yunfei Wang3, Cristina Romany1, James Guest3, Warren Grayson3, Shoji Hall1 and Timothy P. Weihs1; 1Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 2Biomedical Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 3Civil Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

There is a strong need for the next generation of bio-scaffolds that combine biologically activated coatings with porous and biodegradable substrates. Here we present results of studies of 3D woven metallic lattices that are designed using topology optimization to enhance fluidic permeability and mechanical stiffness and are coated uniformly with hydroxyapatite (HAp) to improve bioactivity and osteointegration. The ultimate goal is to weave and coat Mg alloy wires. Here we present initial results describing successful coating of HAp on 304 stainless steel wires and a study of in vitro corrosion of Mg alloy wires of various chemistries and diameters.

304 stainless steel wires with ~200 diameters were woven into pieces with dimensions of 3.6mm x 36mm x 500mm using a 3D weaving machine. Weave samples were then electrochemically coated with HA using an aqueous solution containing and . Various coating parameters were explored to obtain a systematic understanding of the deposition process. The HA coatings are distributed relatively uniformly across the multiple layers of the weave, suggesting that ion flux is high during deposition and local depletion zones within the 3D weaves are avoided. The coatings consist of “nano flakes” or crystals, and X-ray diffraction (XRD), energy dispersive spectroscopy (EDS), and Raman spectroscopy data confirm that the coating is HAp under the optimized deposition conditions. An in vitro study was then conducted to compare coated and uncoated scaffolds. Live/dead stain and PicoGreen DNA/MTS assays were employed to characterize the overall cell viability as well cell number/metabolism. Post-mortem scanning electron microscopy (SEM) was utilized to investigate to the morphology of the cells on coated and uncoated samples.

Prior to weaving with Mg-based wires, immersion testing was conducted on a range of Mg alloy wires using a modified-simulated body fluid (m-SBF) at
In infiltration and gene delivery relative to nonporous hydrogels. Biomimetic mineralized collagen scaffolds with antimicrobial peptide coating for osteogenic applications

by 1.6x and in MAP gels by 3.3x, relative to nonporous controls. These results show the potential for injectable macroporous gel strategies to facilitate cell transduction compared to roughly 100µm in nonporous gels. Bioluminescence due to transduced cell expression of firefly luciferase similarly increased in PEG-MP gels transduction compared to nonporous gels. Infiltrated distance of cells almost doubled in PEG-MP conditions and penetrated the entirety of MAP gels, hydrogels

We demonstrate that the delivery of firefly luciferase-over expressing virus through PEG-MPs or MAP gels both enhance cell infiltration and viral structure. Tunable

In the second system, encapsulated degradable PEG microparticles (PEG-MPs) act as degradable porogens which can be injected alongside an forming hydrogels have been developed to facilitate regeneration by providing structural support, introducing mechanical cues, and delivering cells, gene vectors, or soluble signals in a controlled manner. However, injectable scaffolds have limited macrostructural control compared to their implantable counterparts, leading to limited cell infiltration or transduction by gene vectors.

Currently, macroporous injectable scaffolds have been produced using microparticles which can either be 1) annealed in situ to provide porous space between particles, or 2) encapsulated within an in situ forming gel and degraded to leave behind pores. We investigated the efficacy of both techniques for improving cell infiltration and in vivo transduction from viral vectors compared to nonporous controls.

In the first system, particles are formed by water-in-oil emulsion from thiolated hyaluronic acid (HA) and maleimide-terminated poly(ethylene glycol) (PEG). These particles are produced with an excess of thiol moieties to allow for disulfide-crosslinking between particles to form gels from microporous annealed particles (MAP). Void space between particles allows for loading of viral vectors and infiltration of cells.

In the second system, encapsulated degradable PEG microparticles (PEG-MPs) act as degradable porogens which can be injected alongside an in situ forming hydrogel composed of cross-linked HA and PEG. Thiolated HA and vinyl sulfone-terminated PEG are mixed before injection, forming hydrogels in situ within an hour. PEG-MPs degrade rapidly in vivo, providing a pore template which facilitates cell infiltration

We demonstrate that the delivery of firefly luciferase-over expressing virus through PEG-MPs or MAP gels both enhance cell infiltration and viral transduction compared to nonporous gels. Infiltrated distance of cells almost doubled in PEG-MP conditions and penetrated the entirety of MAP gels, compared to roughly 100µm in nonporous gels. Bioluminescence due to transduced cell expression of firefly luciferase similarly increased in PEG-MP gels by 1.6x and in MAP gels by 3.3x, relative to nonporous controls. These results show the potential for injectable macroporous gel strategies to facilitate cell infiltration and gene delivery relative to nonporous hydrogels.

3:45 PM BM04.08.08
Multi-Responsive Self-Healing Gels as Cellular Delivery Vehicles Aderito J. Amaral and George Pasparakis; University College London, London, United Kingdom.

The development of materials that mimic aspects of self-healing is of paramount importance as it could solve a number of problems in the biomedical field. Interesting self-repair properties have emerged with suitable chemical strategies in bulk materials, which include the incorporation of healing agents in the form of nanoparticles/capsules, or the introduction of dynamic chemical bonds as structural elements. In this regard, remotely controlled healing strategies that allow for on-demand repairing of the material at the site of interest are of utmost importance. In this work, we propose the construction of remotely healable and transiently malleable soft gels based on the dynamic, albeit covalent, boronate ester bonds formation. We designed a system comprising a synthetic thermoresponsive boronic acid copolymer that is crosslinked with poly(vinyl alcohol) to form hydrogels within seconds under physiological conditions. These constructs can further be impregnated with colloidal stable polyvinylpyrrolidone-coated gold nanoparticles, which render the gels optically active without compromising their mechanical properties significantly. The gel nanocomposites can undergo a rapid and reversible gel-sol transition owing to the disruption of the boronate ester crosslinks by thermal (heating above 37 °C) or optical stimuli (irradiation with green light) that are spatiotemporally confined at the area of interest. The reconstituted gels exhibit shear-thinning behaviour, excellent and fast healing properties, even without the application of any external stimuli. It was also demonstrated that the constructs were able to encapsulate living cells and release them without affecting their viability.

We believe that these materials constitute a versatile biocompatible platform for the construction of remotely healable (soft) gels as cell capture and release systems or soft fillers of biological cavities for tissue engineering.

Gene Delivery from Injectable, Hyaluronic Acid-Based Hydrogels with In Situ-Forming Macropores Ardina Ehsanipour, Tommy Nguyen, Tasha Aboufadel, Philip Cox, Chris Walthers, Weikun Xiao and Stephanie Seiditts; University of California, Los Angeles, Los Angeles, California, United States.

Injectable biomaterial scaffolds are ideal for minimally invasive treatments for conditions where the area of injury is difficult to access or ill-defined in structure. Tunable in situ forming hydrogels have been developed to facilitate regeneration by providing structural support, introducing mechanical cues, and delivering cells, gene vectors, or soluble signals in a controlled manner. However, injectable scaffolds have limited macrostructural control compared to their implantable counterparts, leading to limited cell infiltration or transduction by gene vectors.

Currently, macroporous injectable scaffolds have been produced using microparticles which can either be 1) annealed in situ to provide porous space between particles, or 2) encapsulated within an in situ forming gel and degraded to leave behind pores. We investigated the efficacy of both techniques for improving cell infiltration and in vivo transduction from viral vectors compared to nonporous controls.

In the first system, particles are formed by water-in-oil emulsion from thiolated hyaluronic acid (HA) and maleimide-terminated poly(ethylene glycol) (PEG). These particles are produced with an excess of thiol moieties to allow for disulfide-crosslinking between particles to form gels from microporous annealed particles (MAP). Void space between particles allows for loading of viral vectors and infiltration of cells.

In the second system, encapsulated degradable PEG microparticles (PEG-MPs) act as degradable porogens which can be injected alongside an in situ forming hydrogel composed of cross-linked HA and PEG. Thiolated HA and vinyl sulfone-terminated PEG are mixed before injection, forming hydrogels in situ within an hour. PEG-MPs degrade rapidly in vivo, providing a pore template which facilitates cell infiltration

We demonstrate that the delivery of firefly luciferase-over expressing virus through PEG-MPs or MAP gels both enhance cell infiltration and viral transduction compared to nonporous gels. Infiltrated distance of cells almost doubled in PEG-MP conditions and penetrated the entirety of MAP gels, compared to roughly 100µm in nonporous gels. Bioluminescence due to transduced cell expression of firefly luciferase similarly increased in PEG-MP gels by 1.6x and in MAP gels by 3.3x, relative to nonporous controls. These results show the potential for injectable macroporous gel strategies to facilitate cell infiltration and gene delivery relative to nonporous hydrogels.

4:15 PM BM04.08.10
Biomimetic Mineralized Collagen Scaffolds with Antimicrobial Peptide Coating for Osteogenic Applications Zhou Ye, Xiao Zhu, Christine Lui, Yipin Qi and Conrado Aparicio; Minnesota Dental Research Center for Biomechanics and Biomaterials, University of Minnesota, Minneapolis, Minnesota, United States.

Bone and tooth are organic-inorganic composites with hierarchical nanostructures. The major organic component is type I collagen and the major inorganic promise is hydroxyapatite (HAp). Biomimetic mineralized collagen scaffolds with similar compositions and structures have been developed for bone and tooth tissue engineering. A good example is bio mineralization using the polymer-induced liquid-precursor (PILP) process, which shows a great promise in clinical applications. Mineralized collagen scaffolds present strong mechanical properties due to the aligned intrafibrillar HAp crystals and good biocompatibility and osteogenesis. However, the fabricated extracellular matrix also provides an excellent environment for microbial adhesion and biofilm development. Thus, infection could be significant and cause the failure of bone and tooth repair or regeneration.

The use of antimicrobial peptides (AMPs) is a promising approach as they have broad-spectrum antimicrobial activity with low bacterial resistance, as opposed to antibiotics. GL13K is an AMP derived from a salivary protein, which has shown low cytotoxicity and notable antimicrobial activity against gram-positive and gram-negative bacteria and biofilms. In this work, we incorporated GL13K within biomimetic mineralized collagen scaffolds and studied its antimicrobial and osteogenic activity. The collagen gels were mineralized by PILP process for different days and characterized by scanning electron microscope (SEM) and transmission electron microscopy (TEM). The degree of mineralization was quantified by thermogravimetric analysis (TGA) to study the effect of mineral content on the GL13K coating. The distribution of the coated GL13K was investigated by confocal fluorescence microscopy with fluorescent-labeled peptides. Water contact angle analysis revealed that GL13K coating significantly increased the hydrophobicity of the mineralized collagen scaffolds. To study the coating stability, we monitored the released GL13K in solution by mass spectroscopy. To evaluate the
antimicrobial activity, *Streptococcus gordonii* was incubated in the scaffolds for 24 hours and the viable cell number was compared using microbial ATP assays. The attached bacteria was also stained by LIVE/DEAD assays and imaged by confocal fluorescence microscopy. Osteogenic activity was evaluated by the adhesion, proliferation and differentiation of mesenchymal stem cells in the fabricated scaffolds. In this work, we introduced antimicrobial peptides in biomimetic mineralized collagen scaffolds. These scaffolds showed strong antimicrobial activity and osteogenic potential. We also evaluated the specific interactions of collagen and HAp with the antimicrobial peptide so that we will be able to control and further study the effects of each component on the biological properties to optimize their antimicrobial and osteogenic activity.

**SESSION BM04.09: Poster Session III: Biomaterials for Regenerative Engineering**

**Phenotype and Gene Expression of Human Mesenchymal Stem Cells in Response to Varied Mechanical Environment in 3D GelMA Hydrogel Models Cultured In Vitro**

Mechanical stiffness has been shown previously to direct stem cell differentiation and phenotype in multiple in vitro studies, however, many of these studies use 2D surfaces rather than more physiological 3D environments, as well as 3D encapsulation in materials where stiffness and concentration cannot be independently altered. As such, knowledge of the expression profiles of stem cell differentiation in response to 3D mechanical environment alone is unclear. Biomimetic materials should mimic the extracellular matrix (ECM) and the complex architecture of native tissues to be successful in vitro models that give valid cues as to how these cells and tissues would perform *in vivo*. The most popular biomimetic scaffold material for these purposes are hydrogels and we have chosen to work with gelatin methacrylate (GelMA) which has been extensively characterized in numerous models and with various cell types. The degree of methacrylation of GelMA can be controlled to vary the crosslinking density of the resultant hydrogel, allowing for variation of the mechanical properties independent of concentration, while further modulation of stiffness can be effected by altering the gel concentration. Furthermore, the authors and others have demonstrated that GelMA is a versatile and suitable hydrogel for culture of many cell types with positive cellular attachment and natural degradation properties, within a mechanical stiffness range typically up to 30-50 kPa. For these studies, multiple formulations of GelMA were used to study human mesenchymal stem cell (hMSCs) elongation, morphology, proliferation and gene expression using the TruSeq RNA stem cell expression panel over 14 days of static culture. It was hypothesized that the varying elastic moduli of the hydrogels in both the composite and gelMA hydrogels would result in morphological and expression differences typical of what is seen in 2D systems. The data showed that hMSCs elongation occurred early (day 1-4) in both the medium and high stiffness hydrogels with continued growth at day 14 but limited elongation of the hMSCs in the low stiffness hydrogels over 14 days. The morphological differences of the hMSCs between the low, medium, and high hydrogels could indicate the beginning of elastic modulus regulated differentiation. More thorough analysis of cell morphology and RNA expression profiles are still ongoing, but appear to validate the use of this model system both to study stem cell differentiation, as well as to provide an open transcriptome reference data set for other studies.

**Behavior and Phenotype of Cancer Cell Lines in Response to Varied Mechanical Environment in 3D GelMA Hydrogel Models Cultured In Vitro**

Kayla Barton, Tayler Laycox, Ella Bonfield, Sara Hopper and Jason W. Nichol; Endicott College, Beverly, Massachusetts, United States.

Normal, healthy cells will react in response to changes in their mechanical environment typically in an attempt to return their surroundings to homeostatic conditions. In cancerous cells this response is varied, which is one reason why the extracellular matrix (ECM) and mechanical stiffness play key roles in cancer cell phenotype and tumor formation/progression. It is known that cancer cells originating from tissues of different stiffnesses will sense and respond to their environment differently, which could yield important information in better understanding cancer cell physiology. Gelatin methacrylate (GelMA) is a UV-crosslinkable hydrogel that has been shown to be effective in the 2D and 3D culturing of cells in a wide variety of applications including cancer models. Cells can easily bind to GelMA 2D surfaces and within 3D structures, and can proliferate, elongate, and remodel the surrounding due to the presence of natural binding and enzymatic degradation sites in the gelatin backbone. GelMA is a highly elastic material with mechanical stiffnesses demonstrated in the 1 to 30 kPa range through variation of gel concentration and degree of methacrylation. Recently, we have been able to reliably produce hydrogels with compressive moduli below 1 kPa to better mimic the native environment of healthy soft tissues such as breast tissue. It has been established that normal breast tissue has a compressive modulus of roughly 200 Pa, whereas precancerous regions have a modulus of roughly 600 Pa and cancerous regions can be as high as 1-2 kPa, while other tissues have different, but analogous, stiffness ranges as well. The major aims in these studies were to create robust GelMA hydrogels in the 3 mechanical ranges (normal, precancerous, tumor) for breast and other tissues, and once validated to investigate the differences in behavior, morphology and gene expression of cancer cells encapsulated in these hydrogels. Gene expression profiles for normal and cancer specific phenotype will be investigated to determine the relative role in cell behavior in response to changes in stiffness. Initial phenotypic results suggest that cancer cells are less likely to spread, elongate and proliferate when at physiological stiffness, as compared to super-physiological stiffness more on the order of tumor tissues.

**Doping of Carbon Nanodots with Silver Nanoclusters for Saving Cells from ROS Induced Nanotoxicity**

Bodhisatwa Das1, 2 and Santanu Dhara3; 1Biomedical Engineering, Rutgers University, Piscataway, New Jersey, United States; 2SMST, Indian Institute of Technology, Kharagpur, Kharagpur, India.

Silver nanoparticles are explored for many advanced biological applications including the development of antimicrobial surfaces on implants, SERS imaging, nanotherapeutics, biosensing etc. However, recent research findings suggest silver nanoparticles provide blockade of differentiation of mesenchymal stem cells (MSCs), especially into osteogenic lineage through the generation of ROS. These studies suggest that application of silver nanoparticles in orthopedic implants should be prohibited. In the current study, carbon nanodots(CND) supported silver clusters (AgC) is explored as a remedy to solve this problem. The nanostructure was synthesized in a microwave irradiation induced rapid method and characterization was conducted via UV-Vis spectroscopy, fluorescence spectroscopy, HRTEM, XRD, FTIR, Raman spectroscopy, DLS, AFM, and XPS. Fluorescence spectrum showed a quantum yield of 0.25 while Raman spectroscopy showed rapid amplification of CND specific peaks implicating significant SERS property. Further *in vitro* biocompatibility (MTT) and bio-imaging capability was assessed culturing Whatman’s jelly-derived MSCs. In this study, its efficacy as *in-situ* cellular oxidative stress scavenger is also studied using NBT and DCFH-DA assay. Via ALP assay, alizarin red staining, cell membrane nanoindentation studies,
PCR analysis and immunocytochemistry for osteoblast-like gene expression it was confirmed that AgCs can control silver nanoparticle-inhibited induction of osteogenic differentiation in vitro. Further, in vivo implantation of AgC-Gelatin-MSC composite in rodent model showed comparable ectopic osteogenic differentiation potential. Thus AgCs are not only considered to be a dual mode bio-imaging nanoprobe but also a remedy to the silver-induced ROS generation and osteogenic differentiation blockade of MSCs.

**Enhancement of Hydrophobic Drug Loading in Polymeric Nanoparticles Using a Coaxial Turbulent Jet Mixer**

Hyeon-Woo Han and Jong-Min Lim; Soonchunhyang University, Asan-si, Korea (the Republic of).

The development of targeted nanoparticle platforms can indeed open a new age of well-design and tuneable release of drug that would revolutionize the field of pharmaceuticals. A range of formulation parameters and nanoparticle physicochemical properties has been studied for preclinical evaluations during the development of therapeutic agent loaded targeted polymeric nanoparticles. Although conventional bulk nanoprecipitation methods were widely adopted to prepare polymeric nanoparticles in laboratory scale due to its simplicity and versatility, loading of hydrophobic drug that maintain uniform NP size distribution is limited. When initial loading of hydrophobic drug is increased to enhance the final loading in nanoparticles, formation of large hydrophobic drug aggregates is inevitable in conventional bulk nanoprecipitation method. Here, we demonstrated a simple and versatile methods to enhance the loading of hydrophobic drug in polymeric nanoparticles, which were synthesized in coaxial turbulent jet mixer by rapid nanoprecipitation. In this work, we used docetaxel as a model hydrophobic drug and PLGA-PEG as a biodegradable nanoparticle matrix. To enhance the docetaxel loading, we systematically studied the following three steps during the nanoparticle preparation. First, we could remove docetaxel aggregates, which were originated from a high initial loading of docetaxel, by adding one more centrifuge step prior to nanoparticles washing in conventional bulk synthesis method. Second, we could enhance the drug loading as well as explore the possibilities of scaling up the nanoprecipitation process by using a coaxial jet turbulent mixer. Finally, we enhanced the drug loading further with the addition of organic co-solvent that would trap the docetaxel and make it easier to be encapsulated in the hydrophobic PLGA core of the PLGA-PEG nanoparticles. The novel strategy has strong possibility to reduce the gap between nanoparticle formulation prepared in academic laboratories and that in pharmaceutical industry thanks to enhanced hydrophobic drug loading (up to 6.5%) in polymeric nanoparticles and extremely high production rate (up to 3.15 kg/d).

**BM04.09.05**

**Self-Assembled Nanoconstructs Modified with Amplified Aptamers Inhibited Tumor Growth and Retinal Vascular Hyperpermeability via Vascular Endothelial Growth Factor Capturing**

Yeong Mi Lee and Won Jong Kim; POSTECH, Pohang, Korea (the Republic of).

Here, nanoconstructs consisting of a DNA-amplified aptamer with a biocompatible polymer backbone for capturing target biomolecules are presented. First, the polymer–DNA nanon constructs were prepared by hybridization of two complementary single-stranded DNAs that were each conjugated to a dextran polymer backbone. The designed polymer–DNA amplified aptamer nanoconstructs (PA-aNCs) were then prepared by utilizing polymer–DNA nanon constructs conjugated with an aptamer (PA-NCs) using a rolling circle amplification reaction to amplify the aptamer. These PA-aNCs were successfully applied to alleviate tumor growth and vascular endothelial growth factor (VEGF)-induced retinal vascular hyperpermeability in vivo through the highly effective capture of human VEGF as a target molecule. These PA-aNCs could be used as therapeutic agent for anti-VEGF therapy by efficiently capturing human VEGF.

**Keywords:** anti-VEGF therapy; antitumor therapy; DNA nanoconstructs; polymer–DNA conjugates; retinal vascular hyperpermeability

**Sterilization by Gamma Radiation of Hydroxyapatite with Brazilian Native Propolis**

Antonio M. Scatolini, Silvana M. Pugine, Luci C. Vereck, Andres Vereck, Mariza P. Melo and Eliana C. Rijo; University of Sao Paulo, Pirassununga, Brazil.

The aim of this work was to evaluate the possible bactericidal activity the hydroxyapatite (HA) powder containing extracts of green and red propolis, before and after sterilization by gamma radiation (Co60) with a load of 25 Kgy. Ethanol extracts of green (GP) and red (RP) propolis were obtained in 80% alcohol solution. Green and red extracts (8 mg/mL) were incorporated into the material at 10% (w/v) via spray drying, obtaining HA-GP and HA-RP samples. Powder characterization was done by X-ray diffraction (XRD), scanning electron microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR). The cytotoxicity of the materials was determined by the neutral red uptake method. The antimicrobial activity was evaluated by the minimal inhibitory concentration (MIC) and the minimal bactericidal concentration (MBC) against Staphylococcus aureus (S. aureus). The characterization of the powders before and after the sterilization showed crystalline structure and apparently spherical morphology, indicating a decrease in the degree of agglomeration with the addition of propolis, regardless of whether they were sterilized or not. FTIR indicated the presence of functional groups characteristic for HA and propolis. The cytotoxicity assay before and after sterilization showed similar values for IC 50 (concentration reflecting 50% of cell viability) for the HA-GP and HA-RP samples. Higher bactericidal activity was observed for samples without sterilization by gamma radiation. The obtained results in this work suggest that the sterilization process of HA powders with propolis influenced the antimicrobial capacity, however, without any signal indicating that these materials could not be used in medical devices with antimicrobial agent, regarding the requirements of maximum values for the IC 50 index.

**BM04.09.07**

**Graphene Oxide as an Inhibitor of the Interactions Between Nucleoside Diphosphate Kinase (NDPK) and G Proteins**

Rohit Kanaparthi and Isaac Macwan; Univ of Bridgeport, Bridgeport, Connecticut, United States.

During a heart failure, due to the lack of calcium ion homeostasis in cardiomyocytes, the systolic and diastolic functions are affected leading to a higher amount of nucleoside diphosphate kinase (NDPK) enzyme in the sarcolemmna membrane. This inhibits the synthesis of second messenger cyclic adenosine monophosphate (cAMP) that regulates the calcium ion balance for normal functioning of the heart. In a dependent pathway, NDPK normally phosphorylates the stimulatory guanosine diphosphate, GDP, to a guanosine triphosphate, GTP, on the heterotrimeric (α, β and γ subunits) guanine nucleotide – binding protein (G protein) resulting in the stimulation of the cAMP formation. However, in case of a heart failure, an increased quantity of NDPK also reacts with the inhibitory GDP, which is converted to a GTP, resulting in the inhibition of the cAMP formation. Typically the βγ dimer of the G protein binds with hexameric NDPK – B/C complex and receives the phosphate at the residue His266 (histidine ID 266) from His118 of NDPK – B. Previous studies have stated that any enzymatic activity can be inhibited by graphene oxide (GO), which is an oxidized carbon allotrope. In this work, these interactions between NDPK – B and – C are quantified in the presence and absence of GO with respect to the binding site His118. These results are further utilized to simulate the interactions between the heterotrimeric GDP and NDPK – B/C with and without GO to explore the binding events between His118 (on NDPK) and His266 (on Gβ). The system was modelled using visual molecular dynamics (VMD) and four 100ns – 1ns simulations were carried out using nanoscale molecular dynamics (NAMD). The co-ordinate files for the enzyme and the G proteins were acquired from the pdb database and GO X (10A X 9A) having a chemical structure (C4H4O4(OH)2(COOH)2) was modeled using nanotube builder in VMD and further modified using TCL scripting and VegaZZ software. CHARMM (Chemistry at HARvard Macromolecular Mechanics) force field is used for modeling and simulating the interactions.
environment. The temperature is maintained at 300K using Langevin Thermostat and the pressure of 1atm is set through Nose – Hoover Langevin piston barostat with a period of 100ps and a decay rate of 50ps. It is found that GO is capable of suppressing and the interactions between NDPK and G proteins, where it specifically blocks the His118 binding site on ND PK, thereby preventing it to come in contact with His266 on Gβ. Based on the quantification of the van der Waals, electrostatics and conformational energies, it is seen that the affinity of ND PK to GO is higher compared to its affinity to the G proteins. Root mean square deviation (RMSD) and center of mass analysis agrees well with the energetics and the secondary structure analysis of the ND PK and G protein showed only a minor structural arrangement in the protein secondary structure indicating favorable interactions between NDPK and GO.

**BM04.09.08**

Anti-Tumour Property of Pyrrole Doped Electros spun Pei Fibrous Scaffold—A Novel Breast Cancer Therapy

Ahmet E. Mevdın; Ahsen Seyrek and Mehmet Mutlu; TOBB University of Economics and Technology, Ankara, Turkey.

In this study, antitumor biomaterial fabrication targeting the cancer cells without affecting healthy cells was aimed. In accordance with this purpose, heterocyclic pyrrole ring which has antitumor property was doped at 5%, 10% and 20% (w:w) concentrations to PCL scaffolds via electrospinning. The average fiber diameter of PCL, 5%, 10%, and 20% pyrrole doped scaffolds are measured 1.907 ± 0.286 μm, 1.393 ± 0.177 μm, 0.882 ± 0.218 μm, and 1.100 ± 0.285 μm, respectively, with homogenous, bead free and continuous fiber formation. According to the MTT assay, with 11.045% increase, the highest cell viability was observed in PCL in reference of TCP. Besides, less cell viability was seen in pyrrole doped PCL (PdPCL) scaffolds with increase in pyrrole concentration that resulted in 17.357%, 24.457%, and 36.489% decrease, respectively. According to the DAPI staining results which supported MTT assay data, highest cell viability was observed on PCL to decrease in PdPCL scaffolds accordance with increase in pyrrole concentration. As a consequence of this research, first time in literature, antitumour property of pyrrole doped into electros spun fiber matrix was achieved. With this study, a novel approach to cancer treatment methods is developed by supporting different biomaterials with pyrrole.

**BM04.09.09**

pH-Activable Polymeric Nanoparticles Modulate Lysosomal Acidification and Autophagy in Beta Cells

Julian Zeng1, Kevin Smith1, Orian Shirihai1 and Mark Grinstaff2; 1Boston University, Boston, Massachusetts, United States; 2University of California, Los Angeles, Los Angeles, California, United States.

We have developed a novel polymeric pH-activable, acidifying nanoparticle (acNP) that restores the pH of compromised lysosomes to rescue autophagic flux and cellular function in pancreatic beta cells (INS1 cells) under lipotoxicity. In beta cells, chronic exposure to high levels of fatty acids (lipotoxicity) leads to an inhibition of autophagic flux and subsequent cellular dysfunction, which has been recently associated with impaired lysosomal acidification and elevated lysosomal pH. Therefore, restoration of lysosomal pH is essential in alleviating the block in autophagy and promote proper cellular quality control and function. In this study, we designed an acidic nanoparticle (acNP) that contains caged acid which can be released upon moderate pH changes (pH 6.0) to enable controlled acidification of the impaired lysosomes under lipotoxicity. Rhodamine labelled acNPs demonstrate dose dependent uptake into lysosomes of INS1 cells. pH-activation of acNPs in dysfunctional lysosomes at pH 6.0 environment demonstrate acidification of lysosomes and restored lysosomal pH with minimal cytotoxicity. acNPs also increased lysosomal cathepsin enzyme activity, and decreased both autophagic proteins LC3II and p62 levels, indicating a rescue of lysosomal function and autophagic flux due to restoration of lysosomal acidity. Additionally, acNPs restored glucose-stimulated insulin secretion that is reduced in INS1 cells and mouse islets under lipotoxicity. These results indicate that acidifying lysosomes with acNPs improved lysosomal function and autophagic flux in INS1 cells under lipotoxicity, and are of therapeutic interest for pathologies associated with lysosomal acidity impairment such as type II diabetes and non-alcoholic fatty liver disease (NAFLD).

**BM04.09.10**

Synthesis and Characterization of Non-Cell-Adhesive Gelatin/Pluronic Hybrid Hydrogels

Ju-Yi Li, Clement Marmarot, Miriam Rafaelovich and Marcia Simon; Stony Brook University, Stony Brook, New York, United States.

Non-cell-adhesive hydrogels stand important roles in many in vivo applications. In the case of periodontitis, a biodegradable non-cell-adhesive material could isolate the soft gum tissue from the hard bone and promote selective growth of both tissues on each side of the membrane. Many shortcomings are associated with the use of current materials like polytetrafluoroethylene including degradability, workability, cost or cytotoxicity. In this study, we introduce a novel cost-effective material, a hybrid biodegradable of gelatin and Pluronic F127, strong enough to withhold mechanical degradation during the surgical procedure but yet degradable in vivo, non-cytotoxic, porous to promote the diffusion of nutrients and physiological fluids while remaining anti-adhesive. The hybrid films, would be ideal for this type of application. The hybrid gels were crosslinked via microbial transglutaminase (mTG). Hybrid gels with different ratio of gelatin, F127 and mTG were synthesized. Rheological properties of those gels were determined by rheometer and the surface and side cut section of those gels were observed by laser scanning microscope and scanning electron microscope. UV-vis and FT-IR spectroscopy were used for structure characterization of the hybrid gels. Fibroblast with green fluorescent were seeded on the surface of hybrid gels to determine cell adhesive ability. Our results showed the synthesized hybrid gels preserve the mechanical stability of gelatin-based hydrogels, while also exhibiting excellent workability and non-cell-adhesive properties of Pluronic F127.

**BM04.09.12**

Antibiotic Eluting Contact Lenses for the Treatment of Bacterial Keratitis

Lianguo Kuang1, Lokendrakumar C. Bengani1, Amy Ross1, Daniel S. Kohane2 and Joseph B. Ciolino1; 1Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Harvard Medical School, Boston, Massachusetts, United States; 2Departments of Anesthesia and Surgery, Boston Children’s Hospital, Harvard Medical School, Boston, Massachusetts, United States.

Bacterial keratitis is one of the leading causes of corneal blindness. The current standard of care involves an intensive regimen of hourly antibiotic drops to eradicate the infection. A major unmet need for the treatment of bacterial keratitis is a sustained approach of drug delivery to improve treatment efficacy and patient adherence. Contact lenses are emerging as a promising platform for controlled ocular drug delivery and potential release of drugs to the back of the eye. We report here an antibiotic-eluting therapeutic contact lens (TCL) that incorporates a thin drug-polymer film within the periphery of a contact lens using standard materials, which enables the sustained release of drugs at therapeutic rates, while allowing unimpeded vision through a central aperture in the lens. Antibiotic–polymer films were encapsulated in methacrylon via ultraviolet light polymerization and then lathed into contact lenses. Various UV polymerization conditions were examined to achieve the suitable physical properties of TCLs. The physical properties and morphology of antibiotic-eluting TCLs were characterized. Fourth-generation fluoroquinolones and polymers in the drug-polymer films were characterized by Fourier-transform infrared spectrometer. In vitro drug release was evaluated under infinite sink conditions. TCLs enabled the sustained release of besifloxacin and moxifloxacin for more than 24 hours in clinically relevant mass. The release of gatifloxacin from TCLs was also achieved in a temporally controlled manner but was faster than that of besifloxacin and moxifloxacin. Additionally, in vitro drug release profiles were tuned by polymer characteristics (hydrophobicity, hydrophilicity, and molecular weight), polymer/drug ratios, polymer/plasticizer ratio, and polymer ratios in the blend film. The antibiotic-eluting TCL may be used as a convenient alternative for extended ocular drug delivery with translational potential for the treatment of bacterial keratitis.
Self-assembled, a process that assembles molecules into ordered structures can form numerous structures in various conditions. Self-assembled structures when made from biomolecules such as DNA and peptides, form functional and biocompatible nanostructures such as nanotubes, fibers, spheres, which could be used in different biomedical applications. We have synthesized aromatic dipeptide-based nanotubes using dityrosine and tryptophan-tyrosine through solution-phase self-assembly (SPSA) and eco-friendly plasma enhanced chemical vapor deposition (PECVD). Insights into the self-assembly process and driving forces involved were obtained using quantum chemical computational methods at different levels of theories like dispersion-corrected density functional and Moller-Plesset perturbation.

The morphological features of SPSA and PECVD nanotubes were studied using confocal and scanning electron microscopes. These nanotubes were characterized using thermally and spectroscopically using differential scanning calorimetry and thermogravimetric analysis, Fourier transform infrared spectroscopy, liquid chromatography-mass spectroscopy, and Raman scattering, and circular dichroism spectroscopy, and powder x-ray diffraction. The cytotoxicity and biological interactions of these nanotubes with rat adrenal pheochromocytoma (PC-12) and human bone marrow neuroblasts (SH-SY5Y) cells were studied using MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide), dopamine-enzyme linked immunosorbent assay and real-time polymerase chain reaction (q-PCR). We observed substantial differences in proliferation and expression between the cells grown on tissue culture treated and nanotubes coated surfaces.

Creating Rechargeable Anti-Thrombotic Surfaces via Enzyme Mediated Ligation Hyun Ok O. Ham1, 2, 3, Madhukar S. Patel1, 2, 3, Carolyn Haller1, 2, 3, Erbin Dai1, 2, 3, David R. Liu1, Jian Liu1 and Elliot Chaikof2, 4, 5; 1Harvard Medical School, Boston, Massachusetts, United States; 2Wyss Institute, Boston, Massachusetts, United States; 3Beth Israel Deaconess Medical Center, Boston, Massachusetts, United States; 4Harvard University, Cambridge, Massachusetts, United States; 5University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Foreign body reactions at the blood-material interface frequently result in implant failure. Current engineered anti-thrombotic coatings are challenged by bioactive surface breakdown resulting in device-associated complications. This study aims to develop a system for generating ‘rechargeable’ surfaces utilizing reversible bond formation between bioactive molecules and modified implant surfaces through enzyme-mediated ligation. In this scheme, reversibility allows for stripping of degraded coatings with subsequent surface recharging.

Variants of laboratory evolved Staphylococcus aureus sortase A (eSrtA) were generated for reversible transpeptidation of two anti-thrombotic molecules (recombinant thrombomodulin [TM] and heparin oligosaccharide [HS]) on implantable medical devices. Two eSrtA variants were designed to specifically recognize different peptide tags available on therapeutically active TM and HS. Using eSrtA, repeated charging/ stripping of TM was conducted in vitro in whole blood, and subsequent generation of activated protein C (aPC) was demonstrated. Similarly, chemo-enzymatically synthesized ultra-low molecular weight heparin oligosaccharide (HS), which binds to antithrombin III that can inhibit factor Xa activities involved in the blood coagulation cascade reaction, was repeatedly immobilized and striped utilizing reversible enzyme ligase. Within an hour of incubation on pentaglycine-modified surfaces, eSrtA variants could selectively charge/stripe of TM and HS in a sequential or simultaneous manner. Alternating charging/stripping of TM/HS on the surface and thereby switching on/off of aPC generation and anti-Fxa inhibition from the surface was also validated. For a translational application, reactions were subsequently performed and confirmed on the luminal side of implantable vascular catheters.

The ability to regenerate bioactive coatings using eSrtA variants is a means by which engineered implant surfaces can be functionally preserved. Furthermore, using this system to perform site-specific co-immobilization of different anti-thrombotic moieties on vascular catheters and selectively regenerate bioactivity has potential to decrease long-term implant related morbidity through targeted action on distinct parts of the coagulation cascade.

Self-Assembled Peptide Nanotubes for Neural Cell Proliferation Prathyushakrishna Macha, Vikas Soni, Maricris Mayes and Milana Vasudev; University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States.

In the field of tissue engineering, design and fabrication of precisely patterned, highly porous scaffolds/matrices are required to guide overall shape of tissue growth and replacement. Although Rapid Prototyping fabrication techniques have been used to fabricate the scaffolds with desired design characteristics, controlling the interior architecture of the scaffolds has been a challenge due to CAD constraints. Moreover, large thick tissue scaffolds have reported limited success primarily due to the inability of cells to survive deep within the scaffold. Without access to adequate nutrients, cells placed deep within the tissue construct die out, leading to non-uniform tissue regeneration. This study aims to overcome these design and fabrication limitations. In this work, research has been expanded to design of scaffolds which have inbuilt micro scale fluidic networks. In this procedure, inbuilt channels serve as material delivery paths to provide oxygen and nutrients for the cells. First of all, negative of a cylindrical shape with a single channel was designed with AutoDesk Inventor and printed with a 3D printer to be used as a mold. Then, 3D printed mold was filled out with Poly(ethylene glycol) diacrylate (PEGDA) which is a photo-curable solution to fabricate the cylindrical hydrogel. Once PEGDA was exposed to UV light with the wavelength of 365nm, polymerized completely in about 3 minutes. After that, the same procedure was repeated for cylinders with two and three channels respectively. Then, their mechanical characterization tests were done to compare the compressive strengths of the scaffolds that has different internal architectures. Our preliminary results indicate that, 3D printing and polymerization techniques can be used together to control the interior architectures as well as the compressive strengths of scaffolds.

BM04.09.16
Antibacterial Properties of 2D Black Phosphorus Nanosheets for Regenerative Engineering Emre Firlar1, 2, Laura Alzate1, Ramin Rojaee2, Reza Shahbazian-Yassar1 and Tolou Shokhparvar1; 1Bioengineering, University of Illinois at Chicago, Chicago, Illinois, United States; 2Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, United States; 3Biomedical Engineering, EIA University, Envigado, Colombia.

2D black phosphorous is an emerging new material with implications for regenerative engineering. Bacterial infection during implant surgeries has been a major concern for the long-term stability of the installed implant due to the health and cost burdens on the patients. Osseointegration between the implant and tissues will deteriorate due to the presence of bacteria in addition to the spread of bacteria through-out the body. Therefore, novel biocompatible nanomaterials should be developed to fight against the bacteria. Black phosphorus (BP), which is biocompatible, has been proven to be effective in this regard, but mainly with irradiation with near infrared light. Extensive irradiation of photons to emit singlet oxygen will worsen the effectiveness of BP and cause hypoxia to the cells. Thus, independent irradiation strategies should be developed to kill the bacteria using BP. In this work, E. coli and M. magneticum were cultured and the effectiveness of BP was tested for their antibacterial properties through fluorescence imaging, cell counting and
Materials and Methods:

Patient-derived GBM and brain endothelial cells (ECs) – both critical components in the perivascular invasive niche. In general, cells do not interact directly with substrates. Rather, extracellular matrix substrates will depend on the conformation of the adsorbed ECM. Therefore, in order to comprehend the mechanism through which graphene affects stem cell differentiation, it is important to understand the influence of graphene on ECM protein structures. We have previously shown that the differentiation of dental pulp stem cells is greatly affected by the substrate morphology of poly(4-vinylpyridine) (P4VP). It provides a perfect platform to study the additional effect of graphene on the cells. We found that graphene can be easily distributed into this system by electrospinning and spin coating process.

The Effects of Graphene in Different Morphologies of Polymer on Dental Pulp Stem Cells

Linxi Zhang, Kuan-Che Feng, Chung-Chueh Chang, Marcia Simon and Miriam Rafailovich; Materials Science and Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; Oral Biology and Pathology, Stony Brook University, The State University of New York, Stony Brook, New York, United States.

Graphene and graphene-based materials have been developed and widely used in tissue regeneration engineering, due to their excellent physical properties. Many studies have shown that graphene can control and accelerate multi-lineage differentiation of stem cells in vitro. Graphene are commonly used, in most studies, as the substrates which have direct contact with the cells. In general cells do not interact directly with substrates. Rather, extracellular matrix proteins secreted by the cells adsorb first, coating the substrates, enabling cell adhesion. Hence as was previously shown, the response of the cells on these substrates will depend on the conformation of the adsorbed ECM. Therefore, in order to comprehend the mechanism through which graphene affects stem cell differentiation, it is important to understand the influence of graphene on ECM protein structures. We have previously shown that the differentiation of dental pulp stem cells is greatly affected by the substrate morphology of poly(4-vinylpyridine) (P4VP). It provides a perfect platform to study the additional effect of graphene on the cells. We found that graphene can be easily distributed into this system by electrospinning and spin coating process. The cell behavior and biomimralization and differentiation of DPSCs on the graphene-containing scaffolds are determined by multiple techniques, including SEM, Raman and RT-PCR. The results show that the cell-secreted ECM structure and biomimeralization on different scaffolds are affected by the addition of graphene in the original polymer matrices. The research was supported in part by the NSF (Inspire Award #1344267) program.

The Effects of Graphene in Different Morphologies of Polymer on Dental Pulp Stem Cells

BM04.09.18

Biomimetic, 3D Hydrogels to Investigate Effects of Microenvironment Biophysical Properties on Patient-Derived Glioblastoma (GBM) and Endothelial Cells (ECs)

Alireza Sohrabi, Jesse Liang and Stephanie Seidlits; University of California, Los Angeles, Los Angeles, California, United States.

Introduction: This study investigated how the mechanical microenvironment of glioblastoma (GBM) tumors may affect morphology and phenotype of patient-derived GBM and brain endothelial cells (ECs) – both critical components in the perivascular invasive niche.

Materials and Methods: Hydrogels were fabricated from thiolated hyaluronic acid (HA-SH) (0.5 w/v%) and 4-arm PEG-SH (varied), 8-arm PEG-norbomene (varied). Gelation occurred upon exposure to UV light (365 nm, 4 mw/cm²) for 15 s in the presence of a cytoocompatible photoinitiator LAP (Lithium Pehnyl (2, 4, 6-trimethylbenzoyle) phosphinate, 0.025 w/v%). Patient-derived gliomaspheres or single dissociated ECs were mixed with hydrogel precursors prior to gelation. Phase contrast images were acquired every 3 days to monitor cell migration. After 9 days, 3D cultures were fixed, and cells visualized with CellMask® Green (ThermoFisher) and Hoechst (nuclei). Cell survival following encapsulation was evaluated using a Live/Dead Assay (Life Technologies). A Leica LSP5 confocal microscope was used to image 3D cultures. Storage moduli (G′) of hydrogels were measured using shear rheometer (TA DHR-2) with an 8-mm flat plate geometry.

Results and Discussion: Hydrogel stiffness (G′) was controlled by varying Thiol content to achieve a range of 150–1500 Pa, which are representative of the normal brain and tumor microenvironments, respectively. Gliomaspheres and ECs cultured showed comparable survival 7 days post-encapsulation in both soft and stiff gels. Gliomaspheres cultured in stiff hydrogels remained did not migrate away from spheroids, while cells encapsulated in soft hydrogels exhibited robust migration. Our previous results showed that ECs residing in GBM perivascularute differently express high amount of integrin-binding sialoprotein (IBSP). Survival of ECs in hydrogels barring different biophysical properties is an appropriate platform to study the effect of stiffness on ECs protein expression.

Conclusion: Patient-derived GBM and ECs were successfully cultured in 3D HA hydrogels mimicking biophysical properties of brain or GBM tumor tissue. GBM cells cultured in stiffer environments were unable to migrate, but upon culture in soft environments were found to migrate up to 200 µm away from seeded spheroids within 9 days of cultures.

BM04.09.19

Tissue Engineered Scaffolds—Next Generation 3D Bone Mimetic Cancer Metastasis Testbeds

Kalpana Katti, MD Shahjahan Molla, Sumanta Kar and Dinesh R. Katti; North Dakota State University, Fargo, North Dakota, United States.

Tissue engineering through use of scaffolds is a very promising technology for replacement of tissues in regenerative medicine. A unique nanoclay based scaffold that enables mineralization of hydroxyapatite inside nanoclay galleries provides structural support and enables growth, proliferation and differentiation of human mesenchymal cells to form hierarchical mineralized collagen and ECM formation mimicking bone which is useful for regenerative medicine. In addition, it is known that breast cancer and prostate cancer have the propensity to metastasize to bone in the human body. The cancer at this stage of metastasis is incurable. Here we describe the use of tissue engineered bone as a humanoid testbed to create cancer tumors in vitro. We also demonstrate that this engineered test-bed duplicates the last stage of cancer metastasis as indicated by the gene expression and immunocytochemistry analysis of the tumors generated in the testbed. We also report the use of unique nanoindentation methodology to obtain elastic properties of tumors as they grow at the humanoid metastasis stage inside the bone scaffolds. FTIR experiments are also conducted during progression of tumor at metastasis and unique signatures of the DNA and protein contents during cancer progression are reported. Nanomechanical experiments on live tumors during their evolution and growth is related to the gene expression studies to bring mechanobiology as a new biomarker of the cancer progression. The engineering testbed can be used for personalized medicine as well as a screening tool for new anti-cancer drugs. Regenerative medicine thus provides unique opportunities to evaluate cancer metastasis.

BM04.09.21
Collagen is at once a main structural material and the most abundant protein in vertebrates. Collagen hydrogel reflects mechanical behavior of human tissues and is the most commonly used scaffold material and extracellular matrix in tissue engineering. As a structural material, it bears and loads stress and affects cell behavior depending on mechano-sensitivity of each cell type. Thus, providing prediction of cell response and mechanical reliability of collagen hydrogel presents significant challenge, so it is essential to understand mechanical properties of aforementioned material. However, soft collagen hydrogels were only tested shear, compressive and rheological properties because they have instability by gravitational forces and dehydrating issues at existing tensile testing methods. In addition, polymer network structure of collagen hydrogel varies under applied stress with showing non-linear stress-strain relationship and mechanism for the non-linearity was not proven yet. To predict hydrogels’ mechanical behavior completely, previously unavailable tensile data is required, and an alternative methodology is necessary to collect tensile properties of collagen hydrogel. In this study, we aim at investigating the mechanical behavior of collagen hydrogels under quasi-static tensile stress by suggesting a solution for tensile testing of soft collagen hydrogel and providing its mechanical response to tensile stress. Tensile testing on water surface imparts hydrating and free-standing environment to collagen hydrogels. Moreover, microstructure analysis of collagen hydrogels using SEM, and nano-scale 3D X-ray tomography demonstrates the mechanism of shown tensile properties. As the fiber diameter increases and the crosslink density decreases with decreasing gelation temperature, the tensile modulus due to the network structure change increases. In addition, the higher the collagen concentration, the more the crosslink density and the elastic modulus increase. After the first regime of mechanical behavior, the entropic deformation of the collagen network is completed and the enthalpic deformation of the network begins. These results illustrate that collagen hydrogels respond in complex manners to tensile stress, either as network or as fiber, which shows non-linear stress-strain relationship. Furthermore, we propose a new approach for tensile testing method for soft and hydrated materials that can be applied for bioengineering field.

Sphingosine-1-Phosphate-Bound High-Density Lipoprotein-Mimetic Nanoparticles Engineered to Protect Endothelial Functions in Cardiovascular Disease  
Hyun-Ji Park, Jwom Yom, Yoshiataka J. Sei and YongTae Kim; Georgia Institute of Technology, Atlanta, Georgia, United States.

Sphingosine-1-phosphate (S1P) is a natural signaling sphingolipid known to have important roles in regulating vascular and immune systems. In human plasma, S1Ps are associated with high density lipoprotein (HDL) of apolipoprotein A1 (ApoA1) and apolipoprotein M (ApoM) and leads to pleiotropic functions through specific receptors such as S1PR. Specifically, S1P-bound HDL (HDL-S1P) regulates several key biological functions in vascular system, such as endothelial nitric oxide (NO) production and vasodilatation. Plasma S1P levels are reportedly lower in patients with coronary artery disease, indicating that S1P is involved in the pathogenesis of atherosclerosis. However, the pathophysiological and molecular mechanisms leading to such disease-associated shifts in HDL-S1P remain elusive due to multiple reported arguments of the biphasic, pro- and anti-atherosclerotic properties. Here, we leverage out *in vitro* human carotid artery-mimicking model system to study the biological function of S1P using engineered HDL-mimetic nanoparticles (eHNP)s. Our advanced microvortex technology enhanced assembly of hydrophobic lipids (DMPC and/or S1P) and hydrophilic proteins (ApoA1 and ApoM) to continuously produce homogenous discoidal eHNPs, such as eHNP-A1, eHNP-A1-S1P, and eHNP-A1-M-S1P with the size range of 10 to 15 nm, which is consistent to the native HDL. These eHNP-s were endocytosed to human carotid artery-derived cells such as human carotid artery endothelial cells and smooth muscle cells. Moreover, the uptake efficiency of eHNP-A1 was enhanced by incorporating S1P into the eHNP-A1 (eHNP-A1-S1P). More interestingly, we successfully reproduced natural carotid arterial functions such as endothelial NO production and vasodilatation using our *in vitro* cardiovascular model system and investigated the physiological functions of eHNPs under pathophysiological conditions such as TNF-α stimulation or disturbed flow. This study helps to understand the mechanisms of endothelial effect of HDL and S1P and provides clues to improve HDL-based clinical studies of cardiovascular diseases. Our integrated approach using the designed eHNP complex and *in vitro* cardiovascular model system reported in this study are promising prescreening alternatives to costly animal model studies to study the structural and functional heterogeneity of HDL. Moreover, this study potentially leads to novel therapeutic measures that can prevent the progression of cardiovascular diseases such as atherosclerosis and coronary artery diseases.

Cardioprotective Effects of *Asparagus racemosus* Against Doxorubicin Induced Cardiotoxicity in Rats  
Manisha Chatterjee, Raj Kumar Goel, Manish Saxi, K.K. Saxena, Pinki Vishwakarma and Monica Sharma; Lalaji Lajpat Rai Memorial Medical College, Meerut, India.

Recently, herbal remedies have raised considerable research attention as they are safer, less expensive with fewer side effects than synthetic drugs. Here we report, the cardioprotective potential of medicinal plant *Asparagus racemosus* against cardiotoxicity induced by anticancer drug Doxorubicin. The comparison was done with the standard cardioprotective drug (Carvedilol) in albino rats. For this experimental study, the albino rats were divided into four different groups namely Control group (administered pellet diet and tap water for 21 days), Toxic control group (in addition to pellet diet and tap water this group was administered Doxorubicin in a single dose intraperitoneally on 21st day), and two Test groups (they were administered aqueous extract of *Asparagus racemosus* in doses 250mg/kg and 500mg/kg respectively for 21 days, followed by Doxorubicin in a single dose intraperitoneally on 21st day) and a Standard group (treated with Carvedilol per orally for 21 days followed by Doxorubicin in a single dose intraperitoneally on 21st day). All animals were sacrificed 48 hours after Doxorubicin administration. Blood samples were collected and different pathological tests like CK-MB, LDH, SGOT, and SGPT were performed. It was observed that the serum levels of CK-MB, LDH, SGOT, and SGPT were raised significantly in the Toxic control group, whereas these values were raised but to a lesser extent in the test group treated with *Asparagus racemosus* in dose of 250mg/kg, and these were within the normal limits in the test group treated with *Asparagus racemosus* in dose of 500mg/kg which was comparable to the standard group treated with Carvedilol. The histopathological tests of the dissected heart also confirm these observations. Collectively, these data indicate that *Asparagus racemosus* pretreatment could alleviate doxorubicin-induced cardiotoxicity.

CHANNELMAT—Controlling Mechanotransduction in Porous Biomaterials  
Mohammadreza Taale, Katharina Siemsen, Christine Arndt, Fabian Schutt, Rainer Adelung and Christine Sellhuber-Unkel; University of Kiel, Kiel, Germany.

Cells respond to external mechanical stimuli through a biological process called mechanotransduction. Mechanotransduction has great impact on cellular proliferation, migration and differentiation, as well as on cell adhesion. Likewise, diseases such as cancer and cardiac dysfunctions are also related to cellular mechanotransduction. Here we show data on controlling cells by an innovative 3D material that serves as a platform for controlling mechanotransduction by mimicking natural 3D cellular environments. Our material contains microporous structures represented by micron-sized channels that are embedded in a soft hydrogel matrix. For controlling mechanotransduction, the stiffness of the matrix is well-defined by the amount of cross-linker in the hydrogel. In addition we modify the hydrogel such that its surface is equipped with cell adhesion ligands, e.g. RGD and collagen. As the pores in the material provide a large and spatially controlled cell-surface contact area of up to 80%, the mechanical properties of the hydrogel environment will have
large impact on the cells. As an additional feature, we can also control the conductivity of the porous hydrogels by the targeted addition of carbon nanomaterials such as CNTs and graphene. We here show first data on the biocompatibility of the materials, on cell growth in the materials and how we can control the properties of cells by our materials.

**BM04.09.25 Efficient Excision of Proviral HIV-1 Genome in Human Primary Cells with Cell Penetrating TALEN Nanoparticles** Ming Zhao, Jing Wen and Yunfeng Lu; University of California, Los Angeles, Los Angeles, California, United States.

A critical step during human immunodeficiency virus (HIV) infection occurs when the complementary viral DNA is integrated into the host genome. This so-called “HIV provirus” becomes transcriptionally silent and sustains as a latent viral reservoir that can escalate new infections upon self-reactivation. Though the present anti-retroviral therapies could effectively suppress active virus replication, the latent HIV-1 reservoirs remain intractable and a tremendous risk to infected individuals. Therefore, a novel therapy that could abrogate proviral DNA is highly desirable but challenging. Genome-editing technologies whereby cellular genomic information is readapted have become increasingly utilized recently. Targets for gene modification, including the HIV-1 genome itself, have been investigated as a potential therapy for HIV-1 disease using the clustered regularly interspaced short palindromic repeat (CRISPR)/Cas9 endonuclease system and the transcription activator-like effector nucleases (TALEN), yet the off-target cleavage of the CRISPR/Cas9 remains a concern by many scientists. In contrast, TALEN possesses significant accuracy and robust nuclease activity for the targeted sequence. So far, cell-penetrating peptide (CPP) mediated TALEN delivery has been applied to knock down the HIV-1 co-receptor, CCR5, yet the working concentration of TALEN protein was excessively high (~μM). Likewise, transfection of TALEN mRNA abolishes HIV-1 proviral function drastically in T cell lines, which, however, is ineffective in disrupting proviral DNA in primary T cells. Herein, we report a proof-of-concept study that TALEN protein under the guidance of a pH-sensitive nanocapsule could be effectively delivered into the nucleus. The cationic surface charge and the acid-labile crosslinkers of the nanocapsule enable high-efficient transmembrane transportation, cargo release and avoidance of endosome/lysosome sequestration. As a result, the delivered TALEN demonstrated good gene-editing capability under an ultra-low working concentration. In particular, HIV-1 latent reservoirs in primary T cells were efficiently excised with this strategy, thereby providing a useful suggestion for developing anti-HIV drugs, particularly against integrated HIV genome in primary cells.

**BM04.09.26 Hierarchical Decoration of Eggshell Membrane with Polycaprolactone Nanofibers to Fabricate a Bilayered Scaffold for Full-Thickness Cutaneous Wound Healing** Prateek Gupta Ray, Pallabi Pal and Santana Dhara; BMTE, School of Medical Science and Technology, Indian Institute of Technology Kharagpur, Kharagpur, India.

The modern era of skin tissue engineering focuses on engineering and fabrication of scaffolds that can closely mimic the extracellular matrix and its microenvironment so as to facilitate cell adhesion and proliferation. The objective of the present study is to design and fabricate a porous, mechanically stable, biocompatible and non-immunogenic bilayered scaffold for wound healing applications. In order to do so, microfibrous eggshell membrane (ESM) along with nanofibers of Polycaprolactone (PCl) was deployed. In addition to a rich source of collagen, ESM also contains several growth factors and GAGs, essential for the regeneration process. A homogeneous blend of PCl was electrospun onto the ESM to decorate it with randomly arranged nanofibers (200 nm diameter), followed by cross-linking the same with microfibers (2μm diameter) using NHS/EDC coupling (EpN). The surface topography of the 1μm thick bilayered scaffold was explored using FE-SEM and AFM, while the porosity was evaluated using BET analysis. The spectroscopic analyses using FT-IR and XPS reveal successful crosslinking between the nanofibers of PCl and microfibers of ESM in the scaffold which corroborates to FESEM and AFM results. The matrix exhibits considerable enzymatic degradation after 27 days, 70% wettability, tensile strength of 15 MPa and substantial anti–microbial activity. In addition, MT, Rhodamine–DAPI assay and FESEM studies demonstrate excellent cell adhesion and proliferation of human dermal fibroblast (hDF) cells. Furthermore, the samples presented enhanced wound healing characteristics when grafted over a full thickness wound on a rat model. Moreover, the histopathological examination of the treated wounds at different time intervals revealed fast re-epithelization and collagen deposition in the extracellular matrix. Epi implanted wounds demonstrated complete wound closure within 14 days. Excellent physico-chemical properties and superior wound healing efficacy demonstrated by micro/ nano architected EpN mats make it a potential wound healing matrix for clinical skin regeneration.

**BM04.09.27 Terminal Autoclave Sterilization—Impact on Cryogel Properties and Injectableability** Sidi Benchetrit1, 2, 3, Pierre Villard1, Mahboobeh Rezaeeazad1, Kasturi Joshi Navare4, Colombani Thibault1 and Adnan Memee1, 4; 1Department of Chemical Engineering, Northeastern University, Boston, Massachusetts, United States; 2Harvard John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 3Sorbonne University, UTC CNRS UMR 7338, Biomechanics and Bioengineering (BMBI), University of Technology of Compiègne, Compiègne, France; 4Center of Nanotechnology, King Abdulaziz University, Jeddah, Saudi Arabia.

While effective sterilization is crucial for clinical utilization of biomaterials, maintaining both their structural and biological properties post-processing remain a challenge. One of the most popular terminal sterilization methods is heat sterilization and more particularly autocloving. Autoclaves use highly pressurized steam heated up to 134°C which is detrimental to many biomaterials including polymeric hydrogel scaffolds. Three-dimensional scaffolds are attractive for many tissue engineering applications due to their unique properties such as high-water content, tunable mechanical properties and biocompatibility. However, hydrogels typically get sanitized not sterilized, especially in an academic setting, as they are unable to survive the autoclave sterilization process.

Recently, we have developed a new class of more robust hydrogels with unique properties. These cryopolymerized hydrogels or cryogels do not only possess large and interconnected pores, and mechanical robustness sustaining up to 90% deformation, but also shape memory properties allowing their injection through conventional needles. A series of injectable cryogels prepared with various biopolymers have been autoclaved and tested not only for their degrees of sterilization but also for their physico-chemical integrity (i.e. injectability, physical properties, and retention of their intrinsic biological properties). Overall, our preliminary results suggest that unlike conventional hydrogels, injectable cryogels are resilient to the aggressive nature of steam sterilization and are well suited as safe and non-invasive biomaterials for a number of biomedical applications.

Acknowledgement: This work was supported by Northeastern University (Tier 1 Provost grant). Funds by the Thomas Jefferson Fund, FACE Foundation, and the Burroughs Wellcome Fund are acknowledged.

**BM04.09.28 Advanced Drug Delivery Platform—Silica Nanoparticles Engineered with Nanoscale Surface Roughness** Hao Song and Chengzhong Yu; The University of Queensland, Brisbane, New South Wales, Australia.

Recent advances in nanotechnology have greatly boosted the development of drug delivery systems, while the key challenge still lies in the rational design and fabrication of safe and efficient nano-carriers. It is noteworthy that the delivery performance could be possibly maximized by custom-designed nano-
carriers considering the configuration and surface textures of both cargo biomolecules and target cell/environment. Here, we showcase our recent progress on the development of silica-based advanced delivery platform by engineering the surface textures at the nanoscale. First, through a biomimetic approach, silica nanoparticles with an intrinsic spiky surface are fabricated.[1] The nanoscale surface roughness exhibits interesting surface properties at the microscale, enabling the nanoparticles with strong adhesion toward the hairy bacterial surface, thus leading to an efficient antimicrobial enzyme delivery. Then this novel delivery system is well extended for gene delivery.[2] Distinct from small drug or protein molecules, plasmid DNA possesses unique rope-like loop structures. The spiky nanotopography is here further demonstrated with great advantages at the nanoscale, acting as hooks to entangle the DNA loops and protect the gene molecules settled in the spiky layer against nuclease degradation. These spiky nanoparticles show excellent gene transfection efficacy, especially under harsh enzymatic conditions. The intriguing properties enabled by this unique nanoscale rough feature have been further explored in our recent studies. This rough nanoparticle-based novel delivery platform is of significant potential in practical biomedical translations, such as antibiotic-free animal feed and DNA vaccines.

BM04.09.29
pH Sensitive Nanoparticles to Study the Biofilm Interfacial Microenvironment Padryk Merkl and Georgios A. Sotiriou; Karolinska Institutet, Stockholm, Sweden.

Implant associated infections caused by biofilms are a major cause of implant rejection. One promising strategy to help combat biofilms are “smart” anti-biofilm release surfaces. These surfaces are often loaded with antibiotics or other antimicrobials and respond to the creation of a microenvironment characteristic of biofilms by releasing their cargo. One such characteristic biofilm microenvironment is low pH, whereas in healthy tissue the pH should lie close to 7.4 at the biofilm substrate interface the pH can decrease to 5 and below. These heterogeneous pH environments have been studied previously using electrodes and optical devices. However, here a novel ratiometric sensor which relies on the same processes for sensing as for antimicrobial release is presented in order to optically probe the interfacial biofilm surface pH. Calcium phosphate nanoparticles doped with europium were synthesised and directly deposited onto silicon wafer chips by flame spray pyrolysis, the deposited film was then further stabilised by in situ annealing. These phosphorescent nanoparticles exhibit pH dependent dissolution, with an associated decrease in luminescence intensity which provides a sensor response and known pH buffers were used to draw a calibration curve. A panel of clinically relevant biofilm forming bacteria of both the gram-negatives and gram-positives were selected to measure their interfacial pH. Both gram-negatives and gram-positives demonstrated low pH environments, however, differences between bacterial strains and species were observed. These pH responsive silicon chips can therefore be used to guide the development of anti-biofilm surfaces to target particular bacterial infections.

BM04.09.30
Engineering Vascularized Cardiac Tissue Using a Combination of Electrosprinning and 3D-Bioprinting Technologies Ibrahim Mostafavi and Thomas Webster; Northeastern University, Boston, Massachusetts, United States.

Cardiovascular disease is one of the most leading causes of mortality in the USA. Fabrication of 3D large-scale cardiac tissue constructs with functional vascularization has been a great challenge in engineering tissues suitable for repairing injured heart tissue. To address this challenge, here a new combinatorial approach of electrosprinning and 3D bioprinting techniques is employed to make a functional cardiac tissue. First, we engineered highly elastic blood vessel made of gelatin methacryloyl (GelMA) and poly(e-caprolactone) (PCL) by using electrosprinning technique. The engineered tube was then endothelialized in vitro by using human umbilical vein endothelial cells (HUVECs) and perfused by culture media to form a functional blood vessel. In the next step, and a cell-laden GelMA-based hydrogel was 3D printed around the engineered GelMA/PCL vessel to form a vascularized cardiac tissue. Also, the effect of incorporation of Iron Oxide (Fe3O4) magnetic nanoparticles (MNPs) into both electrospin fibers as well as 3D printing GelMA bioink will be investigated to find out its influence on the cell growth, proliferation as well as the cardiac tissue regeneration. Our results revealed that the mechanical properties of the engineered GelMA/PCL vessels are comparable with small diameter porcine blood vessels. Moreover, the fabricated vessels by electrosprinning are suturetable and depicts high suture retention strength. The 3D printed cell-laden GelMA hydrogels exhibited high cell viability over 5 days (>90%) of culture as captured from fluorescent microscopy images using a commercial Live/Dead assay. The metabolic activity of 3D printed cell-laden GelMA hydrogel also increased consistently during 5 days of culture as measured by using PrestoBlue assay. In addition, the number of cells increased around 3-fold from day 1 to day 5, confirming cell proliferation within 3D printed hydrogels.

BM04.09.32
Silver Nanowire/Chitosan Nanocomposite Scaffolds for Tissue Engineering with Enhanced Durability Dilara Aydin1, Eda Ayse Aksoy2, Seyda Senel1, Husnu E. Unalan3 and Doga Doganay1; 1Pharmaceutical Technology, Hacettepe, Ankara, Turkey; 2Hacettepe University, Ankara, Turkey; 3METU, Ankara, Turkey.

We report on a successful scaffold based tissue engineering approach that aims to facilitate maximal cell seeding efficiency and subsequent cell proliferation using durable scaffolds with interrelated porosity with high surface area per volume and enhanced mechanical strength, durability. Among the biopolymers chitosan, which is a biodegradable, biocompatible cationic polysaccharide exerting bioactive properties (eg.antimicrobial, anti-inflammatory, hemostatic immunostimulatory etc) provides several advantageous as tissue scaffold. Previously we have shown antimicrobial activity of nanocomposite films of chitosan and silver nanowires (Doganay, 2017). In this study, silver nanowire/chitosan nanocomposite scaffolds were prepared via freeze-drying method and their durability were enhanced with αβ-glycerophosphate. Morphology and chemical nature of the nanocomposites were characterized by X-ray Diffraction Spectroscopy (XRD), Scanning Electron Microscopy (SEM) and Fourier Transform Infrared Spectroscopy (FTIR). Mechanical strength, compression modulus, bioadhesion, porosity and water holding capacity of nanocomposite scaffolds were investigated. The scaffolds were observed to retain 35 to 65-fold water while maintaining their form and integrity. The nanocomposite scaffolds showed equilibrium swelling index compared to chitosan scaffold. Further mechanical analysis demonstrated that the incorporation of αβ-glycerophosphate enhanced the elastic modulus and tensile strength values of prepared scaffolds. These and other results obtained in this work revealed that the nanocomposite scaffolds can be mechanically and biofunctionally improved through tailoring the chitosan/αβ-glycerophosphate ratio and the amount of incorporated silver nanowires.

BM04.09.33

Shape-memory polymers (SMPs) are polymeric smart materials that have ability to return from a deformed state to their original shape by an external stimulus. Polycaprolactone (PCL) has properties of biocompatibility and biodegradable, therefore having a wide use in medical field such as drug delivery materials and biological tissue engineering. To make a shape – memory property in PCL, we proceed synthesizing poly(caprolactone-co-glycidylmethacrylate) (PCL-co-PGMA) which is network structure polymer by copolymerizing glycidylmethacrylate (GMA) with caprolactone (CL). PCL-co-PGMA was characterized by GPC, 1H-NMR. In addition, we controlled ratio of GMA in copolymer to set a melting temperature which is showing shape-memory property and DSC was performed.
The crosslinked poly(caprolactone-co-glycidylmethacrylate) network were prepared by photo-crosslinking with ultraviolet (UV) irradiation and using Irgacure 2959 by as the photoinitiating agent. The resultant crosslinked polymer was then characterized by DSC and dynamic mechanical analysis (DMA). Nitric oxide (NO) has many physiological functions such as vasodilation, neurotransmission, and angiogenesis in the human body. Especially, the nonthrombogenic properties of vascular surfaces are primarily attributed to NO generated from endothelial cells that line the inner walls of all blood vessels and Nitric oxide derived from endothelial cells regulates blood flow and pressure and inhibits platelet activation and aggregation under normal conditions. To enhance biocompatibility of shape memory polymer, Nitric oxide was introduced on the surface of shape memory polymer. After that, that was evaluated by cell toxicity test.

BM04.09.34 Preparation and Characterization of Poly(Glycerol-Sebacate-Stearic Acid) for Shape Memory Polymer Bo Keun Lee, Seol Jang and Woo Soon Jang; Future Bio Works Co., Seoul, Korea (the Republic of).

For past few decades, a new type of smart material, Shape Memory Polymer (SMP), has developed rapidly. Shape memory polymers can respond to changes in external conditions such as temperature, pH, and ionic strength. However, such as non-absorbable biomedical polymers can undergo undesirable reactions due to the physical or chemical properties of the surrounding biological components that can persist in vivo for a long period of time to cause toxic reactions in vivo. Therefore, these polymers may need to be removed from the body as a second surgery. Poly (glycerol-sebacate) (PGS) is a biocompatible and biodegradable elastomer that is used in a wide range of biomedical applications to manufacture microfluidic devices, vascular scaffolds, and other micro-tissue engineering systems. Polymers containing glycerol and sebacic acid have already been approved for medical use. While the porous form is preferred for the support to permit intracellular growth, PGS degradation has been studied primarily in non-porous form. Some papers describe their biocompatibility and biodegradation, but no studies have been presented on the shape memory effect of these polymers. The purpose of this study was to investigate shape memory properties, porosity and biocompatibility. Another way to strengthen this polymer is to impart new functionality such as poly (glycerol sebacate) -stearte (PGSS). PGSS based block copolymer with glycerol, sebacic acid and stearic acid by bulk polymerization. PGSS was successfully synthesized and characterized by 1H-NMR, GPC and DSC. The DSC was used to study the reversible movement required for temporary shape storage of shape memory materials. PGSS performed in vitro biocompatibility studies.

Characterization of PGSS is important when evaluating polymerization and future use of this biomaterial. The results confirm that PGSS is a shape memory material with a recovery rate of 99.5% or more. PGSS has also been found to be porous and biocompatible. Thus demonstrating that this material can be designed as a potential biomaterial in other applications where it interacts with pharmaceutical and biological systems.

BM04.09.35 Magnetic Hyperthermia Induced Liposomal Doxorubicin Release for Thermo-Chemotherapy Shan Zhao, Samuel Klein, James Petryk, Catalina Spatarella, Fridon Shabtideze, Zi Chen and Jack Hospes, Dartmouth College, Hanover, New Hampshire, United States.

The development of a targeted drug delivery system is an emerging approach to increase the targetability of anticancer agents. One of the most promising technologies to achieve high specificity is using a liposomal delivery system. In this work we developed a magnetic liposomal delivery system that combines magnetic nanoparticles (mNPs), the doxorubicin (Dox) and the application of an external alternating magnetic field (AMF). The mNPs are encapsulated in the hydrophilic core of liposomes and the Dox is embedded in the hydrophobic bilayer. Once the liposome is delivered into the tumor, then the AMF is activated. The AMF transfers the electromagnetic energy to the mNPs, which in return generates heat and increases the temperature locally in the surrounding ambral. When the temperature reaches the liposome melting temperature T_m, the Dox is released. To further increase the liposome’s targetability, in addition to the AMF-mNPs triggered Dox release approach, we have used a non-invasive, non-toxic external static magnetic field (SMF) to target the liposomes to the tumors. This combined AMF-SMF feature could reduce the non-specific side-effects and toxicity of encapsulated drugs, while ensuring a targeted, safe, high percentage Dox release and accumulation at the tumor site. An in vitro release experiment at 37°C showed that more than 80% of the encapsulated Dox was retained in liposomes after 6 hrs in PBS. Under the exposure of AMF (641 Oe, 170 kHz) for 10 mins, liposomes of 10 ug/ml displayed 80% of Dox release, indicating the high efficiency of this triggering technique. Mice inoculated with B16 murine melanoma cell, intradermal, rear limb, were assessed for Dox release and treatment efficacy when the tumors reached 120 mm³. Our preliminary in vivo study indicated that the external magnetic field demonstrated a notable increase of mNP when the STM was applied at the tumor site. 1 hour post-injection. The levels and distribution of Fe in tissue are examined via histopathology, TEM and ICP-MS. The concentrations of Dox in these biological samples (supernatants of tissue homogenates and plasma) are determined using the fluorescence spectrophotometer. This multimodal technology will allow for a safe, targeted, increase in Dox accumulation at the tumor site and ultimately an improvement in the therapeutic ratio and efficacy of Dox with radiation or other possible combinations of therapies.

BM04.09.36 Supercritical Carbon Dioxide Functionalization of Biomaterials with Antimicrobial Molecules Guillaume Nonglétou1,4, Clémentine Darpentigny1,4, Bastien Michel1,4, Pierre R. Marcoux1,4, Julien Bras1,4 and Bruno Jean1,4, 1CEA-Leti, Grenoble, France; 2CERMAT-CNRS, Grenoble, France; 3Grenoble INP-CNRS, Grenoble, France; 4Université Grenoble Alpes, Grenoble, France.

In a context where the need for innovative medical devices is increasing and the environmental issue is becoming a priority, the objective of this study was to develop “active” wound dressings with antimicrobial properties using a bio-inspired strategy and an eco-friendly solvent: supercritical carbon dioxide (SC-CO2). First, two different types of materials were studied: 1) nanocellulose-based aerogels or membranes and 2) polypropylene (PP), polyethylene terephthalate (PET) or polyamide (PA) plastic sheets as standard polymers used in biomedical applications. We choose to use nanocellulose derived from the biomass as biocompatible building blocks. Nanocellulose particles are a class of very promising bio-based material. In the biomedical field, their relatively low cost, low toxicity and biocompatibility have made them very attractive. They were assembled to prepare aerogels or surfaces with structural parameters controlled by the preparation process and the nanocellulose properties.

Then, the different materials were functionalized in SC-CO2 in an attempt to respect green chemistry principles. SC-CO2, considered as a non-toxic, eco-friendly solvent. The resultant functionalized polymer was then characterized by DSC and dynamic mechanical analysis (DMA). Nitric oxide (NO) has many physiological functions such as vasodilation, neurotransmission, and angiogenesis in the human body. Especially, the nonthrombogenic properties of vascular surfaces are primarily attributed to NO generated from endothelial cells that line the inner walls of all blood vessels and Nitric oxide derived from endothelial cells regulates blood flow and pressure and inhibits platelet activation and aggregation under normal conditions. To enhance biocompatibility of shape memory polymer, Nitric oxide was introduced on the surface of shape memory polymer. After that, that was evaluated by cell toxicity test.

Nitric oxide (NO) has many physiological functions such as vasodilation, neurotransmission, and angiogenesis in the human body. Especially, the nonthrombogenic properties of vascular surfaces are primarily attributed to NO generated from endothelial cells that line the inner walls of all blood vessels and Nitric oxide derived from endothelial cells regulates blood flow and pressure and inhibits platelet activation and aggregation under normal conditions. To enhance biocompatibility of shape memory polymer, Nitric oxide was introduced on the surface of shape memory polymer. After that, that was evaluated by cell toxicity test.

The detailed characterization of the structure materials and their chemical functionalization have been carried out using advanced technologies. The antimicrobial activity of the nanocellulose-based materials was assessed and correlated to the structure and chemistry. For impregnated molecules, the drug release kinetics and the zone of inhibition of growth were analyzed. For structures where antimicrobial agents were grafted, the contact killing activity was assessed and log-D reduction was measured against both bacteria and a eukaryote.
Carbon monoxide (CO), known for its toxicity, is a gaseous signaling molecule (gasotransmitter) endogenously produced through heme catabolism. CO is known to interact selectively with the soft metal centers of heme proteins and indirectly modulate other non-heme-containing targets through signaling pathways. This gasotransmitter participates in a variety of roles in mammalian pathophysiology and has been implicated in oxidative stress, cell proliferation, and apoptosis. In addition, CO has been shown to sensitize cancer cells to known chemotherapeutics, as well as induce dose-dependent eradication of malignant cells. The main difficulty with using CO as a therapeutic is its site-specific delivery in a controlled and sustained manner. Direct inhalation of CO requires continuous exposure to relatively high levels of this gas, lacking specificity and promoting negative effects. An alternate approach to deliver CO to tissue is to use CO-releasing molecules (CORMs). Photoactivated CORMs (photoCORMs), with a few exceptions, are metal carbonyl complexes that release CO upon illumination, allowing for the delivery of this gas with spatial and temporal control. Efforts have been made to impart desirable characteristics to these CO donors, such as visible light sensitivity, solubility, stability, and low toxicity. A wide variety of carriers have been used to deliver CO to biological targets. However, desirable delivery materials should retain the photoCORM or the CO-spent product, thus avoiding possible adverse side-effects. In this account, we describe a novel visible light active polyHEMA-based CO-releasing polymer (photoCORP-I). This hydrogel contains a manganese photoCORM ([Mn(CO)x(qbt)(4-vpy)]CF3SO3) co-polymerized to a hydroxyethyl methacrylate/ethylene glycol dimethacrylate (HEMA/EGDMA) backbone via use of a 4-vinylpyridine ancillary ligand. This covalent attachment ensures that the photoCORM as well as the CO-spent product remain inside of the bulk polymeric material. This robust yet flexible CO-releasing hydrogel can be molded, cast, or cut into any shape or form. Its high transparency and gas permeability allow for the rapid and sustained release of CO upon illumination with low power visible light. The release of CO can be visually tracked by the loss of the color arising from I. A fiber optic-based catheter using a photoCORP-Iip (CO-catheter) was constructed for use in light inaccessible cavities. The reported CO-catheter was successfully used to promote apoptosis in human colorectal adenocarcinoma (HT-29) cells by triggering CO photorelease under low power visible light. The easy application/removal of the CO-catheter from the malignant site circumvents toxicity arising from the photoCORM/photo-products while allowing for the delivery of controlled and sustained doses of CO at the target site. The use of this CO-releasing material coupled to a current endoscope can be used deliver required doses of CO to a colonic target.

Nanocellulose membranes and aerogels that exhibit lightweight and high specific surface areas were compared to determine the structure-functionalization-activity relationship. Impregnation

The mode of action and the lifespan of the newly designed antimicrobial materials were studied according to the incorporation process of bioactive molecules in supercritical carbon dioxide. Both impregnation and grafting can be used to impart antimicrobial properties and extend the shelf-life of the bioactive wound dressing. These bioactive materials will be used for the design of external wound dressings and implantable medical devices.

Eradication of HT-29 Colorectal Adenocarcinoma Cells by Controlled Photorelease of CO from a CO-Releasing Polymer (photoCORP-I) Triggered by Visible Light Through an Optical Fiber-Based Device

Miguel N. Pinto, Indranil Chakraborty, Cosme Sandoval and Pradip K. Mascharkar; University of California, Santa Cruz, Santa Cruz, California, United States.

Carbon monoxide (CO), known for its toxicity, is a gaseous signaling molecule (gasotransmitter) endogenously produced through heme catabolism. CO is known to interact selectively with the soft metal centers of heme proteins and indirectly modulate other non-heme-containing targets through signaling pathways. This gasotransmitter participates in a variety of roles in mammalian pathophysiology and has been implicated in oxidative stress, cell proliferation, and apoptosis. In addition, CO has been shown to sensitize cancer cells to known chemotherapeutics, as well as induce dose-dependent eradication of malignant cells. The main difficulty with using CO as a therapeutic is its site-specific delivery in a controlled and sustained manner. Direct inhalation of CO requires continuous exposure to relatively high levels of this gas, lacking specificity and promoting negative effects. An alternate approach to deliver CO to tissue is to use CO-releasing molecules (CORMs). Photoactivated CORMs (photoCORMs), with a few exceptions, are metal carbonyl complexes that release CO upon illumination, allowing for the delivery of this gas with spatial and temporal control. Efforts have been made to impart desirable characteristics to these CO donors, such as visible light sensitivity, solubility, stability, and low toxicity. A wide variety of carriers have been used to deliver CO to biological targets. However, desirable delivery materials should retain the photoCORM or the CO-spent product, thus avoiding possible adverse side-effects. In this account, we describe a novel visible light active polyHEMA-based CO-releasing polymer (photoCORP-I). This hydrogel contains a manganese photoCORM ([Mn(CO)x(qbt)(4-vpy)]CF3SO3) co-polymerized to a hydroxyethyl methacrylate/ethylene glycol dimethacrylate (HEMA/EGDMA) backbone via use of a 4-vinylpyridine ancillary ligand. This covalent attachment ensures that the photoCORM as well as the CO-spent product remain inside of the bulk polymeric material. This robust yet flexible CO-releasing hydrogel can be molded, cast, or cut into any shape or form. Its high transparency and gas permeability allow for the rapid and sustained release of CO upon illumination with low power visible light. The release of CO can be visually tracked by the loss of the color arising from I. A fiber optic-based catheter using a photoCORP-Iip (CO-catheter) was constructed for use in light inaccessible cavities. The reported CO-catheter was successfully used to promote apoptosis in human colorectal adenocarcinoma (HT-29) cells by triggering CO photorelease under low power visible light. pH-Triggered Tumor Targeting Polymeric Micelles Loading with Dimeric Drug for FRET-Traceable Drug Release

Xing Guo1, 2, Lin Wang1, Kayla Duval1, Jing Fan1, Shaojing Zhou1 and Zi Chen1; 1Dartmouth College, Hanover, New Hampshire, United States; 2Southwest Jiaotong University, Chengdu, China; 3City College of New York, New York, New York, United States.

Trans-activating transcriptional activator (TAT), a cell-penetrating peptide, is extensively used for facilitating cellular uptake and nuclear targeting of drug delivery systems. However, the positively charged TAT peptide strongly interacts with serum components and undergoes substantial phagocytosis by the reticuloendothelial system, causing a short blood circulation in vivo. In this work, an acid-active tumor targeting nanoplatform DA-TAT-PECL was developed to inhibit the nonspecific interactions of TAT in the bloodstream. 2,3-dimethylmaleic anhydride (DA) is used to convert the TAT’s amines to carbonyl complexes that release CO upon illumination, allowing for the rapid and sustained release of CO upon illumination with low power visible light. The release of CO can be visually tracked by the loss of the color arising from I. A fiber optic-based catheter using a photoCORP-Iip (CO-catheter) was constructed for use in light inaccessible cavities. The reported CO-catheter was successfully used to promote apoptosis in human colorectal adenocarcinoma (HT-29) cells by triggering CO photorelease under low power visible light. The easy application/removal of the CO-catheter from the malignant site circumvents toxicity arising from the photoCORM/photo-products while allowing for the delivery of controlled and sustained doses of CO at the target site. The use of this CO-releasing material coupled to a current endoscope can be used deliver required doses of CO to a colonic target.

Comparative Study of Ampicillin-Loaded Melanin-Polycaprolactone Nanofibers Prepared by Single-Needle and Co-Axial Electrospinning Methods

Gözde Kabay1, 2, Gizem Ak3, Gizem Kaleli Can1 and Mehmet Mutlu3; 1Biomedical Engineering Division, TOBB University Of Economics and Technology, Ankara, Turkey; 2Biological Systems Engineering Department, University of Wisconsin–Madison, MADISON, Wisconsin, United States; 3Biomedical Engineering Department, TOBB University of Economics and Technology, Ankara, Turkey.

Melanin, natural consistent of human body, has attracted great attention in the last few years by being amorphous biopolymer with semiconducting, biodegradable, biocompatible and non-toxic, antioxidant and abundant biopolymer derived from natural sources 1, 2. Despite its great potential and ease on extraction, it has been rarely studied in pharmaceutical and biomedical fields. So that, in this study, it is decided to use natural melanin nanoparticles by incorporating into PCL solution to achieve controlled release of the ampicillin from electrosprun membrane by coaxial and single-needle electrospinning.

In the experimental setup, 10% (w/v) PCL was mixed with appropriate amounts of extracted melanin (0,001-0,1 g/ml) and ampicillin (0,01 g/ml) to prepare single-needle electrosprun membranes (S). For core-shell structures fiber production, 0,01 g Amp was mixed with 10% (w/v) PCL solution and used as a core solution, whereas 4% (w/v) PCL solution combined with melanin (0,001-0,1 g/ml) for a shell coverage, in turn. After spinnable solutions reached the nozzle tip, they were exposed to high voltage of 12 kV, while tip-to-collector distance was kept at 9 cm and nanofbers were produced. Drug release amounts of PCL-amp core (C), PCL-Mel-Amp single-needle and coaxialy electrosprun membranes (S and CS) were measured by Ultraviolet-Visible Spectroscopy at the wavelength of 203 nm and corresponded drug release profiles were analyzed.

For C membrane, 82% of the ampicillin was released within the first hour indicating burst release. The burst release can be due to the lower compatibility of ampicillin inside PCL fibers or the accumulation of the drug on fibers’ surface during spinning. Besides, in the presence of melanin, slower initial burst release compared to C was observed for the S membrane, which showed a burst release of 37%. In the same period, the release rate of the drug was only 7% for the CS membranes. It states that, more controlled drug release was achieved for CS nanofibrous membrane compared to the S membrane even if the melanin addition was carried out for both processes. This result would be attributed to the shell layer coverage that introduced an additional diffusion barrier.

In all, we first-time evaluated melanin-polycaprolactone composite as a drug nanocarrier, both in coaxial and monolithic forms. The findings of this
Dental Pulp Stem Cells (DPSCs), easily acquired from extracted wisdom teeth, are multipotent stem cells that can transform into osteoblasts, cardiac, and neuron cells and can thus provide cells resulting in an autologous implant. P4VP, a polymer shown to retain cell morphology, can help cells adhere to fibers, on DPSCs and their potential differentiation into neural cells.

Multiphase emulsion drops have wide applications such as in drug delivery and food industry because of their ability to encapsulate active ingredients and to release them in a controllable time. Recently, high-order multiphase emulsion drops have been successfully obtained by mass-transfer induced phase separation in microfluidic devices [1,2]. However, the ternary systems used in these studies always involve organic-solvents, such as oil and polar solvent, and few of them focus on the formation of high-order all-aqueous emulsions which are oil-free and highly biocompatible. Therefore, we propose a robust approach to form high-order multiple all-aqueous emulsions in a glass-based microfluidic device [3]. The proposed method is essentially based on the phase separation induced by the osmolality difference between the drop and the continuous phases. By varying the initial concentration of the drop phase, we also successfully achieve all-aqueous emulsions with different complexity and further summarize the complexity of the droplets into a phase diagram. Our method is simple, and the fabricated high-order all-aqueous emulsions could be templated as biocompatible capsules which are capable of encapsulating and releasing active components upon trigger.

Utilization of P4VP and Graphene to Differentiate Dental Pulp Stem Cells into Functional Neurons

John Chen1, Zaiff Khan1, Linxi Zhang2, Kuan-Che Feng2, Rebecca Isseroff2, Marcia Simon1 and Miriam Rafailovich2; 1Lawrence High School, Cedarhurst, New York, United States; 2Dept. of Materials Science and Chemical Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; 3Stony Brook University School of Dental Medicine, Stony Brook, New York, United States.

Currently, the central nervous system is unable to heal effectively by itself, leading to a search for ways to regenerate or grow neurons for replacement. Dental Pulp Stem Cells (DPSCs), easily acquired from extracted wisdom teeth, are multipotent stem cells that can transform into osteoblasts, cardiac, and neuron cells and can thus provide cells resulting in an autologous implant. P4VP, a polymer shown to retain cell morphology, can help cells adhere to a substrate, potentially eliminating the need for polyornithine. Graphene, known for its electrical conductivity, may prove useful in the differentiation of DPSCs into neurons, since neurons communicate through the electrical impulses of the synapses. This research compares the effects of thin film substrates of P4VP and P4VP+graphene, on DPSCs and their potential differentiation into neural cells.

Four experimental substrates were created: P4VP and P4VP+graphene thin films, as well as P4VP and P4VP+graphene electrospun into fibers. Two sets of each substrate were created; one set was coated with polyornithine and the other set was not coated. A positive control of tissue culture plastic was also plated with DPSCs.

Optical microscopy displayed that DPSCs grown on flat substrates of P4VP and P4VP+graphene grew into longer cells than those grown in the positive control. In addition, they had formed branches of axon-like structures from day 14, even without the use of polyornithine, suggesting that P4VP thin films allow cells to adhere on their own to the substrate. However, electrospun fibers did not show differences in cell growth from the positive control. Confocal Microscopy conducted after 21 days of culture confirmed that the cells directly attached to the P4VP and P4VP+graphene substrate had elongated, while the cells not attached were more round, but both types showed high confluency. Also, cells plated on electrospun fiber samples had the same shape and confluency as flat film samples, suggesting that fibers had similar effects as thin films on DPSC growth into nerve-shaped cells. No visible changes were seen with the addition of graphene. Further results were acquired with Scanning Electron Microscopy (SEM) and Real-Time Polymerase Chain Reaction (RT-PCR), determining whether the DPSCs were starting to undergo differentiation into neurons and thus showing promise that P4VP can provide a suitable scaffold for neuron cell development.

Micropatterning of TiO2 Nanotubes for High-Throughput Study

Qiaoling Huang1,2, Yanran Li1, Yuanjun Dong1, Ping Mu1, Xiang Yang Liu1,2 and Changqiang Liu1; 1Xiamen University, Xiamen, China; 2John A. Paulson School Of Engineering And Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 3National University of Singapore, Singapore, Singapore.

TiO2 nanotubes (TNTs) have attracted extensive attention by virtue of the similarity of their highly ordered nanotubular structure to that of cortical bone. Recent studies have indicated that titanium nanotubes are superior to pure titanium in terms of bone regeneration, blood compatibility and corrosion resistance. However, the optimal properties of TNTs for certain applications remain mystery. For example, the nanotube dimension ranges from several nanometers to hundreds of nanometers. The existing literature reports biological responses to confined dimensions owing to the technique difficulties in evaluating hundreds of TNTs with different properties at the same time. In this study, TNT gradients with different properties were fabricated and applied for high-throughput study. Results showed that TNT gradients provide facile platforms for high-throughput screening of biological responses, including cell responses, protein adsorption, bacterial adhesion, and et al.

Phase-Separation Induced High-Order All-Aqueous Emulsions in Microfluidics

Youchuan Chao1,2, Sze Yi Mak1,2 and Ho Cheung Shum1,2; 1HKU-Shenzhen Institute of Research and Innovation (HKU-SIRI), Shenzhen, Guangdong 518000, China; 2Department of Mechanical Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, China.
Mechanical Properties of Drawn Electrospun Polycaprolactone (PCL) Nanofibers

Katie Sun¹ ² and Vince Beachley³; ¹Rutgers, The State University of New Jersey, New Brunswick, New Jersey, United States; ²Rowan University, Glassboro, New Jersey, United States.

Introduction: Polycaprolactone (PCL) is a biodegradable polymer that has favorable structural, mechanical, thermal, and chemical properties which provide the necessary strength, rheology, porosity, biocompatibility, and flexibility to fulfill the role as a biological scaffold in musculoskeletal tissue engineering and repair. Significantly, PCL nanofibers have historically proved to be able to sustain large amounts of elongation before break. The method of electrospinning provides highly linear and aligned scaffolds like that of natural tissues, produces a favorable surface area to volume ratio, and protects the scaffold’s ability to provide a mechanical strength comparable to that of natural tissue. Thus, the post-draw of PCL nanofibers after electrospinning produces a product with mechanical properties that are correlated with strain rate.

Methods: An electrospinning device designed by our lab utilizes an adjustable frame and aluminum tape tracks controlled by a motor system to both electrospin PCL nanofibers while also post-drawing them to a desired draw ratio and improving alignment. The process of electrospinning 18wt% polycaprolactone (PCL) is protected and humidity-controlled in a polycarbonate enclosure. The electrospinning draw ratio was set at 2 for the PCL fibers. A scanning electron microscope (SEM) was utilized to analyze the fibers’ diameters, densities, and cross-links. The mechanical properties were tested under strain rates of 0.5mm/min, 5mm/min, and 50mm/min for nanofibers laid on a 10mm by 10mm testing square.

Results: The electrospun PCL nanofibers exhibited many trends after mechanical testing. The young’s modulus decreased with increased fiber number and with increased strain rate. The ultimate tensile strength increased with increased fiber number and increased more gradually with increased strain rates. The toughness shows increases correlated to fiber number and a strongly positive and steep correlation with a 0.5mm/min strain rate. The 5mm/min and 50mm/min testing rates and toughness show constant toughness regardless of fiber number. The ultimate tensile strain of the fibers varies little and thus is independent of testing strain rates.

Conclusion: Electrospinning while post-drawing proved to create PCL nanofibers that exhibit an inverse negative correlation to young’s modulus but direct positive correlation to ultimate tensile strength, toughness, and ultimate tensile strain. The increase in testing strain rate decreased the average-per-strain-rate young’s modulus, ultimate tensile strength, toughness, and ultimate tensile strain. This is due to the higher testing strain rates causing rapid plastic deformation. This prevents the PCL polymer chain alignments from accommodating new charge repulsions due to the elongation and movement of PCL fibers during mechanical testing, leading to failure. The data collected indicates that if further mechanical testing strain rates are tested, the same correlations will be exhibited.

Influence of Exposure to TiO₂ Nanoparticles on Staphylococcus aureus Infection

Fan Yang¹, Justin Zhou², Vincent Zhang¹, Jonathan Goldschlag⁴, Ethan Winkler⁵ and Miriam Rafaelovich⁶; ¹Stony Brook University, Stony Brook, New York, United States; ²Patchogue-Medford High School, Medford, New York, United States; ³Sachem High School East, Farmingville, New York, United States; ⁴Hebrew Academy of the Five Towns and Rockaway, Cedarhurst, New York, United States.

Titanium dioxide (TiO₂), commonly used in paints, toothpaste, sunscreen, cosmetics, pharmaceutics, and food additives, has been extensively studied for its anti-cancer and anti-bacterial applications when irradiated with UV light, but there is minimal data on its relative safety for normal human cells. In a previous study, HeLa cell exposed to TiO₂ nanoparticles showed an increased susceptibility to bacterial infection partially attributed to inhibition of enzymatic activity involved in membrane cholesterol distribution.[1] Since HeLa cells are an immortalized cell line derived from tumor tissue, they may not be representative of cells found in healthy human tissue. To investigate the influence on healthy tissue, we chose to focus on skin tissue, since skin is the first barrier to contact with various toxins. Dermal fibroblasts and keratinocytes were plated on tissue culture plastic for 24 hours and then exposed for another 24 hours to 0.1mg/ml of TiO₂. The results indicate that an increased susceptibility to bacterial infection is also present in healthy primary tissue cells. Since cells are also influence by their environment, we also investigated the role of the substrate on the toxicity to TiO₂ nanoparticles, as well as bacterial infection. Preliminary results indicate increased toxicity of the particles, when the cells are cultured on gelatin, and in particular collagen, which is commonly present in the skin tissue.

Preparation and Performance of Polycaprolactone Nanocarrier for the Controlled Release of Interferon-α for the Treatment of Malign Melanoma

Enes Celik, Gözde Kabay and Mehmet Muthu; Biomedical Engineering, Ankara, Turkey.

Melanoma is a type of skin cancer, results in higher mortality rates mostly in metastatic states which constitutes 80% of skin cancer deaths (Miller, A.J., et all. 2006). Because of being such a wild type of cancer, various therapeutic methods such as surgery, radiation therapy, chemotherapy, immunotherapy and targeted therapy are used to decrease the mortality rates. However, none of these procedures are enabled completely to remove the problems such as toxicity and efficacy. To overcome these problems, controlled drug release technology remains as a plausible approach.

Nanofibrous scaffolds designed for drug delivery purpose has various advantages compared to conventional drugs such as high loading and entrapment capacity, protection of therapeutic agent, controlling the release of the drug in a timely manner and accordingly preservation from any toxic effect. Several controlled drug release profiles such as sustained, burst, and delayed can be obtained by using electrospun nanofibrous membranes as carriers (Hui, X., et all, 2014). The ability to adhere the scaffold at the site of infection is another advantage of these systems compared to other drug delivery methods, which would be beneficial for the skin cancer types (Akduman, C., et all, 2016).

Based on the clinical problem defined above and the previous reports, we hypothesized that the good biocompatibility and biodegradability of polycaprolactone (PCL) makes it promising nanocarrier for drug release applications. Therefore, we developed a drug release platform combination of PCL and interferon-alpha-2B (INFα-2B) which is a therapeutic agent approved by the US Food and Drug Administration (FDA) and recently being used for the treatment of metastatic melanoma.

In the experimental setup, electrospun membranes combined of PCL and INFα-2B were produced by single and coaxial electrospinning setups. 10% (w/v) PCL was combined with INFα-2B by mixing with ratios of 5%,10% and 20% (w/w). System parameters such as applied voltage and tip-to-collector
distance were adjusted to 12 kV and 9 cm, respectively. Flow rates were varied between 0.5 and 1.0 ml/h for core and shell solution, in turn. The physical characterization of the electrospun membranes were achieved SEM and TEM analysis and chemical characterizations were carried out by FTIR spectroscopy. Moreover, in vitro drug release profile of INF α-2B from the electrospun membranes was sketched by calculating the concentration of INF α-2B released into the phosphate buffered saline solution (PBS, pH: 7.4) with UV–vis spectrophotometer (Hitachi U-5100, Japan) at 214 nm (Sultanova, Z., et al, 2016).

We showed that, coaxially electrospun INFα-2B loaded PCL nanofibrous membranes can be used to treat melanoma disease by providing controlled release of INFα-2B. The accurate adjustment of the drug release behavior of INFα-2B-loaded PCL nanofibers against tumor cells is currently under investigation.

**Characterization of Thermoreversible Hydrogels from Multiblock Poloxamers and Hybrid Hydrogels for an Application as Cell Barrier Layer**

Juyi Li1, Erica Inyoung Chui1, Christina Tong2 and Miriam Rafailovich1; Stony Brook University, Stony Brook, New York, United States; Fairview High School, Boulder, Colorado, United States; St. Paul’s School, Concord, New Hampshire, United States.

Periodontitis is a highly prominent issue in dental health today and the current solutions such as Guided Bone Regeneration (GBR), or the use of a barrier membrane to separate the alveolar bone and gums, have many shortcomings. These barrier layers can be composed of hydrogels, 3D cross-linked polymeric networks that are used for regenerative medicine; hydrogels are showing very promising applications in the biomedical field due to their biocompatibility and unique properties. Our previous work showed a promising hybrid gel synthesized with gelatin and poloxamer F127. Polymerized multiblock poloxamers maintain the thermo-reversibility but with an improved mechanical property. This study focused on characterization of the multiblock poloxamers PF127, PF108, and PF98 and synthesis/characterization of hybrid gels using these poloxamers to evaluate their potency. Rheology was used to characterize the poloxamer solutions and hybrid hydrogels, revealing that PF108 had a significantly higher elastic modulus compared to the other gels. The laser microscope imaging showed a unique, branching fiber structure of the PF108 hybrid gel, while the structures of the other hybrid gels displayed gelatin mesh networks. The PF108 hybrid hydrogel also showed significantly lower surface roughness. This is associated with decreased cell attachment, thus, gelatin-PF108 hybrid gel may possess promising characteristics to serve as a better cell barrier layer.

**Novel Collagen and Elastin Interlaced Composites for Heart Valve Tissue Engineering (HVTE)**

Sonia Hfehkar1, Colleen Lopez2, Jan Czernuszka1 and Carolyn Carr2; 1Department of Materials, University of Oxford, Oxford, United Kingdom; 2Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, United Kingdom.

Valvular Heart Disease (VHD) is an incurable disease that affects 2.5% of the population in the USA, this includes both congenital and acquired forms of VHD. Valve replacement is the most likely treatment when the valve is severely damaged resulting in stenosis and/or regurgitation. Prostheses used to replace damaged valves are predominantly of two types, biological or mechanical. Both types are temporary non-regenerative solutions that have drawbacks, these include a limited life-time and the prerequisite to take anticoagulants.

A tissue engineered substitute has the potential to overcome such limitations and could form a fully functional and viable heart valve, this is particularly advantageous for infants suffering from congenital VHD.

Heart valves are active, self-repairing tissues that can withstand tremendous magnitudes of pressure due to their unique architecture. They have an interconnected tri-layer structure made up of three distinct zones. Type I collagen and elastin are the two major components of the extracellular matrix (ECM). Elastin is a non-collagenous protein that is present in the form of a three-dimensional network with interconnected collagen fibres, together they provide the ability to bear high loads as well as be flexible and resilient.

Designing a scaffold to mimic the structure and function of native heart valves requires bioactive materials that can easily be processed and fabricated into scaffolds. Naturally based biomaterials are the most promising candidates to be used as the basis for rapidly regenerative scaffolds.

A combined microstructural, micromechanical and stem cell based approach is proving to be the most successful in terms of reproducibility, rapid generation of new ECM and changes to stiffness. Our work follows a biomimetic inspired approach, where we have designed novel scaffolds using ECM components to mimic the interconnected architecture of the heart valves closely. These unique compositions are the first step towards designing tri-layer structures to replicate the entire heart valve structure.

Chaotic Printing—Using Chaos to Fabricate Densely Packed Micro- and Nanostructure at High Resolution and Speed Grisell Trujillo-de Santiago1, 2, Maria Díaz-de León Derby1, 3, Carolina Chávez-Maduro1, 4, Mohammadali Samandari3, 4, Christian Carlos Mendoza-Buenrostro3, Gyan Prakash3, Sara Cristina Pedroza-González3, Brenda Giselle Flores-Garza1, Rute Fabiana Martins-Fernandes2, Yu Shrike Zhang3 and Mario M. Álvarez1; 1Centro de Biotecnología-FEMSA, Tecnológico de Monterrey, Nuevo León, Mexico; 2Departamento de Mecatrónica e Ingeniería Electrónica, Tecnológico de Monterrey, Nuevo León, Mexico; 3Imperial College London, London, United Kingdom; 4School of Mechanical Engineering, College of Engineering, University of Tehran, Tehran, Iran (the Islamic Republic of); 5Department of Engineering in Medicine, Brigham and Women's Hospital, Harvard Medical School, Cambridge, Massachusetts, United States.

Nature generates densely packed micro- and nanostructures to enable key functionalities in cells, tissues, and other materials. Current fabrication techniques, due to limitations in resolution and speed, are far less effective at creating microstructure. Yet, the development of extensive amounts of surface area per unit of volume will enable applications and manufacturing strategies not possible today. Here, we introduce chaotic printing—the use of chaotic flows for rapid generation of complex, high-resolution microstructures. Here we use two classic mixing systems as models, the Journal Bearing (JB) flow and the Kenics mixer, to demonstrate the use of chaotic printing. In a miniaturized JB flow (miniJB) we induced deterministic chaotic flows in viscous liquids. These flows deform an “ink” (i.e., a drop of a miscible liquid, fluorescent beads, or cells) at an exponential rate to render a densely packed lamellar microstructure that is then preserved by curing or photocrosslinking. In a continuous version of chaotic printing, we created chaotic flows by coextruding two streams of alginate (two inks) through a printing head that contains an on-line miniaturized Kenics static mixer with multiple mixing elements (or sections). In this way, we continuously 3D-print multi-material lamellar structures with different degrees of surface area (as a function of the number of elements used) and full spatial control of the internal microstructure. The combined outlet stream is then submerged in a calcium chloride solution in order to crosslink the emerging alginate fibers and preserve the microstructure. We show that the exponentially fast creation of fine microstructure achievable through chaotic printing exceeds the limits of resolution and speed of the currently available 3D printing techniques. Moreover, we show that the architecture of the microstructure to be created with chaotic printing can be predicted using computational fluid dynamic (CFD) techniques. We present different proof-of-principle applications for this technology, including the development of densely packed biocatalytic surfaces and highly complex multi-lamellar and multi-component tissue-like structures for biomedical applications.

2:00 PM BM05.02.02
3D Bioprinted Mini-Brains as a Novel Tool to Study the Glioblastoma Microenvironment Marcel A. Heinrich1, Ruehi Bansal1, Yu Shrike Zhang2, 3, 4, Raymond Schifferels1 and Jai Prakash1; 1Department of Biomaterials Science & Technology, University of Twente, Enschede, Netherlands; 2Division of Engineering in Medicine, Harvard Medical School, Brigham & Womens Hospital, Cambridge, Massachusetts, United States; 3Division of Health Sciences & Technology, Harvard-Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Wyss Institute for Biologically Inspired Engineering, Harvard University, Cambridge, Massachusetts, United States; 5Department of Clinical Chemistry and Hematology, University Medical Center Utrecht, Utrecht, Netherlands.

Glioblastoma-associated macrophages (GAMs) play a crucial role in the progression and invasiveness of glioblastoma multiforme (GBM), however, the exact crosstalk between GAMs and glioblastoma cells is not fully understood. Furthermore, there is lack of relevant in vitro models to mimic their specific interaction in a dynamic and relevant environment. 3D bioprinting offers a promising approach to culture cells with well-defined structure and composition. In this study, we aim to develop novel bioprinted mini-brains that display in vivo-like behavior of both glioblastoma cells and GAMs. We bioprinted mini-brains (WxLxH: 4x6x3mm) comprised of either glioblastoma cells or macrophages or together to study their interaction in a realistic way. Both macrophages and glioblastoma cells remained viable in the mini-brains for at least 10 days. We observed an induction of glioblastoma-specific markers (e.g. Gfap up to 15-fold) compared to 2D cultures at mRNA level. Next, we studied whether tumor cells recruit macrophages to their site. To mimic that, we bioprinted mini-brains consisting of either macrophages or glioblastoma cells and cultured them in the same well. We found a 125-fold upregulation of Ccl2, a chemokine related to macrophages recruitment compared to 2D culture, indicating that tumor cells actively recruit macrophages in the 3D co-culture. Furthermore, we cultured mini-brains consisting of macrophages next to glioblastoma cells to confirm their migration. We found that macrophages significantly migrated towards the tumor site, indicating successful crosstalk between these cells. Next, we investigated the effect of direct cell-to-cell contact of tumor cells and macrophages in the 3D culture. We bioprinted mini-brains consisting of macrophages including a cavity containing glioblastoma cells mimicking the clinical situation. We investigated the gene expression of GAM-specific markers and observed a significant upregulation of markers for the GAM phenotype (Arg-1, Mmp2, Mmp9, Cad) and Gfap, indicating that tumor cells polarized macrophages towards GAMs. In addition, by resecting the tumor area from the mini-brains and investigate the expression of glioblastoma-related markers, we found that markers for tumor progression (Gfap, Chil1) and tumor invasion (Mmp9, Vimentin) were significantly overexpressed in the co-culture, displaying how GAMs support glioblastoma progression and invasion. To examine the clinical relevance of this model, we performed transcriptomic analysis of 159 GBM patients using available database, which showed a significant upregulation of highly relevant markers such as Mmp2, Mmp9 or Chil1. These data indicate that tumor cells induce recruitment of macrophages towards themselves and change their phenotype, as well as how GAMs support tumor progression and invasion. Altogether, our bioprinted mini-brains are a viable tool to study the interactions between different cell types and could potentially be used for drug screening purposes.
Tailoring a Functional Microbiotic Consortium via 3D Printing
Sudeep Joshi and Manu S. Mannoor; Stevens Institute of Technology, Hoboken, New Jersey, United States.

A characteristically well-diverse assemblage of myriad micro-organisms operating in a synergetic environment, constitutes a microbiotic consortium. It possesses a complex spatial and temporal microbial arrangement, which is self-sustained and perform multitudinous task by effective communicative functionality. The ability to custom-tailor a well-diversified microbiotic consortia permitting re-programmability of the microbial composition possess potential application prospects in bacteriology, drug-screening, clinical diagnostics, and therapeutic purposes. Additive manufacturing technique accomplished via 3D printing can serve as an efficient tool to realize such a functional microbiotic consortia. In the present article, we have utilized 3D printing technique to custom-tailor different genera of cyanobacterial cells within biofriendly hydrogel materials to realize a living microbiotic consortium. Moreover, these cyanobacterial colonies were seamlessly merged with abiotic nanomaterials for creating a functional microbiota capable of photosynthetic energy generation. Specifically, we demonstrate 3-dimensional interleaving of 2 genera of cyanobacteria (Anabaena and Nostoc Sp.) pre-seeded in a hydrogel matrix with electronic nanomaterial (graphene nanoribbons, GNRs) into various complex spatial geometries to enable harvesting of photosynthetic bio-electrons. Fluorescence and scanning electron microscopic studies were performed to examine the spatial distribution of cyanobacterial cells and their interaction with GNRs, respectively. Photo-electrochemical studies verified highly-conducting GNRs helped in efficient transfer of bio-electrons generated due to the water-splitting reaction during photosynthesis. UV-visible spectroscopy and standard plate counting methods were used to determine the growth of cyanobacterial cells in microbiotic consortium, hence confirming the cytocompatibility of hydrogel matrix. Significantly, the proposed 3D-printing strategy can organize cyanobacteria within complex arrangements to investigate the influence of spatial and environmental parameters on social behaviors for creating photosynthetically active microbiotic consortia.

Techniques developed in this research can also be extended to 3D print other genera of bacterial species with smart hydrogel materials to determine mutualistic relationships between bacteria, designing of synthetic systems, and post-biotic products. Taken together, our experimental efforts lead towards the better comprehension and understanding of complex microbial arrangement and associated functionality of a robust microbiota.

Numerical Simulation of Inkjet and Extrusion Bioprinting—Role of Resolution
Amir K. K. Miri1 and Iman Mirzaee2; 1Rowan University, Glassboro, New Jersey, United States; 2Mechanical Engineering, University of Massachusetts Lowell, Lowell, Massachusetts, United States.

Since the emergence of the technology, 3D bioprinting has been applied to many areas of biomedicine such as creating customized devices, flexible bioelectronics, and scaffolds for tissue regeneration, novel therapeutic systems, prosthetics, and orthodontics. The macro-architecture of the generated construct can be as complex as the anatomical feature of the desired tissue, which necessitates proper printing fidelity. Printing resolution depends on the technical specifications of bioprinters and the physical properties of bioinks. In this work, a numerical model based on the method of volume of fluid (VOF) was created to obtain some insights on the droplet generation in inkjet bioprinting. Our simulations revealed the spatial and temporal features of the droplets before they impact the substrate, which is highly difficult to observe through experiments. The results further showed that high hydrophobicity of the substrate yielded a better printing resolution and lower stability for bioprinting. We then simulated the process of deposition from a sub-millimeter sized nozzle in extrusion bioprinting. In contrast to inkjet printing, the viscosity was found to be a dominant factor for flow properties inside the nozzle and after deposition. The viscosity dependency of shear rates also affects the surface deformation of the bioink when it leaves the nozzle and the combination of flow-induced stresses with surface tension forces dictates the form of the spherical residue formation. Based on our simulations, by selecting proper bioink properties, the resolution can be improved significantly in extrusion and inkjet bioprinting techniques.

Bioengineering Female Reproductive Tract Tissues
Monica M. Laronda1, 2; 1Stanley Manne Children's Research Institute, Ann & Robert H Lurie Children's Hospital, Chicago, Illinois, United States; 2Department of Pediatrics, Feinberg School of Medicine, Northwestern University, Chicago, Illinois, United States.

Hormones produced by the ovary support reproductive tract development and function, and are important for systemic health. The additional systems that are supported include brain, bone and cardiovascular tissues. There is a great need for mimics that represent the dynamic functionality of reproductive tissues in order to improve our understanding of normal function, function affected by disease or disease treatments and to improve current options for our patients. This includes restoring fertility and hormone function for survivors of childhood cancer who develop premature ovarian failure following their life-saving treatments. This particular population would benefit from hormone restoration in addition to new options for preserving and restoring gametes for future biological offspring, as they transition through puberty and may be put at significant risk of co-morbidities without normal ovarian hormones. The female reproductive tract is uniquely different from most model organisms and has forced researchers to develop creative ways to study the human condition. We have turned to engineering solutions to facilitate our quest for answers to these biological problems. This includes using new biomaterials or tissue reconstructed tissues to recapitulate normal female reproductive tract organs, simulating the paracrine and endocrine crosstalk that occurs among these tissues in a microfluidics system and 3D printing scaffolds to engineer follicle support in a bioprosthetic ovary that restored fertility and hormone function in sterilized mice. We continue to make improvements with these systems to impact reproductive biology research and fertility and hormone restoration for patients.

Glioblastoma (GBM), the most malignant brain cancer, remains deadly despite wide-margin surgical resection and concurrent chemotherapeutic and radiation therapies. Two pathological hallmarks of GBM are diffuse invasion along brain vasculature, and presence of therapy-resistant tumor initiating stem cells. Deciphering the underlying mechanisms of GBM-vascular interaction may add a new therapeutic direction to curtail GBM progression. However, the lack of proper 3D models that recapitulate GBM hallmarks restricts investigating cell-cell/cell-molecular interactions in tumor microenvironments. In this study, we created GBM-vascular niche models through 3D bioprinting containing patient-derived glioma stem cells (GSCs), human brain microvascular endothelial cells (hBMVECs) cells, pericytes, astrocytes and various hydrogels to model glioma/endothelial cell-cell interactions in 3D. Three GBM-vascular models were designed: Model A with large vessels and GBM spheroid; Model B with large- and micro-vessels, and GBM spheroid; Model C with large- and micro-vessels and dispersed GBM cells. Large channels were created by sacrificial 3D bioprinting. Microvessel network was formed through self-assembly of ECs and mural cells (fibroblast, pericytes, and/or astrocytes). Three GBM cell types were used in the study: SD02 and SD03 are GSCs;
U87MG is a commercially-available GBM cell line. GSCs cultured in these models maintained stemness and heterogeneity during the long-term cultures.

In Model A, GSCs actively invaded into the surrounding tissues (~Day26), initially regressed in response to the drug (~Day50), then developed therapeutic resistance and resumed aggressive invasion (~Day57). In Model B and C, three GBM types presented distinctive invasion patterns and EC-interactions. SD02 cells showed a spiky invasion pattern with elongated morphology. SD03 cells showed a more dispersed invasion pattern with many single cell migrations towards surrounding microvessels. U87MG cells showed a blunt invasion pattern, caused EC death in the spheroid form. In summary we have created GBM-vascular niche models that can recapitulate various GBM characteristics such as cancer stemness, tumor type-specific invasion patterns, and drug responses with therapeutic resistance. Our models have a great potential in investigating patient-specific tumor behaviors under chemo-/radio-therapy conditions and consequentially helping to tailor personalized treatment strategy. The model platform is capable of modifying multiples variables including ECMs, cell types, vascular structures, and dynamic culture condition. Thus, it can be adapted to other biological systems and serve as a valuable tool for generating customized tumor microenvironments.

Development of Strong and Biostable Nanocomposite Hydrogels Through Embedded Freeform 3D Printing Coupled with In Situ Precipitation Shenyang Chen, Tae-Sik Jang, Matthew Pan and Juha Song; Nanyang Technological University, Singapore, Singapore.

Embedded freeform 3D printing is an emerging 3D printing technique, where a hydrogel-based viscous medium provides support for extruded ink filaments during the printing process, allowing for omnidirectional printing of soft materials. One of the advantages of printing in a support bath is that the composition of the liquid medium can be modified to induce various chemical reactions in printed objects for solidification or functionalization of extruded ink filaments. Herein, we introduced a hybridization process to a 3D freeform printing system to achieve the direct fabrication of nanoparticle-reinforced composite hydrogels. In most composite hydrogel 3D printing systems, particles are preloaded in the ink prior to printing, which often reduces the printability of composite ink with little mechanical improvement due to poor particle-hydrogel interaction of physical mixing. In contrast, the in-situ incorporation of nanoparticles into a hydrogel during 3D printing achieves uniform distribution of particles with remarkable mechanical reinforcement, while precursors dissolved in inks do not influence the rheological behavior of pure ink materials. Therefore, we successfully fabricated hyaluronic acid (HAc)-calcium phosphate (CaP) nanocomposite scaffolds through 3D freeform printing of HAc, coupled with in-situ precipitation of CaP. Phosphate ions were dissolved in the hydrogel ink and calcium ions were added to the support bath for inducing the in-situ precipitation during 3D printing. The composite hydrogels demonstrated a significant improvement in mechanical strength, biostability as well as biological performance compared to pure HAc. Moreover, multi-material printing of composites of different CaP content was achieved by adjusting the ionic concentration of inks. Our method greatly accelerates the 3D printing of various functional or hybridized materials with complex geometries via the design and modification of printing materials coupled with in situ post-printing functionalization and hybridization in reactive viscoelastic matrices.

4:30 PM BM05.02.08
The Age of Applications for Bioprinting Ricky Solorzano; Allevi, Philadelphia, Pennsylvania, United States.

In an era where bioprinting continues to hold promise, sometimes its hard to understand why and how are they useful. What key applications will allow me to take my research to the next level and stay on the cutting edge. Come and listen to the key ways bioprinting is being most commonly used by researchers around the world.

4:45 PM BM05.02.09
Nanoengineered Inks for 3D Bioprinting Akhilesh K. Gaharwar; Texas A&M University, College Station, Texas, United States.

3D bioprinting is emerging as a promising method for rapid fabrication of biomimetic cell-laden constructs for tissue engineering. However, 3D bioprinting has hit a bottleneck in progress due to the lack of available bioinks with high printability, mechanical strength, and biocompatibility. We have developed multiple approaches to design highly printable bioinks for fabricating large scale, cell-laden, bioactive scaffolds. Specifically, we have introduced a family of bioinks including nanocomposite reinforcement, ionic-covalent entanglement (ICE), and nanoengineered ICE (NICE) based bioinks with excellent printability, mechanical properties, and shape-fidelity. These bioinks follow Herschel-Bulkley flow behavior, that shields encapsulated cells from excessive shear stresses during extrusion. The encapsulated cells readily proliferate and maintain high cell viability over 120 days within the 3D-printed structure, which is vital for long-term tissue regeneration. The unique aspect of these bioink is its ability to print much taller and higher-aspect ratio-structures than conventional bioinks without requiring secondary supports. We envision that these new family of bioinks can be used to bioprint complex, large-scale, cell-laden constructs for tissue engineering with high structural fidelity and mechanical stiffness for applications in custom bioprinted scaffolds and tissue engineered implants.

SESSION BM05.01: Biofabrication for Tissue Modeling
Session Chairs: Su Ryon Shin and Weijia Zhang
Monday Morning, November 26, 2018
Sheraton, 2nd Floor, Liberty C

8:00 AM *BM05.01.01
In Vitro 3D Tissue Construction by Microtissue Assembly Shoji Takeuchi; Univ of Tokyo, Tokyo, Japan.

In this presentation, I will talk about several Microfluidic-based approaches for the rapid construction of 3D cellular construct. Large-scale 3D tissue architectures that mimic microscopic tissue structures in vivo are very important for not only in tissue engineering but also drug development without animal experiments. We demonstrated a method of 3D tissue construction by using point, line and plane-type microtissues as cellular building blocks. For example, to prepare the point type building blocks, we used an axisymmetric flow focusing device (AFFD) that allows us to encapsulate cells within monodisperse collagen beads. By molding these cell beads into a 3D chamber and incubating them, we successfully obtained complicated and milli-sized 3D cellular constructs. As the line type building blocks, a cell-encapsulating core-shell hydrogel fiber was produced in a double coaxial laminar flow microfluidic device. When with myocytes, endothelial, and nerve cells, they showed the contractile motion of the myocyte cell fiber, the tube formation of the endothelial cell fibers and the synaptic connections of the nerve cell fiber, respectively. By reeling, weaving and folding the fibers using microfluidic handling, higher-order assembly of fiber-shaped 3D cellular constructs can be performed. Moreover, the fiber encapsulating beta-cells is used for the implantation of diabetic mice, and succeeded in normalizing the blood glucose level.

8:30 AM BM05.01.02
Tissue engineering holds great promise as an alternative therapy by creating functional tissue constructs that can reestablish the structure and function of injured tissue. However, a major challenge in tissue engineering is recapitulating the in vitro, three-dimensional (3D) hierarchical microarchitecture comprised of multiple cell types and the extracellular matrix (ECM) components of native tissues, along with achievement of continuous function and viability of engineered tissues after implantation. Specifically, survival of implanted cell-laden scaffolds is fully dependent on the oxygenation derived by its connection to blood circulation of the host body. The physiological process of angiogenesis is time-consuming, which results in the failure of clinically sized implants due to starvation-induced cell death, especially in thick and large constructs. Therefore, the incorporation of functional vasculature is important for maintaining thick and large complex tissue constructs, particularly in cardiac and skeletal muscle tissues that require highly vascularized networks to support the large metabolically activity in muscle cells. To address these challenges, 3D bioprinting is emerging as a powerful technique for the development of highly organized and complex 3D constructs. To achieve in vitro-like biological functions in 3D tissue constructs, ECM-based biomaterials are required to mimic biochemical and physical properties that will enhance the resulting tissue function. Furthermore, the bioprinted 3D tissue constructs can be used for toxicity assays based on organs-on-a-chip platforms, which have become increasingly important for drug discovery. The organs-on-a-chip system allows for the testing of cytotoxic effects of pharmaceutical compounds and nanomaterials on physiologically relevant human tissue models prior to moving forward with animal testing or clinical trials. To successfully establish organs-on-a-chip platforms, it is important to monitor the dynamic behaviors of human organ models interacting with drugs in situ for a long time. Furthermore, efficient methods for accurate analysis of the dynamic behaviors of human organ models are in urgent demand for improving the effectiveness of clinical predictions of human disease responses to different therapeutics. We introduce a microfluidic, label-free, biosensing technology combined with a 3D bioprinted human organ-on-a-chip system, which jointly allows for long-term and accurate measurements of the concentrations of the biomarkers secreted by tissues in response to drugs. The electrochemical biosensing chip will demonstrate a capability for regenerating its sensor surface, allowing for continual kinetic studies over extended periods of time. We believe that this novel platform technology may be further extended to a wide variety of applications in academia and pharmaceutics for personalized screenings of drug toxicity, efficacy, and pharmacokinetics in the future.

8:45 AM BM05.01.03
Applications of Multiphoton Polymerized Bio-Functional Platforms Bianca Buchegger1, Johannes Kreutzer1, Richard Wollhofer1, Jaroslaw Jacak1,2 and Thomas A. Klär1, 3 Johannes Kepler Universität Linz, Linz, Austria; 1 Upper Austria University of Applied Sciences, Linz, Austria.

Multiphoton polymerization (MPP) allows fabrication of arbitrary polymer structures in three dimensions with minimum feature sizes down to 100 nm and a lateral resolution around 200 nm. An excitation laser is focused into a photore sist consisting of a highly crosslinking acrylate and a photo-initiator. Adding a second laser beam which induces stimulated emission depletion (STED) of the photo-initiator in the outer rim of the excitation point spread function allows writing of even smaller structures with feature sizes below the diffraction limit.

Including functional groups other than the acrylate groups increases the versatility of the polymer structures, specifically for bio-functionalization. This can be either achieved by mixing of metal-oxo-clusters into the photosensitizers [1] or by using acrylate monomers with different functional rest groups such as thiols or carboxy groups enabling orthogonal functionalization [2]. The reactivity of the polymer structures was shown by covalent linkage of two different, chemically modified fluorophores. MPP scaffolds with bio-adhesive sites can also be used for 3 dimensional immunocaptives [3] and for physiological studies in microfluidic channels.

Using carboxy-acrylate polymer structures in combination with a biotin modified supported lipid bilayer enables orthogonal functionalization with two different fluorescent proteins. One sort of proteins is immobilized on polymer anchors via nickel-nitrilotriacetic acid / histidine interaction. The other one is freely moving within the lipid bilayer surrounding the structures which is enabled using biotin / streptavidin binding [4]. As mobility of proteins and lipids plays a major role in physiological processes, this platform is well suited for modelling of cell interactions with mobilized and immobilized proteins and studying cellular response.

9:00 AM BM05.01.04
Microengineered Human Blood-Brain Barrier Model with 3D Glia Network for Neuroinflammation Modeling and Nanomedicine Testing Song Il Ahn, Jiwon Yoon, Hyun-Ji Park and YongTae Kim; Georgia Institute of Technology, Atlanta, Georgia, United States.

The blood-brain barrier (BBB) is a unique barrier of the central nervous system (CNS) that has a highly selective barrier function that prevents most drugs from entering the brain, leading to a high failure rate in the development of therapeutics for the CNS diseases. Currently there is a large unmet need for the development of new therapeutics for the CNS diseases with an increasing death rate of patients with CNS diseases like Alzheimer’s disease (AD). One innovative approach to address this challenge is to develop a microengineered model of the human BBB that can mimick the pathophysiological conditions of the human brain. Yet, there is no physiologically relevant in vitro human BBB models that can incorporate shear stress, direct cell interactions, and 3D glial physiology of the human brain. Here we present a novel microengineered human BBB model designed to create a 3D co-culture of human brain endothelial cells (HBMECs), human brain vascular pericytes (HBVPs), human astrocytes (HAs) with the physiological morphology and interaction. Furthermore, we construct a neuroinflammation model with 3D incorporation of human microglia (HM) to understand the role of microglia-mediated neuroinflammation in AD pathogenesis.

Our microfluidic BBB model consists of two layers separated by a porous membrane to mimic the luminal and abluminal regions of the BBB. After growing HBVPs on the abluminal side of the porous membrane, HAs were cultured in the same channel. As HAs cultured in 3D Matrigel showed more physiologically relevant morphologies with lower expression of reactive markers compared to that in 2D, the abluminal layer of our model was filled with HAs that are embedded in 3D Matrigel. This Matrigel was confined by surface tension from the two side channels that are designed for culturing HMs.

HBMECs were cultured on the luminal side of the porous membrane and exposed to physiological shear stress that mimics blood flow in the brain microcirculation. As a result, our microengineered human BBB model showed a physiological network of the BBB cells with a polarized expression of aquaporin-4 to the luminal channel in astrocytic end-feet, highly specialized phenotypes of the brain endothelial cells with increased expressions of functional proteins and solute-carrier genes, and a significantly decreased permeability of the endothelial monolayer, as compared to the monoculture of HAs. Neuroinflammation model was constructed by adding HMs that were exposed to IFN-γ into the side channels of the stabilized human BBB model. HMs cultured in the side channels migrated into the Matrigel and showed a dynamic interaction with HAs, resulting in neurotoxic reactivities of HAs. Our microengineered BBB model can be utilized as a tool for the study of the pathological mechanisms of neuroinflammation and exploration of future therapeutic or preventive strategies for AD.
we discovered that even under prolonged UV irradiation (2.5-10 mins @ 18-19 mW/cm²), the viability of mammalian cells was preserved with the shielding effect of PP-alginate particles were thoroughly investigated with quantitative cell proliferation and LIVE/DEAD cell assays. Through our study, (PP) are especially suitable for encapsulation of cells due to the mild coating conditions required. Cell-laden alginate particles are generated followed by PP encapsulation of mammalian cells within cytoprotective polyphenol-alginate compartments before embedding them in photocurable bioinks. Polyphenolics and hIPSC derived neurons that show spontaneous epileptic seizure-like activity without any convulsant agent. This method can potentially provide a new simple yet novel and high-yield method to create polydimethylsiloxane (PDMS) confined scaffold-free 3D neuronal cultures from dissociated rat cortex or hIPSC derived neurons. It further shows significant differences of activity patterns between 2D and 3D cultures. Pharmacological experiments on these cultures showed that they can be reliably used as a powerful tool for high-throughput drug screening for AED development.

Results and Discussion:

- Application of TTX and KYNA abolished all burst activities, indicating the key-role of neuronal firing and glutamatergic network behind this phenomenon to entropic shielding and size exclusion factors.
- Test results showed that they can be reliably used as a powerful tool for high-throughput drug screening for AED development.

A patient-specific drug development system also becomes feasible with the integration of hIPSC with this technique.

Materials and Methods: We used PDMS to create 100 µm high micro-wells of different diameters (500-1500um). Dense solution of cells from neonatal rat cortex or hIPSC derived neurons was put into these PDMS micro-wells. Diluted solution of cells was also seeded outside the PDMS to create 2D cultures. Ca²⁺ indicator (R-GECO1) was applied to these cultures. Optical recordings were performed on both 2D and 3D cultures from day in vitro (DIV) 08 to DIV 21 to observe the spontaneous activity. Multi-electrode array was used to measure the extracellular field potential. Cultures were fixed and stained with antibody to NeuN at DIV21 for confocal imaging. tetrodotoxin (TTX), kynurenic acid (KYNA) and different concentrations of AEDs, phenytoin, carbamazepine, levetiracetam and topiramate were applied to 3D cultures created with rat and hIPSC derived neurons and the activity modulations were observed.

Biofabrication via Cytoprotective Polyphenol-Alginate Compartmentalization of Mammalian Cells in Photocrosslinkable Hydrogels Matthew Pan, Shengyang Chen, Tae-Sik Jung and Juhah Song; Nanyang Technological University, Singapore, Singapore.

Biofabrication technologies have endowed us with the capability to fabricate complex biological constructs at exceptional resolution and accuracy. Photocrosslinking is commonly coupled with biofabrication to produce stable cell-laden hydrogels due to precise control in the polymerization process, short crosslinking times, and minimal heat production. However, there are three major drawbacks: 1) deleterious effects of UV irradiation such as DNA damage or the cancerization of cells, 2) radicals generated during irradiation which react with cells either via direct contact or the formation of reactive oxygen species, and 3) cytotoxicity from unreacted double bonds of hydrogels functionalized with photoreactive groups such as acrylates and methacrylates. Herein, we implemented a cell protection strategy against harmful external stressors present during biofabrication, which involves the encapsulation of mammalian cells within cytoprotective polyphenol-alginate compartments before embedding them in photocurable biokins. Polyphenolics (PP) are especially suitable for encapsulation of cells due to the mild coating conditions required. Cell-laden alginate particles are generated followed by PP loading performed at various concentrations. The actual PP loading was quantified via UV-Vis absorbance spectrometry. The cytocompatibility and UV shielding effect of PP-alginate particles were thoroughly investigated with quantitative cell proliferation and LIVE/DEAD cell assays. Through our study, we discovered that even under prolonged UV irradiation (2.5-10 mins @ 18-19 mw/cm²), the viability of mammalian cells was preserved with the encapsulation of cells in PP-alginate particles. Lastly, in order to evaluate the applicability of our cytoprotective PP-alginate particles in biofabrication, we tested them with three photocrosslinkable hydrogels, Poly(ethylene glycol) diacrylate (PEGDA; 10, 15%), gelatin methacryloyl (GelMA ; 20%) and glycidyl methacrylate hyaluronic acid (GMHA; 4%). Hydrogel structures in the form of a thin substrate and a 3D printed scaffold were prepared at a particle to gel mass ratio of 2.3 and 1:3, respectively. The results clearly indicate that PP-alginate encapsulated cells exhibited higher viability under more stressful biofabrication conditions (extrusion-based 3D printing) and in more cytotoxic hydrogels such as PEGDA with high density of photoreactive side groups. The PP-alginate cell compartment acts not only as UV shield but also as diffusion barrier against harmful small molecules (photoinitiators) and larger macromolecules (polymer chains) as well as mechanical barrier against any external shear stresses. We envision this to be a technological breakthrough in biofabrication, maximizing mechanical stability of cell-laden scaffolds whilst minimizing damage to cells for any bioprinting or bioassembly processes.
A Fast and Simple Replication Technique for Biological and Artificial Surfaces with Superhydrophobicity Jing Xiang1, Hong Wang1, 2, Xun Zhu1, 2, Rong Chen1, 2, Yudong Ding1, 2, and Qiang Liao1, 2; 1Key Laboratory of Low-Grade Energy Utilization Technologies and Systems, Chongqing University, Chongqing, China; 2Institute of Engineering Thermophysics, Chongqing University, Chongqing, China.

Advances in microfluidics technologies have stimulated the development of new materials and the design of surfaces which should require hydrophobic surfaces and interfaces with low adhesion. Biological surfaces are good and natural models for the development of functional surfaces, such as wettability, optical characteristics and water directional transmission. Therefore, learning the microstructure of biological prototype is meaningful for the design of surfaces. Here, a novel and fast molding method has been used to replicate the microstructures of different leaves, and cell-scaffold interaction play a vital role in tissue regeneration. Biomaterials can be either synthetic materials or natural materials and they are widely used to either substitute a living system or fabricate the scaffolds. Scaffolds can be designed in the computer environment and they can be fabricated in the laboratory environment. In this research, scaffolds were designed with Lindenmayer Systems (L-Systems) and they were fabricated with photolithography. L-systems are rewriting processes that are used to design the fractals. Firstly, a single strut was drawn with the L-Systems and it was printed out by a 3-D printer. Then a y-shape, a trunk with three branches and a trunk with four branches were designed by L-Systems and they were also printed out with a 3-D printer. In this process, the final product is a miniaturized repressor of polyethylene glycol (PEGDA) and 2,2-dimethoxy-2-phenylacetophenone (DMPA) mixture and exposed to the UV light for about 4 minutes. Because of the interaction between U-shape, a trunk with three branches and a trunk with four branches were designed by L-Systems and they were also printed out with a 3-D printer.

Liquid overlay samples were prepared from MDA-MB-231 triple-negative breast cancer cells utilizing non-adherent, U-shaped 96-well plates, seeded either with (+) or without (-) the addition of 5% Matrigel growth factor (solubilized basement membrane from mouse sarcoma). The resulting cellular aggregates were imaged through maturity over a 4-day growth period via Optical Coherence Tomography (OCT) to assess construct morphologies. Molding is a fast, simple design of surfaces. Here, a novel and fast molding method has been used to replicate the microstructures of different leaves, and their surfaces decorated with Nano particles or wires by hydrothermal method, and eventually obtained the superhydrophobic property by silane treatment. Molding is a fast, simple and low-cost replication technique for biomimetic surfaces compared with other methods such as etching, lithography, electrochemical deposition and micromachining. The surface preparation process is as follows. At first, a negative is generated by molding. Then, we get the positive by filling the negative with liquid epoxy resins. In this way, we easily replicate the microstructure of various biologic surfaces, but the replicated surfaces just reach the hydrophobic degree after molding. Additionally, MCTSs formed via LDW were able to mimic this spherical morphology without the addition of exogenous factors. These findings have direct implications on the utility of direct-written MCTSs as in vitro tumor models for cancer research.
Microengineered Physiological Biomimicry—Human Organ-on-Chips

Dan Huh;

Human organs are complex living systems in which specialized cells and tissues are assembled in various patterns to carry out integrated functions essential to the survival of the entire organism. A paucity of predictive models that recapitulate the complexity of human organs and physiological systems poses major technical challenges in virtually all areas of life science and technology. This talk will present interdisciplinary research efforts to develop microengineered biomimetic models to reconstitute complex structural, dynamic microenvironment, and physiological function of living human organs. Specifically, I will talk about i) bioinspired microsystems that mimic the structural and functional complexity of the living human lung in health and disease, ii) an organ-on-chip microdevice that emulates the ocular surface of the human eye, and iii) microengineered physiological models of human reproductive organs.
Using light to manipulate liquid is a new approach for the actuation of microfluidic systems with contactless, spatial, temporal and precise control. Optical \cite{1,2} light modulation of electrical actuation \cite{3-5} or light-induced capillary forces \cite{6-8} are three advanced approaches to convert light energy to liquid motion. The last one has advantages over the first two in that it requires neither special optical set-ups nor complex microfabrication steps. Constructing microfluidic systems by photoresponsive materials is an efficient way to achieve light-induced capillary forces. Microfluidic liquid crystal polymers (LCPs) are polymers that show large and reversible deformation and allow temporal, localized, remote and isothermal triggering and actuation. \cite{9,10} Hence, LCPs are good candidates for microfluidic actuators through photodeformation.

In recent years, we have designed a new strategy to manipulate fluid slugs by photo-induced asymmetric deformation of tubular microactuators (TMAs), which induces capillary forces for liquid propulsion. Microactuators with various shapes (straight, 'Y'-shaped, serpentine and helical) are fabricated from a mechanically robust linear liquid crystal polymer. These microactuators are able to exert photocontrol of a wide diversity of liquids over a long distance with controllable velocity and direction, and hence to mix multiphase liquids, to combine liquids and even to make liquids run uphill. \cite{11,12}

Moreover, optofluidic chips were fabricated to integrate multifunctional liquid manipulation through this new strategy and realize micro-analysis and bio-reactions in them. The liquid transportation, combination, mixing, reaction and detection in the chip are all controlled by light, which successfully simplify the microfluidic system by avoiding the connection of external pumps. We anticipate that these optofluidic chips will achieve the portability and domestic use of microfluidics and open a new door to the microfluidic area.

\textbf{Recreating the Hematopoietic Microenvironment In Vitro Using Microfluidic-on-a-Chip Technology Enables the Study of Interactions of Normal and Malignant HSPCs with Specific BM Niches} \footnote{Julio Almeida-Portada\textsuperscript{1,2}, Samil K. George\textsuperscript{1}, Samuel Herberg\textsuperscript{1}, Christopher D. Porada\textsuperscript{1,2}, Aleksander Skradal\textsuperscript{1,2}\textsuperscript{,} and Graça Almeida-Portada\textsuperscript{1,2,3}; 1Wake Forest Institute for Regenerative Medicine, Winston Salem, North Carolina, United States; 2Virginia Tech-Wake Forest School of Biomedical Engineering and Sciences, Winston Salem, North Carolina, United States; 3Comprehensive Cancer Center at Wake Forest Baptist Medical, Winston Salem, North Carolina, United States.}

Under normal conditions, hematopoietic stem/progenitor cells (HSPC) reside within specific bone marrow (BM) niches. These are comprised of an array of different cell types located strategically to provide myriad chemical signals and physical interactions that maintain HSPC \cite{1,2}. In human myeloid malignancies, the BM niche is remodeled by malignant cells, which displace resident HSPC, and create self-reinforcing malignant niches that drive disease progression, chemoresistance, and relapse \cite{3}. Therefore, we engineered a microfluidic platform, inside of which are eight human hematopoietic niche constructs were patterned \textit{in situ} \cite{4}. The corresponding niches contained BM-derived mesenchymal cells (Stro-1\textsuperscript{+}, MSC), arterial endothelium (CD146\textsuperscript{+}/NG2\textsuperscript{-}; AEC), and sinusoidal endothelium (CD146\textsuperscript{+}/NG2\textsuperscript{-}; SEC), a fraction of the Stro-1\textsuperscript{+} cells were induced to undergo osteogenic differentiation, to generate osteoblasts (OB) for the fourth niche. U937 (lymphoma), MOLM13, and normal CD34\textsuperscript{+} cells were fluorescently tagged and independently perfused into the system. At 24h post-infusion, U937 cells already exhibited a marked predilection for AEC, and this persisted throughout the 5-day observation period, with roughly 4.5-times more U937 cells engrafting within the AEC niche than the SEC or MSC niches, and 3-times more U937 cells engrafting within the AEC niche than the OB niche. In contrast, MOLM13 cells exhibited a marked preference for the OB niche, and a moderate affinity for the AEC, SEC, and MSC niches. In contrast to malignant cells, normal CD34\textsuperscript{+} HSPC did not show a dominant engraftment within the niches, but exhibited moderate preferential engraftment within the OB niche.

In conclusion, our studies establish the feasibility of using microfluidic “on-a-chip” technology to recreate the various niches within the BM microenvironment, and prove proof that this novel system can be used to study the interactions of normal and malignant HSPC with distinct cells of the niche. We are currently using this system to delineate the signaling pathways responsible for the observed preferential HSPC niche cell interactions, with the ultimate goal of using this knowledge to develop more effective treatments for hematological malignancies and to enhance engraftment following HSC transplant.

\textbf{Microfluidic Fabrication of Dynamically Trigger-Responsive Microcapsules as Actively Manipulatable Microreactors} \footnote{Joerg Werner, Saraf Nawar, Zhang Wu, Brendan Deveney and David Weitz, Harvard University, Cambridge, Massachusetts, United States.}

Exploring and analyzing processes in small volumes such as droplets enables the screening of large parameter spaces with only small amount of materials, but active and selective control over the supply and removal of molecular matter in these systems is a missing feature. In droplet microreactors, critical parameters such as reagents and their concentrations can be screened over a wide range for their chemical and biological activities. In biological systems in particular, the confinement to aqueous microdroplets allows for the analysis of cellular behavior on the single-cell level. In aqueous emulsion drop systems, however, nutrients and reagents have to be included during the drop formation or added via coalescence events. Furthermore, the harvesting of products for analysis and further processing without the destruction of the drop is often unattainable. The active manipulation over molecular access to such droplets without changes to the microreactor space itself would enable increased control on the picoliter scale and single-cell level. A trigger-responsive and permselective membrane around the water drop that acts as a gate-keeper allows to turn diffusion to and from the microreactor on and off controllably, to supply new reagents and nutrients or harvest products when needed, while keeping the active species trapped within the droplet. Here we describe a number of polymer chemistries that allow for the synthesis of functional water-core microcapsules with tunable properties that are reversibly-responsive to various triggers. We employ microfluidic fabrication of double emulsion drops to synthesize trigger-responsive hydrogel membranes directly around water drops. These dynamic capsules can be repeatedly cycled between their permeable and impermeable state, enabling active control and manipulation over the accessibility of the capsule’s aqueous interior with molecular selectivity.
The endothelial resistance presents a critical barrier to molecular transport from blood to the interstitial space, hindering access of therapeutic proteins to their intended cellular targets. Understanding the physicochemical properties of protein therapeutics that affect transendothelial transport may aid development of therapeutic molecules with improved efficacy. Current in vitro methods that measure the distribution of these molecules are not representative of the complex human endothelial microenvironment and often yield results that are inconsistent with in vivo observations.

Our microfluidic platform addresses this problem, by utilizing a three-dimensional microvascular network with significant morphological similarities to in vivo capillaries that enables spatiotemporal control over solute measurements within a microfluidic device. These microvascular networks are self-assembled from human umbilical cord endothelial cells (HUVECs) and human lung fibroblasts within seven days, and are fully perfusable over a range of physiological fluid pressures. Molecular transport measurements can be made as a function of intravascular pressure for a variety of macromolecules. Quantification is achieved with fluorescently-labeled solutes using time-lapsed confocal microscopy. Furthermore, because the pressure difference between lumen and interstitium produces transendothelial flow, interstitial fluid is expelled from the device and can be collected for direct sampling. Good agreement is observed between transport measurements made within the device and with the direct sampling method.

We find that the endothelial resistance to the passage of both macromolecules and fluid are within the ranges observed in vivo. The mode of transport can be discerned between active and passive by considering the dependence of endothelial permeability on pressure. The approach we present allows for rapid measurement of physiologically-relevant transendothelial transport of labelled and unlabelled molecules. Therefore, this model system appears suitable to investigate the impact of physicochemical properties of therapeutic proteins on their relative biodistribution profiles.

**An Additive Manufacturing-Based Microfluidic System for Evaluation of Cancer Immunotherapies**

Ashley L. Beckwith1,2, Luis F. Velazquez-Garcia2 and Jeffrey T. Borenstein1; 1Biological Microsystems Group, Draper, Cambridge, Massachusetts, United States; 2Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Microfluidic models of the tumor microenvironment typically comprise cultured cells or spheroids embedded in matrix materials, and have shown wide utility in the study of key phenomena involved in cancer progression, including angiogenesis, metastasis and intravasation. However, the recent emergence of immune checkpoint inhibitor (ICI) therapies highlight the need for model systems that can incorporate the dynamics of immune cell interactions with tumors, imposing additional design requirements for microfluidic systems as well as the need for higher throughput systems. These requirements include the incorporation of biopsied tumor fragments rather than engineered spheroids to better recapitulate the influence of matrix and stroma, extended operation while maintaining tumor viability in perfused media, and the ability to investigate tumor killing mediated by drugs either introduced directly into the system following treatment of extrinsic immune cell populations in a separable and quantifiable manner.

Here we report on the demonstration of a customized microenvironment for testing cancer immunotherapies, built using additive manufacturing techniques in a monolithic manner that enables an accelerated design-fabrication-testing development cycle. The central element of the model is a tumor trapping scheme that captures a biopsied fragment at the junction of a network of flow streams, permitting controlled introduction and flow rate of media containing drug compounds and potentially circulating lymphocytes to study specific mechanisms of tumor killing. The microfluidic device, which contains a tumor trap, loading channels and circulating media and tumor-infiltrating lymphocyte (TIL) channels as well as a bubble trap, is constructed using a monolithic three-dimensional printing process with spatial resolution on the order of 25 microns. Materials and processes for generation of these devices have been selected on the basis of cytotoxicity and optical transparency considerations, and experiments run for several days confirm viability of tumor fragments across the duration of studies. Initial results presented here demonstrate the effect of ICI on human non-small-cell lung cancers, presumably mediated by the action of the ICI treatment on resident TIL populations present in the tumors. These results point the way toward mechanistic studies of immunotherapies, either singly or in combination with small molecules or other ICI antibodies, that extend far beyond current capabilities offered by existing animal or tumor microenvironment models.
Skeletal muscle has ability to repair due to the role of muscle satellite cells (MuSCs) in the regeneration but this capacity declines with aging. Recent in vivo studies using heterochronic parabiosis, in which two animals are surgically attached to share blood circulation, demonstrated that systemic factors in the blood of young animals can rejuvenate regenerative capacity of aged muscle. The exact mechanisms by which circulating youthful factors mediate the rejuvenating abilities of muscle stem cells, however, have yet to be elucidated. Due to the complexity of in vivo parabiosis and the dynamic nature of blood-borne factors, reliable identification of these humoral factors remains a major hurdle. To address this challenge, we leverage microengineering technologies to build 3D co-culture system of cells and tissues exposed to controlled biochemical cues with pathophysiological relevance. We first present microvascularized MuSC niche on a chip (VMoC) designed to harness key characteristics of the native muscle microenvironment where MuSCs are cultured on a myofiber-laden 3D hydrogel covered by a vascular endothelial cells (ECs). We then employ our VMoC devices integrated to mimic heterochronic parabiosis to identify potential rejuvenating factors that enhance myogenesis of MuSCs. Our VMoC was engineered using a double-layered microfluidic device that has 1) a top channel for the luminal side over a porous membrane, and 2) a bottom channel with a series of micropillars designed to confine the hydrogel. The primary MuSCs harvested from hind limb muscles of GFP-mice established multi-nucleated myotubes on the myofiber surface in the bottom channel, while immortalized mouse aortic ECs created a monolayer in the top channel. We first found that the MuSCs co-cultured with ECs significantly enhanced myogenic proliferation and differentiation as compared to the monoculture, while exhibiting similar differentiation to VEGF treatment to the monoculture. This result demonstrated that a biological paracrine effect of vascular ECs can be investigated in our chip 3D co-culture platform. We then found, more interestingly, that the administration of serum respectively isolated from young, old, and Sodl-/- (oxidative stress-accelerated model) mice showed distinct myogenic activities of MuSCs; those treated with old and Sodl-/- serum showed significantly lower myogenic differentiation. This result confirmed the more interestingly that the administration of serum respectively isolated from young, old, and Sodl-/- (oxidative stress-accelerated model) mice showed distinct myogenic activities of MuSCs; those treated with old and Sodl-/- serum showed significantly lower myogenic differentiation. This result confirmed the importance of the MuSC ECM in vitro to the 2D monolayer cultures which in no way represents the physiological tissue microenvironment in vivo. Therefore, preclinical and translational cancer research trends are moving toward organoid studies and 3D biomimetic models to provide more clinical relevance. Here, we set out to generate a biodegradable scaffold consisting of alginate, gelatin, and nano-crystal hydroxyapatite loaded with primary human osteoblasts and MSCs to produce a robust 3D bone-like microenvironment for studying human bone metastasis. A hydrogel (1% alginate; 7% gelatin) model for cancer cell-migration was modified to incorporate nanocrystal hydroxyapatite, primary human osteoblasts and primary human bone marrow derived stromal cells. Primary osteoblasts were isolated from vertebral bodies of organ donors and bone marrow MSCs were from Rooster Bio. The constructs were cultured for 28 days in either control medium (DMEM) or osteogenic medium (OM) with and without 0.5 mg/mL hydroxyapatite (HA). Live/Dead assays were performed to quantify viability and fixed frozen sections were stained with Alizarin red for calcified matrix deposition, and H&E to observe cells. High osteoblast viability in all conditions was observed after 28 days of culture: 91.3 ± 3.18 % for DMEM/HA+, 92.5 ± 2.5 % for DMEM/HA-, 88.6 ± 0.38 % for OM/HA+ and 85.9 ± 6.2 % for OM/HA-. MSCs showed approximately 85.1, 69.4, 87.8 and 90% viability in the same four conditions. Alizarin red staining showed that cells grown in DMEM without HA had the least amount of bone mineralized matrix. The combination found to have the most amount of bone mineralized matrix was OM/HA-.

Our data indicate that combination of 0.5mg/mL nano-HA with OM produces a favorable bone-like microenvironment for primary human osteoblasts and MSCs. Our preliminary work with low-cost bioprinting indicates this biodegradable scaffold is extrudable and will be ideal for screening therapeutics against patient-derived tumor cells cultured within a bone-like microenvironment. Ongoing work is assessing migration of fluorescein labeled tumor cells within this construct in the presence or absence of various chemotherapeutics. Furthermore, ongoing immunostaining for collagen type I, osteopontin and sclerostin will elucidate presence of bone matrix and osteocytes within the model. This work will allow better understanding of interactions between normal osteoblasts, stromal cells osteocytes and patient derived bone metastases cells while also placing higher clinical relevance on therapeutics screening.
tangentially, is imperative for determining foliar shape and size. While much is known about the genetic pathways involved in the GPC to GrC differentiation process, the effects on GPC differentiation and proliferation conferred by the mechanical stresses they experience during foliation is largely unknown.

In our present study, we employ a novel 4D printing technique to fabricate a rationally designed chip model of the Cerebellar cortex, which we use to simulate the foliation process in order to query the effects that mechanical compression and stretching has on the proliferation rate and differentiation potential of seeded GPCs. In order to simulate the gyration and sulcation processes of foliation in a biologically relevant manner in vitro, we have fabricated our chip construct using a novel, carbon nanotube (CNT) functionalized shape-memory polymer. Our shape-memory polymer can be printed into a convoluted shape with anatomical geometries, flattened, seeded with GPCs, and will then return to its original folded shape in a physiologically relevant time-course when thermally triggered at 37°C. We are able to achieve favorable cellular adhesion to our printed chip construct by coating it with CNTs, which functionally operate as artificial extra-cellular matrix scaffolding for adherent cells. The progressive restoration of the original folded shape of the polymer faithfully simulates the foliation process and can exert compressive and stretching stresses on resident GPCs that are comparable to that of developing Cerebellar tissue.

BM05.04.04

Biopsenised Silicification on Close-Packed Silica Bead Arrays by Liquid Phase Deposition

Yun Yeong Lee and Jin Seok Lee; Department of Chemistry, Sookmyung Women’s University, Seoul, Korea (the Republic of).

Organisms can biosynthesize hierarchically patterned three-dimensional (3D) biominerals, called as biomimeralization, such as calcium carbonate (mollusk shells), calcium phosphate (bone), and silica (diatom cell walls). The structural hierarchy in biominerals attributes strengths and stiffness, leading to protect themselves from natural environment. Especially, the process for production of silica into the living organism is known as biosilicification, which are often discovered in the diatom. Diatoms are complex and elaborated nano- and microstructured materials, whose architectures have numerous nanoscale pores with high porosity and high mechanical stability. Their extraordinary properties may have a potential for applications, such as sensors, molecular filters, and energy harvesting.

In this work, we explored the silicification on the arranged nanoscale-scaffold surface, such as the hexagonally close-packed silica bead arrays with porous structures, to mimic 3D hierarchical structures of diatoms by local liquid phase deposition. The energy and local concentration of silicic acid on the nanostructured surface are different; therefore, it is important to investigate the liquid phase deposition (LPD) on the nanostructure with diverse conditions to mimic and understand the mechanism of bioinspired morphogenesis. The different amount of water in LPD solution and reaction temperatures were used to investigate the effect of diverse environment because the biosilicification of diatoms occurs in the various surrounding environment such as concentration, temperature, and pressures. In addition, the silicification on the nanostructured surface deposited at the pinholes among the beads due to high local concentration, and this was monitored by Electrochemical Quartz Crystal Microbalance (EQCM).

BM05.04.03

Fabrication of Dome-Shaped Porous Alumina Microstructures and Their Applications for Drug Injector

Yoobeen Lee and Jin Seok Lee; Sookmyung Women's University, Seoul, Korea (the Republic of).

Nanostructures are promising candidates to inject and control of active agents such as drugs or biomaterials into cells. In particular, porous alumina is widely used as a template for nano-sized materials due to its high surface area. Many previous studies have been investigated injection of drugs using porous aluminum, carbon nanotubes and nanocapules as drug delivery systems. However, these drug delivery systems have some limitation to control the amount of injected drugs into cells.

In this work, we fabricated the dome-shaped porous alumina microstructures with hexagonal or cubic array, which are called simply ‘microdomes’, through the use of imprinting process on the initial surface over a large area with controllable diameter, thickness, and array. The different pitch of mold figure out the nanotopological effect on the morphology, which are range of 0 to 20 min. Furthermore, we investigated the amount of injected drugs into cells.

BM05.04.04

Optimization of Gold Nanostars Conjugated with Cell Penetrating Peptides for Intraoperative SERS Application

Tatiana Mironava1 and Bruce E. Cohen2; 1Stony Brook University, Stony Brook, New York, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

According to National Cancer Institute more than 12% of women in USA will develop invasive breast cancer during their lifetime. This project aims to develop imaging methodology based on SERS that combines sub-cellular resolution with ability to differentiate between normal and cancer cells. Amount of lipids in breast cancer cell is distinguishably different from the lipid content in normal and benign cells enabling cells distinction by means of Raman spectroscopy. Here we enhanced conventional Raman technique utilizing locally applied nanoparticles conjugated with cell penetrating peptides that ensure rapid nanoparticles penetration through the cell membrane. In this study normal and cancer breast cell lines - MCF-12 and MCF-7, respectively, were used. In addition, two types of nanoparticles - gold nanostars and nanospheres were conjugated to Tat-cell penetrating peptide for rapid intracellular delivery. Obtained results demonstrated sufficient differences in SERS spectra of cancer and normal cells providing the foundation for intraoperative cancer/normal tissue delineation by SERS imaging.

BM05.04.05

Engineered Phage-Based Immunostimulatory Materials for Virus Infectious Disease

Hyo Jung Lee and Hyo-Eun Jin; College of Pharmacy, Ajou University, Suwon, Korea (the Republic of).

Enterovirus 71 (EV71) is a contagious virus can cause hand-foot-and-mouth disease, severe neurological complications and death most commonly in infants and children under 5 years of age. Prophylactic vaccine and therapeutic agent against EV71 infection are not clinically available yet. Inactivated EV71 is under developing as a vaccine still now, however, safer immunostimulatory materials need to be developed for infants and children. Here, we developed filamentous bacteriophage (phage) as an immunostimulatory material to deliver enterovirus-specific protective immune responses for preventing EV71 infection. The engineered phage-based immunostimulatory materials could be a promising vaccine because it is generally regarded as safe to human and cost-effective owing to its property that infects only bacteria. Engineered phages displayed the identified epitopes of EV71 in high valency on the major coat protein and ligand for inducing mucosal immune response on the minor coat protein of phages. Following two dosages of immunization in 6-week C57BL/6 mice, EV71-specific immune responses including both T cell independent and dependent antibodies were induced by phage-based immunostimulatory materials without adjuvant, and all data were compared to experiments using EV71 subunit proteins with adjuvant. Our immunostimulatory materials showed high immunogenicity as preventing EV71 infection through EV71 challenge study. We expect that our

In recent years, many researchers have been interested in the physical and biological roles of topological defects in biological tissues [1,2]. One of the main issues faced by the study of these defects is the reproducibility with which they can be formed. Previous studies achieved the partial control of defect formation by culturing cells in a closed circular [1,2] or star-shaped [2] area. However, the position of the defects could not be precisely controlled, and no method has been established for designing the positions of defects in an arbitrarily shaped area. To solve this problem, this study proposes a systematic method for efficiently forming topological defects at specific points in a cell population by combining lithographic technology and computer-assisted design.

An overview of the proposed method is as follows. With our method, 2-methacryloyloxyethyl phosphorylcholine (MPC) polymers are patterned on a glass substrate, and closed cell adhesion areas are formed on the substrate. The patterned cells spontaneously form topological defects by proliferation and spontaneous alignment along the boundary between the MPC patterned and non-patterned areas. The positions of the defects in the cell adhesion area can be predicted by extending the results of [1]. First, two topological defects are placed in certain positions, and a Poisson equation is solved numerically to obtain the cell alignment. Then, the elastic energy of the cell population is calculated from the calculated cell alignment. By changing the position of the defects, it can be predicted that the defects work together to minimize the elastic energy.

The proposed method was confirmed experimentally as follows. We fabricated MPC polymer coated glass substrates that had cell adhesion areas with ellipsoidal shapes (major axis length: 300 – 800 μm, ratio of major/minor axes: 1 – 2). Then, NIH-3T3 or HFF cells were cultured on the substrate. When the ratio of the major and minor axes was about 2 – 3, two topological defects were reproducibly formed near the major axis as predicted by the above computational calculations. With the HFF cells, the defects vanished when the lengths of the major and minor axes were 600 μm and 400 μm, respectively. Considering that the HFF cell was larger than the NIH-3T3 cell, this result suggests that the sizes of the cells and defects are important when estimating the defect positions.
Our results showed that the direction of the topological defects could be achieved by computational calculations and that it is possible to design the optimal boundary for an efficient defect direction without using a trial-and-error approach.

**BM05.04.10 Engineering Perfusionable Microscaffold for Meso-Physiological Systems Using Projection Micro Stereo-Lithography** Pierre Sphabmixay, Linda G. Griffith and Nicholas Fang; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Current efforts in biomedical research are facing the necessity to improve in vitro systems towards more physiological and relevant models in order to recapitulate specific human in vivo mechanisms. The introduction of three-dimensional (3D) culture techniques have dramatically impacted our understanding of cellular biology and altered conclusions drawn from historically old two-dimensional in vitro models. The biggest challenge in the development of these 3D techniques remains the difficulty to sustain dense multi-cellular systems which requires to provide enough oxygen and nutrients deep within the tissue. In particular, the liver is one of the most difficult organs to culture in 3D in vitro, it constitutes only 2.5% of the total body mass but consumes 25% of the total cardiac output, making it unarguably the most oxygen and nutrient demanding organ of the human body, therefore requiring an extensively dense network of blood vessels in order to maintain its elevated metabolic activity. Furthermore, by being the central metabolizing organ in the human body, it is the organ most exposed to damage by chemicals and their metabolites entering the body. Pharmaceuticals pose a particular risk that can lead to drug-induced liver injury, whose mechanisms of actions are still poorly understood and are still the subject of controversy. For that reason, hepatotoxicity is a major cause for drug withdrawals from the market resulting in huge financial losses for the pharmaceutical industry. Therefore, tremendous efforts are being carried in order to improve current liver microphysiological systems (MPS) towards more predictive and physiologically relevant systems. Advances in micro/nano fabrication techniques offer promising solutions to tackle these challenges as they have enabled the development of devices and scaffolds capable of perfusing larger mass of cells, in combination with vascularization approaches in order to mimic the native microenvironment required for the cell function.

Here we have developed 3D perfusible scaffolds fabricated using Projection Micro-Stereolithography Apparatus (PuSLA) in order to provide improved 3D culturing techniques for liver MPS. Characterization of the fabrication technique allowed 3D printing of scaffolds with intricate architecture with resolution (3 microns) dramatically lower than the diffusion limit of oxygen (100 microns) therefore allowing efficient perfusion of dense tissue. Materials were engineered in order to feature favorable mechanical and biological properties for tissue formation and maintenance of mature phenotype. The designs of the scaffolds were engineered using a simulation approach by performing computational fluid dynamics in parallel with oxygen reaction simulation in order to predict viability of subsequent tissue in vitro. A commercially available bioreactor (Liverchip) was adapted in order to provide high flow rate and real time oxygen consumption monitoring.

**BM05.04.11 Novel Microfluidic In Vitro Intestinal Model for Studying Drug Transport and Metabolism** Haysam Ahmed1, Yang Li2, Igor Middel1, Nick Langerak1, Jos Maat1 and Rosalinde Masereeuw1; 1Utrecht Institute for Pharmaceutical Sciences, Utrecht, Netherlands; 2Orthopedics, Regenerative Medicine Utrecht, Utrecht, Netherlands; 3Physics, Institute for Theoretical Physics, Utrecht, Netherlands.

Caco-2 cells are widely used in pharmaceutical industry as a model to study intestinal absorption of drugs. Even though this 2D model provides enough insights into the intestinal absorption aspect, it lacks the metabolic functions that are exhibited in vivo (first-pass effect). In order to circumvent this shortcoming, a novel microfluidic device has been developed combining 3D printing, microfluidics and bio-functionalized hollow fiber membranes in one device. 3D printing is advantageous over the conventional soft lithography method for fabricating complicated structures, e.g., 3D flow chambers with hollow microchannels, microdevices with varying height in different locations. Moreover, it provides an alternative to polydimethylsiloxane (PDMS) that was shown to adsorb small molecules such as drugs hindering its use in a pharmaceutical setting. Here, we optimized the microfluidic design to allow for physiologically relevant shear stresses at low flow rates. The collagen-coated polyethersulfone hollow fiber membrane used in the developed device acts as a support for the cells and provides curvature to better mimic the in vivo microenvironment, thus providing both mechanical and dynamic signaling cues to Caco-2 cells to better differentiate into the various cell types observed in the human intestine.

The optimal shear stress rate was determined based on the cell differentiation (confirmed by immunofluorescent staining), villi formation, formation of a tight monolayer as a function of barrier function and more importantly enhanced metabolic function. In addition, it was shown for the first time that intestinal cells play a role in the generation of p-cresol metabolites, namely p-cresol sulfate and p-cresol glucuronide.

Taken together, this microfluidic gut device is a promising tool to study both the absorptive and metabolic functions of human intestine in pharmaceutical drug development compared to the currently used 2D models. Moreover, the modular design of the device allows for combining various organs to study not only the absorption but also metabolism (by connecting a liver device) and excretion (by connecting a kidney device).

**BM05.04.12 A Convenient and Effective Antibiofilm Coating on Vascular Catheters** Zheng Hou and M. B. Chan-Park; Nanyang Technological University, Singapore, Singapore.

Vascular catheters made from polyurethane (PU) are widely used in clinical settings and catheter-related infection are a serious clinical problem. It is mainly caused by the bacterial adhesion onto catheters’ surface. Once bacteria attach onto a catheter surface, they likely develop into biofilm that are hard to eradicate. Hence, it is important to develop a catheter surface with antibiofilm ability. In this project, a convenient method of modifying PU catheter surface was developed and optimized. A zwiterionic monomer was coated onto a 30-cm long catheter surface via a polymerization technique to form a hydration layer that retards biofilm formation. To demonstrate the feasibility of the coating method for industrial application, a 30cm PU catheter was coated by the same method.

PU catheter was treated with ozone to introduce peroxide group on surface. Different concentration of [2-(Methacryloyloxy) ethyl] dimethyl-(3-sulfopropyl) ammonium hydroxide (SBMA) was dissolved in water and isopropanol (IPA) mixture. The solution was purged with Argon for 30mins. The catheters were then put into the solution; polymerization was initiated by addition of ammonium iron(ii) sulfate and carried for 24hrs. The antibiofilm efficacy of the coating was tested by incubation of the coated catheter in bacteria inoculum at 37°C for 24hrs and shows >99.0% prevention of surface biofilm for both Gram-Positive Methicillin-resistant Staphylococcus aureus (MRSA) and Gram-Negative Pseudomonas aeruginosa (PAO1). The antibiofilm efficacy of coated 30cm PU catheter was tested with a intraluminal microbial biofilm model and shows >99.5% inhibition of MRSA growth.

**BM05.04.13**
Effects of Bioink Rheological Properties on Stability of Extrusion Bioprinting  Reza Avaz1, 2 and Amir K. K. Miri1, 2; 1Rowan University, Glassboro, New Jersey, United States; 2Bioengineering, University of California, Los Angeles, Los Angeles, California, United States; 1Institute for Computational Engineering and Sciences, University of Texas at Austin, Austin, Texas, United States.

3D Printing techniques have been flourished in the fabrication of advanced scaffolds for tissue engineering and regenerative medicine. For selected platforms, bioink formulation should be optimized for the desired application, in which it requires a deep understanding of bioprinting mechanism. The hydrogel-cell bioink is printed as a sol-state and then solidified following the deposition (or dispensing) process. This deposition process is occurred in extrusion-based bioprinting technique, which uses a cone-shape nozzle head to deposit the bioink. The deposition process ideally leaves spatially-controlled continuous strands of the bioink. However, mechanical issues can lead to instability of the deposited strands. The presence of mechanical instability can generate oscillatory forces and kinetics-related stress components that effect the behavior of cellular components within the hydrogel. This further hampers the printing resolution. A key factor in designing bioinks and selecting bioprinting parameters is to minimize instability of the bioink after leaving the nozzle. Although cell-laden bioinks often possess significant non-Newtonian properties, such as power-law and yield stress behaviors, the effect of such properties on the stability and spatial resolution of the fluid deposition has not been studied. In this work, assuming a slender flow model, we estimated the onset of instability as functions of the rheological properties of the fluid, such as rate-dependent viscosity and yield stress, as well as the geometry of the nozzle, such as size and bluntness. A moderate shear thinning behavior was found to stabilize the deposition process; in contrast, a high yield stress led to an unstable deposition of the bioink on a stationary substrate. The long-term goal of this work is to provide a simulation-assisted framework for high-fidelity 3D-printing of cell-laden bioinks.

BM05.04.14 Fabrication of Complex Vasculatures by 3D Printed Biomaterials  Terry T. Ching1, 2, 3, Yi-Chin Toh1 and Michinao Hashimoto1, 2; 1Pillar of Engineering Product Development, Singapore University of Technology and Design, Singapore, Singapore; 2Digital Manufacturing and Design Centre, Singapore University of Technology and Design, Singapore, Singapore; 3Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore.

3D printing has enabled the fabrication of microfluidic devices, but it remains challenging to recapitulate the full complexity of the architecture in vasculatures. Despite several approaches used to print vascular-inspired features (such as surgical molding and embedded 3D printing), the complex hierarchical branching networks as seen in vivo is yet difficult to achieve by 3D printing. Herein, we proposed a design approach that enables existing commercial 3D printer to fabricate complex vasculatures in bio compatible hydrogels. Instead of directly printing the entire network as a unibody, our approach involved the decomposition of the system into simple and printable elements. We demonstrated to use two materials with different Young’s modules to fabricate such 3D networks—exterior elements printed in rigid polymers and interior elements printed in elastomeric polymers—to obtain tightly sealed 3D microchannels. The rigid elements served as an exterior shell to secure the interior elements in place while the elastomeric nature of the interior elements made conformal contacts when compressed, confining fluid in its intended space to form complex networks of microchannels. We used polymer jet (PJ) and stereolithography (SL) printers to demonstrate fabrication of vascular-inspired networks such as rectilinear lattice and helical networks of microchannels. Hierarchical branching of 1, to 4, to 16 channels with diameter of 850, 600 and 250 µm were achieved with the spacing between channels below 300 µm within the oxygen diffusion limit of 200 µm. The same strategy was applied to fabricate vascular-inspired networks in a bio compatible composite material. The assembled 3D microchannels were readily disassembled for imaging of different segments of the microchannels. Overall, we developed a design approach to enable 3D printing of complex vasculature-inspired architecture of microchannels. This is a general approach that can be demonstrated by most commercial 3D printers. To our knowledge, this is the first demonstration to fabricate 3D microchannels at this complexity (i.e. hierarchical branching) and the size scale (spacing between channels are maintain below 300 µm). Our current work opens opportunities to fabricate microchannels in a wide array of biomaterials. Devices created in this approach shall serve as effective in vitro model for vascularized tissue engineering, bioinspired surrogates for drug development, and regenerative medicine.

BM05.04.15 Engineering a Synthetic Analogue to the Nucleus Pulposus for Spinal Disc Repair Therapies  Juyi Li, Clement Marmorat, Yeshayahu Talmon, Raphael Davis and Miriam Rafailovich; Stony Brook University, Stony Brook, New York, United States.

The role of synovial fluids is to enable frictionless motion of joints and provide shock absorbance within the spinal cord for the central nervous system. Injury, disease, and even aging can degrade the structure and mechanical response of the fluid. Here we report on engineering a substitute for the nucleus pulposus, the viscous fluid within the spinal cord discs. Herniation of lumbar discs is a painful condition, which often requires surgical intervention, where the nucleus pulposus is removed and the disc space is fused. Recently hydrogels have been proposed as possible replacements. Here we report on the use of Pluronic physical gels, which we have successfully bioprinted, injected, and shown to prevent scarring and degradation in-vivo in dog trials. The results were very surprising since, despite their tremendous mechanical flexibility, these tri-block copolymers are very sensitive to fluid volume changes. We demonstrate, using SEM microscopy on gel cryo-sections, together with in-situ x-ray analysis, that in addition to the standard parameters defining the equilibrium state, the stability of physical gels is dependent on the dynamical aspects of the fluid medium. Using a specially constructed flow chamber, we show that for a Pluronic F127 physical gel, the degradation process can be greatly reduced under high fluid flow rate tangential to the gel surface. Since the physical gel is formed by an ordered crystal of micelles, stabilized by entanglements within their coronas, a simple model is proposed where swelling can occur only when the flow rate is less than the repuation time. Otherwise, rather than dissociating into individual micelles, the micelle gel responds collectively to the surface shear forces as an elastic solid, which deforms in a direction perpendicular to the flow in order to minimize stress. This aspect of the Pluronic triblock copolymer system greatly extends their application from an injectable drug delivery carrier to a structural component which is at once injectable, and yet able to sustain deformation and resist dissolution in physical fluids.

Poly(vinyl alcohol) (PVA) is a synthetic, biocompatible polymer that has been widely studied for use in bioengineered scaffolds due to its highly attractive properties, such as high strength, creep resistance, and porous structure. These properties can be fine-tuned by controlling the physical, non-covalent crosslinks through various techniques. Typically, PVA hydrogels are relatively brittle, non-elastic materials. Blending in gelatin, a natural collagen derivative, and using poly(ethylene glycol) (PEG) as a porogen for theta-gel formation, forms a highly organized, cell-instructive hydrogel with increased stiffness. Theta-gels are formed from the solidification and phase separation of high molecular weight gelatin and PVA from low molecular PEG during a decrease in temperature. To increase the stiffness and energy storage of PVA-gelatin theta-gels, the materials were additionally processed using cryo-gel techniques, which involved freezing theta-gels, lyophilizing and re-hydrating. The result was a stronger, more elastic material. Compressive rheological data suggest significant changes in the elastic modulus of PVA-gelatin theta-cryogels with increasing freeze-thaw cycles. The crystallinity as measured by Fourier transform infrared spectroscopy increased with increasing freeze-thaw cycles. Scanning electron micrographs showed an increased pore size of the PVA-gelatin theta-cryogels with increasing pore size, as expected from reports in the literature. Interestingly, however, the more crystalline materials demonstrated an increase in energy dissipation, which may be reflective of a higher water content. It is hypothesized that a stiffer material with larger pores may contribute to increased fluid flow, creating a tough yet resilient material for soft tissue repair.

Organoids, organ-mimicking multicellular structures derived from pluripotent stem cells or organ progenitors, have recently emerged as an important system for both studies of stem cell biology and development of potential therapeutics; however, a large-scale culture of organoids and cryopreservation for whole organoids, a prerequisite for their industrial and clinical applications, has remained a challenge. Current organoid culture systems relying on embedding the stem or progenitor cells in bulk extracellular matrix (ECM) hydrogels (e.g., Matrigel™) have limited surface area for mass transfer and are not suitable for large-scale productions. Here, we demonstrate a capsule-based, scalable organoid production and cryopreservation platform. The capsules have a core-shell structure where the core consists of Matrigel™ that supports the growth of organoids, and the alginate shell forms robust spherical capsules, enabling suspension culture in stirred bioreactors. Compared with conventional, bulk ECM hydrogels, the capsules, which could be produced continuously by a two-fluidic electrostatic co-spraying method, provide better mass transfer through both diffusion and convection. The core-shell structure of the capsules also leads to better cell recovery after cryopreservation of organoids probably through prevention of intracellular ice formation.

8:30 AM • BM05.05.03
Synthetic Human Embryo-Like Structures—A New Paradigm for Human Embryology Jianping Fu; Mechanical Engineering, University of Michigan, Ann Arbor, Ann Arbor, Michigan, United States.

Early human embryonic development remains mysterious due to drastic species divergences between humans and other mammalian models and limited accessibility to human embryo samples. Recent studies from my laboratory and others have shown that under culture conditions, human pluripotent stem cells (hPSCs) can undergo intricate morphogenetic events and self-organize to form patterned human embryo-like structures in vitro. These synthetic human embryonic tissues hold great promises for advancing human embryology and reproductive medicine. In this talk, I will first discuss a micropatterned hPSC-based neuroectoderm patterning model, wherein pre-patterned geometrical confinement induces emergent patterning of neuroepithelial and neural plate border cells, mimicking neuroectoderm regionalization during early neurulation. In the second part of my talk, I will discuss a hPSC-based, synthetic model of early human post-implantation development that recapitulates key developmental landmarks successively, including pro-amniotic cavity formation, amnion-epiblast patterning, primordial germ cell specification, and development of the primitive streak with controlled anteroposterior polarity. Together, our studies have developed powerful synthetic embryological platforms and provided new understandings of previously inaccessible but critical embryonic processes in human development.

Formation of Planar Intestinal Crypt with Distinct Proliferative and Differentiated Regions Raehyun J. Kim1, Yuli Wang2, Shee-Hwan J. Hwang2, Peter J. Atteyak1, Nicole M. Smiddy2, Christopher E. Sims1 and Nancy L. Allbritton1, 2; 1Joint Department of Biomedical Engineering, UNC at Chapel Hill and North Carolina State University, Chapel Hill, North Carolina, United States; 2Department of Electrical and Biomedical Engineering, University of Michigan, Ann Arbor, Ann Arbor, Michigan, United States.

A simple in vitro intestinal model system that recapitulates key aspects of the intestine in vivo can enhance our understanding on the physiology of the intestine and the impacts of drugs or biochemical stimuli such as metabolites and signaling molecules. We developed a planar platform recapitulating the segregation of the three-dimensional intestinal epithelial cells in vivo. A thin layer of collagen was overlaid onto microhole array made of an impermeable photoresist film, creating two distinct regions with different porosity and stiffness. When mouse primary colon epithelial cells were grown on the platform, the cells formed a monolayer across the microhole array with segregated cell populations: proliferative cells over the microholes and non-proliferative cells distanced from the microholes. Generation of growth factor gradients across the cells via the microholes resulted in in vivo-like cell behaviors where proliferative cells over the microholes migrated outward, differentiated as they migrated and then eventually reaching the end of their lifespan in regions apart from the microhole sources of growth factors. Short chain fatty acids, bacterial metabolites that are present in the colonic lumen, significantly influenced the proliferation and differentiation of the primary mouse colon epithelial cells as has been demonstrated to occur in vivo. With simple fabrication, ease of use, and low maintenance, this platform enables observation and quantification of proliferative and differentiated cells simultaneously and the interplay between these two cell zones. Access to both the luminal and basal sides of the polarized tissue permits the screening of drugs, metabolites and food stuffs for their impact on intestinal cell epithelium. This platform will be a valuable tool for to understand intestinal physiology in health and disease.

Folding Artificial Mucosa with Cell-Laden Hydrogels Guided by Mechanics Models Ruike Zhao1, 2, Hon Fai Chan1, German A. Parada3, Kam W. Leong1, Linda G. Griffith1 and Xuanze Zhao1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Mechanical and Aerospace Engineering, The Ohio State University, Columbus, Ohio, United States; 3Columbia University, New York, New York, United States.

The surfaces of many hollow or tubular tissues/organisms in our respiratory, gastrointestinal, and urogenital tracts are covered by mucosa with folded patterns.
The patterns are induced by mechanical instability of the mucosa under compression due to constrained growth. Recapitulating this folding process in the development of engineering of mucosa in various tissues/organisms. However, scant attention has been paid to address the challenge of reproducing mucosal folding. Here we mimic the mucosal folding process using a cell-laden hydrogel film attached to a pre-stretched tough-hydrogel substrate. The cell-laden hydrogel constitutes of human epithelial cell lining on stromal component to recapitulate the physiological feature of mucosa. Relaxation of the pre-stretched tough-hydrogel substrate applies compressive strains on the cell-laden hydrogel film, which undergoes mechanical instability and evolves into morphological patterns. We predict the conditions for mucosal folding as well as the morphology of and strain in the folded artificial mucosa using a combination of theory and simulation. The work not only provides a simple method to fold artificial mucosa but also demonstrates a new paradigm in tissue engineering via harnessing mechanical instabilities guided by quantitative mechanics models.

9:30 AM BM05.05.06
Alginate-Based Electrodeposition for On-Demand Fabrication of Tubular Structures for Applications in Vascular Tissue Engineering David Kingasley, Jared Capuno, Rachel Antmann, Cassandra Roberge and David T. Corr; Renssealaer Polytechnic Institute, Troy, New York, United States.

One of the major challenges in tissue engineering is the fabrication of tubular cell-loaded structures (e.g., blood vessels). This is due, in part, to the difficulties in generating a self-supporting luminal structure with an appropriate spatial distribution of loaded cells. Alginate - a polysaccharide derived from brown algae that gels in the presence of divalent cations, such as Ca²⁺ - has gained great traction as an exciting candidate material for biofabrication, due to its tunable mechanical properties, ease of gelation, overall biocompatibility, and ability to be gently resolved through reverse crosslinking. Typically, alginate structures are created through homogenous internal crosslinking systems in which insoluble CaCO₃ particles are suspended in an alginate solution, and the alginate slowly dissociates from the carbonate upon introduction of a weak acid (e.g., GDH), to crosslink the alginate network. Recently, electrolysis has been shown as an alternative method to generate crosslinked alginate gels. In this method, a current is run through an electrolyte solution to produce products of hydrogen and carbon dioxide, with a reaction byproduct of protons generated at the anode surface. These protons can be exploited to produce free calcium from CaCO₃ and cause local crosslinking when performed in an alginate solution. Herein, we utilize electrolysis to produce a pH change at a cylindrical copper anode surface, resulting in the radial deposition of an alginate gel around the anode wire. Furthermore, we investigate how alginate deposition is effected by key variables in the fabrication process, including: applied voltage, CaCO₃ particle size, anode wire diameter, alginate concentration, calcium concentration, and overall electrolysis duration. Within these experiments, the rate of alginate deposition increased inversely proportionately with CaCO₃ particle size (and therefore available surface area), however this effect appeared to diminish at longer deposition times. Furthermore, we observed that greater diameter anode wires were able to produce thicker gels, likely due to the available surface area for proton generation. Similarly, alginate and calcium concentration also affected the thickness of deposited gels on anode surfaces, and the overall robustness of the gels (qualitatively speaking). Last, we apply this technique to generate alginate tubular structures entrapping multiple layers of discretized cells. By performing sequential electrodeposition using two different alginate solutions, suspending either GFP or RFP labeled cells, we observe via fluorescent microscopy radial compartmentalization, i.e., the encapsulation of each cell line at different layers in the luminal thickness. Overall, within this work we demonstrate a novel, on-demand technique to fabricate alginate-based tubular structures with encapsulated discretized cells, using the principles of electrodeposition.

Sheraton, 2nd Floor, Liberty C

10:15 AM BM05.06.01
Nanowire Arrays Restore Vision in Blind Mice Jing Tang; Materials Science and Engineering, Stanford University, Stanford, California, United States.

The restoration of light response with complex spatiotemporal features in retinal degenerative diseases towards retinal prosthesis has proven to be a considerable challenge over the past decades. Herein, inspired by the structure and function of photoreceptors in retinas, we develop artificial photoreceptors based on gold nanoparticle-decorated titania nanowire arrays, for restoration of visual responses in the blind mice with degenerated photoreceptors. Moreover, neurons in the primary visual cortex respond to light after subretinal implant of nanowire arrays. Improvement in pupillary light reflex suggests the behavioral recovery of light sensitivity. Our study will shed light on the development of a new generation of optoelectronic toolkits for subretinal prosthetic devices.

10:30 AM BM05.06.02
A Novel Technique for In situ Characterization of 3D Tissues Using MEMS Mohamed Elhebeary and Taher Saif; University of Illinois-Urbana Champaign, Urbana, Illinois, United States.

The development of multicellular tissues is highly dependent on the mechanical forces associated with cell-cell and cell-matrix interactions. Cellular forces are measured using Traction Force Microscopy (TFM) on 2D soft substrates. However, TFM cannot provide forces in 3D tissues. Also, the effect of cross talk between cells within the tissue microenvironment cannot be captured in 2D culture. Here, we propose a technology that introduces a new device and a new method that radically changes the way we form 3D biometric tissues, and study them in situ. The method exploits the advances in micro-fabrication and combines them with classical theories of capillarity to offer new functionalities, namely self-assembly and self-alignment of tissues on a sensor stage. Currently there is no technology available to measure tissue force (due to cells) and tissue stiffness simultaneously. The new device closes this gap for the first time. It not only provides a time lapse measure of both force and stiffness, it allows simultaneous inspection of the microstructure of the tissue in situ, thus linking tissue biophysics with pathophysiology. Such in situ quantitative inspection will offer new insights that cannot be achieved with existing methods.

A novel design of a silicon platform, that integrates a stretching and sample self-assembly mechanisms, is introduced. First, a mixture of collagen I solution and fibroblasts (3T3) is dispensed on the silicon platform at room temperature (500x500x200 μm³). After curing, the chip is imbedded in cell culture media within an incubation chamber. The small thickness of the chip (200 μm) makes it compatible with live cell microscopy and avoids any histological sectioning needed in the case of thick sample. The tissue forces are measured using an optical microscope by imaging the co-fabricated gauges on the chip and follow-up image analysis. An external 3D manipulator is used to stretch the tissue sample to measure its elastic modulus at different stages of tissue...
morphogenesis. Image analysis gives a displacement resolution of approximately 200 nm and a corresponding force resolution <1 µN. The proposed technology offers advantages over available techniques to study the biomechanical tissue due to the following reasons: no need to expose the sample to light which might affect its response, small size allows portability between different chambers during imaging and/or incubation, and ability to monitor the stiffness change along with microstructure development with time. Results from different cell lines showed the evolution of force with time after seeding cell/collagen mixture. Stiffness measurements of samples and effect of drugs on force relaxation are studied.

10:45 AM BM05.06.03 Improvement Performance of Ionic Liquid-Based Pressure Sensor for Integration into Body-on-a-Chip Yusuke Tsuji1, Yoshikazu Hirai1, Ken-ichiro Kamei1, Toshiyuki Tsuchiya1 and Osamu Tabata1; Kyoto University, Kyoto, Japan.

Body-on-a-Chip (BoC) platform holds a great potential for new pre-clinical tests in drug screening as in vitro human models by mimicking in vivo physiological and pathological conditions. Recently, the authors have reported a proof of BoC concept for recapitulation of the cardio-toxic side effects of an anti-cancer drug [1]; however, there is still a technological challenge to integrate a pressure sensor for monitoring or controlling pressure in BoC, leading to create cellular microenvironments close to in vivo physiological conditions in the BoC platform. Among existing polydimethylsiloxane (PDMS)-based pressure sensors, the sensor with ionic liquid (IL pressure sensor) [2] is promising due to allowing direct integration into a PDMS-based BoC platform by multilayer soft lithography. But previously reported sensors lack proper performance with respect to sensitivity and linearity. Here we propose a novel fabrication approach of an IL pressure sensor by using simulation-based three-dimensional (3D) lithography and show its improved sensor performance.

An IL pressure sensor is composed of a flow channel to circulate cell culture medium and an electro-fluidic (EF) channel filled with IL, and they are overlapped with separation by a PDMS microstructure (tens of µm). The pressure in flow channel can be measured by monitoring electrical resistance change of an EF channel induced by membrane deformation by pressure. Since the sensor performance such as sensitivity and linearity depend on cross-sectional shape of the EF channel, we focused to tune a cross-sectional shape of mold for EF channel.

To improve the sensor performance, the electrical resistance change of EF channel by deformation of PDMS membrane were simulated with FEM analysis for four sensors with different cross-sectional geometries (rectangle: 400, 600 µm width x 25 µm height, triangle: 400 x 25 µm², and semi-ellipse: 400 x 25 µm²). The triangular channel showed 10-time higher sensitivity than the rectangular channel.

Then, designed sensors were fabricated by digital micromirror device-based grayscale lithography [3] with a numerical process optimization, and resistance changes were measured by an impedance analyzer. The results on static pressure with the range of 0 to 12 kPa exhibited good agreement with the numerical simulation results. Moreover, to validate the performance to measure heart beating, the periodic pressures with a triangular wave were applied to the sensor. As the results, the sensor with triangular channel was able to follow at least pressure change at 1 Hz. We believe that our proposed approach and developed sensor will allow measuring pressures at the physiological levels.

11:00 AM BM05.06.04 Multiplexed Single-Cell Secretomic Profiling on 3D Scaffolds Yao Lu, Dalian Institute of Chemical Physics, Chinese Academy of Sciences, Dalian, China.

Single cell barcode microchip (SCBC) has become an informative tool for comprehensive monitoring of the immune effector functions of single cells and has great value for quantifying cellular heterogeneity at the functional level in the complex biological systems such as the immune system or tumor microenvironment [1-4]. Despite its rapid progresses, efforts to control the three dimensional microenvironment for single cell measurements have been lacking [5]. We developed a simple method to incorporate three dimensional scaffolds with PDMS stencils into a multiplexed single cell secretomic analysis platforms to mimic the extracellular physical matrix and mechanical support for single cells [6]. Applying this platform to brain tumor cell line U87 to investigate single cell protein secretion behavior on different substrates, we revealed that single cell protein secretions were regulated differently in different microenvironments. The finding was further verified with intracellular cytokine staining, highlighting the significance of 3D single cell microenvironments. This new single cell biomimetic platform can be easily adaptable to other single cell assays and may become a broadly applicable three dimensional single cell analysis system to study the effect of microenvironment conditions on cellular functional heterogeneity in vitro.

11:15 AM BM05.06.05 Integrated Measurement of Cytosolic Proteins and Transcripts in Single Cells Alexander Xu1,2, Qianhe Liu1, Kaitlyn Takata1, Sarah Jeoung1, Yapeng Su1, Igor Antoschechkin1, Sisi Chen1, Matthew Thomson1 and James Heath1,3; 1California Institute of Technology, Pasadena, California, United States; 2Institute for Systems Biology, Seattle, Washington, United States.

Single cell measurements have revamped our understanding of biological tissues by resolving their single cell heterogeneity. New technologies such as droplet microfluidic transcriptomics and microchip proteomics provide better insights on how healthy tissues function, and how aberrant cells in the tissue cause disease. However, our understanding of how the single cells in a tissue perform their functions is limited by the types of information that can be captured from each cell. Here we present a method for measuring the whole transcriptome and cytosolic proteins in single cells on a microfluidic chip. By coupling single cell barcode chip (SCBC) proteomics and bead-based sequencing technologies, we capture multiple measurements of a single cell without splitting cell contents, and we use gold standard measurement modes – fluorescence sandwich immunoassays for proteins and sequencing for transcripts. This technology is enabled by a DNA labeling strategy that allows measurements to be taken independently and robustly, and linked after data processing.

We measure two cell types, showing that there is a unique molecular signature for both cell types in both protein and transcript data. The microfluidic chip is designed such that location barcodes scale geometrically and the chip can be readily scaled to produce larger single cell integrated datasets. This strategy...
for taking multiple measurements from single cells is unique in that it does not require either the protein or transcript signal to be converted from its native measurement mode. This is done in an effort to produce the best possible data using established technology. By using established technology, we are also able to further modify the integrated SCBC to capture metabolic measurements in the future. Ultimately, this technology presents a generalizable DNA encoding strategy to augment sequencing methods, as well as a powerful tool to better understand single cell biology by expanding the scope of their measurements.

Ultra-Small Biocompatible Iron Oxide T1 MRI Contrast Agents with Reduced Magnetic Coupling
Fabian H. Starsich1, Christian Eberhardt2, Kerda Keevend3, Andreas Boss2, Ann Hirt1, Inge Herrmann1 and Sofie S. Pratsinis1; 1ETH Zurich, Zurich, Switzerland; 2Institute of Diagnostic and Interventional Radiology, University Hospital Zürich, Zurich, Switzerland; 3Department Materials Meet Life, Swiss Federal Laboratories for Materials Science and Technology (Empa), Zurich, Switzerland.

Contrast agents are essential to magnetic resonance imaging (MRI) for the evidential visualization of soft tissue pathologies in regenerative medicine. MRI can be categorized into T1- and T2-weighted sequences that require as contrast agents paramagnetic and superparamagnetic materials, respectively. Typically, T1-weighted MRI is preferred over T2- due to the faster data acquisition using gradient-echo sequences and sharper image analysis. Commonly used and FDA-approved T1 contrast agents are based on highly paramagnetic Gd complexes. Although very efficient in terms of contrast enhancement, these complexes have been associated with nephrogenic systematic fibrosis due to Gd3+ release, especially in long and repeated exposure scenarios. Here, ultra-small iron oxide nanocrystals co-oxidized with SiO2 are investigated as a biocompatible alternative. By using SiO2 as a spacing material, the effective magnetic size of iron oxide is reduced resulting in significant T1 contrast enhancement due to minimized magnetic coupling. The nanocrystals are produced by scalable and sterile flame aerosol technology with potential production rates up to kg h-1. The optimized FeOx/SiO2 nanoparticles attain comparable relaxivities to harmful Gd-complexes, however, with no apparent cytotoxicity at clinically relevant concentrations tested in vitro against four different cell types (PC3, HepG2, THP-1 and red blood cells). With this, these flame-made ultra-small iron oxide nanoparticles offer safe and efficacious access to T1 contrast agents fulfilling major prerequisites for a future translation into clinics.

SESSION BM05.07: Breakthrough Technologies for In Vitro Tissue Modeling

1:30 PM *BM05.07.01
Infections and Inflammation-on-a-Chip—Neutrophil Swarming Against Fungi D. Irimia; Department of Surgery, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts, United States.

Neutrophil swarms protect us from microbes by sealing off sites of infection. In the absence of swarming, microbes could invade into healthy tissues, and severe infections could progress. Recent observations in animal models have shown that neutrophil swarming is one essential immune response against large microbes and clusters of microbes. Although relevant, such models are low throughput and are also too complex to allow for the precise dissection of the innate immune actions that protect against infections. Large microscale arrays of targets for the study of human neutrophils during swarming ex vivo provide an attractive alternative and enable the observation of thousands of swarms at once against live-microbe. Moreover, the synchronized swarming in small volumes enables the detailed analysis of the amount and timing of mediators released during human-neutrophil swarming, responsible for the early activation and late resolution of the process. In the clinical setting, we compared the swarming behavior of neutrophils from patients following major trauma and healthy individuals and found various deficiencies that resolve over time. The new technologies for studying Infections and Inflammation-on-a-chip represents a valuable discovery and screening platform, which could lead to novel anti-inflammatory and anti-microbial treatment strategies.

2:00 PM *BM05.07.02
Biofabrication of Biomimetic 3D Models of Musculoskeletal Tissues W. Swieszkowski1, M. Constantini1,2, Chiara Rinoldi1, J. Idaszek1, A. Kosik-Kozio1 and E. Kijenska-Gawronska2; 1Faculty of Materials Science and Engineering, Warsaw University of Technology, Warsaw, Poland; 2Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland.

An innovative technique that may overcome current limits in reproducing complex structures of human tissues and organs is 3D biofabrication. This emerging fabrication technology relies on the simultaneous deposition of cells and biomaterials, mostly in a layer-by-layer fashion, to form 3D well-organized living heterogeneous porous structures that can mirror physiologically and morphologically relevant complex biological architectures. In this study, we present an innovative strategy to biofabricate biomimetic 3D models of musculoskeletal tissues, like muscle, tendon, or cartilage. Our 3D biofabrication approach is based on a microfluidic system coupled to a co-axial needle extruder for high-resolution computer-controlled 3D deposition of hydrogel fibers laden with different cells. By formulating tailored hydrogel based bioinks and precisely controlling the 3D spatial organization of the extruded hydrogel fibers, it was possible to biofabricate advanced engineered living constructs mimicking natural musculoskeletal tissues. Furthermore, the influence of mechanical loading and biochemical stimulation on proliferation, alignment, and differentiation of the cells as well as ECM deposition in 3D biofabricated constructs will be discussed. Additionally, the preliminary in vivo performance of selected 3D biomimetic 3D tissue models will be presented.

2:30 PM *BM05.07.03
Engineered Tumor Ecosystem for Personalized Anti-Cancer Therapy S. Sengupta; Division of Engineering Medicine, Department of Medicine, Brigham and Women’s Hospital, Harvard Medical School, Cambridge, Massachusetts, United States.

Being able to select the most effective therapy for each individual cancer patient remains the Holy Grail in cancer treatment. In today’s precision medicine, this selection is made based on molecular and genetic profiling of biomarker expression. However, a biomarker often does not translate into a successful
clinical response to the selected therapy. We have engineered a ‘micronized tumor ecosystem’ that conserves the patient tumor characteristics with high fidelity, and integrated with a novel machine learning algorithm can accurately predict anticancer drug responses. This talk will discuss how such a micronized tumor ecosystem can be used to choose the most effective therapy for a patient before initiation of treatment.

3:30 PM *BM05.07.04
Origami Microfluidics for Biomimetic Organs on a Chip
C. Livermore1, 2, 3; 1Department of Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States; 2Department of Mechanical and Industrial Engineering, Northeastern University, Boston, Massachusetts, United States; 3Northeastern University, Boston, Massachusetts, United States.

Fluid mechanics at the shortest length scales enables many functions of life, such as microcirculation in the human body and transpiration in plants. Ideally, we would be able to translate these properties directly into engineered tissues and organ on a chip systems, but there remains a significant gap between the materials and techniques of conventional microfluidics and the functions of the human body. For example, conventional organs on a chip can struggle to replicate the massively parallel flow and perfusion architecture of the liver. Origami-based microfluidics offer a new paradigm for addressing these challenges. Folding offers a low-cost, rapid means of creating flow structures to mimic vasculature. Multi-material architectures enable additional transport via diffusion, and directed assembly of cells offers hierarchical structure at the smallest length scales. This talk will present the enabling tools of origami tissue engineering, including the use of origami-based techniques to create multi-material, flow/perfusion microfluidic devices as a platform for scalable tissue engineering. In particular, the presentation will focus on the application of these multifunctional systems for the design, fabrication, and characterization of origami liver tissue units.

4:00 PM *BM05.07.05
Putting 3D Bioprinting to the Fabrication of Tissue Models
Yu Shrike Zhang; Division of Engineering Medicine, Department of Medicine, Brigham and Women’s Hospital, Harvard Medical School, Cambridge, Massachusetts, United States.

The talk will discuss our recent efforts on developing a series of bioprinting strategies including sacrificial bioprinting, microfluidic bioprinting, and multi-material bioprinting, along with various cytocompatible bioink formulations, in facilitating the fabrication of biomimetic 3D tissue models. These platform technologies, when combined with bioreactors and bioanalysis, are anticipated to provide new opportunities for constructing functional microtissues with a potential of achieving improved drug screening and precision therapy by overcoming certain limitations associated with conventional models based on planar cell cultures and animals.

Plasma-Bio Interactions—Linking Plasma-Induced Liquid Phase Chemistry with the Biological Impact of Plasma
Peter Bruggeman; University of Minnesota, Minneapolis, Minnesota, United States.

Non-equilibrium atmospheric pressure plasmas interacting with biological matter offer a unique source of highly reactive chemistry beneficial for many applications including food decontamination, wound healing and cancer treatment. Many of these applications require controlled and selective interactions. For example, in decontamination processes, the inactivation of bacteria on healthy tissue or food samples needs to occur with minimized off target effects. Controlling selectivity requires a detailed understanding of the underlying plasma-bio-interaction mechanisms. As the majority of these plasma-bio interactions occur in an aqueous environment, linking plasma-produced reactive species in this environment with biological responses is of key importance to develop controlled and selective applications of plasmas in biomedical applications.

My group, in collaboration with microbiologists, has investigated the reactive species responsible for plasma-induced liquid phase processes such as the
inactivation of bacteria and virus and the interaction of plasma with mammalian cells using a well-characterized atmospheric pressure plasma jet with a known composition of the reactive species in the gas phase. As in several other reports we found the importance of long-lived species such as H2O2 and OCl-. However many results indicated the direct or indirect importance of short-lived species. We will discuss these results in detail illustrating the unique character of the plasma treatment and also outline the strong possible sensitivity of plasma-bio interactions on treatment modalities.

Investigation of Damage to Nucleic Acids Induced by Plasma Irradiation Hirofumi Kurita, Tomoko Nakajima, Kaori Sano, Saki Miyachika, Yoshito Uchihashi, Natsuki Haruta, Hachiro Yasuda, Kazunori Takashima and Akira Mizuno; Toyohashi University of Tech, Toyohashi, Japan.

Cold atmospheric pressure plasmas have been intensively studied due to growing interest in biological and medical applications. Especially the plasma has been considered as a promising tool for cancer therapy. One of the proposed molecular mechanism is DNA damage-associated cell death. Therefore DNA is one of the most important biomolecular targets for investigating the effects of exposure to the plasma. Over the last decade, many studies have attempted to characterize DNA damage and the associated cellular responses induced by plasma irradiation. In the early stage of the investigation, most of the reports used isolated plasmid DNA molecules in liquids and the analysis was based on gel electrophoresis. For example, it has been reported that oxidative damage is induced by exposure to the plasma, resulting in single-strand breaks (SSBs) and double-strand breaks (DSBs) separated by conventional agarose gel electrophoresis [1]. In recent years, the analysis of genomic DNA in the plasma-irradiated cells were reported. For example, the single cell gel electrophoresis assay, also known as the comet assay, is a versatile method for measuring DNA damage. Although gel electrophoresis is relatively inexpensive and easy to perform, it requires long run times. Therefore we have developed non-electrophoretic methodologies. Our first investigation is a single-molecule-based method for evaluating strand breaks in large linear DNA molecules that allows the length of individual DNA molecules to be measured [2]. In this investigation plasma-induced DNA breakages have been kinetically analyzed. However, the single-molecule method requires the acquisition and processing of many fluorescence images for reliable analysis. We have also investigated rapid detection of DNA strand breaks induced by plasma irradiation using a molecular beacon (MB) [3]. MBs are oligonucleotides that adopt a stem-and-loop structure and carry a 5'-fluorescent moiety and a 3'-nonfluorescent quenching moiety. Scission of the stem by plasma irradiation leads to separation of the fluorophore-quencher pair, resulting in an increase in fluorescence that directly correlates with the extent of DNA strand breaks. In addition, we reported that a plasma jet readily induced DNA strand breaks in synthetic models of tissue and cells, surprisingly without any significant rupture of the phospholipid membrane [4]. Furthermore, the feasibility of MB-based methodology for detecting intracellular DNA damage was investigated. Our novel methodology may allow investigations of the effects of atmospheric pressure plasma on DNA damage-associated cell death in plasma treatments.

9:45 AM BM06.01.03
Effects and Mechanism of Electric Stimulation Through Carbon Nanowalls Scaffold on Proliferation and Differentiation of Cultured Cells Hiroki Kondo1, Tomonori Ichikawa1, Kenji Ishikawa1, Hiromasa Tanaka1, Takayoshi Tsutsumi1, Keigo Takeda2, Makoto Sekine1, Masaru Horii1 and Mineo Hiramatsu2; 1Nagoya Univ, Nagoya, Japan; 2Meijo University, Nagoya, Japan.

In recent years, nanomaterials, such as carbon nanotubes, graphene nanoflakes, and so forth, have attracted much attention as a cell culturing scaffold. It has been reported that an introduction of nanometer level fine structures affects cell differentiation induction. Very recently, it has also been reported that an electric stimulation through conductive scaffold of resin containing carbon nanotubes can affect proliferation and differentiation of cultured cells. Based on these backgrounds, we have focused on carbon nanowalls (CNWs), in which multiple layers of graphene sheets are vertically grown on a substrate and form randomly intricate wall structures like maze. Due to their unique morphology, the CNWs have very high aspect ratio over 100 and high specific surface area. In addition, they also have high conductivity and robustness against chemical treatments. Therefore, the CNWs are promising as electrically conductive cell culturing scaffold with nanometer level fine structures. We have reported that the wall density and the chemical termination of CNWs influence the proliferation rate and morphology of HeLa cell. Furthermore, electric stimulation through the CNWs scaffold increased proliferation rate of human osteoblast-like cells (Saos-2) and suppress their ossification only if frequency of electrical stimulation was 10 Hz. In this study, the effects and mechanisms of such the electrical stimulation through the CNWs scaffold with the different wall densities were investigated. Proliferation rates and intra- and extra-cellular calcium amounts were measured for the Saos-2 cells cultured on the CNWs scaffold with the electric stimulation.

The CNWs were grown on Ti substrates by a radical injection type plasma excited chemical vapor deposition (RI-PECVD) system. In order to change the wall densities, the total pressures during the growth were controlled from 1 to 3 Pa, which realizes density controls of hydrogen and methyl radicals. According to scanning electron microscopy (SEM) images, distances between neighboring walls were 208 and 341 nm, when the total pressures were 1 and 3 Pa, respectively. Saos-2 cells were cultured on these CNWs scaffolds in an environment at 37°C and with CO2 concentration of 5%. Electric stimulation with a frequency of 10 Hz, square wave shape and a peak-to-bottom voltage of 226 mV was supplied for 24 hours after seeding the cells. Then, after culturing for a total of 100 hours, the number of cells and morphology were observed. A 58% increase in proliferation rate was observed on CNWs with a wall density of 341 nm, while that on the CNWs with a wall density of 208 nm hardly changed. At the same time, it was confirmed that aggregates of cells were formed only on the on the CNWs with a wall density of 341 nm. This suggested that an intercellular adhesion can be controlled by the electrical stimulation on the CNWs scaffold. These results could open the way of novel cell control system.

Non-Thermal Atmospheric Pressure Plasma as a Tool to Control the Proliferation of Various Adult Stem Cells

Kiwon Song1, Jeongyeon Park1, Hyunyoung Lee2 and Jae June Lee2; 1Yonsei University, Seoul, Korea (the Republic of); 2Pusan National University, Pusan, Korea (the Republic of).

Non-thermal atmospheric pressure plasma (NTAPP) is described as a quasi-neutral mixture of charged particles and radicals in a partially ionized gas at atmospheric pressure. Recently, many researches attempted to take advantage of the low temperature of NTAPP for biomedical applications thanks to the controllability of plasma chemistry and kinetics. Adult stem cells can differentiate into various mature cell types within tissues or organs at specific conditions. Adipose-derived stem cell (ASC) is a kind of mesenchymal stem cell, which is able to self-renew and differentiate into adipocytes, chondrocytes, osteoblasts and neurons. In this study, we exposed ASCs to NTAPP generated in a helium-based dielectric barrier discharge (DBD) device 10 times, for 50 sec each time every hour, and incubated the cells till 72 h. NTAPP exposure increased the proliferation of ASCs by 1.57-fold on an average, compared with unexposed cells. NTAPP-exposed ASCs maintained their stemness, capability to differentiate into adipocytes but did not undergo the cellular senescence. In addition, the mRNA level of well-known pluripotent genes, Oct4, Sox2 and Nanog, was increased in NTAPP-exposed ASCs compared with that of the unexposed cells. Also, signaling pathways that activate the cell proliferation such as Akt, ERK1/2, and NF-κB were activated and the proliferating cell nuclear antigen (PCNA) was highly increased at 72 h in NTAPP-exposed ASCs. Studies using the scavengers for nitric oxide (NO) and reactive oxygen species (ROS) demonstrated that NO rather than ROS is responsible for the enhanced proliferation of ASCs following NTAPP exposure. Moreover, NTAPP induced the increased proliferation of bone marrow-derived stem cells (BM-MSCs) and hematopoietic stem cells (HSCs) by 80 % and 100 %, respectively. These results suggest that NTAPP can activate the proliferation of ASCs without affecting their stem cell properties. Taken together, this study supports that NTAPP would be an efficient tool to activate the proliferation of various adult stem cells for the medical application of stem cells both in vitro and in vivo. Currently, we are investigating the whole genome expression profile of NTAPP-exposed ASCs to understand the molecular mechanism of the activation of adult stem cell proliferation by NTAPP.

Effectiveness and Safety of Plasma Activated Medium
Hiromasa Tanaka, Masaaki Mizuno, Kenji Ishikawa, Shinya Toyokuni, Hiroaki Kajiyama, Fumitaka Kikkawa and Masaru Horii; Nagoya Univ, Nagoya, Japan.

It is important to investigate effectiveness and safety for clinical applications of new therapeutic methods. Non-thermal plasma is pretty new technology which is expected to be applied for various medical applications such as blood coagulation [1], wound healing [2], and cancer treatments [3]. We have previously developed plasma activated medium (PAM) for cancer treatments [4]. We have also developed plasma activated Ringer’s lactate solution (PAL) for cancer treatments [5]. We would like to discuss effectiveness and safety of these solutions based on our accumulated knowledge through numerous studies.

PAM selectively killed glioblastoma brain tumor cells against astrocyte normal cells [4]. Selective killing of cancer cells by PAM have been reported in not only glioblastoma, but also ovarian, pancreatic, and other cancer cells. We have reported that PAL also selectively killed glioblastoma against normal keratinocyte cells and mammary epithelial cells. These in vitro experiments are good evidence to use PAM/PAL safely. Various in vivo experiments also demonstrated safety of PAM/PAL. For example, PAM inhibited ovarian cancer cell metastasis, resulting in prolonged survival in a mouse model, while PAM intraperitoneal injection exerted little influence on body weight [6]. Intravitreal injection of PAM suppressed laser-induced choroidal neovascularization, while PAM injection had no effect on regular retinal vessels, nor did it show retinal toxicity [7]. These in vivo experimental results are important evidences to use PAM effectively and safely.

To establish plasma medical science, understanding molecular mechanisms and effectiveness and safety tests are necessary. Since PAM was developed, many in vitro and in vivo experiments have demonstrated its effectiveness and safety especially in cancer treatments. Selective killing of cancer cells by PAM are good evidences for effectiveness and safety of PAM. These results suggest PAM therapy may be a promising treatment option.

Helium Plasma as a Tool for Interacting with Cells and Pathogens
Emilio Martines; Consorzio RFX, Padova, Italy.

This contribution reviews recent activity of the Padova group on the use of helium plasmas in plasma medicine. Following the initial emphasis on disinfection of the cornea [1], the research activity has developed along several research lines, which cover the topics of wound healing, cancer treatment and non-thermal coagulation.

Plasma source characterization from the physical and chemical point of view has been performed, comparing two different sources: a RF source for indirect plasma treatment [2] and a Dielectric Barrier Discharge jet for direct treatment, specifically designed for non-thermal blood coagulation applications. The comparison has included an assessment of disinfection properties. The specificity of helium as working gas has been emphasized by mass spectrometry measurements, which hint to the importance of metastable excited states.

The wound healing activity has seen a set of in vitro tests, which have shown the ability of a RF indirect treatment to stimulate cell proliferation and migration, processes which are related to an increase of intracellular ROS level [3]. Subsequently, an in vivo study on large animals (sheep) has been performed, showing the ability of the plasma treatment to significantly reduce bacterial charge on the wound, to reduce inflammation, to promote the regeneration of cutaneous annexes, such as hair follicles and glands, and to lead to an anticipated induction of blood vessel formation.

The work on cancer treatment has been carried out in vitro, using primary cells cultivated from tissue samples of patients affected by laryngeal and lung cancer. The plasma treatment has been shown to lead to an increased RONS level in cells, with a stronger effect observed in cancer cells than in healthy ones. As a consequence, apoptosis is induced in a remarkable fraction of cancer cells, with a preferential effect with respect to healthy ones. This result could be enhanced by combining the plasma treatment with incubation with a molecule known to increase the ROS level in cells.
Finally, the first results of a project on non-thermal blood coagulation induced by the direct interaction with a helium plasma jet will be reported. In vitro studies have shown that the applications of the plasma indeed accelerates coagulation. The result has been confirmed by in-vivo tests on animal models.

High Throughput Toxicity Assay on Cooperatively Ordered Single Cells with Individual Identity Qiuxuan Li and Ming Su; Northeastern University, Boston, Massachusetts, United States.

Cytotoxicity at single cell level plays an important role in understanding biological mechanisms, detecting diseases, and screening therapeutics. Since cell populations are heterogeneous, differentiating individual cells in large populations become very important. This abstract reports a single cell array where the identity of each individual cell can be determined from coordinators assigned to the cell. Cytotoxicity upon X-ray radiation exposure and drug treatment are determined through reactive oxygen species (ROS) signal in cells and quantified by fluorescent intensity with MATLAB. This method can provide toxicities of over thousands of cells with superior statistics power after different treatment. The heterogeneity of cells in response to chemical and physical stimuli can be easily obtained to allow deep analysis of obtained toxicity data.

Plasma Processing of Liquid Media for Biology—An In Vitro Study of Chemical Actors and Biological Effects Elisa Sardella1, Valeria Veronica2, Francesco Fracassi3, Michele Casiolo1, Lucia d’Accolli1, Loris Grossi1, Francesco Cimina1, Pietro Favia1, Michael Schmidt2, R.D. Wilmann1 and Roberto Cristina1; 1Institute of Nanotechnology, CNR-NANOTEC, Bari, Italy; 2Department of Chemistry, University of Bari, Bari, Italy; 3University of Rimini, Rimini, Italy; 4Leibniz Institute for Plasma Science and Technology, Greifswald, Germany; 5University of Bari, Bari, Italy.

During the last 10 years atmospheric pressure plasmas have shown great promise for the treatment of wounds and cancer. All reported literature attests that the synergy between the plasma and liquid is critical to understanding the outcome of plasma treatment and envision targeted breakthrough in medical therapeutic approaches. In this work chemistry of cell culture liquid media was investigated after application of dielectric barrier discharges switched on at 6KHz with different gas feed: Air, Nitrogen, Oxygen and mixtures of them. A DBD closed system and a controlled gas environment were used in order to address important answers to the question: is the H2O2 really involved in promoting certain cell behaviors during in-vitro testing? Has the NO and its derivatives an active role in promoting some cell responses stimulated by a plasma activated biological media? Is there a clear role of biological molecules of cell culture media eventually modified by plasma in stimulating some biological responses? Plasma activated liquid media (PALM) have been analyzed by ESR, LC-MS and spectrophotometric quantification of reactive oxygen and nitrogen species. The chemical composition of such kind of plasma activated media show that [H2O2] increases while [NOx] species decreases with the percentage of O2 in the gas feed. Such results have been correlated to the biological characterization of plasma activated DMEM 10% FBS incubated for 2 hours with an osteoblasts cell line (SAOS2) and primary cells (BMSC). Cell growth of cells incubated with PALM have clearly shown that, the plasma processing with O2 (6KHz, 13kV, 25%DC, 1min) is more effective than that one carried out with N2 and air, performed in the same experimental conditions, in promoting a reduced cell adhesion, an absence of cell clusters and contemporary inhibiting cell growth of SAOS2 cell lines. Meanwhile, a different behaviors have been observed for the primary BMSC, with a less detrimental effect on cell adhesion and growth both on 2D and 3D growth. Two-dimensional (2D) cellular monolayers remain the standard for validation of several kind of biomedical and therapeutic approaches, even though 2D monolayers are unable to replicate the complicated environment and mechanisms of a tissue or a solid tumor and its growth. The production of three-dimensional (3D) in vitro models is now established as a much more accurate representation of in vivo conditions when compared to other in vitro models, such as the production of 2D monolayers. For these reasons the co-author of this paper will show the cell responses exposed to PALM both on 2D and 3D environment. The obtained results give important insight on plasma interfaced to biological liquids showing the potential for future application of plasma assisted approach both in regenerative medicine and cancer therapy.

Cold Atmospheric Plasma Device for Decontamination of Space Equipment Hubertus M. Thomas1, Petra Rettbeg4, Gregor Morfill1, Julia Zimmermann1, Meike Mueller1, Markus Thoma1 and Tetsuji Shimizu1; 1DLR-Institute of Materials Physics in Space, Wessling, Germany; 2University of Giessen, Giessen, Germany; 3terraplasma GmbH, Garching, Germany; 4Institute of Aerospace Medicine, DLR, Cologne, Germany; 5National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Cold Atmospheric Plasmas (CAP) are commonly used in plasma medicine and plasma hygiene due to its sterilizing conditions. We are presenting a new device based on the circulation of the long-living species of an afterglow air CAP for the decontamination of space equipment. In space exploration the decontamination of equipment for the visit to other planets or moons is very strictly regulated through the planetary protection policies of the Committee on Space Research (COSPAR). Proven methods for the decontamination are using for treatment of the equipment dry heat or H2O2-gas, both having negative side effects in addition to the decontamination efficacy. In a first project we investigated the use of afterglow plasma produced in a CAP for the decontamination effects on bacterial spores [1]. The afterglow plasma contains only the long-living species like ozone, NO2, etc. which allows the treatment of very sensitive materials at room temperature. In a follow-on project the apparatus was completely redesigned to gain efficacy, stability and reproducibility.

Measurements of the decontamination efficacy combined with physical measurements of the produced reactive components (measured by FTIR and UV absorption spectroscopy) and their effect on treated materials allow a better understanding of the involved processes.

We will give an overview on the status of the plasma decontamination project funded by the Bavarian Ministry of Economics.
Superhydrophobic surfaces with hydrophilic patterns have great application potential in various fields, such as microfluidic systems and water harvesting. However, many reported preparation methods involve complicated devices and/or masks, making fabrication of these patterned surfaces time-consuming and inefficient. Here, we propose a high-efficient, simple and maskless micro-plasma jet (MPJ) treatment method to prepare hydrophilic patterns like dots, lines and curves on superhydrophobic Al substrates. Contact angles, sliding angles, adhesive forces and droplet impact behavior of the created patterns are investigated and analyzed. The prepared “dot” patterns exhibit high water adhesion, while the “line” patterns show anisotropic adhesion. Additionally, MPJ treatment does not obviously change the surface structures, which makes it possible to achieve repeatable patterning on one substrate. Adhesion behavior of these patterns could be adjusted using MPJs with different diameters. MPJs with larger diameters are efficient for creating patterns with high water adhesion, which can be potentially used for open channel lab-on-chip systems (e.g., continuous water transportation); while MPJs with smaller diameters are preferable in preparing patterns with low water adhesion for diverse applications in biomedical fields (e.g., loss-less liquid droplets mixing and cell screening).

Surface modification of microplates with plasma polymerization technique was achieved by low pressure plasma system. In this particular study, acrylic monomers included, the most significant anti-biofilm effect was shown for DP at 90W. In this study,Regardless of the monomers and plasma parameters used, biofilm formation was inhibited for all plasma modified microplate wells (p<0.000). Of all the different plasma powers (30, 60 and 90W), the most significant inhibition of biofilms was observed on DP coated microplate wells at 90W, for all cultures were inoculated in triplicates onto microplate wells. Individual strains isolated from patients as well as negative and positive controls were incubated for 48 hours. Biofilm formation on plasma modified and non-modified surfaces were evaluated both at 48 hours and two weeks after.

Evaluation was done using crystal violet (CV) binding assay. After staining with CV, the optical density (OD) of each well stained with CV was measured at 570 nm against the OD of negative controls (at 48 hours and at two weeks).

Surface modification of microplates with plasma polymerization technique was achieved by low pressure plasma system. In this particular study, acrylic acid (AA), 2–hydroxyethyl methacrylate (HEMA) and diethyl phosphite (DP) were assessed for their biofilm inhibition efficacy. On non-coated control surfaces 100% biofilm formation by Candida spp isolated from blood as well as two ATCC control strains (C. albicans ATCC 10231 and C. parapsilosis) were included in this study. Biofilm formation was determined as described by quantitative plaque assay method. Suspensions of Candida spp isolated from blood cultures were inoculated onto microplate wells. Individual strains isolated from patients as well as negative and positive controls were incubated for 48 hours. Biofilm production on plasma modified and non-modified surfaces were evaluated both at 48 hours and two weeks after. Evaluation was done using crystal violet (CV) binding assay. After staining with CV, the optical density (OD) of each well stained with CV was measured at 570 nm against the OD of negative controls (at 48 hours and at two weeks).

Surface modification of microplates with plasma polymerization technique was achieved by low pressure plasma system. In this particular study, acrylic acid (AA), 2–hydroxyethyl methacrylate (HEMA) and diethyl phosphite (DP) were assessed for their biofilm inhibition efficacy.

Regardless of the monomers and plasma parameters used, biofilm formation was inhibited for all plasma modified microplate wells (p>0.000). Of all the monomers included, the most significant anti-biofilm effect was shown for DP at 90W. In this study, in-vitro results indicated a potential for reducing biofilm associated Candida infections on selected plasma modified surfaces.

**Plasma Jet Delivery on Targets Relevant for Skin Treatments—Towards In Situ Monitoring and Loop Controlled Plasma Gun Based Device**

**Eric Robert**, Azadeh Valinattaj Omran, Giovanni Busco, Sébastien Dozias, Catherine Griffon, Jean Michel Pouveles and Loick Ridou; CNRS-Univ d'Orleans, Orleans, France.

We will first report on the key role of conductive targets mimicking biological samples (such as those involved during in vitro, ex vivo and in vivo skin or skin cells), on most of the plasma characteristics during non-thermal plasma treatments. Drastic mutual influence of plasma jet and targets has been shown to induce critical modifications of: reactive species balance and densities, current amplitude, temperature, gas flow features when comparing with the situation of the so called “free jet expansion” in ambient air. This strong interplay between plasma and targets has to be considered before (gas flow impingement before plasma ignition) and during plasma delivery as a dynamic feature. Both plasma and targets may indeed encounter various continuous evolutions during plasma treatment such as: plasma source feed gas purity, plasma kinetics, target humidity, target electrical conductivity, thermal load, on target charge deposition, cell microenvironment modulation (oxygen level, plasma induced permeabilization) … When translating results obtained during in vitro or preliminary skin sample experiments to clinical situation, one has also to account for the critical role of plasma nozzle to surface gap variation and of the skin specificity of individuals.
The first objective of our work is to try to achieve a safe, reproducible and individual-independent plasma delivery on human skin. This approach includes first the implementation of, as simple and user friendly as possible, diagnostics tools providing signals likely to be correlated with the plasma jet source operating parameters (voltage, repetition rate, gas distance). This requires to select the most sensitive in situ signals captured by diagnostics tools and then try to reach a "real time" modulation and loop controlled operation of the plasma source. This first task represents a prerequisite for the development of a safe and reliable plasma device likely to offer new opportunity for anti-aging issues or skin treatments in cosmetics or dermatology applications. This work is supported by the research project PlasmaCosm-ARD 2020 Cosmetosciences, Région Centre Val de Loire.

Ultrafast Laser Spectroscopy of Plasma Liquid Systems Stephan Reuter1, Benjamin Goldberg1, Yibin Zhang1, Arthur Dogariu1 and Richard Miles1,2; 1Mechanical and Aerospace Engineering, Princeton University, Princeton, New Jersey, United States; 2Department of Aerospace Engineering, Texas A&M University, College Station, Texas, United States.

Non-thermal atmospheric pressure plasmas provide high reactivity at low gas temperatures, ideally suited for sensitive surface treatment. Recent studies have, for example, demonstrated that plasma jets in clinical use provide great potential for novel chronic wound therapies and cancer treatment. Plasma generates reactive oxygen and nitrogen species triggering biological responses that initiate healing processes. In order to target plasma-based therapy to a specific medical application, control over the plasma generated reactive oxygen and nitrogen species composition is required. First concepts in tailoring plasma reactivity for targeted therapies show exciting results. Controlling plasma requires in-depth knowledge of its parameters. Especially atmospheric pressure plasma jets pose a challenge to the diagnostics of reactive species and reaction processes due to small dimensions and high gradients in space and time. As mediator for the plasma interaction effect, liquid interfaces frequently play a major role. In plasma liquid systems, these liquid interfaces need to be taken into account for diagnostic studies. Methods based on laser spectroscopy have proven invaluable to study species generation and transport in atmospheric pressure plasmas. Our work focuses on the diagnostics of accurate flow profile measurements and determination of the electric field initiated by the ionization wave of plasma jets. The use of ultrafast lasers allows for a high time resolution together with space resolved measurements. Electric field induced second harmonic light generation (E-FISH) for electric field measurements and femtosecond laser electronic excitation tagging (FLEET) for flow profile measurements are presented for plasma jets that can be used in plasma liquid interaction: Plasma reaction kinetics is governed by the electron energy distribution function of the discharge, which can be controlled by the supplied electric field. We present 1D-electric field measurements, to study the electric field. To study the flow field of the plasma jet, we employ FLEET, which permits unseeded velocimetry in gas flows containing nitrogen and argon. A strongly focused femtosecond laser excites and ionizes nitrogen, which subsequently dissociates via electron ion recombination. Subsequent nitrogen recombination forms excited nitrogen species that can be tracked for flow field studies. Knowing electric field and gas flow development is of paramount importance for plasma tailoring. Single shot measurements allow to detect stochastic processes. The high resolution in space and time given by the described measurement techniques and the active probing by laser radiation advance insight into the reaction dynamics of plasma liquid systems.

Emission Propagation in Low Energy Atmospheric Pressure Plasma Jet Hiromasa Yamada1,2, Tetsuji Shimizu1,3, Masanori Fujiwara1, Susumu Kato1, Jeoho Kim1, Sarae Ikehara2, Yuzuru Ikehara1,4, and Hajime Sakakita1,3; 1Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2Nagano College, National Institute of Technology, Nagano, Japan; 3Graduate School of Medicine, Chiba University, Chiba, Japan; 4Biotechnology Research Institute for Drug Discovery, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Abstract
Atmospheric pressure plasma jet (APPJ) is attracting attention in many research fields such as biology and medicine. Low energy atmospheric pressure plasma (LEAPP) equipment specially designed by Sakakita et al. [1] is one of the APPJ. Stop bleeding accompanied with blood coagulation without thermal damage using the LEAPP has been confirmed as an attractive surgical procedure necessary for minimally invasive surgery [2]. To control the interactions between the plasma and treated targets such as blood, it is necessary to understand the plasma’s behavior. We have already reported several characteristics of the APPJ, such as dynamic gas-flow behavior [3], gas temperature [4], spatial distribution of reactive species [5], electrical characterization [6], and emission propagation phenomena [7]. In the emission propagation phenomena, a bullet-like emission [9] and a spatially continuous emission [10] were observed depending on the treated target conditions [8]. Moreover, striations have been also observed in the LEAPP [7, 8]. In this study, the characteristics of the emission propagation in the LEAPP under several experimental conditions were analyzed using a high-speed camera. All the observations were synchronized with the measurement of electrical characteristics such as the applied voltage, current and power consumption. As working gases, helium, argon, and neon gases were used. For the target, a copper plate was used and the emission propagation was measured with and without the target. In case with the target, the distance between the nozzle exit of the LEAPP equipment and target surface were changed. Furthermore, an optical emission spectroscopy (OES) was applied in order to identify the reactive species in the plasma. The experimental results are summarized and at the symposium, we discuss the mechanism of emission propagation associated with the characteristics of plasma such as electrical property and optical emission.

Potential Formation on Insulator Film by Atmospheric Pressure Plasma Jet Tetsuji Shimizu1, Kazuya Kikunaga2 and Hajime Sakakita1; 1Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2Advanced Manufacturing Research Institute, National Institute of Advanced Industrial Science and Technology, Tosu, Japan.

Biomedical applications using cold atmospheric plasmas (CAPs) have been studied extensively. At the beginning of this new field, sterilization and wound care were the main applications using CAPs because the plasma can supply reactive species similar to what the immune system produces. For sterilization,
CAPs can inactivate bacteria including antibiotics-resistant strains, fungi, and viruses in tens of seconds to minutes. Within a few years, biomedical applications by CAPs expanded to include cancer therapy, gene transfection, activation of cell functions, blood coagulation, and regenerative medicine. From CAPs, there are several agents reacting with targets such as reactive oxygen and nitrogen species, charged particles, UV photons, heat, and electric field. So far, the biomedically effects driven by CAPs have been discussed mainly in terms of reactive species. However, the charged particles can also play an important role in the biomedically effects because they can also initiate chemical reactions. Moreover, the accumulation of charge on the target can influence the production of CAPs and the transport of reactive species. In addition, the developed electric field by the accumulated charge themselves can cause a biomedically effect. In order to understand the behavior of the charged particles, we aim to investigate a potential formation on an insulator film by the CAP treatment in this presentation.

The used CAP device was an atmospheric pressure plasma jet specially designed for blood coagulation. This device has a dielectric barrier discharge plasma source driven by an AC high voltage power supply with low energy consumption. The frequency of the applied voltage was ca. 62 kHz, and the peak-to-peak voltage was 5–6 kV with sinusoidal waveform. As the working gas, helium, argon or those admixtures was used in order to control the distribution of ions species. A plasma flare was ejected from a quartz tube of 1.4 mm in inner diameter and the insulator film was exposed to the plasma flare. The surface potential distribution on the insulator film was observed by using a static electricity scanner system which can measure an area of 30 x 30 mm² at a spatial resolution of 1 mm within 3 s by scanning an object surface along a vibrating linear array sensor. This method allowed us to measure the potential distribution in a non-contact manner. For the plasma treatment, the insulator films were treated by the CAP for a certain period of time and the potential distribution was measured immediately after the plasma exposure. In the presentation, we discuss the potential profile developed by the CAP treatment and the charging mechanism by the charged particles from the CAP.

NO$_2^-$ and NO$_3^-$ as long-lived reactive species as well as ClO$_2^-$ and ClO$. The reason for focusing on ClO$_2^-$ and ClO$^-$ is that KCl is contained in the buffer solution (100 mm KCl, 25 mm HEPES, pH 7.4 (NaOH)). DOPC (dioleoylphosphatidylcholine) and RB-DOPC (rhodamine B dioleoylphosphatidyl-ethanolamine) were used as a lipid and fluorescent dye-labeled lipid, respectively, and SLB consisted of them. SLB was prepared in a buffer solution (pH 7.4) by the vesicle fusion method, and introduced into a DBD-plasma irradiator [1], which was settled in a glove box and filled with He. We applied AC high voltage at 15 kV for the DBD-plasma irradiation of DOPC-SLB with the electric energy in the range of 28 – 148 kJ/cm$^2$, which was standardized by electrode area. We observed the morphology of DOPC-SLB using an epi-fluorescence microscope (epi-FM) and atomic force microscope (AFM) [1].

Pack tests (RIKEN, Japan) were used for the measurement of H$_2$O$_2$, O$_2^-$, NO$_2^-$, NO$_3^-$, ClO$_2^-$ and ClO$^-$. In the liquid phase, O$_3$-3F (Kasahara Chemical Instruments Corp., Japan) was used for measurement of O$_3$ in liquid phase.

Measurement of the concentration of long-lived reactive species generated by the plasma showed that the main long-lived reactive species generated in this experimental system are H$_2$O$_2$, NO$_2^-$ and NO$_3^-$. These reactive species concentrations increased with increasing the electric power. We predicted that when DOPC reacted with these reactive species, the concentration in the suspension was lower than that in the buffer solution. However, concentrations of H$_2$O$_2$, NO$_2^-$ and NO$_3^-$ were higher when DOPC vesicle was exist. Therefore, it is suggested that these reactive species may not react with DOPC. From the above, it is considered that lipid oxidation causing pore formation in SLB is induced by short-lived active species.

Hemolysis and Coagulation by Plasma Treatment Kenji Miyamoto1, 3, 2, Sanae Ikehara2, 3, Hajime Sakakita4, 2, Tetsuji Shimizu2, Nobuyoshi Takeuchi2, Ken Wakaizumi and Yuzuru Ikehara2, 3, 4; 1Graduate School of Engineering, Yokohama National University, Yokohama, Japan; 2Graduate School of Medicine, Chiba University, Chiba, Japan; 3Biotechnology Research Institute for Drug Discovery, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 4Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan.

We are integrating the plasma technology of low-temperature at atmospheric pressure into the medical sciences through the development of hemostatic equipment.

The first report on blood coagulation using LTP was from Drexel University, which exclusively highlighted the effects on the natural blood coagulation process but for hemolysis or serum protein aggregation. On the other hand, we have focused on the plasma effects on hemolysis to form coagulation from red blood cells and on aggregation of serum proteins that were not involved in natural blood coagulation system [1]. It was the volume of erythrocytes and concentration of albumin that are much higher than platelets and fibrinogen. In our previous studies, we have observed and maximized the plasma effect that alters them to cellular and molecular “glue” in clot formation using the instrument to produce a plasma with a dielectric barrier discharge (66 kHz), sinusoidal peak-to-peak voltage of 6.0 kV applied to an electrode [1, 2].

In this study using the above setting, we monitored the clot formation, the input voltage onto the plasma generator, the gas flow rate, and the value of the current flowing through the conductor A by measuring system connected to the toroidal coil (Rogowski coil). The formed aggregations in serum proteins solutions (albumin and Immune globulins) and RBC solutions were analyzed by either histological, ultrastructural or protein biochemical methods [3].

Moreover, the threshold for hemolysis was much higher than for aggregation of albumin and hemoglobin [4]. RBC clot formation didn’t occur without exceeding a current limit for hemolysis [4]. Furthermore, the conductivity of the sample tray correlates with more active hemolysis. From the viewpoint of plasma physics and pathology, these findings that “electric current’s contribution to hemolysis” accelerates blood coagulation help to develop more effective hemostatic equipment by applying these results [1].

International Standardization of a Low Energy Ionized Gas Haemostasis Equipment Hajime Sakakita1, 2 and Yuzuru Ikehara1, 2; 1National Institute of Advanced Industrial Science and Technology, Ibaraki, Japan; 2Chiba University, Chiba, Japan.

In the surgical procedure, surgeons conventionally control bleeding by cauterization, clipping, or ligation, depending on the types of blood vessel. Even in the bleeding case from capillaries and small vessels, cauterization has been used. Medical devices such as high-frequency electrical coagulator, ultrasonic wave equipment, laser, and high-temperature plasma induce cauterization, and produce smoke by the heat which is sometimes difficult to ensure the visual field during the operation. Moreover, cauterization causes prolonged postoperative disorder and scar tissue formation in the abdominal cavity. The scarring tissues are characterized as proliferation of fibroblast and blood vessels, so called as granulation tissue, which limits the performance of 2nd surgery. As a disorder caused by the digestive surgical operation, it is difficult to treat the subacute disorder by opioids [1]. Therefore, minimally invasive method to stop bleeding in capillaries is desired. It was reported that low temperature plasma treatment can reduce invasiveness under hemostasis, and risk of postoperative disorders [2,3]. Many of bleeding devices are already defined by international standards such as IEC 60601-2-2, 2016. Particular requirements for high frequency surgical equipment, but not for low temperature plasma. International standards on the basic performance and safety of medical plasma equipment for blood coagulation will accelerate and extend the usage of medical plasma equipment. To apply the plasma effectively, safety and reproducibly, it is necessary to certify the correlation between the plasma components and biological effects. To ensure the safety of medical plasma equipment, specifications such as current must be measured and evaluated. Recently (2018/4/10), IEC 60601-2-76: 2018, Particular requirements for the basic safety and essential performance of low energy ionized gas haemostasis equipment was published. In the meeting, detailed contents of this standard will be presented.

Atmospheric-pressure plasma jets (APPJs) have recently attracted much interest not only for biomedical applications [1] but also for plasma physics [2]. One of the most interesting phenomena in APPJs is bullet propagation [3], which has been observed in experiments and analyzed by computer simulations [2,4]. Another is a striation phenomenon which widely appears in discharges [5]. A stratified emission was observed and analysed in a positive column of a neon gas discharge [6]. The striations between a nozzle exit and a conductive target plate were observed in neon plasma ejected from low-energy atmospheric-pressure plasma device [7]. It is not clear, however, how the bounded plasma is sustained in APPJs. Especially, the role of the excited state (metastable) are not clear even though it is believed to be an important role [8]. In order to elucidate the sustaining mechanism of striations of APPJs, optical emission or laser absorption spectroscopy are used [9].

In this paper, we proposed a simple kinetic model to analyse the optical emission from the atmospheric-pressure neon. The kinetic model includes only noble gas atom, metastable, some excited states, ion, dimer, dimer ion and electron reactions. The most of the optical emission consists of the transition from excited Ne(2p3p3p) states to Ne(2p3s). The Ne(2p3p) is dominantly generated by both the electron collisional excitation of metastable and ground state and the dissociative recombination of ion dimer [10]. In the atmospheric pressure, the collisional deactivation of the Ne(2p3p) become significant and comparable to the radiative decay [11]. The spectrum strongly depend on the plasma deactivation.

Agricultural applications using nonthermal atmospheric pressure plasmas have attracted much attention not only from plasma researchers but also from biologists. So far, we have found that seeds irradiated by a scalable dielectric barrier discharge (DBD) plasma show growth enhancement of the plants [1]. Three minutes plasma irradiation to Arabidopsis thaliana seeds shows 11% harvest time reduction and 56% crop yield enhancement [2]. The growth enhancement of plasma-irradiated plants is probably caused by eustress response. However, the details of the molecular mechanism involved in plasma-induced signal initiation and response regulation are unknown. Here we have evaluated the amount of reactive oxygen nitrogen species (RONSs) absorbed by seeds as a first step to understand the response regulation. First, we studied the relationship between growth of radish sprouts (Raphanus sativus L.) and a number density of seeds during the plasma irradiation using the scalable DBD device [2,3]. We arranged the seeds within 20x20 mm2 at the center of the electrodes at 3 mm below the electrodes. After 180 s plasma irradiation, 30 seeds for each number density were cultivated under dark condition for 3 days. We obtained seed number dependence of the averaged length of radish. While the growth is suppressed for the seed number of 3 and 5, the growth is enhanced for the seed number of 10, 15 and 30. The plant growth for 30 seeds is slightly less than that for 15 seeds. The results suggest that the dose of RONSs depends on the number of seeds, leading to the plant growth suppression and enhancement. We also measured the electron spin resonance (ESR) spectra of seeds to detect the radicals in seeds [4]. The signal intensity of radicals correlated with the biochemical compounds in seeds is increased by the plasma irradiation. Comparative study of the effects of seeds density using the ESR measurements will reveal RONS transport and absorption mechanism in seeds.

Porous Superstructural Raman Nanosensors for Ultrasensitive Biochemical Detection and Electrically Controlled Molecule Release Jianhe Guo1, Jing Liu1, 2 and Donglei (Emma) Fan3, 4; 1Materials Science and Engineering, The University of Texas at Austin, Austin, Texas, United States; 2Institute of Solid State Physics, Chinese Academy of Sciences, Hefei, China; 3Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United States.

It is highly desirable, while extremely difficult to actively control the release dynamics of molecules from nanoparticle-carriers and to monitor the release process in real time. In this work, we report the design, fabrication, and manipulation of a superstructural Raman nanosensor, offering integrated dual functions in ultra-sensitive biodetection and dynamic control in molecule release. The device has a designed porous superstructure, consisting of gold (Au) nanorod cores and silica shells embedded with arrays of nanocavities arranged in concentric layers in three-dimensions (3D), where high-density plasmonic silver (Ag) nanoparticles are grown both in the nanocavities and on the outer surfaces. The Ag nanoparticles provide substantially enhanced Raman sensitivity for detection of molecules, owing to the large number of hotspots, as well as the near-field coupling of Ag nanoparticles due to their 3D concentric arrangement. Furthermore, by controlling the external electric field, the release of molecules can be facilely controlled at tunable rates owing to the induced electrokinetics at the junctions of Ag nanoparticles. Finally, the biosensing-release-unibody devices can be readily motorized, including
transport and rotation, which opens new opportunities for single-cell bioresearch and precision medicine.

BM06.05.08
Preparation and Evaluation of Radiopaque and Biodegradable Microbeads Based on Lipiodol and Polycaprolactone for Transarterial Chemoembolization Yutaka Okamoto1, Kenta Hitoh1, Terumitsu Hasebe1–2, Shunto Maegawa1, Kosuke Tomita1, Tomohiro Matsumoto2, 1 and Atsushi Hotta1. 1Keio University, Yokohama-shi, Japan; 2Tokai University, Hochojo, Japan.

Surface modification by the molecular grafting of a biocompatible polymer on biomaterials is an attractive technique in several fields such as tissue engineering and drug delivery. Especially, the air-plasma treatment can readily modify a polymer surface under atmospheric pressure at low cost without using inactive gas and vacuum chambers. Using the air-plasma treatment, we modified the surface of the gel composed of an oil and a polymer, from which new drug-eluting beads (DEB) were made for transarterial chemoembolization (TACE). TACE is generally applied to liver cancer by embolizing arteries feeding tumors with DEB under fluoroscopy. During the embolization of the arteries, DEB are injected into the targeted tissue using a catheter. However, since the conventional DEB are not radiopaque in themselves, it is difficult to control an influx of the DEB in a blood vessel. An unintentional reflux into non-targeted blood vessels would end up in complicating diseases. Furthermore, since the conventional DEB are not biodegradable, problems would persist and become more serious.

Here, we focused on Lipiodol and polycaprolactone (PCL) to fabricate Lipiodol/PCL beads as new DEB. Lipiodol is an oil-based contrast agent, and PCL is one of the biomaterials actively studied owing to its excellent biocompatibility and biodegradability. However, Lipiodol/PCL beads agglutinate in water-soluble disperse media, which makes it hard to handle because of the hydrophobicity. Therefore, the air-plasma treatment was applied in order to graft gelatin molecules on the surface of the beads since gelatin is hydrophilic and biocompatible to prevent the beads’ aggregation. The surface chemistry was characterized using the X-ray photoelectron spectroscopy (XPS), and the gelatin existence was confirmed by observing the N1s peak derived from gelatin molecules. In order to evaluate the biodegradability, the beads were immersed in phosphate-buffered physiological saline (PBS) or 1 mg/mL of lipase/PBS solution at 37°C before and after the surface modification with gelatin. Furthermore, as angiography was performed with the soluble contrast agent, the beads were injected into a hepatic artery of a healthy rabbit through a catheter, after which CT scanning was performed. Our results indicate that the degradation of Lipiodol/PCL beads was promoted by lipase, and that the gelatin molecules grafted on the surface of the beads did not prevent the degradation. In addition, the surface-modified beads were successfully dispersed in soluble media. The embolization of the hepatic artery of the rabbit could be assessed by angiography, and the location of the beads in the rabbit could be recognized through the CT scan. Therefore, the Lipiodol/PCL beads were found to be a promising candidate for new DEB, and the success of the surface modification using air plasma on the beads indicated that the procedure was highly useful for the surface modification of the oil and polymer mixtures.

Enhanced Gas Sensing Performance by In2O3 Nanostructures Functionalized with Conducting Polymers Wang Wei Chien, Kuan-Wei Chen, Yu-Shan Hsu, Ying-Hao Pai and Chun-Hua Chen, National Chiao Tung University, Hsinchu, Taiwan.

A number of studies have demonstrated a strong correlation between exhaled breath components and specific diseases. Accurate detection of specific volatile organic compounds (VOCs) can thus provide essential information for screening and diagnostic tests. For instance, the acetone concentration in exhaled breath of diabetes is much higher than that of healthy people (below than 1.1 ppm) and the CO concentration of people who smoke a pack of cigarettes per day is ~20 ppm where a nonsmoker is only less than 8 ppm. In this work, we have successfully synthesized a series of conducting polymer functionalized In2O3 nanostructures for sensing low-concentration VOCs. To achieve the required sensing performance, a series of conducting polymers functionalized In2O3 nanostructures with a high surface-to-volume ratio and porosity were successfully synthesized through hydrolysis of InCl3 in NaBH4 aqueous solution at room temperature with the subsequent heat treatments. It was found that the novel organic-inorganic heterogeneous nanocomposites exhibit a high sensitivity and an excellent selectivity for specific VOCs, which evidently originated from the essential role of organic functional groups of the conducting polymer.

BM06.05.10
Accurate Point-of-Care Diagnosis of AIDS Based on Label-Free One-Step-Immunoassay Young-Eun Jang, Jounghyeok Kwon, Boram Lee, Ok Jeong Moon and Jeewon Lee; Chemical and Bioengineering, Korea University, Seoul, Korea (the Republic of).

We developed an accurate, rapid, simple, and label-free assay method for point-of-care diagnosis of AIDS, which quickly produces strong optical signals through one-step-immunoassay. The HIV proteins, gp41, p24, and/or gp120 were used as the probes to detect anti-HIV antibodies in AIDS patient sera. In particular, gp41 and p24 were genetically presented on the surface of engineered protein nanoparticles to prepare sensitive 3-dimensional (3D) probes. The 3D probes also present multi-copies of hexa-histidine peptide (His6) on their surface to chemisorb gold ions (Au3+), which is essential to producing strong optical signals. Point-of-care diagnostic performance of the developed one-step-immunoassay was compared with that of conventional lateral flow assay (LFA) using 30 AIDS patient sera. The sensitivity of LFA was only 63% when a single antigen (gp41) was used but enhanced to 90% when three different antigens (gp41, p24, and gp120) were used together as the assay probes. On the contrary, the one-step-immunoassay using gp41 only produced strong optical signals within 15 min without causing any false negative/positive signals, showing 100% sensitivity and 100% specificity. This technically advanced immunoassay method holds a promising potential as a clinical point-of-care diagnosis of AIDS.

BM06.05.12
Novel Nanoparticles as a Contrast Agent for In Vivo Computed Tomography Imaging for Vascular Inflammation Sun-Mi Lee and Kyung-Hwa Yoo; Yonsei Univ, Seoul, Korea (the Republic of).

Bismuth nanoparticle (Bi NPs) and gold nanoparticles (Au NPs) are a potential x-ray computed tomography (CT) contrast agent. We have designed multifunctional hybrid nanoparticles of targeting vascular cell adhesion molecule 1 (VCAM-1), which is up-regulated in numerous inflammatory processes in atherosclerosis. Early diagnosis of high-risk plaques using nanoparticles as CT contrasts may be useful for preventing ischemic events. One major hurdle in detecting high-risk atherosclerotic plaques in coronary arteries is the lack of an imaging modality that allows for the identification of atherosclerotic plaque composition with high spatial and temporal resolutions. Here we show that VCAM-1 in atherosclerotic plaques of ApoE−/− mice can be detected with a clinical CT scanner after the intravenous injection of a contrast agent. These novel VCAM-1 targeting Bi-Au nanoparticles may become an important adjunct to the clinical evaluation of coronary arteries with CT.

BM06.05.13
Immobilization of Antibacterial Monomer onto Dentin Substrate by Non-Thermal Atmospheric Plasma Qi Liu1, 2, Buling Wu1 and Yong Wang1. 1University of Missouri-Kansas City, Kansas City, Missouri, United States; 2Southern Medical University, Guangzhou, China.

The antibacterial effects of quaternary ammonium methacrylates (QAMs) included in adhesives are not sustainable due to their no/little interactions with
dentin substrate. In this first of its kind study, the use of non-thermal atmospheric plasma (NTAP) brush on immobilization of dimethylaminohexadecyl methacrylate (DMAHDM), a typical QAM, on dentin bonding substrate, and resulting antimicrobial activity against Streptococcus mutans were investigated. A bonding substrate with several-micron-decalcified layer was created from human dentin. DMAHDM was applied onto the demineralized layer with or without plasma exposure. SEM and FTIR spectroscopy were employed to verify immobilization/grafting of DMAHDM onto the substrate. Antimicrobial activity of the resulting substrate was assessed by using colony-forming unit (CFU) and confocal scanning laser microscopy. Effects of saliva pellicle treatment and aging process on the DMAHDM immobilized-substrate were also evaluated. The SEM and FTIR results demonstrated that plasma-treatment could induce DMAHDM immobilization onto dentin substrate, which was further verified via quantitative IR spectral analysis (i.e. 2925 cm⁻¹/1635 cm⁻¹, 1455 cm⁻¹/1635 cm⁻¹, DMAHDM/collagen ratios). Comparing with non-plasma-treated, the plasma-treated dentin bonding substrate, with CFU 4 log lower, exhibited much stronger inhibitory effects, which were minimally affected by saliva or aging. The DMAHDM-immobilized dentin substrate showed effective and sustained antibacterial characteristics.

In this proof-of-concept study, it was found that NTAP effectively induced immobilization of a quaternary ammonium methacrylate onto dentin bonding substrate within a clinically acceptable treatment time of 30s, generating an antibacterial surface with remarkable and long-lasting inhibitory function. Further investigations should be performed with respect to the NTAP/DMAHDM’s overall effect when incorporated into actual bonding procedures [1-2].

For example, by combining DMAHDM with a dental primer or adhesive, more systematic NTAP studies on antibacterial effects of dental restoration under clinically relevant settings are needed. It is expected that highly reactive particles from NTAP should also induce DMAHDM immobilization in presence of other monomers [1].

BM06.05.14 Low-Energy Ion Dose Thresholds of DNA Double Strand Breaks P. Thopan1, 2 and L.D. Yu2, 3; 1Rajamangala University of Technology Isan, Khonkaen, Thailand; 2Chiang Mai University, Chiang Mai, Thailand; 3Thailand Center of Excellence in Physics, Chiang Mai, Thailand.

DNA double strands break (DSB) is the critical damage of DNA to induce cell mutation/cancer or death. Energetic ion irradiation of biological living systems can possibly result in DNA DSBs via both direct physical and indirect physical and biochemical interactions with DNA. To investigate the interactions separately for understanding the fundamental mechanisms, we focused our study in the direct interaction between ions and DNA. In this model study, we used ultra-low-energy ions generated and extracted from a plasma source and then decelerated for uniformly low ion energy which could be as low as a few eV/amu to bombard naked dry DNA so that physical and biochemical secondary effects could be avoided as much as possible. The plasma ion species used in the study included He, C, N and Ar, for He and Ar to investigate ion mass effect, for N to investigate ion activity effect when compared to He and Ar, and for C to investigate its effect in the medical application significance. The DNA used was plasmid pGFP which was a simple DNA model containing the green-fluorescence-protein character gene for easy detection of the DNA. The ion energy was ranged from 1000 eV down to 10 eV and the ion fluence was typically ranged in 1014 – 1016 ions/cm², and the dose could be converted from both energy and fluence. The DNA damage was observed using the gel electrophoresis which was operated after the ion bombardment of DNA. The electrophoresis could separate different DNA forms, including original supercoiled form, relaxed form which was normally caused by single strand breaks (SSBs) and linear form which was due to DSBs. We clearly observed that only under certain combinations of the ion energy and fluence which indicated a dose could DSBs start to occur. For He ions, the threshold was at the energy of 1,500 eV and the fluence of 2×1015 ions/cm², for Ar ion the threshold was at the energy of 1,000 eV and the fluence of 1×1015 ions/cm² or the energy of 750 eV and the fluence of 2×1015 ions/cm², for N ion the threshold was not found even at the energy as low as 26 eV and the fluence of 2×1015 ions/cm², indicating the threshold for the N ion case to be lower than this energy and fluence combination (which was already beyond the instrumental capability), and for C ion the threshold was at the energy of 50 eV and the fluence of 4×1015 ions/cm² or the energy of 100 eV and the fluence of 1×1015 ions/cm². The threshold was obviously dependent on the ion mass and activity, namely, the heavier the ion, the lower the threshold, and the more the ion activity, the lower the threshold. Why the DNA DSB has the threshold in such values is discussed in terms of the DNA double strand structure. There was a puzzle that the DSB dose threshold found here was considerably higher than the cell lethal dose. A discussion on the puzzle argued that our study implied cell death mostly caused by indirect interaction between radiation and cells.

BM06.05.15 Nanoscale Surface Engineering and Sterilization on Rice (Oryza sativa L.) Seed via Hybrid Nonthermal Discharge Plasma Siwapon Srisonphan; Department of Electrical Engineering, Kasetsart University, Bangkok, Thailand.

Well-controlled wettability and liquid spreading of seed surfaces can help achieve seedlings of better quality, especially in difficult-to-grow regions, including those affected by drought. Nonthermal (cold) atmospheric plasma (NAP) can provide the complex mixture of surface functionalities, leading to nanoscale surface modification and dramatically change in seed surface wettability. However, for coated biological objects, such as seeds, plasma interaction is not entirely understood. Herein, we employed atmospheric hybrid cold plasma (HCP) by combining the pulsed corona discharge plasma in conjunction with a dielectric barrier discharge (DBD) to elucidate how NAP fundamentally interacts with seed surfaces. Moreover, we applied HCP to inactivate microorganisms that commonly attach the rice (Oryza sativa L.) seed husk to elucidate seed surface modification and biological sterilization.

Overall results show that the HCP can provide NAP with low power consumption and high efficiency for surface activation. The cold plasma treatment modified the surface of the rice seeds, resulting in accelerated germination and enhanced water imbibition (WI). The HCP treatment completely inactivated pathogenic fungi and other microorganisms, enhancing the germination percentage and seedling quality without destroying the viable seed membrane. The SEM firmly indicate the nanoscale modification of the surface morphology and the decontamination of pathogen infestation. We also show that the modified surface was primarily attributed to the combined effects of physical ions-enhanced etching and chemical surface functionalization. The WI time of modified seeds is initially decreased as an exponential function of exposure time, and gradually reaching to the WI saturation time in which the absorption rate is constant. We explained such phenomena via electron-ions initiated impact ionization inducing the reactive species (RS) for surface functionalization.

Therefore, microcorona discharge on a single dielectric barrier provides a nonaggressive cold plasma that can be applied to organic materials without causing thermal and electrical damage, and open up new avenues for the NAP treatment for the surface sterilization and disinfection of organic and biological materials with large-scale compatibility.
Optical imaging is one of the most important techniques in biomedical studies. Recently, usage of near-infrared light has been extensively tried because of the higher transparency in biomaterials than the visible light. Single-walled carbon nanotubes (SWCNTs) are nanocarbon materials that show optical absorption and fluorescence in the near infrared (NIR) wavelength region. Especially, due to the bright fluorescence in NIR, SWCNTs have been expected as imaging probes.

In this talk, we first review the optical properties of SWCNTs and then show our recent results about the bio-application of oxygen-doped SWCNTs. Interestingly, covalent doping of the nanotube surface with a low concentration of oxygen atoms can create a new optically allowed defect state. Consequently, nanotube fluorescence is red-shifted and can be over 10 times brighter. Fluorescence vascular angiography and observation of the intestinal contractile activity of mice are demonstrated by using the produced oxygen-doped SWCNTs as infrared fluorescent labels and imaging agents. Further, the biodistribution analysis after the administration of the oxygen-doped SWCNTs in mice is also discussed by the resonance Raman spectroscopy and NIR fluorescence microscopy.

We obtained penetration depth for porcine tissues of fat, skin and muscle, and also obtained the increasing rate of local temperature at different tissue temperatures. These laser pulses were practically used as laser therapy in clinic treatment for recovering functions of muscle and cartilage from athletic injury.

Researchers have utilized infrared (IR) lasers as energy source for laser therapies for curing skin diseases and skin injuries with remarkable positive effects. Preliminary experiments also showed that high-intensity IR laser pulses could penetrate thick body tissues, resulting in remarkable effects for recovering from injuries in deep muscles and cartilage tissues. Yet for the deep-level IR laser therapies, it is not clear how much of the laser flux had penetrated the body tissues at certain depths, and which of the three major effects of laser irradiation, i.e., laser induced photo-chemical effect, photo-thermal effect and mechanical dragging effect, played the key role in the curing process. How to design a new applied device to measure the penetration effect about high-intensity infrared laser pulses through body tissues is our concern.

Here we developed sensitive micro-sized thin-film thermocouple (TFTC) arrays on freestanding SiN thin-film windows as sensors for laser flux and local temperature. These devices showed excellent linear response in output voltage to a laser flux of wavelength 325 - 1064 nm, and meanwhile indicated the local temperature at the laser spot. By using these devices we systematically measured the penetrating effect and thermal effect of near infrared, high-intensity Nd:YAG laser pulses passing through several kinds of thick porcine tissues. These laser pulses were practically used as laser therapy in clinic treatment for recovering functions of muscle and cartilage from athletic injury.

We obtained penetration depth for porcine tissues of fat, skin and muscle, and also obtained the increasing rate of local temperature at different tissue temperatures.
depth. Our results offered reliable references as the thresholds for maximum irradiation doses of IR laser in clinic treatments. The method also offered an alternative approach for measuring the flux and heat under laser irradiation. Therefore we think the novelty and technique presented in this work are valuable for the communities of medical applications of laser technology, health-care, sports biology and biophysics in tissues.

Cold Atmospheric Pressure Plasma Treatment to Assist Bacterial Inactivation and Tooth Restoration in Endodontic Procedures Victorino Colombo1, Matteo Gherardi1, Romolo Laurita1, Emanuele Simoncelli1 and Riccardo Tonini2; 1Department of Industrial Engineering, Alma Mater Studiorum - Università di Bologna, Bologna, Italy; 2School of Dentistry, University of Brescia, Brescia, Italy.

In recent years, cold atmospheric plasma (CAP) - an ionized gas where the electronic temperature is much higher than the macroscopic plasma temperature - have raised great interest for the treatment of living tissue. A potential application of CAP is in the field of dentistry, where preliminary studies have demonstrated its potential use to improve osteointegration, dental instrument cleaning, adhesive polymerization, tooth bleaching, root canal disinfection and other purposes. The present study aims to investigate the use of an innovative and handheld DBD-jet plasma source, properly designed to be translated to the clinical environment and in a realistic endodontic procedure for the disinfection and restoration of root canals. Root canal disinfection experiments have been performed on tooth models and were designed to also address: i) the influence of the humidity of the root canal on the treatment efficacy ii) the possibility of employing plasma activated liquids with antibacterial properties as irrigants. On the side of endodontic restoration in the coronal region, the adhesive-dentin interface has been well recognized as the weaker area for dental composite resin restoration; the improvement, through the development of new materials and techniques, of its characteristic is essential to extend the longevity of dental restorations. To evaluate the enhancement of adhesive properties induced by CAP treatment of dentin, a push-out analysis is carried out on extracted teeth, where the shape of the root-canal has been standardized, using EDTA and phytic acid as etching reagents. Finally, the restoration of the apical region of root canal aims at avoiding a new bacterial colonization in the tooth apex. Filling materials such as gutta-percha, are generally used to completely seal the root apex, but they are characterized by low adhesive performances; thus, endodontic cements, known as sealers, are generally applied after their cytotoxicity to improve the adhesion with dentine. The present study investigates the enhancement of adhesion between these materials and apical dentine of ex-vivo teeth treated by a DBD-jet plasma source by means of pushout tests and confocal microscopy analysis. Although investigations on long-term stability of adherent monoblock to dentine surface and clinical studies are required, the present study supports the exploitability of cold plasma devices in real-life endodontic clinics.

V. Colombo et alii, “Cold Atmospheric Plasma (CAP) treatment to improve the bond strength of adhesive system in endodontic restoration,” Submitted to Dental Materials, 2018

A Principle of Blood Coagulation Induced by Low-Temperature Plasma Treatment to Develop the Rational Medical Practices for Bleeding Control Yuuara Bekhari1,2*, Chiba University, Chiba, Japan; 1Biotecnology Research Institute for Drug Discovery, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 2Electronics and Photonics Research Institute, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan.

1. Introduction
The low-temperature plasma (LTP) technology at atmospheric pressure is being integrated into methodologies in the medical and biological sciences. Bleeding control using LTP was one of the applications to reduce the heat damages on hemostasis in surgery, based on the novel plasma effect to induce aggregation of soluble serum proteins. In my talk, I will introduce our concept of LTP use in hemostasis and illustrate our feature plan to integrate LTP technology into the biomedical manufacture.

2. Blood coagulation using LTP treatment
The first report on blood coagulation using LTP was from Drexel University, which highlighted the plasma effects on natural blood coagulation process, but for hemolysis or serum protein aggregation. On the other hand, we have focused on the plasma effects on hemolysis, and aggregation of albumin that was not involved in blood coagulation and the fibrogenesis system, because erythrocyte volume and albumin concentration are much higher than the amounts and levels of platelets and fibrinogen. To maximize the plasma effect that alters them to cellular and molecular “glue” in clot formation, we developed the instrument to produce plasma using a dielectric barrier discharge (66 kHz, sinusoidal peak-to-peak voltage of 6.0 kV applied to an electrode. In in vivo experiments, our plasma treatment succeeded to form clots solidly more than the naturally formed clot, and could generate aggregation on the solution that contained either albumin and immune globulins, resulting in the protein disc at 1-cm diameter with continuous contact with the plasma flare.

3. Significance in Medicine
A basic concept on the electronic surgical devices is to evaporate water components in tissue and to close bleeding points by shrinking the tissue, and the treatment using electronic surgical devices sometimes caused severe heat damage in parenchymal tissues. On the other hand, the LTP treatment is an innovative approach with minimal invasion because it can stop blood flow by sealing the bleeding point and creating a possibly favorable healing process. Moreover, the fundamental concept behind LTP hemostasis is to provide an essential method that can suppress excessive host inflammatory responses.

In other words, plasma treatment is a tissue-processing technology, insulating local inflammation to start the scar formation. Consequently, I believe that LTP will become a conventional processing technology in tissue and biomaterial engineering with the progression of plasma science. I hope that our results will serve as a stepping-stone for the advancement of plasma science.

Investigations into plasma interaction with cysteine are currently limited to DBD1, COST-jet and kINPen3, and less directly via a DC plasma jet4. Remote modification of the beads by air plasma was useful to induce the mixture of oil and polymer. Confirmed that the beads were visible using the X-ray photoelectron spectroscopy (XPS), and the existence of gelatin was confirmed by the presence of the N1s peak coming from the gelatin. The surface modification by a biocompatible polymer such as PCL through molecular grafting on biomaterials is an attractive technique in tissue engineering. For the surface modification and the molecular activation for grafting, plasma treatments are widely used. It is expected that air-plasma treatment could easily modify polymer surface under atmosphere pressure at low cost without using reactive gases and vacuum chambers. Thus in this study, air-plasma treatment was studied to graft gelatin molecules on the bead surface, as gelatin is hydrophilic, biocompatible, and low cost, which may prevent the bead aggregation. Such Lipiodol/PCL beads may be applied to several parts in the drug-delivery system and the tissue engineering.

In this study the plasma induced interactions with cysteine are investigated using a remote RF plasma source containing He-H2O and isolated from atmospheric impurities in order to observe effects with a relatively simplified plasma chemistry. The liquid sample containing cysteine is located in the far effluent of the plasma source and the arrival species are predominantly H2O2 and OH. We also study the case of liquid exposure to the near effluent/afterglow region, where atmospheric gas impurities can be expected to influence the chemistry. This provides a reference to allow comparison with literature reports. We also present results using a droplet in plasma system whereby cysteine is passed through the plasma for ~100 μs and exposed to a high flux of electrons and OH as well as H2O2, H2O, etc. High rates of electron solvation and reduction reactions, similar to that found with radiolysis, has previously been demonstrated with this system. The corresponding modification of cysteine via each treatment method is analysed using FTIR and Raman spectroscopy. Differences in damage characteristics between individual methods and those previously published are detected and attributed to a change in the plasma induced chemistry. To aid the understanding of the plasma chemistry involved, buffer and radical scavenger solutions were also added. The droplet in plasma setup showed a significant increase in magnitude of cysteine modification in comparison to the other setups.

Preparation of a Radiopaque and Biodegradable Microbead Surface-Modified Using Air-Plasma Treatment for Transarterial Chemoembolization

Yutaka Okamoto1, Kenta Bito1, Terumitsu Hasebe1, 2, Shunto Maegawa1, Kosuke Tomita2, Tomohiro Matsumoto1, 2 and Atsushi Hotta1; 1Keio University, Yokohama-shi, Japan; 2Tokai University, Tokyo, Japan.

Drug-eluting beads (DEB), used as embolic agents for transarterial chemoembolization (TACE), are required to have radiopacity and biodegradability at the same time, to be visualized in a body under fluoroscopy and CT scanning, which should not lead to complicating disease. In this study, we fabricated radiopaque and biodegradable beads composed of Lipiodol (ethiodized oil) and polycaprolactone (PCL), a biocompatible and biodegradable polymer. However, since the Lipiodol/PCL beads were hydrophobic, they aggregated in water-soluble dispersive media, causing difficulty in handling. Therefore, the surface modification of the beads is necessary for the prevention of occlusion that is caused by the injected beads in catheters. The surface modification by a biocompatible polymer such as PCL through molecular grafting on biomaterials is an attractive technique in tissue engineering. For the surface modification and the molecular activation for grafting, plasma treatments are widely used. It is expected that air-plasma treatment could easily modify polymer surface under atmosphere pressure at low cost without using reactive gases and vacuum chambers. Thus in this study, air-plasma treatment was studied to graft gelatin molecules on the bead surface, as gelatin is hydrophilic, biocompatible, and low cost, which may prevent the bead aggregation. Such Lipiodol/PCL beads may be applied to several parts in the drug-delivery system and the tissue engineering. Lipiodol/PCL beads were first fabricated with a home-made microfluidic device. Then the beads were treated with air plasma to introduce -COOH groups on the surface, followed by the covalent grafting of gelatin molecules using carbodiimide as a coupling agent. The surface chemistry was characterized using the X-ray photoelectron spectroscopy (XPS), and the existence of gelatin was confirmed by the presence of the N1s peak coming from the gelatin molecules. The surface-modified beads were injected with water-soluble dispersive media into a hepatic artery of a rabbit, and the CT image of the liver confirmed that the beads were visible in vivo. Furthermore, the beads before and after the surface modification with gelatin molecules were immersed in phosphate-buffered physiological saline (PBS) or in 1 mg/ml of lipase/PBS solution at 37°C to analyze degradability by measuring the weight loss. It was found that the degradation of the beads was significantly promoted by lipase, and that the gelatin molecules grafted on the bead surface did not prevent the degradability. It was, therefore, concluded that the Lipiodol/PCL bead obtained in this study was a promising candidate for new DEB, and that the surface modification of the beads by air plasma was useful to induce the mixture of oil and polymer.

production of active species (e.g. O$_2$, NO, NO$_2$, and OH) in the gas and consequently the PAW properties can be controlled by the discharge regime and gas flow and liquid-flow parameters. Low power air corona discharge are dominated by O$_2$ production which enhanced the biocidal effects. In the higher power TS, dominant gaseous products are NO$_2$, that lead to significant NO$_2$ and NO$_3$ in the PAW and practically no O$_2$. Both discharges produce H$_2$O$_2$. The antibacterial action is then mainly due to the synergy of H$_2$O$_2$, NO$_2$ and acidic milieu (via ONOO$^-$ formation) and typically decays in time within several hours post plasma activation, depending on temperature and pH [1,2]. We use UV-VIS colorimetric and fluorescence methods for the analysis of RONS in the PAW.

PAW produced by TS air discharge has been tested for agriculture applications, such as enhanced plant growth (lettuce, radish, tomato, wheat) or seed germination rate. Testing various medical applications of PAW or plasma activated media in dentistry (periodontal biofilms, endodontics), wound disinfection, urinary tract infections, or cancer cells are under way.

In a similar concept, TS air discharge was successfully demonstrated to induce antimicrobial effects in fresh fruit juices to extend their shelf lifetime without thermal pasteurization and without reducing their composition and nutrition/vitamin qualities. Potential effects of cold plasma on chemical changes of pH, degradation of organic acids, polyphenols, sugars) and sensory juice properties (color, taste) were carefully tested and it was shown that the juice quality was not significantly affected.

Innovative Agricultural Productivity Improvement Using Atmospheric Pressure Plasmas Kazunori Koga and Masaharu Shiratani; Kyushu Univ, Fukuoka, Japan.

Seeking for low energy consumption and high productivity processes for biomass and harvest is an important topic on agriculture. The conventional improvement methods of the agricultural productivity are irrigation, fertilization, and crop protection. Atmospheric pressure nonthermal plasmas can contribute to such methods by various ways such as sterilization, fertilization, water treatment and purification, soil treatment, seed treatment, storage improvement, insecticide, pre-harvest treatment, and post-harvest treatment. Nonthermal atmospheric plasmas are attractive for agricultural applications because they provide a large amount of reactive oxygen species (ROSs) and reactive nitrogen species (RNSs) with a little thermal damage to plants, crops, and fruits [1-8]. So far, we developed a scalable dielectric barrier discharge (DBD) device [5]. Using the device, we found that plasma-irradiated seeds of Arabidopsis thaliana show 11% reduction in a first harvest period from sowing and 56% increase in seed yield [1]. Plasma irradiated seeds of Sorghum, which is a strong candidate of biomass plants to produce ethanol [9], show 74 % increase in the volume of the plant. The energy consumption of 4.7MJ/ha for plasma irradiation corresponds to only 0.14% of 3.3 GJ/ha for cultivation and harvesting. The energy gain by plasma irradiation is 43.2 GJ/ha, in other words, the energy leverage is a quite high value of 1x104. Thus, atmospheric pressure nonthermal plasma offers an innovative agricultural productivity enhancement method with a high impact on our society.

Optical Diagnostics of Atmospheric-Pressure Microwave-Excited Plasma Jets Jaeho Kim and Hajime Sakakita; National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Non-equilibrium air plasmas at atmospheric pressure have been attracting special attentions for practical applications in various industrial fields including sterilization, decontamination, pollution control, surface materials processing, aerodynamics, high-speed combustion, microwave propagating, and lighting discharge control. Recently, their medical applications such as blood coagulation, bleeding control, and wound healing have been also reported [1-6]. Natural air is a mixture of gases including N$_2$, O$_2$, Ar, CO$_2$, H$_2$O, and so on. Air plasmas can provide molecular radicals such as OH, NO, CN, atomic radicals such as H, O, N, and other active species.

In this work, we have developed a minimalized microwave-exited plasma source using a 2.45 GHz magnetron source. The plasma source produces stable air plasma jets even at atmospheric-pressure. We have considered their materials processing applications as well as biological and medical applications. Optical diagnostics were carried to better understand the fundamental properties of the plasma jets for the applications using an optical emission spectroscopy. The kinds of air plasma-induced radicals were identified with a variety of operation conditions. Temperature properties of a plasma jet were also investigated by measuring rotational temperatures and vibrational temperatures of nitrogen molecules. In the conference, we will present these experimental results.

Bioinspired Wet/Dry Adhesion for Bioelectronics
Changhyun Pang1, 2; 1School of Chemical Engineering, Sungkyunkwan University, Suwon-si, Korea (the Republic of); 2Advanced Institute of Nanotechnology (SAINT), Sungkyunkwan University, Suwon, Korea (the Republic of).

Recently, extraordinary performances of natural creatures living in various conditions have been explored to understand their reversible dry/wet adhesion, including gecko feet, insect secretion, mosquito needles or endoparasitic worm’s proboscis, octopus suction cups, and slug’s footpad with viscous mucus. Extensive studies on the adhesive properties of such animal skins have revealed various multiscale architectures inducing various physical interactions. The attachment phenomena of various hierarchical architectures found in nature have extensively drawn attention for developing highly biocompatible adhesive on skin or wet inner organs without any chemical glue. Structural adhesive systems have become important to address the issues of human-machine interactions by smart outer/inner organ-attachable devices for diagnosis and therapy. Breakthroughs in flexible and conductive materials have accentuated the development of wearable or organ-attachable bioelectronics for stable biosignal monitoring and drug delivery. For such medical applications, the devices need to manifest conformal contact on human skin even under dynamic movements, as well as repeatable, long-term attachment without skin irritations or chemical contaminations. Here, we investigated an artificial reversible wet/dry adhesion systems biologically inspired by the suction cups of octopi and amphibian’s pad. Our biologically inspired architectures exhibit strong, reversible, highly repeatable adhesion to silicon wafers, glass, and rough skin surfaces under various conditions. Applying these bioinspired architectures to interfacial adhesive layers can attribute to developing skin-attachable or implantable bioelectronics for health diagnosis, controlled drug therapeutics, and achieving multifunctional integrated devices for ubiquitous-healthcare systems.

Nanocellulose Printed Circuit Boards for Human Monitoring
Jonathan Yuen1, Dan Zabetakis1, Lisa Shriver-Lake1, Md Qumrul Hasan2, David A. Stenger1, Scott A. Walper1 and Gymama Slaughter2; 1Naval Research Laboratory, Washington, District of Columbia, United States; 2Computer Science and Electrical Engineering, University of Maryland, Baltimore County, Baltimore, Maryland, United States.

Flexible and ultrathin substrates supporting microelectronic components have the potential to spur the development of pervasive healthcare and the internet of things by providing sensors and bioelectronics that can provide seamless and imperceivable integration. We will describe our ongoing work to develop sensing electronics on microns-thin bacterial nanocellulose for human monitoring applications. The porosity and hydrophobicity of nanocellulose sheets offer advantages that typical plastics cannot provide, such wicking of analytes and absorption of inks. We have developed a printing method to form nanocellulose printed circuit boards (PCBs), and created a simple low temperature soldering process to form circuit structures using standard surface-mount components on our nanocellulose PCBs. This has been used to create nanocellulose decals that measure human body temperature and perform pulse oximetry. We have also developed self-powered electronics for sensing of bioanlytes, such as glucose. For all applications, the fabrication processes are solution-based and requires only ambient processing, and therefore simple, potentially low-cost, and can be aimed for a wide range of applications.

8:30 AM BM07.01.03
Intrinsically Stretchable Polymer Semiconductors and Electronics as an Emerging Platform for Bioelectronics
Sihong Wang; Institute for Molecular
The vast amount of biological mysteries and biomedical challenges faced by human provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, the main bottlenecks are the huge mechanical mismatch between the current form of rigid electronics and the soft biological tissues.

In this talk, I will first describe a new form of electronics with skin-like softness and stretchability, which is built upon a new class of intrinsically stretchable polymer materials and a new set of fabrication technology. As the core material basis, intrinsically stretchable polymer semiconductors have been developed through the physical engineering of polymer chain dynamics and crystallization based on the nanoconfinement effect. This fundamentally-new and universally-applicable methodology enables conjugated polymers to possess both high electrical-performance and extraordinary stretchability [1]. Then, proceeding towards building electronics with this new class of polymer materials, the first polymer-applicable fabrication platform has been designed for large-scale intrinsically stretchable transistor arrays. [2] As a whole, these renovations in the material basis and technology foundation have led to the realization of circuit-level functionalities for the processing of biological signals, with unprecedented mechanical deformability and skin-conformability. Equipping electronics with human-compatible form-factors has opened a new paradigm for wearable and implantable bio-electronic tools for biomedical studies, personal healthcare, medical diagnosis and therapeutics. [3]

BM07.01.06
Human Inspired Bio-Electronic Sensor Skins Benjamin C. Tee1, 2, 3; 1Materials Science and Engineering, National University of Singapore, Singapore, Singapore; 2Biomedical Institute for Global Health Research and Technology, National University of Singapore, Singapore, Singapore; 3Institute of Materials Research and Engineering, Agency for Science Technology and Research Singapore, Singapore, Singapore.

Human sensory organs such as the skin have evolved to have excellent sensing performance and ultra-robustness. Electronic versions of skin have witnessed tremendous interest and development over the last decade. Functional soft, flexible and stretchable materials are crucial to the continued evolution of skin-like sensor applications in emerging robotic systems, new human-machine interfaces and life-like prostheses.

Here, I will discuss our recent work in next generation technologies for bio-electronic skins using an integrated hybrid materials approach that synergizes the best qualities of organic and inorganic materials. For example, recent developments in self-healing polymeric systems have propelled the exciting notion that electronic systems can repair themselves when damaged. Bio-inspired digitization of analog signals have also enabled us to develop artificial mechanos-receptors that optically interfaces with neurons. These sensor and materials technologies would be extremely applicable in an increasingly advanced cybernetic and Artificial Intelligence (AI) robotics future.

BM07.01.05
Fully Printed All-Polymer Tattoo/Textile Electronics for Electromyography Eloise Bihar1, Timothee Robert2, Jozina De Graaf2, Mohamed Saadaoui3, Esma Ismailova4, George G. Malliaras4, Khaled Salama1 and Sahika Inal5; 1King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2Aix Marseille Université, Marseille, France; 3École des Mines de Saint Etienne, Gardanne, France; 4University of Cambridge, Cambridge, United Kingdom.

Driven by the ever-growing needs for developing portable, easy-to-use, noninvasive diagnostic tools, biomedical sensors that can be integrated on textiles or even directly on human skin have come to fruition. Wearable sensor technologies that seamlessly interface electronics with human skin can be especially promising for detecting a wealth of biologically relevant signals ranging from neuro-muscular activity, to electrophysiology, even to metabolite profiles.

In this work, we present a simple and low cost platform fabricated on a tattoo paper used for on-skin electromyography (EMG) measurements. The electrodes comprising the conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) are directly inkjet-printed on the tattoo paper. Addressing the integration challenge common for stretchable electronic devices, we connect the tattoo electrodes to the acquisition system through a textile in the form of a wristband comprising of printed PEDOT:PSS contacts. While the textile wristband conforms around the “tattooed” skin, it enables a reliable contact with the electrodes beneath due to its conformability around the limb. We show that this tattoo/textile electronics system, which does not rely on gels or expensive metallic materials, is able to detect the biceps activity of the arm during muscle contraction for a period of seven hours, with comparable performance to conventional wet biopotential electrodes. Combining the tattoo electronics with the electronic system, which does not rely on gels or expensive metallic materials, is able to detect the biceps activity of the arm during muscle contraction for a period of seven hours, with comparable performance to conventional wet biopotential electrodes.

BM07.01.06
Fabrication of Fabric Biomedical Electrode Array with Printable Electronic Ink and Hot-Melt Film for Electromyography Seiichi Takamatsu and Toshihiro Itoh; The University of Tokyo, Kashiwa City, Japan.

We have developed fabric biomedical electrode array where silver paste, conductive polymer and ionic liquid gel are printed and insulation layers are formed with hot melt film on the fabric substrate. Recently, wearable electronic devices such as Microsoft Hololens, google glass, sportband, or other tools have been developed and commercialized for human healthcare monitoring and information tools. Among wearable electronic devices, wearable ECG or EMG electrodes are promising for human motion sensing tools. Especially for monitoring human hand or foot motion sensing, the biomedical electrode array which is made of fabric is necessary.

To make biomedical electrodes array, new fabrication process of fabric multilayer electrodes which consists of biomedical electrode parts to contact human skin and the wiring parts from biomedical electrodes parts to the amplifiers are required. Previous study (S. Takamatsu et al., "Direct patterning of organic conductors on knitted textiles for long-term electrocardiography," Scientific Reports, vol. 5, 15003(7pp), Oct 2015.) reports single layer fabric electrodes, but the multilayer electrodes has not been fabricated on the fabric and the biomedical electrode array has not been achieved. The most difficult fabrication
The developed fabrication process of fabric biomedical electrode array with printable electronic ink and hot-melt film for Electromyography is following and can combine several layers of functional fabric and films.

1. Patterned urethane film is attached on the knit fabric with hot melt film. 2. Laser cut hot melt film is placed on the electrode and heated. 3. The patterned urethane film is attached on the knit fabric with hot melt film. 4. Conductive polymer of PEDOT PSS and ionic liquid gel is patterned on another knit fabric for making biomedical electrode part. 5. Wiring part fabric and biomedical electrode fabric are attached by hot melt film and glue. By using our process, the 2x5 array biomedical electrode which has 1cm² biomedical electrodes parts and 0.5 mm wide wiring can be successfully fabricated. The impedance between electrodes and human skin is less than 1 MOhm, which is useful for EMG monitoring. Thus, our process will useful for wearable multi array of EMG measurement.

9:45 AM BM07.01.07
Sub-300 nm Thin-Film Au/Parylene Dry Electrodes for Motion Artifact-Less sEMG and sECG Monitoring Robert A. Nawrocki1, 2, 3, Hanbit Jin1, Sunghoon Lee1, Tomoyuki Yokota1, Masaki Sekino1 and Takao Someya1, 4; 1Univ of Tokyo, Tokyo, Japan; 2Purdue University, West Lafayette, Indiana, United States; 3Birck Nanotechnology Center, West Lafayette, Indiana, United States; 4Thin-Film Device Laboratory & Center for Emergent Matter Science (CEMS), Wako, Japan.

Accurate, imperceptible and long-term monitoring of vital biopotential signals promises to revolutionize healthcare industry by shifting from costly and uncomfortable hospital visits to in-home usage. Currently available wearable electronics are typically rigid with non-conformal skin contact resulting in poor data quality, necessitating the integration of such bioelectronics [1] directly onto the skin [2]. Increasing the conformity of the artificial electronic skin to the soft, irregular and stretchable human skin typically results in improved signal quality and user comfort [3].

We report on the fabrication of self-adhesive and conformable to highly irregular three-dimensional soft surfaces, sub-300 nm thin dry electrodes that produce biopotential (sEMG and sECG) recordings of excellent quality (SNR). The electrodes are based on thermally evaporated thin film (100 nm) of Au, sandwiched between two layers (100 nm each) of CVD-deposited biocompatible parylene (parylene/Au/parylene). They are fabricated on glass substrates, with fluorinated polymer (85 nm) and poly(vinyl alcohol) (PVA, 5 µm) sacrificial layers used for delamination and ease of handling. Parylene is etched away at the skin-interface side, allowing for direct Au contact with the skin. Following delamination, electrodes are placed on pre-stretched human skin and sprayed with H2O to remove PVA, forming a skin/Au/parylene structure. The skin is then dried and relaxed, with the ultra-thin film conforming to the skin grooves via van der Waals forces [4], without any additional adhesives.

These simple-to-fabricate and use, ultra-thin sensors show single-day electrical and mechanical stability of up to ten hours. Their bending stiffness was calculated to be comparable to stratum corneum, the uppermost layer of human skin, at ~0.33 pN/m², which is over two orders of magnitude lower than the bending stiffness of a 3.0 µm thick sensor. Compared with the thicker sensor, its impedance also decreased by almost two orders of magnitude. Laminated on a pre-stretched elastomer, the sensor forms wrinkles with a period of 17 µm and amplitude of 4 µm, agreeing with theoretical calculations.

In contrast to wet adhesive Ag/AgCl electrode, with skin vibrations of up to ~15 µm, the sensor demonstrates motion artifact-less sEMG monitoring. Additional impedance and sEMG measurements reveal that the decrease of impedance, as well as the motion artifact-less operation, is likely due to improved skin adhesion of the sub-300 nm thin sensor.

With compatible fabrication to our previously demonstrated sub-300 nm thin electronics [5], this demonstrates a path for integration of skin-laminated systems consisting of sensors and electronics.

Multifunctional Silk Adhesive for Epidermal Electronics Ji-Won Seo, Hyojung Kim and Hyunjoo J. Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

In order to improve the signal accuracy and long-term monitoring of electronics on biological skin, it is essential to achieve a conformal and robustly adhered electronics/biological skin interface. Here, we suggest a biocompatible calcium (Ca)-modified silk adhesive for robust epidermal electronics on biological skin. At optimized weight ratio of silk:CaCl₂ of 70:30, the silk adhesive shows strong adhesion force (> 600 N/m) through enhanced mechanical interlocking at interface. The physical mechanism facilitates a high adhesion on various substrates and a reusability of silk adhesive. Moreover, a water-degradability of silk adhesive shows the easy detachment without any high external force. With the multifunctional characteristics such as reusability, biocompatibility, and water-degradability, we fabricate the practical epidermal electronics: strain sensor, touch sensor, and long-term drug delivery system to demonstrate the potential of the proposed silk adhesive.

10:45 AM BM07.01.09
Deformable Electronic Materials for Two-Way Communication with Biological Systems Darren J. Lipomi; University of California, San Diego, La Jolla, California, United States.

The goal of this project is to create a class of electronic materials that can measure signals and interface with the nervous system for two-way communication with biological systems. The project is exploring two classes of materials. (1) Metallic nanosilands on single-layer graphene for cellular electrophysiology and wearable sensors. We have used these materials to measure the forces produced by the contractions of cardiomyocytes using a piezoresistive mechanism. Separately, we have developed orthogonal methods of stimulating myoblast cells electrically while measuring the contractions optically (a modality we nicknamed as “piezoplasmic”). We have also used these sensors to measure the swallowing activity of head-and-neck cancer patients who have received radiation therapy and are at risk of dysphagia arising from fibrosis of the swallowing muscles. The combination of strain sensing, surface electromyography, and machine learning can be used to measure the degree of dysphagia. (2) We have developed ionically conductive
organogels for haptic feedback. Medical haptic technology has myriad potential applications, from robotic surgery and surgical training, to tactile therapy for premature infants and patients with neurological impairment.

**11:00 AM • BM07.01.10**

**UltraSoft, Bio-Compatible Electronic Systems for Neuroscience** Tsuboshi Sekitani, Osaka University, Osaka, Japan.

We present an implantable sheet-type flexible electronic sensor system for long-term simultaneous monitoring of an electrocorticogram (ECoG) from the brain surface and local field potential (LFP) from the deep brain. UltraSoft gel electrodes provide a minimally invasive interface consisting of highly conductive nano-conductive materials including Ag-based nanowires, thermoplastic polymers, and bio-compatible gels. The gel composite shows conductivity greater than 10,000 S/cm and can be stretched more than 100% without any reduction to its electrical and mechanical performance. Hence, it can be stretched across arbitrarily curved surfaces, including the ultra-soft brain surface.

By integrating ultraSoft gel electrodes, an ultraflexible amplifier, and a wireless Si-LSI platform with a thin-film battery, we intend to demonstrate the applications of long-term implantable wireless sheet sensors, including 64-channel sheet-type electric potential monitoring systems. This wireless system with soft gel electrodes can measure biological signals of less than 1 µV. Taking full advantage of this system, simultaneous signals from the cerebral cortex in the ECoG and LFP have been wirelessly measured in animal experiments including non-human primates for over a month. Long-term bio-compatibility, electrical performance, and mechanical stretchability and durability are discussed for the integration of nanomaterials and processes and wireless low-noise sheet-type systems.

This research is partially supported by the Brain Mapping by Integrated Neurotechnologies for Disease Studies (Brain/MINDS) from Japan Agency for Medical Research and development,AMED.

**11:30 AM BM07.01.11**

**Flexible Biosensors for Non-Invasive Medical Diagnostics** Agostino Romeo¹, Paul Eduardo David Soto Rodriguez², Ana Moya², ³, Gemma Gabriel², ³, Rosa Villa², ³, Rafael Artuch², ³ and Samuel Sanchez², ³, ¹Institute of Bioengineering of Catalonia, Barcelona, Barcelona, Spain; ²National Centre of Microelectronics - Microelectronics Institute of Barcelona, Barcelona, Barcelona, Spain; ³Research Networking Center in Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN), Barcelona, Spain; ⁴Instituto Carlos de Recerca i Estudis Avançats (ICREA), Barcelona, Spain; ⁵CIBER-ER (Biomedical Network Research Center for Rare Diseases), Instituto de Salud Carlos III, Madrid, Spain; ⁶Laboratory of Hereditary Metabolic Diseases, Hospital Sant Joan de Déu, Barcelona, Spain.

In the last few decades the quality of life has significantly improved due to the achievements of biomedical technology. Innovative healthcare solutions contributed to these advances by decreasing costs and making health assessment easier and more accessible. Versatile bioelectronic sensors targeted to health biomarkers and bioanalytes (metal ions, proteins, amino acids, glucose, lactate, etc.) can non-invasively monitor the health status of the user by analyzing external body fluids (sweat, saliva, tear fluid) alternative to blood.[1,2] On-demand biosensing is envisaged due to the versatility of sensing platforms that can adapt to specific needs in terms of target biomarkers and health issues to monitor. To this regard, several recognition systems, including antibodies, enzymes, and inorganic nanomaterials can be used to modify the sensors to achieve high selectivity towards target analytes. In this scenario, recent advances in microfabrication, sensor technologies and data transmission led to the developments of point-of-care (PoC) diagnostics.

Here we present few examples of biosensors for painless and on-demand self-assessment of health conditions. In particular, we describe a non-invasive electrochemical sensor for the non-enzymatic analysis of tear glucose.[3] Electrochemical sensing is chosen among other types of transduction because it is well suited for simple, rapid, and cost-effective personalized medicine devices. Electrodes are fabricated on soft and flexible materials using inkjet printing and then modified with CuO microparticles (CuO-µPs) to carry out non-enzymatic detection of glucose. This detection mechanism is based on the CuO-catalyzed electro-oxidation of glucose in alkaline environment, due to the electrochemical conversion of CuO into strong oxidizing Cu(II) species such as CuOOH or Cu(OH)₄⁻. Glucose detection is achieved by CA, with an excellent linearity observed in the 3–700 µM range, matching typical glucose levels in tears. A sensitivity of 850 µA mM⁻¹cm⁻² and a limit of detection (LOD) of 2.99 µM are calculated. This sensor shows good selectivity, reproducibility, and life-time, resulting in a reliable tool for painless and non-invasive self-assessment of diabetes, as confirmed by tests on tear samples.

Personalized and non-invasive sensing technologies allow to easily and frequently monitor the health status of an individual as often as needed. This helps make early-stage detection simpler and more convenient, thus enhancing the efficacy of therapeutic treatments. Rapid and cheap PoC diagnostics also allows improving the life style of patients, by interfering in low or negligible extent to their daily activities.

**Highly Durable, Ultrasensitive Nanoscale Crack Based Mechano-Sensor for Bio-Signal Monitoring Inspired by Spider’s Sensory Organs** Byeonghak Park¹, Daeshik Kang¹ and Tae-il Kim¹; ¹Sungkyunkwan Univ, Suwon, Korea (the Republic of); ²Ajou University, Suwon, Korea (the Republic of).

With increasing demand for the detection of delicate bio-signals for medical electronics, the Internet of Things (IoT), E-skin and flexible integrated circuit (IC) devices, an enhancement in sensitivity has become a major issue in flexible mechanosensors, however, overcoming the limited sensitivity remains problematic. Here, we introduce mechanosensors inspired by spiders having an ultrasensitivity, durability. For ultrasensitivity and durability, we considered the geometrical effects in cracks and self-healable polymers. By controlling crack depth by simple propagating process, the sensitivity of our sensor shows ~15,000 in 2% strain, which is the world best sensitivity value. Due to the high sensitivity, the signal-to-noise-ratio is 6 times higher than before, up to ~35 so that it can be used in sensing human voice clearly. Also, self-healable polymer helps to recover the crack gaps after 25,000 cycles. We introduce the possibility of semi-permanent uses over 1,000,000 cycles in our sensors. The spider inspired sensory system with high sensitivity and durability would provide versatile novel applications such as E-skins, devices for medical applications, and IoT applications etc.

Interacting Ion and Electron Currents

Paul Meredith; Swansea University, Swansea, United Kingdom.

Ionic and electronic conduction mechanisms are underpinned by fundamentally different physics [1]. For example, ions diffuse through a conducting matrix via centre of mass transport that can be described by classical processes. Electrons and holes are quantum mechanical entities characterised by delocalisation, tunnelling or hopping. These fundamental differences impose radically different length-and-time-scales on ionic and electronic conduction – and generally speaking the solid-state physics of ions and electrons have remained two very different fields requiring different skill sets [2]. However, bioelectronics, where a central challenge is the transduction between ion and electron currents, is a scientific collision point between the two worlds.

In my talk I will summarise the major differences between ionic and electronic solid state electrical conduction. I will also describe methods that can probe the relevant time-and-length scales in order to identify and disentangle the native signatures of each carrier type [3, 4]. A number of model systems and devices will be exemplified that allow the study of ion and electron conduction processes, and indeed provide a means to test prototypical concepts in transduction and bioelectronic logic interfaces [5, 6].

The Device Physics of Organic Electrolytic Photocapacitors—From the Nanoscale to the Single Cell Level

Vedran Derek1, Marie Jakosova1, Tobias Cramer2, Marek Havlicek3, David Rand4, Yael Hanein5, Daniel Simon5, Magnus Berggren6, Fredrik Elinder4 and Erik D. Glowacki5; 1Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Norrköping, Sweden; 2Department of Physics and Astronomy, Università di Bologna, Bologna, Italy; 3Department of Nanometrology and Technical Length, Czech Metrology Institute, Brno, Czechia; 4School of Electrical Engineering, Tel Aviv University, Ramat-Aviv, Tel-Aviv, Israel; 5Department of Clinical and Experimental Medicine, Linköping University, Linköping, Sweden.

We have recently developed the organic electrolytic photocapacitor (OEPC), a nanoscale optoelectronic device for eliciting action potentials in neurons. Herein, we cover in detail the physical mechanisms behind the charge generation and dynamics of charging and capacitive coupling in these devices using optoelectronic/electrochemical measurements combined with simulation and modeling. Electrochemical impedance measurements allow corroboration of these models, and reveal the nature of photocapacitive and photofaradaic effects in the devices. Using scanning probe microscopy techniques, we have evaluated the mechanical properties of the nanocrystalline films, finding relatively low Young’s moduli in the range of 500 MPa. In order to take a reductive approach compared with previous measurements of neurons and electrolytic tissues, we have validated the performance of OEPCs using nonexcitable cells, *xenopus laevis* oocytes. We find rapid membrane potential changes in the range of tens to hundreds of millivolts are induced by OEPC devices, showing extremely effective capacitive coupling and explaining previous findings of action potential generation. The overall result of our work is a fully physical and mechanistic understanding of this novel device platform, and a roadmap for guiding future development.

2:15 PM BM07.02.03/EP05.02.03
The Design of Air Stable, Redox Active Conjugated Polymers and Their Applications in Accumulation Mode OECTs

Alexander Giovannitti1, Reem Rashid2, Jenny Nelson1, Iain McCulloch1 and Jonathan Rivnay2; 1Imperial College London, London, United Kingdom; 2Northwestern University, Chicago, Illinois, United States.

Organic electrochemical transistors (OECTs) are receiving a great deal of attention due to the ability to efficiently transduce biological signals. The working principle of OECTs relies on the modulation of the conductivity of an organic semiconductor, which can be modified by applying a potential at the gate electrode and driving electrochemical redox reactions in aqueous solution (doping/de-doping of the organic semiconductor). OECTs can either be operated in accumulation [7] or depletion mode [8] where the operation in accumulation mode has the advantage of lowering the operational voltage and therefore improve the power consumption of the device (device is in an off state rather than an on state when no gate voltage is applied). Recently, high performing OECT materials have been reported based on electron rich alkoxybithiophene copolymers which show low oxidation potentials in aqueous electrolytes and enable OECT operation at low voltages [9]. However, one drawback of these easily oxidizable polymers is that the copolymers can become oxidized by reactions with oxygen from ambient air. This result in the formation of p-doped polymers and superoxide anions (O2−) where the latter is a reactive radical and might cause harm to biological systems or degrade the organic semiconductor. As a result of this oxidation reaction, a constant gate voltage would need to be applied to keep the material in its neutral state (and the device off).

We will present the development of an air-stable conjugated polymers based on donor-acceptor type copolymer. The copolymer shows reversible redox reaction at potentials below 0.3 V vs Ag/AgCl. When exposed to aqueous ambient conditions, the polymer does not become oxidized. Long-term stability tests were carried out where devices were exposed to ambient conditions for more than 6 months with no sign of degradation. The polymer shows a good stability when charged with up to one hole per repeat unit (polaron) with transconductances in the range of 80 S/cm (at -0.7 V). This work demonstrate the importance of chemical design strategies for the development of accumulation mode OECT materials to mitigate reactions with oxygen in aqueous electrolytes and ambient conditions.

This talk will give an overview about our recent activities on electronic and ionic conductivity in conjugated and redox polymer thin films with different molecular architectures. Preparation of films is done either by electropolymerization or solution deposition followed by morphology tuning, e.g. by solvent vapor annealing.[1]

We are particularly interested in three-dimensional architectures based on branched monomers such as terthiophenes (3T) or triphenylamines (TPA). TPA redox moieties are useful to allow for electrochemical or chemical crosslinking of as-deposited films. Both, with TPA redox polymers[2] and with polymers which bear TPA as pending redox moieties of linear polythiophenes[3] we could perform successful crosslinking and simultaneous doping of polymer films. The films provide very high stabilities with high electronic conductivities as evidenced by cyclic voltammetry coupled with in-situ conductance measurements and four-probe measurements. In the case of 3T we have reported on homopolymer and copolymer films of 3T and ethylenedioxythiophene which allow polymer-analogous reactions to induce ionic functionalities, thereby creating branched conjugated polyelectrolyte films.[4],[5]

To get a better understanding on mixed conductivity in polymer films, we have recently performed a study on electronic and ionic conductivity of linear conjugated polyelectrolytes by impedance spectroscopy and dc-measurements.[6] The clear dependence of the conductivities as function of humidity and degree of doping will be discussed in the talk in more detail.

Soft Electronic and Ionic Neural Interfaces
Klas Tybrandt,1,2, Dion Khodagholy,1, Flurin Stauffer3 and Janos Vörös3; 1Department of Science and Technology, Linköping University, Norrköping, Sweden; 2Institute for Biomedical Engineering, ETH Zürich, Zurich, Switzerland; 3Department of Electrical Engineering, Columbia University, New York, New York, United States.

Two-way communication between electronics and neural tissue is key for advancing diagnosis and therapies for neurological diseases and disorders, as well as providing detailed information about brain signaling. Establishing such neural interfaces is a major challenge, as the tissue response to implants can have a detrimental effect on the signal quality and functionality of the implant. Also, electrical stimulation is inherently limited in its stimulation of neural tissue, in comparison to the sophisticated chemical signaling processes within biological tissue. Here, I present our efforts in addressing two critical technological aspects for the creation of versatile neural interfaces: the matching of mechanical properties of tissues and electronics, and the development of fast and low-leakage chemical interfaces. Soft electronic biomedical implants have a demanding set of requirements, including biocompatibility, mechanical and electromechanical properties, long-term stability and electrode performance. To meet these requirements, we have developed a high-performance, long-term stable soft and stretchable composite for neural electrodes. Based on this composite, high-density soft electrode grids were developed and implanted onto brain surface of rats. The electrodes provided high-quality recordings during three months of implantation. Next, I will outline our strategy for creating high-speed low-leakage chemical neural interfaces, by discussing the relationship between delivery delay and leakage, and then present an iontronic approach to achieve low leakage and small delay simultaneously.

4:30 PM BM07.02.07/EP05.02.07
Organic Electronics for Neuromorphic Computing
Yvoert van de Burgt; Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, Netherlands.

Neuromorphic computing could address the inherent limitations of conventional silicon technology in dedicated machine learning applications. Recent work on silicon-based asynchronous spiking neural networks and large crossbar-arrays of two-terminal memristive devices has led to the development of promising neuromorphic systems. However, delivering a parallel computation technology, capable of implementing compact and efficient artificial neural networks in hardware, remains a significant challenge. Organic electronic materials offer an attractive alternative to such systems and could provide neuromorphic devices with low-energy switching and excellent tunability, while being biocompatible and relatively inexpensive.

This talk describes state-of-the-art organic neuromorphic devices and provides an overview of the current challenges in the field and attempts to address them1. We demonstrate a novel concept based on an organic electrochemical transistor2 and show how some challenges in the field such as stability, linearity and state retention can be overcome2.

Furthermore, we investigate chemical doping mechanisms in the active material for improved material functionality and demonstrate that this device can be
entirely fabricated on flexible substrates, introducing neuromorphic computing to large-area flexible electronics and opening up possibilities in brain-machine interfacing and adaptive learning of artificial organs.

4:45 PM BM07.02.08/EP05.02.08
Anisotropic Conducting Polymer Films for Bioelectronics Patricia Iastrewska-Perfeci, Georgios Spyropoulos, Jennifer Gelinis and Dion Khodagholy; Columbia University, New York, New York, United States.

Anisotropic conductive films, which consist of electrically conductive particles dispersed in nonconductive media, are increasingly being applied to establish high-density electrical bonds between electronic boards and chips. However, current anisotropic composites utilize metallic particles, often nickel and epoxy-based media, that require high thermocompression energy for bonding. Therefore, they have limited applicability in thin-film, conformable, and plastic-based devices that are used in bioelectronic applications. Furthermore, these materials are not biocompatible, significantly limiting their use in biological systems. We hypothesized that replacing the metallic particles with conducting polymer particles combined with a biocompatible nonconducting matrix would address this limitation. We developed a novel anisotropic conducting polymer (ACP) consisting of poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) conducting polymer particles dispersed in a matrix of crosslinked chitosan (CS). To determine the permeability of PEDOT:PSS to CS, we characterized the resistances of thin CS-based films sandwiched with PEDOT:PSS and gold pads. We investigated the particle size, structure, density and distribution of pure PEDOT:PSS particles and PEDOT:PSS-coated CS particles. The anisotropy was defined by the ratio of horizontal and vertical impedance between interconnects. We benchmarked the anisotropy of the developed ACPs by geometrically varying an array of gold electrodes. The final ACP, which was created at 70°C with minimal pressure, yielded anisotropy of 10^5-10^6. The ACP was then used to maintain precise connections between a high density conformable implantable neural probe and back-end electronics. It enabled complete chronic in vivo implantation of these electronics with minimal encapsulation layers, highlighting applicability for use in bioelectronic and clinical devices

SESSION BM07.03: Neural Interfacing/Implantable Devices I

8:00 AM BM07.03.01
Toward Biocompatible and Degradable Electronics—A Comprehensive Material Approach Ashkan Shafighi, Elham Ghadiri, Kunzhao Li and Anthony Atala; 1 Institute for Regenerative Medicine, Wake Forest School of Medicine, Winston-Salem, North Carolina, United States; 2 Chemistry Department, Wake Forest University, Winston-Salem, North Carolina, United States; 3 Biology, Wake Forest University, Winston-Salem, North Carolina, United States.

Over the past 10 years, regenerative medicine has witnessed a significant technological and scientific advancement. For instance, numerous revolutionary progress in stem cell science as well as additive manufacturing, namely 3D printing, have opened up new horizons in research and brought them closer to reality than ever before. However, for more sophisticated indications, fabrication of biological structures such as human tissues and organs may require an optimized procedure to obtain the impeccable final product. Therefore, the need for biocompatible electronic devices is a focus of attention in academia and industry. Moreover, biodegradable electronic devices for healthcare applications can also produce a revolution in the electronics industry and reduce electronic waste products. Currently, thousands of tons of silicon that is used to manufacture computers, cell phones, and other devices are discarded into the environment annually. It is critical that such waste be curtailed. Here, we report a systematic investigation on finding biocompatible/degradable functional electronic materials. To address this aim two different approaches were employed: 1-study the electronic properties of biomaterials, 2- study the biocompatibility of functional electronic materials. Materials with energy band gap between 1 to 3 eV are categorized as semiconductors and bigger than 3 eV as insulators. Various biomaterials were sought in terms of energy band diagram. Most biomaterials showed energy band gap bigger than 3 eV confirming them as insulators, for example, fibrinogen, glycerol, and gelatin showed 3.54, 3.02, 3.0 eV. Meanwhile, a few biomaterials were found as semiconductors such as phenol red in the cell culture medium with 1.96 eV energy band gap. On the other hand, the biocompatibility of organic semiconductors, such as P3HT and PCBM for different cell types such as satellite cells were examined. The cells were exposed to the thin layer of films prepared with the organic materials, and essential biomarkers (Desmin and MF20) were used to determine the consequence effect on the cells, their functionality, proliferation, and differentiation. The outcomes of this research can be used to fabricate biocompatible/degradable electronic devices for medical applications.

8:15 AM BM07.03.02

Deciphering complex neural circuits relies on the developments of neural interface devices with good biocompatibility, mechanical compliance, high spatial resolution, and high quality recording. There has been significant development in neural interface devices in the past decades, mostly based on silicon and metal electrodes or contact printed film electrodes. More recently, thermally drawn polymer fibers have been utilized as neural recording probes which exhibit good flexibility and biocompatibility. However, due to the low conductivity of conventional polymer electrodes, the size of a polymer fiber probe is typically much larger compared to the size of a single neuron in order to have the overall impedance fall in the recordable range, resulting in a poor spatial resolution of these probes. Therefore, it is of great importance to reduce the impedance of the polymer electrode while maintaining the miniaturized footprint in order to increase the spatial resolution and minimize the brain damage. In this study, we deposited metallic nanostructures on the tip of the polymer fiber probe to enhance the electrical properties as well as the electrophysiological recording performance. Soft nanolithography patterning technique was utilized to create dense vertical 3D nanopillar nanoelectrodes on the small area of the flexible polymer fiber tips via gold nanohole array masks. Because of the large surface area of the nanopillar nanoelectrode structure, the resulting impedance of the modified electrode has been reduced to be able to capture neural signals. The power density of local field potential (LFP) from both the modified and unmodified electrode showed the better recording performance of the modified one. Finally, we evaluated these nanoelectrode integrated polymer fiber probes in terms of chronic recording and long term tissue response. These results show that nanoelectrode-based surface modification can significantly reduce the impedance of polymer electrodes, thus increase the spatial resolution and improve the electrophysiology recording performance of polymer fiber probes.
As our understanding of the brain’s physiology and pathology progresses, increasingly sophisticated materials and technologies are required to advance discoveries in systems neuroscience and develop more effective diagnostics and treatments for neuropsychiatric disease. Localizing brain signals may assist with tissue resection and intervention strategies in patients with such diseases. Precise localization requires large and continuous coverage of cortical areas with high-density recording from populations of neurons while minimizing invasiveness and adverse events. We describe a large-scale, high-density, organic electronic–based, conformable neural interface device (NeuroGrid) with embedded integrated circuitry capable of simultaneously recording local field potentials (LFPs) and action potentials from the cortical surface. We demonstrate the feasibility and safety recording with such devices in anesthetized and awake subjects. Highly localized and traveling physiological and pathological LFP patterns were recorded, and correlated neural firing provided evidence about their local generation. Application of NeuroGrid technology to disorders such as epilepsy may improve diagnostic precision and therapeutic outcomes while reducing complications associated with invasive electrodes conventionally used to acquire high-resolution and spiking data.

Adhesion quality and biocompatibility are the main obstacles to a successful use of conducting polymers coatings on metal microelectrodes for recording and stimulation. Such microelectrodes have very small dimensions, resulting in a high impedance. One way to address this problem is to deposit a conducting polymer, PEDOT, on their electroactive area to lower the impedance and reduce the foreign body reaction [1]. However, the small size of such microelectrodes and the poor adhesion of conducting polymers on most inorganic substrates remain practical difficulties for large scale production. In our recent experiments using electrochemical polymerization, we explored the influence of different solvents (acetonitrile, propylene carbonate) [2] and electropolymerisation methods (potentiodynamic, galvanostatic, pulsed deposition) on the adhesion of an electropolymerized thin layer of PEDOT:BF4 on platinum electrodes. We also investigated the use of a diazonium salt as an anchoring layer for PEDOT on platinum [3]. We evaluated the stability of our PEDOT-coated electrodes ex vivo by passive aging in physiological solutions and under repeated electrical stimulations, similar to those used for deep brain stimulation. Finally, we investigated in vivo aging to hopefully gain more insights on the stability of our PEDOT coating in contact with living tissues.

Graphene-Based Neural Interfaces for Probing Brain Activity Yichen Lu, Xin Liu and Duygu Kuzum; University of California, San Diego, La Jolla, California, United States.

The complexity of neural activities has challenged both neuroscience research and clinical practice for decades. Understanding neuronal dynamics and information processing performed by neural populations requires advanced technologies with high-resolution sensing and stimulation capability. Clinical neuromodulation therapies widely used for neurological disorders also depend on the ability to manipulate the dynamics of neural circuits. Conventional neural interfaces offering electrical, optical, or chemical signals have greatly advanced our understanding of neural functions, however, most of these technologies are based on a single functionality. Combining multiple functionalities in a single system has recently been pursued as an integrative approach in new neurotechnology development. Graphene has recently emerged as a neural interface material offering several outstanding properties, such as optical transparency, flexibility, high conductivity, functionalization and biocompatibility. The unique combination of these properties in a single material system makes graphene an attractive choice for multi-modal probing of neural activity. In this talk, I will present our recent work on graphene-based neural interfaces, highlight key applications, and finally discuss future directions and potential advances for graphene-based neurotechnologies in both basic neuroscience research and medical applications.
A soft, fully biocompatible, stretchable strain sensor device based on ultra-thin stretchable electronics is reported. The sensor is able to monitor stretch of the bladder wall, via a resistive strain sensing approach. The stretchable sensor is used to determine bladder stretch, and hence volume, without the need for complex and invasive surgical procedures used currently, enabling the development of new safer and cheaper treatment options for various urological conditions. Such instances where a means to monitor bladder stretch could be invaluable are for sufferers of overactive bladder syndrome (OAB), urinary incontinence or after spinal cord injury.

Thermally evaporated Cr/Au thin films (~150 nm) on compliant, stretchable polyurethane (PU) film (~50 μm), were deposited to produce resistive sensors. The sensors were patterned into a ‘dogbone’ design by laser patterning, with sensor W and L dimensions on the mm scale. The sensors display a linear response as a function of strain from 0 to 50 %, and as sensor length increases, sensor sensitivity as a function of strain increases. We show that the sensitivity is highest for L = 6 mm, at 3.18 Ω-%-strain, which is around 15 times higher than the sensitivity for L = 2 mm, at 0.21 Ω-%-strain. Furthermore, cycling tests performed on sensors of various length reveal that the devices display good stability, with virtually no hysteresis.

The highest sensitivity sensors were subsequently tested in vitro on an isolated pig bladder. The sensors were attached onto the external wall of the bladder using a biocompatible hydrogel adhesive. The bladder was repeatedly filled and emptied using a syringe system designed to mimic natural bladder behaviour. As bladder volume changes, the sensor changes resistance as a function of stretch, and displays very good repeatability over several bladder filling/emptying cycles. We found a maximum sensitivity of 0.1 Ω/ml for the most sensitive device. Our sensors pave the way towards completely implantable health monitoring systems of the future.
population ages. Response to medications for these conditions has plateaued, paving the way for a revolution in implantable devices as the next wave of effective treatments for these “brain network disorders.” Key to developing these new devices are advances in computation, batteries, sensors and closed loop algorithms. New and more versatile materials is one of the main requirements and drivers of innovation in new medical devices and technologies. In this lecture I will outline major applications in the area of neurodevices/brain computer interfaces, present unmet needs, and discuss the path to clinically translate innovations from the laboratory to patients. I will give examples from our own research and other labs on this path, touch on common failure modes and novel tools for collaboration, bringing engineers, clinicians and industry together to advance clinical care.

SESSION BM07.04: Neural Interfacing/Implantable Devices II
Session Chairs: Dion Khodagholy and Stephanie Lacour
Tuesday Afternoon, November 27, 2018
Sheraton, 2nd Floor, Constitution B

1:30 PM BM07.04.01
Highly Stable PEDOT-CNT Nanotube as Neural Electrode Coating Nuan Chen1, 2, Baiwen Luo2, Nitish Thakor2 and Seeram Ramakrishna1; 1Department of Mechanical Engineering, National University of Singapore, Singapore, Singapore; 2Singapore Institute for Neurotechnology (SINAPSE), National University of Singapore, Singapore, Singapore.

During the past decades, neural electrodes have been developed as promising interface technology for direct communication with the neural tissues for diagnosis of the nervous disorders and treatment of the injury. Considering the significant material mismatch between the external implant and native tissue, a thin coating is employed on the electrode sites as an intermediate layer to bridge the difference. However, great challenges still exist regarding the long-term performance of the electrode coating in vivo.

In this study, a tubular electrode coating made of poly(3,4-ethylenedioxythiophene) (PEDOT) and carbon nanotube (CNT) was designed, targeted to long-term neural recording. The PEDOT-CNT nanotube coating was fabricated and showed compatibility with flexible polyimide electrode. The coating exhibited a 3D network-like structure made of hollow tube with an outer diameter of ~70nm and wall thickness of ~90nm. The electroactivity of the PEDOT-CNT coating was investigated using electrochemical impedance spectroscopy and cyclic voltammetry. The coated electrode sites showed significantly decreased impedance and increase charge storage capacity compared to bare site, which would allow more charge transfer at the interface and increase the sensitivity during neural recording. To test the mechanical adhesion of the PEDOT-CNT nanotube coating, ultrasonic treatment was employed in the study. The PEDOT-CNT nanotube could sustain 20min sonication with less than 20% delamination area while the PEDOT-PSS nanotube showed more than 60% delamination area after 5min treatment. The incorporation of CNT significantly reinforced the nanotube structure and improved the mechanical durability against sonication which would address the delamination issue of PEDOT coating and support chronic recording. We have also studies the different deposition condition and their effects on the morphology, electrical property and mechanical property of the coating. In vitro culture of neurons showed positive neuron attachment and neurite extension on PEDOT-CNT nanotube immobilized with poly-lysine and laminin.

1:45 PM BM07.04.02
Conducting Polymers for Stretchable and Healable Electronics Fabio Cicoira1, Yang Li1, Shinning Zhang2, Floriane Miquet-Westphal3 and Leslie Liu4; 1Ecole Polytechnique de Montreal, Montreal, Quebec, Canada; 2University of California, Los Angeles, Los Angeles, California, United States.

Organic electronic devices, apart from consumer applications, are presently paving the path for key applications at the interface between electronics and biology. In such applications, organic polymers are very attractive candidates, due to their distinct properties of mechanical flexibility, self-healing and mixed conduction.

My group investigated the processing conditions leading to high electrical conductivity, long-term stability in aqueous media as well as robust mechanical properties of the conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) and polystyrene sulfonate (PEDOT:PSS) [1-3]. We have demonstrated that stretchable PEDOT:PSS films can be achieved by adding a fluorosurfactant to the film processing mixture and by pre-stretching the substrate during film deposition. We have achieved patterning of organic materials on a wide range of substrates, using orthogonal lithography and pattern transfer [4-5]. Recently we have discovered that PEDOT:PSS films can be rapidly healed with water drops after being damaged with a sharp blade [6] or show autonomous self-healing if processed in presence of certain additives.

My talk will deal with processing, characterization and patterning of conducting polymer films and devices for flexible, stretchable and healable electronics. I will particularly focus on the strategies to achieve films with optimized electrical conductivity and mechanical properties, on unconventional micro patterning on flexible and stretchable substrates, on the different routes to achieve films stretchability and self-healing.

2:00 PM BM07.04.03
Multimodal Characterization of Soft Bioelectronics Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Geneva, Switzerland.

Soft bioelectronics incorporates all the functional attributes of conventional rigid electronics in formats that enable reversible mechanical loading and, in the case of implantables, performance under physiological conditions. Understanding the underlying mechanisms of stretchable materials and establishing the performance boundaries of such devices under the multiple operation conditions are fundamental to research efforts in the field. The biomimetic context also imposes a challenging experimental environment that is difficult to replicate or predict. There is an unmet need for experimental set-ups that combine multiple modes of loading e.g. mechanical, thermal, electrical, biological, and provide real-time, concurrent probing of the devices.

This talk will describe our recent efforts in constructing multimodal experimental set-ups and establishing standardized tests and experiments that can clearly define the reliability and lifetime for soft bioelectronics. Using stretchable metallization integrated in wearable sensors and spinal implants as test vehicles for the new characterization platforms, we will report on failure modes, repeatability, robustness, and reliability. These metrics are often underestimated in academic research yet critical to advance the translation of soft bioelectronics.
Bioelectronics with Nanocarbons—From Transparent to Fuzzy Interfaces

2:30 PM BM07.04.04
Chronic and Acute Stress Hormone Monitoring/Stimulation in Adrenal Gland
Yiel Jae Shin¹, SungHyuk Sunwoo² and Tae-il Kim¹; Sungkyunkwan University, Suwon, Korea (the Republic of); ²Seoul National University, Seoul, Korea (the Republic of).

Living organisms mainly use nervous and endocrine systems to control the body and maintain homeostasis independently. Endocrinal signal based on the flow of special chemicals called hormone affects the body chronically and massively. When stress is applied to human body, hypothalamus releases corticotropin-releasing hormone (CRH) to the pituitary gland that generates adrenocorticotropic hormone (ACTH) which flows into the adrenal cortex, especially adrenal zona fasciculata (AZF) cell in adrenal gland. The adrenal cortex then produces cortisol, a stress hormone that rebalances body functions and performances of neural and muscular system. However, repeated and chronic stress can cause malfunctions in cortisol releasing endocrine system. Chronic stress involves accumulation of excessive and unnecessary cortisol that eventually cause several diseases such as amnesia, depression, fatigue, anxiety. It is necessary to continuously monitor the cortisol concentration to prevent such diseases which caused by chronic stress. Recently, it was revealed that the electrophysiologic (EP) signal induced by ion flux through cellular membrane was responsible for hormone releasing process in connection endocrine organs. We assumed that accurate recording of electric signal representing physiological activities of endocrine cells could be applied to characterize cortisol change. Here, we introduce a long lasting, implantable Anchor - like flexible probe that can be used to quantify relationship between cortisol releasing level and electrophysiologic (EP) signals from adrenal gland based on flexible EP sensors. This anchor – like probe penetrated through Adrenal Gland, which ensured minimal invasion to organs and stability, low impedance increment over 13 weeks. Through our research, we identified EP signal Frequency was increased in AZF cells, only induced by acute stress or ACTH injection. Thus, our team successfully determined activities of hormonal cells and relative change of cortisol hormone level under stress environment in in vivo animal model. Next, we hypothesized that electrical stimulation of surface of adrenal gland could improve or suppress activity of adrenal gland. We designed elastomer based, conformally attaching stretchable serpentine electrodes. It is known that cortisol secretion is also increased by not only stress but blood loss, therefore we extracted small doses of blood from inferior vena cava (IVC) of rat with every 5 minutes to suppress artificial hemorrhage. By comparing Cortisol concentration of Non - electrical stimulated rat with electrically stimulated showed us that high frequency electrical stimulation tend to suppress activity of AZF cell. However, low frequency electrical stimulation improved AZF cell activity, which showed higher cortisol concentration then standard cortisol concentration. This research of Adrenal gland could provide fundamental knowledge to medical applications such as stress regulator.

2:45 PM BM07.04.05
Design of Conductive Gel for Sensing Weak Biosignals with High S/N Ratio
Yuki Noda¹, Naomi Toyoshima¹, Teppei Araki¹,², Shusuke Yoshimoto¹, Takafumi Uemura¹,² and Tsyoshi Sekitan¹,²; ¹Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Japan; ²Advanced Photonics and Biosensing Open Innovation Laboratory, Suisa, Japan.

Conductive gel enabling precise measurement of weak electrical signals are desired for the detection of biomedial signals such as an electroencephalogram (EEG) or a fetal electrocardiogram (ECO). Since these signals are intrinsically weak less than 100 µV, the noise level has to be lowered to acquire signals with the high S/N. In general, one strategy for obtaining the high S/N ratio signal is to increase the electrode area to lower the contact resistance between skin and electrode or to shorten the length of the wiring to prevent invasion an external noise, however, we propose another option to detect signals with high quality by modifying gels on electrode. Here, we designed the biocompatible conductive gel to obtain weak EEG signals with the high S/N ratio by reducing the contact resistance and mains hum intensity.

The developed gels are based on Amylopectin contained in rice and NaCl. By just printing and heating the precursor solution on a noble metal, conductive gel can be fabricated. The impedance spectrum of gels shows almost frequency-independent characteristics through a range of 0.1 Hz to 100 kHz lower than 1kΩ. Hydrogen-bonded network of Amylopectin gives sufficiently strong adhesive force to the skin with its strength comparable to adhesive plasters. Other components enable to suppress mains hum that is one of the origin of lowering the S/N ratio of EEG signals. By combining the developed gels and the wireless measurement system, we successfully obtained EEG signals from forehead. As with Ten20 conductive paste that is commonly used to measure EEG signals in hospitals, the developed gels can also detect representative brain wave like alpha waves that appears at 10 Hz when eyes are closed. Additionally, the intensity of mains hum appeared between 50-60 Hz are effectively suppressed to about 50% against that of Ten20 conductive paste.

Bioelectronics with Nanocarbons—From Transparent to Fuzzy Interfaces
Tzahi Cohen-Karni², ¹; ¹Materials Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; ²Biomedical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

We focus on developing a new class of nanoscale materials and novel strategies for the investigation of biological entities at multiple length scales, from the molecular level to complex cellular networks. Our highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials. Recently, we have demonstrated highly controlled synthesis of 3D out-of-plane single- to few-layer fuzzy graphene (3DFG) on a Si nanowire (SiNW) mesh template. By varying graphene growth conditions, we control the size, density, and electrical properties of the NW templated 3DFG (NT-3DFG). This flexible synthesis inspires formation of complex hybrid-nanomaterials with tailored optical and electrical properties to be used in future applications such as biosensing, and bioelectronics. Currently, we target the limits of cell-device interfaces using out-of-plane grown 3DFG, aiming at electrical recordings with subcellular spatial resolution (~5μm) and jsec temporal resolution. Last, we have developed a unique transparent graphene-based electrical platform that enables concurrent electrical and optical investigation of ES-derived cardiomyocytes' intracellular processes and intercellular communication. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science, and open up the potential to seamlessly merge either nanomaterials-based platforms or unique nanosensor geometries and topologies with cells, fusing nonliving and living systems together.

Bioinspired Nanowire Devices Utilizing Perylene Diimides
Kuo-Yao Lin¹, Andrew Bartlett², Alon Gorodetsky² and Jason D. Slinker¹; ¹The University of Texas at Dallas, Richardson, Texas, United States; ²Chemical Engineering and Materials Science, The University of California-Irvine, Irvine, California, United States.

Despite remarkable examples of difficult-to-produce isolated molecular devices, the scalable nanomanufacturing of such electronics remains at a standoff due to fundamental roadblocks associated with the synthesis of large quantities of modular nanoscale circuit elements. We have introduced a methodology for rapid, scalable production and facile purification of nanowire devices. We have synthesized organic semiconductor moieties, perylene-3,4,9,10-tetracarboxylic diimides (PTCDIs), within DNA-like scaffolds, leveraging the rapid, efficient, and precise coupling afforded by traditional DNA bioconjugate chemistry. These DNA-inspired nanowires enable the self-assembly of active, nanoscale circuit elements at patterned electrodes. The
assembly and electrical performance of these arrayed devices have been characterized through scanning microscopy techniques and custom, automated electrical test equipment. Further characterization under controlled environmental and temperature conditions revealed absolute currents of fully well matched duplexes incorporating perylene units were enhanced by twofold over such nanowires incorporating two C-A mismatches and 4.4 fold over conventional DNA nanowires. Temperature dependence revealed a sharp current drop with temperature consistent with the dissociation of the modular duplex. Our unique and economically viable approach offers a new paradigm for the fabrication of nanoscale electronic circuits.

Ink-Jet Printed 3D-Microelectrode Arrays for Neuroelectronic Interfaces and Sensing Applications - Sourad Adly1, Leryo Grob1, Philipp Rinklin1, Sabine Zips1, Lennart Weiss1, Hideaki Yamamoto3, Ayumi Hirano-Iwata4, and Bernhard Wolfraum2; 1Neuroelectronics - Munich School of Bioengineering, Department of Electrical and Computer Engineering, Technical University of Munich, Garching, Germany; 2Institute of Complex Systems ICS-8, Forschungszentrum Jülich GmbH, Jülich, Germany; 3Advanced Institute for Materials Research, Tohoku University, Sendai, Japan; 4Research Institute of Electrical Communication, Tohoku University, Sendai, Japan.

Microelectrode arrays are used in a variety of sensing and stimulation applications including electrochemical biosensor platforms and neuroelectronic interfaces. Typically, these arrays are produced with state-of-the-art fabrication methods such as photolithography or electron beam lithography, which provide high-resolution capabilities to include thousands of electrodes on a single chip. However, these methods are expensive and restricted to certain substrate or electrode materials. Thus, they are not ideally suited for low-cost rapid prototyping of devices with alternative geometric features or materials.

Ti3C2 MXene Neural Electrodes for Sensitive Detection of Neuronal Spiking Activity - Nicolette Driscoll1, 2, Andrew G. Richardson1, 4, Kathleen A. Malecki1, 4, Babak Anasori1, 2, Oladayo Adewole1, 2, Pavel Lelyukh1, 4, Lila Esfendro1, 2, D. K. Cullen1, 2, Timothy H. Lucas1, 2, Yury Gogotsi1, 4, Flavia Vitali1, 2, 4, and Dennis A. Jaklevic1, 2, 4; 1Department of Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Center for Neurotrauma, Neurodegeneration, and Restoration, Corporal Michael J. Crescenz Veterans Affairs Medical Center, Philadelphia, Pennsylvania, United States; 3Center for Neuroengineering and Therapeutics, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 4A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States; 5Department of Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 6A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States; 7Department of Chemical Engineering, Cornell University, Ithaca, New York, United States; 8Department of Neurology, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

High-resolution neural interfaces are essential tools for studying neural circuits underlying brain function and disease. As electrodes are miniaturized to achieve high spatial resolution and resolve individual neuronal spiking activity, maintaining low impedance and high signal quality becomes a significant challenge. Nanostructured materials have the potential to address this challenge by offering a combination of unique electrical and mechanical properties and the ability to interact with biological systems on a molecular scale. Ti3C2 MXene, a recently discovered 2D nanomaterial, possesses remarkably high volumetric capacitance, conductivity, surface functionality, and processability in aqueous dispersions, making it unique among 2D nanomaterials. In this work, we seek to evaluate the recording performance of MXene for detection of neuronal spiking activity in vivo. We employed a high-throughput microfabrication process for micropatterning MXene onto flexible, parylene-C substrates, and fabricated a 16-channel laminar probe. The laminar probe has 5 sets of side-by-side MXene and gold (Au) electrode contacts (25 μm diameter) arranged in a stereotrode configuration to enable direct comparison of signal quality between the two materials during in vivo recording. Electrochemical impedance spectroscopy revealed that the MXene electrodes in the array exhibit remarkably low 1 kHz impedance compared to their Au counterparts: 219 ± 31 kΩ vs. 865 ± 125 kΩ, respectively. The MXene electrodes have a rough and layered surface morphology (Ra = 32 nm), which likely contributes to their ~4x improvement in impedance properties compared to Au. We performed acute recording experiments in anesthetized rats and recorded multiunit neuronal spiking activity on adjacent MXene and Au stereotrode contacts implanted in sensorimotor cortex. Spikes that occurred simultaneously on adjacent MXene and Au electrodes were considered to have been generated by the same neuron, and their signal-to-noise ratios (SNR) were computed and compared. We found that MXene electrodes recorded neural spiking activity with significantly higher SNR than Au electrodes. We also found that MXene electrodes recorded more spikes overall than the Au electrodes, and that the spikes unique to the MXene electrode in a stereotrode pair tended to be low amplitude, suggesting that MXene electrodes have a larger “seeing distance”, allowing them to resolve spiking activity from a larger volume of tissue. Finally, we assessed the neuronal biocompatibility of Ti3C2 MXene in vitro and found that neurons cultured on MXene films proliferated, showed axonal growth, formed synaptic connections, and were as viable as control cultures. This work highlights the suitability of Ti3C2 MXene for high resolution neural interfaces and suggests that MXene has significant potential to enhance the performance of neural microelectrodes beyond current capabilities.

With the advent of the hyperconnected era, visual IoT devices attracted great interest. Flexible displays are powerful candidates for interactive visual communication. Inorganic-based micro light-emitting diodes (μLEDs) have been regarded as key technologies in RGB micro LED TVs due to their excellent electrical/optical properties, fast response, long lifetimes and high stability in harsh environments. Several groups have studied various inorganic LED materials for various applications. Despite previous reports of flexible micro LEDs, GaN f-VLEDs on plastic substrates have not yet been demonstrated due to the difficulty of vertical GaN interconnections. Flexible energy sources for f-LEDs are also required for practical applications of flexible optoelectronic systems.

Herein, we report a flexible 30x30 GaN VLED array through a simple manufacturing process. The GaN LED chip was separated from the sapphire wafer by the ILLO process. Stand-alone micro LEDs are isolated by biocompatible layers and are interconnected vertically with AgNW-based conductors by resolving the high step coverage of f-VLEDs. Ultra-thin, transparent and flexible GaN VLEDs are attached to the human nail in a conformal structure with high light output of 30 mW mm⁻². The lifetime of the f-VLED was experimentally investigated by a high accelerated stress test (HAST) and theoretically estimated by simulation. In addition, our f-VLEDs exhibited excellent mechanical durability during cyclic bending cycles. A wireless power supply system for human skin has been successfully demonstrated by delivering electrical energy to the f-VLED. Finally, the blue f-VLED successfully emitted blue light into the mouse brain without severe tissue damage.

BM07.05.02
Metal Nanoparticles-Grafted Functionalized Graphene Coated with Nanostructured Polyaniline ‘Hybrid’ Nanocomposites as High-Performance Biosensors Sanjiva Gupta and Romney Meek, Western Kentucky University, Bowling Green, Kentucky, United States.

We report on the development of next-generation chemical, electrochemical and biological sensors from nanocomposites with broader electrical conductivity and anticipated linear time response, specificity and stability. We synthesized metal nanoparticles-grafted functionalized graphene nanosheets with nanostructured polyaniline (PANI) ‘hybrid’ nanocomposites for ascorbic acid (AA) sensing. The versatility of the nanocomposite performance was corroborated by altering the size and areal density of metal nanoparticles (AgNP, AuNP and AgNP) on the graphene-family nanomaterials, GFNs namely, graphene oxide (GO); GO, thermally reduced GO; rGO, and nitrogenated functionalized graphene; NFG. In addition, the globular surface morphology and charge density of electropolymerized polyaniline (PANI) onto GFNs can also influence the biosensor performance. The noble metal nanomaterials are selected due to their higher electrical conductivity, facile synthesis, easier processability, antimicrobial applicability and scalability. The as-synthesized multilayer architectures (PANI|AgNP|GFN and PANI|AuNP|GFN) on fluoride-doped tin oxide (FTO) coated glass, graphite foil (GF) and graphene rod (GR) electrodes increased the electrical conductivity of the electrodes significantly and reduced the charge transfer resistance dramatically promoting localized orbital re-hybridization and heterogeneous integration with PANi. We all contribute toward enhanced electroactivity and ensure rapid charge transfer and ion conduction. These multilayer ‘hybrid’ nanocomposite electrodes are also useful as advanced electroanalytical platforms for platinum-free electrocatalysis, electrodes for energy storage pseudocapacitors and enriching biofuel cell development. This work is supported in parts by NSF EPSCoR Grant and WKU Graduate School Fellowship.

BM07.05.03
Biosensor for the Simultaneous Monitoring of Breath Isoprene and Acetone Jan van den Broek, Amy Wang, Andreas T. Günnter and Sotiris E. Pratsinis; ETH Zürich, Zürich, Switzerland.

Volatiles from the human body, especially from breath, contain a wealth of physiological and pathological information. Chemo-resistive metal-oxide gas sensors stand at the interface to the human biosystem as they specifically interact with such biomarkers and are capable to measure their concentrations even at the lowest parts-per-billion (ppb) levels. This way, individual emanating volatiles can be monitored to infer and better understand metabolic states and processes. In specific, breath isoprene has been suggested to be an indicator for the efficacy of blood cholesterol-lowering therapy and cardiac output, while acetone is an established biomarker for fat metabolism. Thus, online monitoring of these two gases simultaneously by a portable device can be a promising tool to optimize effective weight loss through physical exercise and diet planning.

Here, we present a sensor system for the simultaneous detection of isoprene and acetone in complex breath mixtures. It consists of nanostructured films of inorganic metal-oxides designed by flame aerosol synthesis to selectively interact with these biomarkers on a molecular level, resulting in a detectable electrical signal. The resulting biosensor can detect acetone and isoprene simultaneously down to 5 ppb in real time at breath-related relative humidity. It has high selectivity to other major breath markers like methanol, ethanol and ammonia. The biosensor is also tested in vivo by direct sampling of breath through a breath sampler and simultaneously cross-validated by state-of-the-art mass spectrometry. All the components utilized can be readily miniaturized and integrated into a portable device enabling monitoring of these important metabolic tracers.

BM07.05.04
Transparent, Flexible Deep-Well Micro-Structured PEDOT:PSS/Au Nanorods Based Electrode Array for Neural Recording Yeounguk Cho and Ki Jun Yu; Electrical and Electronics Engineering, Yonsei University, Seoul, Korea (the Republic of).

Neural interfaces offer an insight into the mechanism of nervous system by recording signals from neurons. Conventional neuro-electrodes are made of metal that may occur clinical image distortion by its inherent opacity. Electrode transparency is ultimately important factor, because electrical artifacts from light stimulation for opto-genetics hinder the neural recording and interfere with the pinpoint control of neural activity. Ultrathin metal based devices for neural recording have been reported as alternatives with transparency, but the relatively low transmittance rate (<40%) requires novel materials and micro/nanopatterning techniques that offer significant enhancement of signal to noise ratio (SNR) of electrophysiological signals while maintaining its transparency.

Biocompatibility is also important factor to be considered for electrodes that are used for implantable neural arrays. Numerous materials for biocompatible implantable devices with the outstanding electrical properties have been discussed for the electrophysiological recordings or stimulations. However, only small number of reported such electrodes satisfy the conditions where multiple characteristics such as high transparency, flexibility, and high SNR, together with credible bio-stable property require, thereby enabling conformal electrical and optical neural recording simultaneously. Conducting polymers
are excellent material choice for the neural electrodes that satisfy the characteristics mentioned above. Recently, poly(3,4-ethylenedioxythiophene)(PEDOT) as the representative conducting polymer is widely used for the neural electrodes due to the good conductivity with a high degree of an optical transparency.

Herein, we present a facile fabrication of deep-well structured PEDOT:PSS/Au nanorods array that can greatly improves SNR of neural recordings compared to the conventional PEDOT:PSS based electrodes. In our work, Au nanorods with three-dimensional(3D) deep-well microstructures by self-assembly are exploited as particles that can greatly enhance electrode conductivity while maintaining its optical transparency. Au nanorods are also suitable for the implantable neural interface design because of its well-known biocompatibility. Electrical and optical characterizations were conducted on both the deep-well microstructure and the plain surface-based PEDOT:PSS/Au nanorod electrode as a point of comparison. These experimental results show the much lower impedance plot and higher optical transparency with the deep-well surface structure compared to that with the planar device. Conducting cytotoxicity and implantation experiments on animal models also support its good biocompatibility. We expect this novel microstructure electrode array to be the unprecedented candidates for electrodes in a field of biomedical engineering such as an implantable cell regulating device or neural interface.

Screening methodologies of potential G-protein-coupled receptor (GPCRs), which transfer external signals into the cell, drugs has been developed for several decades. Recently, the field-effect transistor (FET) has been used in the development of diagnostic tools, leading to high-performance biosensors, especially liquid-ion gated FET biosensors. Therefore, the FET platform can provide the foundation for the next generation of analytical methods. A principle application of GPCRs is screening new drugs, so the development of a GPCR-conjugated analytical device is highly desired. In this study, we firstly proposed a new approach for studying receptor agonism and antagonism by combining the FET and GPCR roles in a dopamine receptor D1 (DRD1)-conjugated FET system, which is a suitable substitute for conventional cell-based receptor assays. DRD1, for the first time, was reconstituted and purified to mimic native binding pockets that have highly discriminative interaction toward DRD1 agonists/antagonists. The real-time responses from the DRD1-nanohybrid FET were highly sensitive and selective for dopamine agonists/antagonists, and their maximal response levels were clearly different depending on their DRD1 affinities. Moreover, the equilibrium constants ($K_a$) were estimated by fitting the response levels. Each $K_a$ value indicated the variation in the affinity between DRD1 and the agonists/antagonists: greater $K_a$ value corresponds to a stronger DRD1 affinity in agonism, whereas a lower $K_a$ value in antagonism indicates a stronger DA-blocking effect.

BM07.05.09
High-Performance Biosensor Using Multi-Channel System Graphene Field Effect Transistor (GFET) Microfluidics for the Rapid Bacteria Detection
KyoungHo Kim and Oh Seok Kwon; Korea Research Institute of Bioscience & Biotechnology (KRIBB), Daejeon, Korea (the Republic of).

Over the past of decades, bacteria monitoring is critical in detecting bacteria from contaminated drinking water and food. A various kind of bacteria detection methods such as electrical or optical sensor has been developed. Nevertheless, although many studies with bacteria detection sensors have been reported for high performance detecting properties, the development of the bacteria sensor still remains as challenge. Herein, we study the demonstration of graphene field-effect transistor (GFET) microfluidics using single-layer graphene micropatterns and characterize its monitoring capacity in bacteria detection. The GFET microfluidics had excellent mechanical/electrical properties in fluidics and showed high sensitivity and selectivity for a target in bacteria mixture. Based on those results, our GFET microfluidics can provide potential applications in the field of disease diagnostics at early stage.

BM07.05.10
Field Effect Transistor Based In Vitro Dopamine Aptasensor
Jiyoon Lee and Oh Seok Kwon; Korea Research Institute of Bioscience and Biotechnology, Yuseong-gu, Korea (the Republic of).

In this study, ultrasensitive and precise detection of a representative brain hormone, dopamine was pursued and demonstrated using functional conducting polymer nanotubes modified with aptamer. The produced aptasensor was composed of a micropatterned gold electrode, carboxylated polypyrrole nanotubes, and specific aptamer molecules. The sensor was constructed by sequential deposition of the PPy-COOH nanotubes and aptamer molecules on the electrode. The sensitivity and selectivity of this sensor were monitored using field effect transistor type measurements. In addition, real dopamine released from PC12 and SH-SY5Y cells induced by high concentration potassium ion (K+) stimulus were also analyzed and compared with the data obtained from the sensitivity (1 nM) and selectivity tests. This article can provide the feasibility for practical use of simple and efficient field effect transistor type aptasensor.

BM07.05.11
Traditional Conjugated Polymer as Efficient Mixed Conductors for High-Performing Electrochemical Transistors
Priscila Cavassin and Gregorio C. Faria; Universidade de São Paulo, São Carlos, Brazil.

Organic electrochemical transistors have garnered attention for applications in biological interfacing, logic circuits and neuromorphic devices. [1] Despite recent advances in device fabrication and materials development, however, only a narrow class of polymers have been found to stably operate in these new applications. To this end, we have developed general guidelines that allow for the fabrication of OECTs with semiconducting polymers that do not uptake water efficiently. The methodology produces devices that operate stably at room temperature, exhibits excellent transistor characteristics, (e.g., transconductance and volumetric capacitance), and is versatile, making it possible to fabricate OECTs with virtually every conjugated polymer synthesized to date. Using the general guideline here proposed, we have successfully fabricated high-performing OECTs using standard conjugated-polymers, such as, poly(3-hexylthiophene) (P3HT). Additionally, by fitting the transient curve response and transfer curves of our OECTs, we are able to extract key fundamental properties of both the device and the active channel materials, including the volumetric capacitance ($C_v$), the intrinsic hole/electron mobility ($\mu$), as well as the product $\mu*C_v$, which has been used as the benchmark for comparing OECT device. [2] We have used such benchmark to compare our OECTs performance with previously reported materials and show that some of our devices are the best published to date. Furthermore, we showed applications of these devices in biosensing.

Anion-Dependent Doping and Charge Transport in Organic Electrochemical Transistors
Lucas Q. Flagg, Rajiv Giridharagopal and David S. Ginger; Chemistry, University of Washington, Seattle, Washington, United States.

We study the effects of different dopant anions on mixed ionic/electronic transport in organic electrochemical transistors (OECTs) based on poly(3-hexylthiophene-2,5-diyli) (P3HT). We show that the electronic transport properties depend on the anion present in the electrolyte, with greater transistor currents resulting from the use of polyatomic anions such as such as trifluoromethanesulfonilimide (TFSI) as compared to halide anions. Using spectroelectrochemistry, we show the maximum doping level at a given bias is also anion dependent. Furthermore, we find that the average electronic carrier mobility depends on the identity of the compensating counterion. We investigate this effect further using electrochemical quartz crystal microbalance (EQCM) measurements, showing the solvation shell of the dopant anions within the polymer varies drastically depending on the type of anion. Surprisingly, we find that the doping kinetics in these OECTs is faster for larger anions. Lastly, we use electrochemical strain microscopy (ESM) to resolve ion-dependent differences in local swelling on the nanoscale, providing further insight into the interplay between local polymer structure and ion uptake. These measurements show that the chemical properties of the compensating ion are an important design consideration for polymer materials with mixed ionic/electronic conductor applications.

BM07.05.13
Liquid-Ion Gated Field-Effect Transistor (FET) with Human Dopamine Receptor Integrated-Multidimensional Conducting Polymer Nanofiber for Dopamine Detection
Seon Joo Park and Oh Seok Kwon; KRIBB, Daejeon, Korea (the Republic of).

Dopamine (DA) has been studied in the field of nervous and cardiovascular systems. Abnormal levels of dopamine is an indicator of neurological
disorders, resulting in Alzheimer's and Parkinson's diseases. Therefore, dopamine is a clinically useful diagnostic sign and requires a novel approach with high sensitivity, selectivity and a rapid response. Various sensors have been developed, such as high-performance liquid chromatography (HPLC), mass spectrometry, and spectrophotometry. However, they are limited by their high cost, low sensitivity, and variable label response.

The field-effect transistor (FET) has been used in the development of diagnosis for several decades. It is gated by changes of charge carrier density in the channel induced by the binding of target molecules, leading to high-performance biosensors. In addition, the FET platform has attracted due to their low cost, easy operation, fast response, label-free operation, parallel sensing as well as high sensitivity.

In this article, we introduced a high performance dopamine sensor based on FET assay. Multidimensional carboxylated poly(3,4-ethylenedioxythiophene) (MCPEDOT) NFs membrane was utilized as the conductive channel of sensor in the FET system. Interestingly, it provided high performance sensing due to enhanced interaction from high surface area and gate-potential modulators. Moreover, hDRD1, G protein-coupled receptors (GPCRs) as the recognition elements, was first expressed in Escherichia coli and modified with the surface of MCPEDOT NFs, leading to high selectivity. As a results, the hDRD1-MCPEDOT NF-based FET exhibits a rapid real-time response (~2 s) with high dopamine selectivity and sensitivity performance (approximately 100 FM).

BM07.05.14

Nanoionic Electronic Nose with Human olfactory Receptor-Functionalized Graphene Micropatterns for the Analysis of the Spoiled Odor, Trimethylamine Sung Fun Seo and Oh Seok Kwon; Korea Research Institute of Bioscience and Biotechnology, Daejeon, Korea (the Republic of).

Trimethylamine(TMA), a odor from the spoiled meat, is a positive proof that we can decide if the food is spoiled or not. We demonstrated the nanoionic electronic nose using the human olfactory receptor(hOR) functionalized graphene field-effect transistor (GFET). At first, the hOR is prepared from the Escherichia coli (E. coli) for the sensing of the real food sample’s TMA. The nanoionic electronic nose was characterized by SEM, TEM, I-V and transfer curve. The real-time responses under liquid-ion gated system showed that the bioelectronics nose with hOR-conjugated GFET had higher selectivity and specificity compared to conventional electronic noses without bio-receptors. Moreover, the nanoionic electronic nose could provide the effective criteria to judge the food’s freshness. The most advantage of this research is the quantitative analysis of the popular fish. Moreover, it can be utilized to any other real food samples with only the reactive receptor.

BM07.05.15

High Molecular Density Bio-Electronic Sensor Based on 2D Crystalline Interface and QTY Modified GPCR Proteins Rui Qing1, Andreas Breuwiesser2, Giovanni Azellino1, Mantian Xue1, Jiuyuan Zhao1, Uwe Sleytr1, Jing Kong1 and Shuguang Zhang1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2University of Natural Resources and Life Sciences Vienna, Vienna, Austria.

Bio-electronic is an emerging interdisciplinary subject which utilizes biomolecules in electronics or mimics biological architectures. One important aspect of the field is to fabricate sensors for biomolecules detection, i.e. ligands. Researchers previously designed sensors based on metal-oxide-semiconductor (MOSFET), polymers and inorganic crystalline materials which produce decent sensitivity but lacks selectivity. Recent efforts are devoted on directly connecting biological receptors with electronic systems. G protein-coupled receptors (GPCR), are the largest family of membrane receptors that detects information (molecules and lights) and transduce to cell internal signals to regulate body functions. There are nearly 1000 types of GPCR proteins in human body, each one being highly specific to a particular signal, which make them suitable candidates as sensors in bio-electronic devices. Based on our previous reported novel approach of QTY modification on GPCR proteins, we were able to obtain water soluble receptors active to their natural ligands without adding any detergent. Recombinant SbpA S-layer proteins can reproduce ordered 2-dimensional crystalline monolayer in vivo and were employed as the intermediate layer between biomolecules and electronic substrates. By fusing –Fc region of human IgG protein to GPCRQTY and Protein G onto SbpA, we successfully formed GPCR-S-layer complex and anchor them onto the electronic active surface, i.e. Si wafer, graphene, etc. SbpA proteins also helped to guide the orientation of attached GPCRQTY proteins and expose their active binding sites. The assembly yields functional molecule monolayer density as high as 2.37-4.73*1012 molecule/cm2. 

BM07.05.16

The Charge Carrier Modulation in PEDOT:PSS Films via Chemical Crosslinking with PVA Ji Hwan Kim and Myung-Han Yoon; School of Materials Science and Engineering, Gwangju Institute of Science & Technology (GIST), Gwangju, Korea (the Republic of).

Recently, the charge carrier modulation in semiconducting polymer films has drawn much attention, but there exist a relatively small number of studies on the charge carrier modulation in highly conductive polymer films despite their potential for energy storage and bioelectronics applications. In this work, we report the charge carrier modulation of poly(3,4-ethylenedioxythiophene)/poly(styrenesulfonate) (PEDOT:PSS) films and its application to organic electrochemical transistors (OECTs) with finely-tuned threshold voltage characteristics by crosslinking with polyvinyl alcohol (PVA) as a de-dopant. PVA was blended with an aqueous solution of PEDOT:PSS and the PEDOT:PSS-PVA blend films were chemically crosslinked in the solid state. The electrical characterization revealed that the crosslinking with PVA significantly lowered the conductivity from 1800 to 80 S/cm, the volumetric capacitance form 100 to 1 F/cm, and the hole concentration from 3.3 × 1017 cm−3 to 7.5 × 1016 cm−3 in the PEDOT:PSS-PVA hybrid films. Despite the inclusion of electrically insulating polymer in the conductive material, however, the resultant OECT devices exhibited relatively high on-current (~1 mA), large current on/off ratio (>104), and excellent transconductance (>2 mS), which are acceptable for bioelectronic sensors with the customized electrical/electrochemical properties. In addition, the concurrent threshold voltage shift from 0.5 to 0.3 V upon PVA crosslinking suggests that the PEDOT:PSS-PVA hybrid channel can offer finely tunable threshold voltage characteristics to OECT devices without the significant degradation in OECT performance.

Nano-curvature Effect on Electrical Properties of Conductive Polymer Thin Films for Bioelectronics Applications Grazia M. Messina, Nunzio Tuccitto, Giovanni Li Destri and Giovanni Marletta; University of Catania, Catania, Italy.

The use of conducting polymers has a great deal in the last decades. It is mainly due to the possibility to employ them in tissue engineering, neural probes, biosensors, drug delivery and bioactuator in order to create an interface with living cells and tissue. Electrical stimulation (ES) is one of the agents that may modulate the interaction at the interface, in particular at the bioactive interface. The optimization of the CP bioactive interface is crucial since the first contact between biological systems and biomaterials is done at interface. In this study we investigate the preparation and modification of thin film of P3HT and PEDOT:PSS, in view of tuning their electrical properties by appropriate surface nanostructuring. In particular, we have studied the effect of nano-curvature of the electrical properties on the conductive layers of the polymer films. Controlled modification of the nano-curvature of conducting polymer film has been obtained by preparing hexagonally packed arrays of colloidal nanoparticles of different diameter and using these nanostructured surfaces as substrates for the deposition of the conducting polymer thin films. Interdigitated electrodes, having strips 5μm width, have been used as structure for the electrical measurements. The nanostructured surfaces have been
Highly Sensitive Lactate Sensors Based on Carbon MEMS (CMEMS) Shafrad Forouzanfar, Chunlei Wang and Nezih Pala; Florida International University, Miami, Florida, United States.

L-Lactic acid is one of the important metabolites produced during the anaerobic phase of glycolysis, making its precise determination highly important in various fields such as clinical diagnosis, sport, and military activities. Lactate plays a crucial role in several areas of human health, including heart failure, hepatic dysfunction, shock, respiratory insufficiency and systemic disorders. In sports medicine, knowledge of optimal blood lactate levels is vital to ensuring the maximum performance of an athlete during intensive exercise and endurance-based activities. Various methods have been developed for determining lactate levels, such as optical, nuclear magnetic resonance, liquid chromatography, fluorimetry, and amperometry. Among these methods, electrochemical ones possess advantages such as simple instrumentation, low detection limit, and wide dynamic range, as well as high selectivity and stability. A Carbon-microelectromechanical system (CMEMS) is one in which Carbon is synthesized through pyrolysis of micro patterned photore sist polymer in an oxygen-free environment under high temperatures. Carbon possesses various remarkable properties such as a wide electrochemical window, low non-specific adsorption of biomolecules, excellent biocompatibility, and low cost. Furthermore, carbon-based materials exhibit good electrical conductivity, as well as good tolerance toward bio-fouling. The surface of the carbon can be functionalized efficiently via various physical, chemical, or electrochemical treatments. CMEMS devices circumvent the major drawbacks associated with commercialized screen-printed carbon electrodes such as low resolution and miniaturization.

We developed an electrochemical CMEMS-based sensing platform to detect L-Lactic Acid. The sensing platform of the biosensor—interdigitated carbon micro fingers—was synthesized by pyrolysis of photo-patterned photoresist polymer in oxygen-free and high-temperature conditions. The surfaces of the fingers were functionalized by an oxidation pretreatment technique involving oxygen reactive ion etching (RIE) to form –COOH on glassy carbon. Taking advantage of having high concentrations of this carboxylic group on the surface of the carbon, we immobilized Lactate Oxidase (LOx) on the surfaces of the interdigitated carbon micro fingers without any other surface pretreatments. We employed various analytical characterization methods such as Fourier-transform infrared spectroscopy (FTIR) and Scanning Electron Microscopy (SEM) for material characterization. Sensing capabilities were measured by cyclic voltammetry (CV), electrochemical impedance spectroscopy (EIS). The carbon capacitive sensor demonstrated detection of lactate over a wide dynamic range of 50 nM-5 mM for the electrode area of 0.5×0.5 cm². The sensitivity of this linker-free lactate sensor was found to be 40 nM/cm², making it the first carbon capacitive L-lactate sensor with such high sensitivity.
Microfiber-Based Organic Electrochemical Transistors for Channel Dimension-Independent Single Strand Wearable Sweat Sensors Youneseok Kim¹, Seong-Min Kim¹, Taekyung Lim², Sanghyun Ju³ and Myung-Han Yoon¹; ¹Gwangju Institute of Science and Technology, Buk-gu, Korea (the Republic of); ²Kyunggi University, Suwon, Korea (the Republic of).

Herein, we report conjugated polymer microfiber-based organic electrochemical transistors (OECTs) for single strand fiber-type channel dimension-independent wearable sweat sensors. The highly conductive microfibers were fabricated by simple wet-spinning of aqueous poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) solutions, and PEDOT:PSS microfiber-based OECTs were successfully constructed showing high on-current (>5 mA), current on/off ratio (>10³), and transconductance (> 80 mS). Owing to excellent electrical/electrochemical characteristics and aqueous stability of PEDOT:PSS microfibers, the resultant OECT devices exhibited the linear response to aqueous cations at the large dynamic range (10⁻⁴ - 10⁻² M) as well as the high device fabrication reproducibility. Moreover, the proposed method for extracting the ion concentration sensitivity is independent of microfiber channel dimensions (e.g., length, width, diameter), leading to the definition of the suitable figure-of-merit even at arbitrary channel dimensions. Finally, we developed single strand fiber-type wearable sweat sensors, and demonstrated that the resultant sensors can perform real-time repetitive measurements of ion concentrations in human sweat samples.

Simultaneous Co-Electrodeposition of Plasma Protein/Iridium Oxide Hybrid Film for Electrically Controlled Drug Release Applications Fu-Erh Chen¹, Zheng-Ting Tang², Pochun Chen¹ and Wei-Chen Huang²; ¹National Taipei University of Technology, Taipei, Taiwan; ²Taipei Medical University, Taipei, Taiwan.

Implantable neurostimulation devices have been attracted considerable attention recently. When a neural stimulating electrode is implanted in vivo, neural disorders can be treated by electrostimulation. Additionally, electrically controlled drug release has been particularly attractive for bioelectronics because the electrical signal is portable and controllable on-demand, without the requirement of large or special equipment. However, protein-based bioactives such as growth factors or antibodies are easily denatured to lose their bioactivity in response to external stimulation. It is challenging to develop a bioelectrode system that permits the electrically responsive release of proteins without damage. In this study, a facile co-electrodeposition method has been developed to form a hybrid film of iridium oxide and plasma protein. We carried out a cyclic voltammetry approach to co-electrodeposit iridium oxide and plasma protein on ITO-coated glass substrates. We characterized and evaluated the hybrid electrolytes and deposited films for bio-electrode applications. We also demonstrated the releasing behavior triggered by an electric field. In addition, the biocompatibility of the hybrid films was also investigated by testing the cell viability.

Development of Highly-Conductive Crystallized PEDOT:PSS Microfibers for Wearable Bioelectronics Applications Myung-Han Yoon; Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of).

Despite the great potentials of polymer microfibers toward human-friendly wearable and implantable bioelectronics, most of the previous polymeric electronics have been limited to thin film-based devices due to the practical difficulties in preparing conductive microfibers with desired characteristics and fabricating free-standing fiber or woven textile devices. Herein, we report highly conductive polymer microfibers prepared by wet spinning and their application to microfibrillar bioelectronics. First, we developed the simple wet-spinning process to form highly conductive crystalline poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) microfibers. PEDOT:PSS microfibers with various cross-sectional areas, compositions, and crystallinity could be prepared by varying wet spinning conditions such as needle size, injection speed, coagulation bath, etc., while the corresponding mechanical, electrical, electrochemical properties were carefully examined. The resultant microfibers showed very high conductivities (~1000 S/cm) and capacitances (~70 F/g) with decent mechanical strength (~1 GPa), which exceed the metrics of PEDOT:PSS microfibers reported in the previous literature. Finally, we successfully proved the potential of conducting polymer microfiber-based bioelectronics by demonstrating the PEDOT:PSS microfiber-incorporated textile for wearable electrolymography sensor and the PEDOT:PSS microfiber organic electrochemical transistor for cation concentration sensor in human sweat.

Organic Bioelectronic Fibers and Capillaries Magnus Berggren, Daniel Simon, Eleni Stavrinidou and Roger Gabrielson; Linköping University, Norrköping, Sweden.

Organic electronic materials offer mixed ion electron conduction and signal processing and can be manufactured into various flexible and soft device configurations using solution-based processing protocols. While bridging the biology-technology signaling gap, to record and regulate biological functions, it is crucial to develop a bioelectronic form factor that enables signal translation at high spatiotemporal resolution, close proximity and at minimal invasiveness. Fiber and capillary structures are natural and common structures of most biological systems, they serve as confined transportation highways of biological components, biochemicals and signals. Here, developments of organic bioelectronic fibers and capillaries are reported. Conductors, electrodes, transistors and electronic ion pumps have been manufactured into capillary and fiber structures to enable non-invasive integration and high-quality signal translation across the biology-technology gap. For instance, organic electronic ion pumps have been manufactured inside glass capillary structures, with an outer diameter of 60 micrometers, and has been applied to various biological systems to deliver signal substances at high spatial resolution. Conductors, electrodes and transistors have been manufactured or have been applied into or onto the vasculature or fibers, of living system, resulting in passive and active bioelectronics for recording and sensing of physiology and bio-signaling. The resulting technology, which utilizes the twinning of living biological components and organic bioelectronic materials, to form active devices have been applied to various biological settings to for instance monitor action potentials and to form small scale bioelectronic circuits.
The efficiency of devices for bioelectronic applications, including neuronal stimulation, is heavily dependent on the scale and the performance level. With miniaturization of stimulation electrodes, achieving a sufficiently high current pulse to elicit action potentials becomes an issue. We have developed the organic electrolytic photocapacitor (OEPc) for stimulation of light-insensitive retinas, previously achieving pixels of 100 μm in diameter. In the work herein, we report on our approach of arranging pixels of photocapacitors vertically in order to substantially increase the photovoltage and charge density without sacrificing lateral area. The tandem devices are created by stacking vertically p-n junctions made of semiconducting organic small molecules with 1 nm recombination layers of gold in between. These devices still do not exceed a total thickness of 300-500 nm. These devices represent a substantial improvement over previously-reported single p-n junction OEPcs, and are able to generate five-times higher voltages and at least double the charge densities. We have tested the efficacy of tandem devices using measurements of xenopus oocytes, where we find substantially enhanced stimulation of K+ channels relative to single-junction devices. Finally, we have used the tandem approach to microfabricate optoelectronic stimulation pixels (< 50 μm) for retinal prosthesis, validating their performance by measuring light-insensitive retinal extracts. These results corroborate the conclusion that OEPc technology not only has achieved parity with state-of-the-art silicon devices, but can exceed them in miniaturization and performance.

Photosynthetic Bacteria-Based Biohybrids for Organic Bioelectronics Gianluca M. Farinola1, Francesco Milano1, Roberta Ragni1, Marco Lo Presti1, Simona la Gatta1, Livia Giotta2, Angelo Agostiano1-3 and Massimo Trotta1,1University of the Studi-Bari Aldo Moro, Bari, Italy; 2Dipartimento di Chimica Universitá degli Studi di Bari “Aldo Moro”, Bari, Italy, CNR IPCF UOS BARI, Bari, Italy; 3Dipartimento di Scienze e Tecnologie Biologiche e Ambientali, Ecotekne, Monteroni, Lecce, Italy.

The photosynthetic bacterial Reaction Center (RC) is a specific transmembrane multi-subunit protein complex which photogenerates charges to fuel the photosynthetic process [1]. The RC exhibits a conversion efficiency of photons to electrons close to 100%. The possibility of taking advantage of such excellent photoconversion efficiency to create functional nanomaterials and bio-hybrid devices is very attractive [2]. We recently demonstrated that the light harvesting capability of the native RC in the visible spectral region is increased by covalently affixing different tailored molecular antennas, thus obtaining hybrid systems which outperform the native protein in solar light absorption and photogeneration [3,4]. The RC integration in bioelectronic devices is an appealing challenge that has recently been explored. It demands for proper approaches to implement the biological photoconverter in either nanocostructs and/or bio-integrated devices. The lecture will discuss chemical routes to hybrid RC-based materials, focusing on: i) retainment of perfectly unaltered functions of the RC photoenzyme in confined environments [5]; ii) creation of functional interfaces between the biological structure and the electrodes’ surface. Highly selective chemical strategies to address these systems at the interfaces with electrodes in bioelectronics devices will be presented. The role of organic synthesis and self-assembly techniques in bridging the gap between the biotechnological production of materials and engineering of the devices will be highlighted.

References
recently combined fiber-based fabrication with direct tough-hydrogel integration. These probes exhibited tunable mechanical moduli allowing for deep-brain implantation without adverse tissue response and permitting tracking of identifiable action potentials for 6 months. In addition to enabling neural activity, fiber-based devices can guide nerve growth. To produce biocompatible nerve guidance scaffolds, we have developed porous fibers, where the pores were established via salt-leaching following thermal drawing. This process allowed for control over the pore sizes in fibers produced from arbitrary polymers with a range of dimensions and cross-sectional geometries.

Miniature, Wireless Neural Stimulation Using Magnetoelectric Materials Jacob T. Robinson; Rice University, Houston, Texas, United States.

Wireless neural stimulation is important for implantable bioelectronic devices, and neuroscience experiments in freely moving animals; however many wireless stimulators require batteries or large receiver coils, that limit the ability to make miniature implants. Here we present a new approach for wireless neuromodulation that uses a material to convert magnetic fields that freely penetrate the brain into electric fields that stimulates nearby neurons. Because these materials do not rely on electromagnetic waves for power harvesting, they can be made millimeter sized while retaining high power conversion efficiencies. To create these biocompatible “magnetoelectric” materials we fabricated a film of a piezoelectric material polyvinylidene fluoride bonded to a magnetostriuctive film of Metglas. We then encapsulated the final films to make them biocompatible. We find that these magnetoelectric films can generate voltages above ten volts using alternating magnetic fields with an amplitude of about 1 mT. We also demonstrate that a simple film is able to stimulate cellular activity in vitro in excitable HEK cells and acute brain slices. We also show that light-weight millimeter-scale films enable wireless activation of neural activity in freely-moving rats. Overall, our results show that magnetoelectric materials offer great promise for wireless electrical stimulation of specific brain areas. The basic understanding of magnetoelectric neural stimulation can also be used to develop novel magnetoelectric materials (such as nanoparticles or nanofibers) to achieve even more targeted and less invasive wireless neural stimulation technologies.

Wireless Magnetoelectrical Neural Stimulation Mediated by Magnetic Nanodics Alexander Senko, Danijela Greguric, Ian Tafel, Pooja Reddy, Dekel Rosenfeld, Siyuuan Rao, Michael G. Christiansen, Po-Han Chiang, Seongjun Park and Polina Anikeeva; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

A new technique has been developed for magnetic nanoparticle-based neural stimulation. Unlike magnetothermal neural stimulation, which is based on the transfection of neurons to sensitize them to heat, this magnetoelectromechanical approach does not rely on transgenes, making it potentially safer for clinical applications. In contrast to previously reported magnetomechanical stimulation techniques, in which neurons are typically hundreds of microns or less from a magnetic field source, the field required for this technique (1–50 mT, 1–20 Hz) is produced at the scale of an entire rodent model using a simple solenoid and a 200 W audio amplifier. This advantage in stimulated volume is enabled by magnetic nanodics with volumes hundreds of times larger than conventional magnetic nanoparticles, but which have favorable colloidal properties due to their disc shape. These magnetic nanodics possess a spin vortex state, which nearly eliminates stray field and results in less inter-particle attraction compared to isotropic magnetic particles of similar volume. The neural stimulation technique enabled by these magnetic nanodics has also demonstrated to robustly induce calcium influx in sensory neurons in rat dorsal root ganglion (DRG) explant cultures and enhance rat expression of an immediate early gene c-fos in DRGs of adult rats. This technique may find applications in basic studies of neural circuits as well as pave the way for future neuromodulation therapies.

SESSION BM07.07: Electronic Actuators/Novel Architectures II
Session Chairs: Mehmet Kanik and Jacob Robinson
Wednesday Afternoon, November 28, 2018
Sheraton, 2nd Floor, Constitution B

1:30 PM BM07.07.01
On-Demand Generation of Chemical Signals with Electromagnetic Fields for Neuronal Modulation Jimin Park1,2, Junsang Moon1,2, Po-Han Chiang1, Dena Shahbazi1, Atharva Sahasrabudhe1, Siyuuan Rao1, 2 and Polina Anikeeva1, 2; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The development of electromagnetic tools for neuronal stimulation can significantly enhance our understanding of signaling pathways in the brain and enable treating neurological disorders. To date advances in the design of neural probes and magnetic nanoparticles have provided promising opportunities for electrical and mechanical stimulation of neurons under electromagnetic fields. However, robust chemical stimulation of neurons has not yet been achieved with these systems due to difficulties in generating chemical signals under electromagnetic fields. Here, we developed two material systems that formed either protons or reactive-oxygen-species (ROS), which are both important chemical species in the nervous system, under electromagnetic field and demonstrated their utility for chemical stimulation of neurons. In the first system, a polymer-magnetic nanoparticle nanohybrid was designed that released protons upon exposure to an alternating magnetic field. Hysteretic heat dissipation by magnetic nanoparticles accelerated the degradation process of biodegradable polymer matrix within the nanohybrid, which in turn led to the release of protons and
change in pH of solution. The proton release kinetics from the nanohybrid was regulated by adjusting material properties, synthesis method, and magnetic field conditions. The ability to optimize nanohybrid system indicated its potential for wireless magnetic-field driven stimulation of acid-sensitive ion channels.

The second material system composed of transition-metal based nanoparticles that generated ROS. Inspired by biological enzymes interacting with ROS, an iron-based nanocatalyst, which has a crystal structure and material properties similar to those of these enzymes were designed. Through combined electrochemical and spectroscopical analyses, we confirmed that the catalyst could convert soluble precursor ions to ROS in solution in the presence of electric field. It is noteworthy that, by changing electric field conditions, such as current or voltage, ROS releasing behavior from the catalyst was quantitatively controlled. In vitro tests suggested that this system could stimulate ROS-sensitive channels, which may be a potential method to differentiate the roles of ROS in the nervous system.

We envision that these material systems can broaden the current palette of electromagnetic approaches for neuronal stimulation.

1:45 PM BM07.07.02

A Bioelectronic Solution for a Health Problem—An Implantable Integrated System to Treat Neurogenic Underactive Bladder

Faezeh Arab Hassanini1, 2, Chengkuo Lee1, 2 and Ninath V. Thakur1, 2; Singapore Institute for Neurotechnology, National University of Singapore, Singapore, Singapore; 2Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore.

Bioelectronics shapes a new era aiming to solve the health problems by merging the electronics, and biology science [1]. Incomplete emptying of the bladder may happen due to the atrophy of the detrusor muscle, or disease or damage to the afferent nerve system, i.e. neurogenic underactive bladder (UAB) [2]. For neurogenic UAB patients, the nerve stimulation maybe a solution, however, it may lead to several complications [3]. Using of catheters is the other treatment for these patients, but this treatment is not without shortcomings [2]. Therefore, we proposed a device that could physically contract the bladder muscle to void [4-6]. The recently proposed device, is an implantable integrated system that consists of a sensor to detect the fullness status of the bladder, and an actuator to initiate assisting the bladder muscle for the consequent voiding [6].

The shape memory property of shape memory alloy (SMA) components allows the voluntary activation and voiding of the bladder by patient. The actuator was designed by using of two flexible polyvinyl chloride (PVC) sheets as the substrate for the SMA components. A spring SMA with the transition temperature of 45°C was the main component for the actuation that resulted in a bi-stable bending of the PVC sheet during one 20 s cycle of activation. Two compression and restoration phases was designed for the device for multiple activations. We have designed, fabricated, and experimentally tested various designs and configurations for the actuator on anesthetized rat animal models [4-6]. The recent SMA spring-based actuator provided a substantial voiding percentage of about 80% with the reduced total energy consumption compared to the originally proposed devices. We have tested various types of sensors for the integration with the actuator from commercial piezo-resistive force sensors [5], quantum tunnelling composite-based sensors [7], and finally triboelectric energy harvesting (TENG) sensors [6]. The wet sponge-based TENG sensor consists of water and polydimethylsiloxane (PDMS) as the two materials with different electron affinities. The output triboelectric voltage can be used as a feedback control signal to the patient for initiating the activation of the actuator and voiding.

The integration of a sensor with the actuator is necessary for neurogenic UAB patients. However, the integrated sensor should be flexible enough not limiting the voiding capability of the actuator, and at the same time provide repeatable output signal to the patient. Our future work, is focusing on designing new solutions to assist the lost sensation of neurogenic patients.

2:00 PM *BM07.07.03

Nanostructures as Electromagnetic Bio-Transducers

Jürgen Kessel1, Aldo I. Martinez Banderas1, Ainur Sharip1, Antonio Aries Trupote2, Nofa Alsharif1, Aitziber Lopez Cortajarena1, Jasmeen Merzaban1 and Timothy Ravasi1; 1King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2IMDEA Nanociencia and Nanobiotechnology Unit associated to Centro Nacional de Biotecnología (CNB-CSIC), Campus Universitario de Cantoblanco, Madrid, Spain; 3CIC BiomaGUNE, Parque Tecnológico de San Sebastián, San Sebastian, Spain.

Unique features of magnetic nanowires render them attractive materials for biomedical transducer applications. Due to the high aspect ratio, they are characterized by single magnetic domain properties, which can be exploited by electromagnetic interrogation. This allows utilizing such nanowires as remotely operated nanorobots, i.e. induce motion, produce heat or sense their location. Their versatility is further enhanced by surface functionalization, making them cell-specific targeting agents or drug delivery vehicles. Magnetic nanowires are fabricated by a facile and efficient method using electrodeposition into nanoporous membranes. Iron nanowires are highly biocompatible, and they can be further optimized by annealing, resulting in nanowires with an iron core, an iron oxide shell and tailored magnetization. In combination with polymer matrices, nanowires are employed as ultra-low power flow sensors, for realizing bioinspired artificial skins with tactile sensing capabilities, or to trigger remotely controlled drug delivery particles. Magnetic nanowires are readily internalized by cells via phagocytosis. When applying an alternating magnetic field, they kill cancer cells by a magnetomechanical effect. When further functionalizing the nanowires with drugs, they deliver these drugs into cells, and a combined treatment effect can be obtained together with a magnetic field and/or laser irradiation. The later exploits a photo-thermal effect, that utilizes the near infrared light absorption of iron oxide. Surface coating with antibodies give nanowires specific targeting capabilities, as will be shown for the case of anti-CD44 antibodies to target leukemic cells. The nanowires also have excellent properties as magnetic resonance imaging contrast agents, providing high transverse magnetic relaxivities. This enables high-resolution cell tracking in combination with their manipulation. Nanostructured substrates for cell growth can be produced, when partially releasing the nanowires from the nanoporous membranes. Due to mimicking the mechanical properties of cellular environments, stem cells growing on top of such substrates show alterations in their differentiation behavior. Thereby, nanowire dimensions modify the stiffness of the cellular environment, affecting the cells’ behavior. A mechanical stimulus can be applied via activating the substrate by an electromagnetic field, providing means for additional manipulations of the cell fate. Differentiation of mesenchymal stem cells into osteoblasts can be achieved on such substrates by electromagnetically induced mechanical stimuli within a few days. With the growing relevance of nanomaterials in biomedical applications, multifunctionality of nanoprobes is being discovered and exploited. Combining a high capacity for functionalization, with diagnostic capabilities and therapeutic functions, iron nanowires are ideal candidates for these theranostics approaches.

2:30 PM BREAK
An important aim of regenerative medicine is to restore tissue function with implantable, laboratory-grown constructs that contain tissue-specific cells that replicate the function of their counterparts in the healthy native tissue. In this talk I will describe our recent work in the development of materials for bioelectronics including polymers and functionalised nanoneedles. I will also describe our new imaging technologies for monitoring and elucidating the cell-material interface.

Complicated real-world tactile information is efficiently processed by the biological mechanosensory system. The basic building blocks of the biological mechanosensory system are mechanoreceptors, neurons, and synapses. We fabricated flexible organic devices to emulate the building blocks and the signal processing of a biological mechanosensory nerve. Our organic artificial mechanosensory nerve [1] consists of pressure sensors, organic ring oscillators, and organic synaptic transistors. A cluster of pressure sensors receive pressure inputs, which are converted to voltage pulses by a ring oscillator. A synaptic transistor integrates the voltage pulses from multiple ring oscillators. We used our artificial mechanosensory nerve to detect movement and large-scale textures of an object and distinguish braille letters. Also, our artificial mechanosensory nerve and biological motor nerves in a detached insect leg formed a hybrid reflex arc to actuate the muscles of the leg. Our flexible organic artificial nerve can be used in neurorobotics and neuroprosthetics.

An important aim of regenerative medicine is to restore tissue function while bone marrow stem cells (BMSCs) can differentiate into Schwann cells under appropriate conditions. We have investigated the differentiation of BMSCs into Schwann cells on scaffolds comprised of electrosprun nanofibers. We changed the alignment, diameter, and surface properties of the fibers to optimize the differentiation efficiency. The uniaxial alignment of fibers not only promoted the differentiation of BMSCs into Schwann cells but also dictated the morphology and alignment of the derived cells. Coating the surface of aligned fibers with laminin further enhanced the differentiation and thus increased the secretion of neurotrophins. When co-cultured with PC12 cells or chick dorsal root ganglion, the as-derived Schwann cells were able to promote the outgrowth of neurites from cell bodies and direct their extension along the fibers. Furthermore, we constructed a multi-tubular conduit with a honeycomb structure from the electrosprun fibers by mimicking the anatomy of a peripheral nerve. A bilayer mat of electrospun fibers was rolled up to form a single tube, with the inner and outer layers comprised of aligned and random fibers, respectively. Seven such tubes were then assembled into a hexagonal array and encased within the lumen of a larger tube to form the multi-tubular conduit. By introducing an adhesive to the regions between the tubes, the conduit was robust enough for handling during surgery. The seeded BMSCs were able to proliferate in all the tubes with even circumferential and longitudinal distributions. Under chemical induction, the BMSCs were transdifferentiated into Schwann-like cells in all the tubes. The cellular version holds great promise for the potential repair of large defects in thick nerves peripheral nerve repair.
Self-Assembling Peptide-Based Tissue-Like Hydrogel for Highly Effective Neural Interface

Jinyoung Nam,1 Hyung-Kyoung Lim,2 Minah Suh1 and Yong Ho Kim1,2,3
1SKKU Advanced Institute of Nanotechnology (SAINT), Sungkyunkwan University, Suwon, Korea (the Republic of); 2Center for Neuroscience Imaging Research, Institute for Basic Science (IBS), Suwon, Korea (the Republic of); 3Department of Biomedical Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

The biomechanical dissimilarity between rigid electrodes and soft neural tissues is a recurring problem in recording neural activity from the live brain, yet the development of stable neural interfaces that enable a complete biointegration remains a challenge. Self-assembling peptide has great advantages in developing a new biomaterial because along with its inherent biocompatibility, chemical and physical properties in macroscopic level can be controlled by sequence modulation. However, unwanted proteolytic degradation of α-peptide based material imposes challenges on chronic utilization. Here, we present a new, biocompatible, and bioactive neural interface with a peptidomimetic foldamer-based biopolymer hydrogel which forms a complex with carbon nanotubes (CNTs). We utilized a β-peptide as a molecular building blocks to form the hydrogel because it has not only the ability to mimic natural peptides, but excellent structural and proteolytic stability. To endow conductivity into β-peptide-based hydrogel, hierarchical assembly of β-peptide was designed to self-assemble into nanofiber that associate with carbon nanotubes (CNTs). Transmittance electron microscopy images revealed the end-to-end assembling of β-peptide nanofibers and tight wrapping of the nanofibers around CNTs. The mechanical properties of β-peptide/CNTs hydrogel was found to completely mimic the viscoelastic behavior of neural tissue. The intercortical and epidural neural signal recorded with the conductive hydrogel were found to be augmented, especially in high frequency range, due to increased contact area and tight coupling with neural tissues. We expect the tissue-like hydrogel-based neural interface will suggest many possibilities for developing advanced neural implants with secured signal reliability and recording sensitivity.

Shape-Reversible Magnetic Hydrogel Drug Carriers for Remote Neural Modulation Cindy Shi, Siyuan Rao and Polina Anikeeva
1Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Simons Center for Social Brain, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Minimally invasive magnetothermal technology that uses heat dissipation from magnetic nanoparticles (MNPs) in the presence of an alternating magnetic field offers the convenience of remotely controlling heat-sensitive processes. We applied this remote control capability of MNPs to enable an on-demand release of pharmacological substances to modulate neuronal activity. Thus, we developed a magnetic hydrogel that permitted local drug release with reversible shape contraction triggered by the heating of MNPs under an external magnetic field. By adjusting the composition of the MNPs and the hydrogel, drug loading capacity and release efficiency were optimized. When preloaded with clozapine-N-oxide, a substrate for the designer receptors exclusively activated by designer drugs (DREADDs), the magnetic hydrogel enabled the remote manipulation of neural activity in DREADD-expressing neurons upon exposure to magnetic field. The biocompatibility and chemical stability of the thermally responsive hydrogel were investigated. The introduced magnetic hydrogel drug carrier provides the remote release of pharmaceutical drugs for neural modulation with a long-lasting carrier lifetime and can potentially be expanded to other chemicals and pharmacological agents.

Electrical Performance after Mechanical Stress of Hafnium Oxide Capacitors on Deformable Softening Polymer Substrate Ovidio Rodriguez Lopez1,2, Gerardo Gutierrez-Heredia3,4, Alexander J. Polednik1, Adriana C. Duran-Martinez1, Edgar Guerrero1, Aldo Garcia-Sandoval2 and Walter Voit1,5
1Department of Electrical and Computer Engineering, The University of Texas at Dallas, Richardson, Texas, United States; 2Department of Biomedical Engineering, The University of Texas at Dallas, Richardson, Texas, United States; 3Centro de Investigaciones en Optica, Leon, Mexico; 4Department of Material Science and Engineering, The University of Texas at Dallas, Richardson, Texas, United States.

Recently, the microfabrication of thin film devices on flexible substrates has attracted great interest due to the broad field of applications where they can be used. In particular, the biomedical field has taken advantage of this technology for the development of chronic and implantable devices based on stimulating and recording electrodes. However, its commercial production remains elusive because of the rigorous demand of these applications. High performance, reliability, stable behavior, and resilience to the periodic mechanical stress of the electronic circuits are some characteristics needed for the fabrication of these devices. Therefore, further research on electronic components such as transistors, diodes, and capacitors among others devices is needed to develop reliable complex circuits on flexible substrates. This work presents the electrical performance of hafnium oxide (HfO2) thin-film capacitors on a softening polymer, as a flexible substrate. The softening polymer used as the substrate is a shape-memory polymer (SMP), which has been previously used for implantable devices. It is well known that SMP has the capability to retain a certain shape after being deformed and return to its original state when an external stimulus is applied. The metal-insulator-metal capacitors were fabricated using gold as top and bottom contacts and HfO2 as a dielectric, deposited by atomic layer deposition (ALD) at 100°C. This study centers on the electrical characterization after a mechanical stress of the HfO2 capacitor fabricated on SMP. Different HfO2 thicknesses were used. Capacitors of each thickness (20, 30, 40 and 50 nm) were measured and compared with capacitors fabricated on silicon with the same structure. The devices were evaluated after 102, 104, 106 and 108 cycles of bending with a 5 mm bending radius. Electrical parameters such as capacitance density, dielectric constant, leakage current and breakdown voltage of these devices were evaluated. This research might pave the way towards the fabrication of complex circuitry based on thin film devices using SMP as softening substrate, and assist in the development of implantable electronic, where mechanical resilience is required.

Improving the Compatibility of Semiconducting Polymers for Biological Interfacing David Ohyun1, Weiyuan Du1, Sahika Inal1 and Iain McCulloch1,2
1KAUST, Thuwal, Saudi Arabia; 2Imperial College London, London, United Kingdom.

Organic semiconductor polymers have been extensively used as efficient bio-transducers thanks to their unique mixed ionic and electronic conductivity. Their applications include biosensors, drug delivery, neural interfaces, etc. Nonetheless, if these semiconductor materials are able to translate biological signals from cells, the translation is not always easy and sometimes not as efficient as it could be. The main limitation of organic polymers in bioelectronic tissue-like hydrogel-based neural interface will suggest many possibilities for developing advanced neural implants with secured signal reliability and recording sensitivity.
are promising to use such biofunctionalized polymers to record/stimulate neural signals more effectively as the cells adhere directly to the protein-like surfaces.

**Inkjet Printed Stretchable Organic Electrochemical Transistor with Petal-Molded Substrate**  
Yuanzhe Li, Naixiang Wang, Anneng Yang and Feng Yan; Hong Kong Polytechnic University, Hong Kong, China.

Organic electrochemical transistor (OECT) modifies its channel current by injecting ions from the electrolyte. The employment of organic polymer as the channel material is so central to OECT that it deeply affects most all aspects of the device. It gives OECT excellent biocompatibility and contributes to its successful application as biological interfacing. The organic nature also provides space for solution processing, where powerful patterning method such as inkjet printing can be introduced and therefore realize the high-throughout, roll-to-roll fabrication of OECT.

However, the benefit of organic channel still hasn’t been exploited to its limit. When we have device-level integration with rigid metal electrode, for instance, gold, the intrinsic stretchability of organic polymer is greatly wasted. The poor mechanical performance of gold electrode is now a bottleneck and may risk the device being missed as an effective solution for wearable electronics, which are widely considered as next generation of human-computer interaction medium.

Encouragingly, efforts have been made in various aspects to bypass the limit imposed by rigid electrodes. Both prestretching of substrate and laser-patternning of electrodes achieve considerable improvements by creating buffer for electrodes so that the device is practically not deformed even under great strain.

The place we cut into is when this inevitable deformation finally occurs, and more and more cracks are tearing the electrodes into pieces. We propose with periodic ridge morphology, it is possible to suppress the expansion of the crack and make it stay at the ridge of each nearest pit. To make this kind of periodic structure, we no longer use expensive and complicated photolithography techniques, but instead turn to nature for inspiration and find the petals as an ideal mold for replicating its honeycomb structure. Gold electrodes and poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) channel are then deposited on molded polydimethylsiloxane (PDMS) substrate by magnetic sputtering and inkjet printing respectively. Fabricated devices show stretchability up to 30% under multi-axial strains.

Given that the proposed principle works at different stages of device deformation and there is no conflict in the manufacturing process, it should function well as an augment to existed solutions, paving way for devices with even higher stretchability by adopting hybrid strategies.

**Progress Towards a Silicon-Based Cochlear Nucleus Hearing Prosthesis**  
Nicholas Nolta, Pejman Ghelich and Martin Han; University of Connecticut, Storrs, Connecticut, United States.

Over the past decade, we have developed a silicon-based neural recording and stimulation electrode array for a cochlear nucleus hearing prosthesis. The current design and fabrication process are presented and published in vivo results are summarized. The materials used in the array include the silicon and silicon oxide of the silicon-on-insulator wafer, titanium/platinum/gold for the interconnects, silicon oxide and silicon nitride for passivating layers, and titanium/iridium for the electrode sites. Deep reactive ion etching defines the shape of the array, with the burried oxide layer in the silicon-on-insulator wafer serving as the etch stop. Backside thinning with an SF6-based dry etch precedes manual release of the array from the wafer. Mechanical grinding sharpens the tips of the array’s shanks into sharp points rather than a vertical wedges. Finally, the arrays are cleaned, packaged, and sterilized. In vivo testing in cat auditory brainstem demonstrates the viability of the array. The array’s physical sharpness and stiffness allowed for successful implantation into cochlear nucleus and inferior colliculus, which are considered deep and difficult-to-reach targets, using an inserter tool. Once in tissue, the array’s 3D multi-shank layout allowed for tonotopic stimulation in different tissue volumes throughout the cochlear nucleus. The electrode and passivation materials proved to be sufficiently long-lasting and biocompatible to allow for in vivo recording and stimulation for over one year. Other applications include any situation in which mechanical robustness, a 3D multi-shank layout, and stable long-term stimulation and recording performance are desired, such as in the spinal cord or for deep brain stimulation. In the future, we plan to push this device towards human clinical use as an alternative hearing prosthesis to the cochlear implant for patients with ossified cochleas or damaged auditory nerves.

**Controlled Corrosion for Electrochemically Modified Surfaces in Nanofabrication Process**  
Francis McEachern and Geraldine Merle; Surgery, McGill University, Montreal, Quebec, Canada.

Pseudomonas aerugenosa (PA) is a ubiquitous and drug-resistant bacteria responsible for approximately 27% of hospital-acquired infections (Alatraktchi et al, 2016). Current diagnostic standards rely upon labor-intensive bacterial culturing, which demand multiple measures over several days for conclusive results. Fortunately, the development of electrochemical biosensors proves an encouraging avenue for further diagnostic advance. Biosensors are small, relatively simple to fabricate, easily implantable and can provide real-time measurements with excellent spatial and temporal resolution. Pyocyanin (PYO) is a redox-active toxin uniquely expressed by PA, and stands as a novel biomarker for PA infection. Due to its unique oxidation window (at 0.59 V), PYO proves to be a viable target to which we may tailor future electrochemical diagnostic tools (Alatraktchi, 2016). Previous studies have indicated that PYO can be clinically isolated from patient samples and validated effectively via square-wave voltammetry (Simaet et al, 2017).

Our research focuses on tuning everyday medical tools to powerful analytical devices to provide a dichotomous yes/no response to the presence of biomarkers in real-time. Minimally invasive, low-cost stainless steel acupuncture needles (AN) were modified via a two-step process: 1) controlled corrosion microfabrication, and 2) polymer free deposition of carbon nanoparticle (CNP). Following physical, electrical and chemical characterization of the probe (AFM, CV, SEM, microCT, EIS, compressive strength testing with Instron), we validated this electrochemical detection needle with in vitro and in vivo measurements of PYO.

We successfully developed a well-controlled corrosion environment that produces reproducible and robust pitted needles. These pitted needles exhibit high capacitance, increased SSA, and a homogeneous porosity with the presence of large voids. Despite the porosity, the structural integrity of the pitted ANs remained high according to the compressive strength analysis using the ballistic gel simulating human tissue. Adding CNPs on the surface of the pitted needles enhances drastically the electron transfer, and maximize the signal to noise ratio. PYO has been successfully detected in vitro and clinically viable
concentrations (2-100μM), and the testing on clinical isolates from patients has yet to be applied (Alatraktchi, 2016). This finding potentially removes one of the remaining obstacles to highly efficiency point-of-care diagnostics and the ability to tailor antibiotic therapy using inexpensive materials and equipment.

Multi-Frequency Assessment of the Electrical Impedance Myography Parameters on 3D Malignant Breast MD Nurul Anwar Tarek1, Ahmed H. Jalal1, Fahmida Alam2 and Mohammad Ahad1; 1ECE, Georgia Southern University, STATESBORO, Georgia, United States; 2ECE, Florida National University, Miami, Florida, United States.

Electrical properties such as conductivity and permittivity of biological material have notable dependency on frequency. These frequency dependent changes in biomaterial properties can play a prominent role in impedance signature of Electrical Impedance Myography (EIM). EIM is a non-invasive and painless four electrode measurement tool, measuring the impedance based on the response of the low amplitude alternating current. In this study, multifrequency Electrical impedance Myography assessment was performed using an applied range of frequencies for getting valuable insight of the biomaterials. In this paper, the objective of our study is to explore the effects of different sized malignant tumor in female breast tissue on the multifrequency signature of EIM. In this study, a finite element model of a female breast has been developed based on electro-biophysical data for each malignant tissue within a frequency range of 2 GHz to 3 GHz and log frequency vs resistance and log frequency vs reactance of EIM have been analyzed for various sized tumor on breast. It is found that the slope of log reactance vs. frequency and resistance vs log frequency decrease with increasing tumor size. For instance, the percentage deviation of log reactance slope for 8 mm tumor and 6mm tumor from 2 mm (1mm radius) tumor size is 4.12% and 0.412% respectively. The study provides evidence that evaluation of the frequency dependent impedance data can provide rich assessment of the abnormal biological tissue.

BM07.09.10
Biomimetic Modification of Biopolymers for Electrochemical Synthesis of Organic-Inorganic Composites Amanda Clifford and Igor Zhitomirsky; Materials Science and Engineering, McMaster University, Hamilton, Ontario, Canada.

A conceptually new approach has been developed for the fabrication of organic-inorganic composite films for orthopaedic coatings and biosensors, using cathodic electrophoretic deposition (EPD). This technique is based on the biomimetic modification of biopolymers such as chitosan (CHIT), and poly-l-lysine (PLL) with a catechol containing moiety, 3,4-dihydroxybenzaldehyde (DHBAla), utilizing a Schiff base reaction. CHIT is a naturally occurring biopolymer, which has been used for a variety of biomedical applications due to its structural similarity to glycosaminoglycan, which is the primary component in the extracellular matrix of bone and cartilage. The surface morphology and roughness of PLL allow for remarkable cell adhesion, and as a result it has been used in the past as a coating agent to promote cell adhesion as well as for drug delivery applications. Benefits of biopolymer modification with catechol group include superior adhesion to inorganic nanoparticles, as well as tissue adhesion in the presence of body fluid. Catechol modification also imparts redox-activity upon the coating, which is useful for in-situ reduction of metallic nanoparticles and biosensing applications. These unique properties allow catechol modified biopolymer films to be used as reducing, capping, charging, dispersing and film forming agents for the fabrication of advanced nanocomposite films utilizing cathodic EPD. In the following work, catechol-modified CHIT polymer was used for the in-situ reduction of Ag+ to silver nanoparticles, and the unique redox properties were utilized for the development of photovoltaelectrochemical (PEC) DNA biosensors. Modified CHIT and PLL were both used for fabrication of nanocomposite coatings, containing advanced functional biocarriers such as hydroxyapatite (HA) and rutile (TiO2), to improve osseointegration for orthopaedic and dental applications. Preliminary cell testing revealed that composite PLL-DHBA films containing HA and TiO2 promoted cell proliferation due to its hydrophilic nature and rough surface morphology. These techniques pave the way for the continued development of biomimetic materials processing, and the fabrication of advanced multi-functional materials for use in a variety of biomedical applications, from orthopaedic coatings to DNA biosensors.

BM07.09.11
Following Anticancer Drug Activity in Cell Lysates with DNA Devices Dimithree Kahanda1; 2, Naveen Singh1, David Boothman1 and Jason D. Slinker1; 1The University of Texas at Dallas, Richardson, Texas, United States; 2Department of Biosciences, Rice University, Houston, Texas, United States; 3Department of Biochemistry and Molecular Biology, Indiana University Simon Cancer Center, Indianapolis, Indiana, United States.

There is great need to follow the selectiveness of anticancer drug activity and to understand the mechanisms of biological activity. Here, multi-electrode chips with DNA monolayers are used to track anticancer drug activity in cellular lysates and correlate cell death activity with DNA damage. Cells were prepared from the triple-negative breast cancer (TNBC) cell line, MDA-MB-231 (231) to be proficient or deficient in expression of the NAD(P)H:quinone oxidoreductase 1 (NQO1) enzyme to represent cancerous and control cells. Cells were lysed and added to chips, and the impact of β-lapachone (β-lap), an NQO1-dependent DNA-damaging drug, was followed with DNA electrochemical signal changes arising from drug-induced DNA damage. Devices showed a 3.7-fold difference in the electrochemical responses to NQO1+ over NQO1− cell lysates, as well as 10 to 20-fold selectivity to controls deactivating DNA damaging pathways. Concentration dependence study revealed that 1.4 μM β-lap correlated with the onset of cell death from viability assays and the midpoint of DNA damage on the chip, and 2.5 μM β-lap correlated with the mid point of cell death and the saturation of DNA damage on the chip. Results indicate that these devices could inform therapeutic decisions for cancer treatment.

BM07.09.12
DNA Sizing and Quantification Using Multi-Frequency Impedance Cytometry Jianye Sui1, Neeru Gandotra2, Pengfei Xie1, Zhongtian Lin1, Curt Scharfe2, Mehdi Javanmard1 and Hemanth Maddali1; 1Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Yale University, New Haven, Connecticut, United States.

In recent decades, DNA quantification has attracted substantial research efforts due to its significance in disease diagnosis and analysis. A number of DNA quantification methods have been established. Traditional methods to quantify nucleic acids usually use fluorescent labels or dyes and require bulky instruments for excitation. Previously, Saleh et al. demonstrated quantification of biomarkers through resistive pulse sensing using a DC measurement to
detect changes in particle diameter due to analyte binding on the surface of a bioactivated colloid [1]. In this work, we proposed a new approach for label-free nucleic acid strand recognition by using multi-frequency impedance flow cytometry.

The process begins by amplifying (PCR) and biotinylating target DNA, and immobilizing the DNA onto streptavidin coated magnetic beads. The cytomter consists of a pair of electron-beam deposited gold electrodes on glass wafer, with a Polydimethylsiloxane (PDMS) microfluidic channel embedded on top. Various quantities of DNA on the surface of the bead will affect the surface conductance, permittivity, and charging profile and thus modulate the frequency-dependent impedance response. When a bead flowed through the sensing region, it partially blocks ions conducted between two electrodes. Thus, there is a frequency-dependent impedance increased. By probing peak intensities at different frequencies, beads coated with differing quantities of DNA can be differentiated from each other. The impedance response is captured in real-time at 8 frequencies using a multi-frequency lock-in-amplifier.

Different beads immobilized with a series of DNA quantities (ranged from 0.1 ng to 1000 ng) to the surface were investigated using impedance flow cytometry. The bare magnetic streptavidin coated beads that had no DNA captured were used as a negative control. We implemented multi-frequency analysis, which provides a more comprehensive result, since the impedance response of different samples at single frequency may not be separable. The peak intensity increased as frequency increased from 100 kHz to 5 MHz and then decreased as frequency increased to 15 MHz. Results showed that using multi-frequency analysis, we can differentiate beads with different concentrations of DNA. In addition, a study on the effect of different DNA lengths on impedance responses was performed. We demonstrated that as the length of DNA increased, the impedance responses increased linearly. The results of these studies suggest that this approach can be applied for DNA quantification using small sample volumes using a miniaturized electronic chip.

BM07.09.13
Artificially Well-Designed Biomonolayer for Prevention of Nonspecific Electrical Signal
Shohei Himori, Shoichi Nishitani and Yoshiya Sakata; The University of Tokyo, Bunkyo-ku, Japan.

[Introduction]
An artificially well-designed biointerface is required for a new strategy of biosensor such as an enzyme-free glucose sensor. A solution-gate field-effect transistor (FET) is based on the potentiometric measurement of intrinsic ionic or biomolecular charges at the gate surface of the FET without enzymatic reactions. Moreover, an extended-Au film-gate FET enables a highly-sensitive detection of small biomarkers, because the Au film exhibits a strong catalytic action, resulting in the oxidation of organic compounds such as uric acid and glucose. However, the selective detection of small biomarkers, which involves a signal to noise ratio, with the Au film electrode is not sufficient for a real sample containing impurities. In this study, we have designed a Au film/solution interface for the selective detection of small biomarkers and investigated the effect of diazonium monolayer on the prevention of nonspecific signals based on non-targeted small biomarkers.

[Methods]
An Au(Cr) film was fabricated by sputtering on a glass substrate. The Au electrode was modified by nitro group-terminated aryldiazonium monolayer in acetonitrile including 1 mM 4-nitrobenzenediazonium tetrafluoroborate (NBD), 25 mM tetrabutylammonium hexafluorophosphate (nBuPF6), and 2 mM DPPH via cyclic voltammetry (CV), which was in the potential range of +0.3 V to -0.7 V at the scan rate of 50 mV/s. The immobilization density of NBD monolayer was controlled via CV treatment. On the other hand, the same method was applied for the modification of NBD multilayer in the solvent without DPPH. The change in the surface potential was monitored using the NBD-grafted FET. In particular, uric acid was used as a small biomarker and introduced onto the Au film electrode with the different densities of NBD monolayer or NBD multilayer. The concentration of added uric acid was changed in the range of 5 µM to 1 mM. The thickness of diazonium film was analyzed by laser microscope. Besides, the surface coverage was calculated by reduction from nitro group of NBD to amino group.

[Results and Discussion]
The uric acid response for the NBD monolayer-grafted FET was smaller than that for the NBD multilayer-grafted FET. That is, the NBD multilayer-grafted FET suppressed the nonspecific electrical signal based on the interaction of uric acid with the Au film. This is because the surface coverage by the NBD multilayer was insufficient, that is, there were some vacancies among the grafted NBDs, through which uric acid approached to the Au surface. On the other hand, the grafting density of NBD monolayer on the Au film was higher than that of NBD multilayer. Moreover, the effect of NBD multilayer on the prevention of nonspecific signal was enhanced with increasing potential cycles via CV method, resulting in the increase of immobilization density.

[Conclusions]
Our work suggests a new strategy of selective detection of small biomarkers using the extended-Au film-gate FET biosensor.

Observation of Local Ionic Concentration at the Hippocampal Neuron with Nano-Pipette
Jong Wan Son1; Tomohide Takam1, Woong Sun2 and Bae Ho Park1; 1Konkuk Univ, Seoul, Korea (the Republic of); 2Kogakuin University, Hachioji, Japan; 3Korea University, Seoul, Korea (the Republic of).

Selected cationic currents at the cell membrane inside and outside of hippocampal neuron were measured using nano-pipette probes. A polyvinyl chloride film was prepared in the nano-pipette probes, and the film contains each cation ether ligands that collector of potassium, sodium or calcium cations. The currents of the collected cations were detected through a silver wire electrode and the currents were recorded with a sub-picoampere current measurement system, developed from the techniques of TΩ-gap impedance scanning tunneling microscopy. Depending on the position of the nano-pipette probes, the local ionic concentration at hippocampal neuron is measured as the selected cationic currents. We also demonstrate the progress of our work about real-time measurements of ionic concentration when stimulate the hippocampal neurons.

Magnetocochemical Technique for Remote Manipulation of Neurons
Siuyan Rao1, 2, Ritchie Chen2, Ava LaRocca3, Michael G. Christiansen3, Alexander W. Senko1, Cindy Shi1, Po-Han Chiang1, George Varnavides2, Seongjun Park2, Junsang Moon3 and Polina Anikeeva1, 3; 1Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Simons Center for Social Brain, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Targeted delivery of neuromodulators within the brain is essential in linking the activity of their molecular targets to behavior. However, existing delivery methods are often non-specific, e.g. intravenous and peritoneal systemic administration, or invasive, e.g. implantation of microfluidic devices. To facilitate spatially-restricted and remotely-controlled delivery of neuromodulators to neural circuits of interest, we sought to gate the release of small molecules
using non-invasive stimuli. Here, we coupled weak alternating magnetic fields (AMFs) in the low radiofrequency range to trigger the release of chemical compounds encapsulated within liposomes loaded with magnetic nanoparticles. Multiple micro-doses with minimal leakage could be delivered upon liposome permeabilization through localized heating of magnetic nanoparticles. When combined with chemogenetic neuromodulation approaches, we find that the activation times can be decreased from hours to seconds at multiple time points within genetically-defined neural populations. This scheme was also applied to control over endogenous receptor function using magnetochemical delivery of known antagonists and agonists, demonstrating applications of this approach to various ligand-receptor pairs. We anticipate that the magnetochemical tools will facilitate investigation of neural circuits during behavioral experiments and enable neuromodulation studies in rodent models incompatible with permanently implanted hardware.

BM07.09.17
Nanowell Array Impedance Platform for Multiplexed Label-Free Quantification of Cytokines in Serum at Femtomolar Level Detection Limits Pengfei Xie, Tuan Le and Mehdi Javanmard; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Protein microarrays, on which thousands of discrete proteins are printed, provide a valuable platform for functional proteomic analysis. A protein microarray provides a multi-functions platform for the comprehensive and high throughput studies. Label-free techniques avoid interference due to the tagging molecules, which is the fundamental preparation for the labeling based detection methods. Detection of proteins in blood using label-free impedance based techniques is difficult due to high salt concentration of the matrix, which results in screening of the charge of the target proteins. In this work, we describe a novel sensing configuration where sensitivity benefits from the high salt concentration of the matrix, and demonstrate robust performance through testing in rat serum. To be exactly, we developed a platform with nanowell array sensor, which can monitor multiplexed cytokines in serum at femtomolar level. The nanowell impedance sensor involves the fabricating the micro-wells array patterned electrodes with nanometer level gap, and the continuous impedance measurement using lock-in amplifier based automatic monitor platform. And we have demonstrated the ability of the platform with 100 femtomolar level cytokines detection of mouse TNF-alpha, IL6, IL10 and CXCL2. The titration curves of all 4 cytokines ranging from 10 fM up to 1 nM are also plotted in this work.

BM07.09.18
Electronic Quantitative Surface Markers for Cancer Cells Based on Bead-Cell Aggregate Sizing and Multi-Frequency Impedance Spectroscopy Zhongtian Lin1, Siang-Yo Lin2, Pengfei Xie3, Joseph Bertino1 and Mehdi Javanmard3; 1Cancer Institute of New Jersey, Rutgers University, New Brunswick, New Jersey, United States; 2Department of Electrical and Computer Engineering, Rutgers University, Piscataway, New Jersey, United States.

Rapid analysis of surface markers on the membrane of cancer cells can be used for point-of-care device for monitoring patient’s response to various cancer treatments. Here, we introduced a microfluidic sensor for quantification of proteins on membrane of cancer cells using multi-frequency impedance cytometry. To demonstrate proof-of-concept, we successfully detected “activated” matrigel on the surface of cultured breast cancer cells. Activated matrigel is overexpressed in most epithelial cancer cells. In order to target the cancer cells, magnetic beads were coated with an anti-matrigel monoclonal antibody (M69) that recognizes activated matrigel. The beads then form aggregation with cancer cells as a result of expression of matrigel on the cells’ membrane. The magnetic beads and the bead-bound cancer cells were extracted from the test sample via immuno-magnetic separation. Multi-frequency electrical impedance cytometry was applied to the bead-cell mixture which enable differentiating between unbound beads, non-target cells and bead-cell aggregates. This method can be used for detection and quantification of membrane bound protein (i.e. matrigel) levels, as the concentration of matrigel expressed on the cancer cells is related to the size and quantity of peaks from bead-cell aggregates.

The biochip consists of two microelectrodes on a glass substrate with a PDMS micro-channel above it. Gold electrodes were fabricated using standard photolithography, electron beam evaporation, and lift-off processing. The micro-channels are 400 µm wide and 20 µm high connecting to a sensing region which is 100 µm wide and 20 µm high. M69 coated 2.8 µm sheep anti-mouse IgG beads were mixed with cancer cells off chip. A portion of the beads bind together with cancer cells in the positive assay which form effectively large aggregates compared to the negative control assay where beads were not treated with M69. The mixture is then injected into the inlet of micro-channel. As beads and bead-cell aggregates pass over the microelectrodes that is connected to a multi-frequency lock-in amplifier and AC voltage source, a frequency dependent increase in impedance was detected. The amplitude of the current peak is proportional to particle size. Utilizing simultaneous multiple frequencies measurement of peak intensity, we can demonstrate the quantification of the number of bead-cell aggregates which allows for estimation of matrigel expression levels.

BM07.09.19
Conducting Polymers for Axonal Regeneration—Effect of Surface Topography on Modulation of Axonal Growth Martin Antensteiner, Anthony M. Kisucky and Mohammad Reza Abidian; Biomedical Engineering, University of Houston, Houston, Texas, United States.

Nerve injuries in the peripheral nervous system caused by trauma (i.e. nerve lesions) or debilitating disorders such as Parkinson’s disease have affected more than 20 million people and are estimated to account for 2.8% of all trauma cases in the United States. Autografts are the clinical gold standard for the treatment of nerve gaps, the disadvantages of which include a limited supply of donor nerve, inability to reconstruct complex nerve gaps, sensory deficits in the distribution of the donor nerve, painful dysesthesias following sensory nerve harvest, and structural-ultrastructural nerve mismatch. To overcome these limitations, artificial conduits have been widely investigated to bridge nerve gaps. However, functional recovery after nerve injury remains a challenge.

Biocompatible Conducting Polymers (CP) can be utilized to guide neurons and eventually repair nerve injuries such as nerve gaps due to their unique electrical, physical, and chemical properties. However, few works address the effect CP roughness has on axonal regeneration. In this work, we have investigated two common biocompatible CPs, poly(pyrrole) (PPy) and poly(3,4-ethylenedioxythiophene) (PEDOT), fabricated using galvanostatic (GSTAT) and potentiostatic (PSTAT) methods, and characterized the surface roughness of these two polymers. While PPy is well-known for its electrical conductivity and physical stability, PEDOT displays superior chemical stability and electrical conductivity, making it an ideal candidate for artificial conduits.

Electrodeposition was performed on microfabricated Au electrodes using a solution of EDOT or Py monomer and poly(styrenesulfonate) under GSTAT (0.1 to 1.5 mA/cm²) or PSTAT (0.5 to 0.95 V) deposition modes over intervals ranging from 1 to 10 minutes. Each surface was analyzed with materials confocal microscopy (MCM) to measure the CP film thickness and surface roughness. Additionally, the impedance and charge storage capacity (CSC) of the films were measured with impedance spectroscopy and cyclic voltammetry, respectively. Preliminary data suggests a dual dependence of all measured properties (roughness, thickness, impedance, and CSC) on both deposition time and applied charge. For example PPy/GSTAT films on Michigan neural electrodes, roughness (Rq) increased from 2.1±0.25 nm to 12.0±0.84 nm; CSC also increased from 5.7 mC/cm² to 98.7 mC/cm²; finally, impedance at 100 Hz decreased from 8.94±2 Ω to 3.83±2 Ω. These measurements were taken from films deposited at 1 min, 0.1 mA/cm² and 10 min, 1.5 mA/cm² respectively. PPy properties exhibited generally linear trends, and PEDOT properties tended to display nonlinear trends. Dorsal root ganglion (DRG) cells will be cultured on these CP films and neurite outgrowth will then be assessed as a function of surface roughness. These results can be leveraged to improve the control of regenerating axons via surface cues.
Organic semiconducting polymers hold great potential to act as electrically active materials at the interface with a biological environment due to their biocompatibility, soft nature and ability to support both ionic and electronic transport. Recently, functionalization with polar ethylene glycol chains of thiophene-based polymer backbones led to p-type materials with high transconductance and stability in accumulation mode organic electrochemical transistors (OECTs). When a similar side-chain engineering strategy was employed for n-type OECT materials based on naphtho[2,3-b:6,7-b′]dithiophene-4,5,9,10-tetracarboxylic-diimide (NDTI) units, a high stability for n-type doping in aqueous solution and a high volumetric capacitance were observed. However, the overall performance of the device was limited by the poor electron mobility of the material. In search of n-type OECT materials with improved electron mobility, we report the design and synthesis of a series of copolymers containing more planar and rigid naphtho[2,3-b:6,7-b′]dithiophene-4,5,9,10-tetracarboxylic-diimide (NDTI) units as the electron acceptor building block. The properties of these copolymers will be discussed in the context of OECTs.
in comparison with the ND1 analogues, elucidating strategies for backbone engineering in order to develop high-performance electron transport materials for bioelectronic applications.

Novel P-Type Small Molecules for Organic Electrochemical Transistors Zachary S. Parr1, Benjamin Poggi1, Jonathan Rivnay2 and Christian B. Nielsen1; 1SBCS, QMUL, London, United Kingdom; 2Biomedical Engineering, Northwestern University, Chicago, Illinois, United States.

Conducting and semiconducting organic materials have existed for over forty years and have seen a broad range of applications from transistors to photovoltaics to logic circuits to OLEDs and more recently biosensors. Among the biosensing devices developed in recent years the most promising has been the organic electrochemical transistor (OECT). Much of the research into OECT’s has mainly involved PEDOT:PSS which has proved itself a champion material for biosensors. Very recently, it has been demonstrated that traditional p-type conducting polymers can be modified with polar ethylene glycol sidechains to allow for mixed ionic and charge conductance affording a polymer with higher transconductance than comparable PEDOT:PSS devices with this design methodology also affording the first n-type biosensing device1–3. Ionic conductance or capacitance combined with charge mobility are the two critical material properties required to achieve high transconductance ($g_m$), the figure of merit of an OECT. With this in mind, we have investigated the potential of small molecule semiconducting materials which often display very high charge mobility in OFETs as materials for OECTs via modification of the conjugated small molecule with ethylene glycol side chains.

We have designed and synthesised a series of molecules primarily based on EDOT oligomers via direct arylation end capped with phenyl groups functionalised with tri-ethylene glycol side chains. The molecules have been fully characterised structurally, electrochemically and optically and exhibited repeatable, stable redox behaviour in aqueous environment with low onsets of oxidation as well as strong electrochromism in thin films. Finally, the molecules have been characterised operationally in the OECT regime. We have achieved OECT devices which can be solution deposited and promising OECT performance is achieved for a number of the molecules. This promising initial result opens an avenue to achieve scalable synthesis of attractive materials for OECTs based on small molecules which with some further structural modification and optimisation of side chain length and solid state morphology are likely to compete with the properties of reported OECT polymers as well as afford access to significantly more varied processing methodologies than for polymer systems.

8:30 AM *BM07.10.03
Organic Mixed Conductors for Bioelectronic Devices Jonathan Rivnay; Northwestern University, Evanston, Illinois, United States.

Polymeric materials capable of ionic-to-electronic signal transduction are important for enhancing bi-directional communication in bioelectronics. Prototypical conducting polymers such poly(3,4-ethylendioxythiophene):poly(styrenesulfonate), PEDOT:PSS, have enjoyed prolonged success as organic bioelectronic mainstays, but they are challenging to study, and may suffer from stability issues and other potentially disqualifying drawbacks. Studying the strengths of PEDOT-based systems, we are able to establish design rules in order to develop new conjugated mixed conductors. Introducing glycolated side chains to carefully selected semiconducting polymer backbones, for example, has produced a class of high performance bioelectronic materials that feature high volumetric capacitance, and enabled electrochemical transistors with transconductance >10mS (device dimensions ca. 10um), and steep subthreshold switching characteristics. A sub-set of these materials outperform PEDOT:PSS and show significant promise for low power, biocompatible devices for implantable bioelectronics. These materials and devices have led to enhanced sensing circuits with the potential for hybrid integration with inorganic transistors.

Imaging Ion Dynamics on the Nanoscale with Time-Resolved Electrostatic Force Microscopy Jeff Harrison1, Dean Waldow2, Phillip Cox1 and David S. Ginger1; 1Chemistry, University of Washington, Seattle, Washington, United States; 2Pacific Lutheran University, Tacoma, Washington, United States.

Ionic transport processes govern performance in many classic and emerging devices, ranging from battery storage to modern mixed-conduction electrochemical transistors. Here, we study local ion transport dynamics in polymer films using time-resolved electrostatic force microscopy (trEFM). We compare time-domain behavior using both local trEFM and macroscopic electrical impedance spectroscopy (EIS). We use poly(exo-(2-(2-methoxyethoxy)ethyl)-7-oxabicyclo[2.2.1]hept-5-ene-2,3-dicarboximide)(Poly-ONDI) films doped with lithium bis(trifluoromethane)sulfonimide (LiTFSI) as a model system. Our results show that the local polymer response measured in the time domain with trEFM follows stretched exponential relaxation kinetics, consistent with the Havriliak-Negami relaxation we measure in the frequency-domain EIS data for macroscopic samples of the same polymers. Furthermore, we show that trEFM data correlate with bulk samples in EIS—changes in ion dynamics with increasing temperature, increasing salt concentration, and increasing volume fraction of ethylene glycol side chains in the polymer matrix evolve with the same trend in both measurement techniques. We conclude from this correlation that trEFM data reflect, at the nanoscale, the same ionic processes probed in conventional EIS at the device level. Finally, as an example application for emerging materials syntheses, we use trEFM and infrared photoduced force microscopy (PiFM) to image a novel diblock copolymer electrolyte for next-generation solid-state energy storage applications.

9:15 AM BM07.10.05
The Influence of Water on the Ion-to-Electron Transduction of Organic Semiconductors Achilleas Savva1, Camila Cendra Guinassi2, Alberto Salleo2, Jonathan Rivnay1 and Sahika Inal1; 1Biological and Environmental Science and Engineering Division, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2Department of Materials Science and Engineering, Stanford University, Santa Clara County, California, United States; 3Department of Biomedical Engineering, Northwestern University, Evanston, Illinois, United States.

Organic electrochemical transistors (OECTs) comprised of organic (semi)conductor channels operate in aqueous, biological media and translate low
magnitude ionic fluctuations of biological origin into measurable electrical signals. The growing technological interest in these bio-transducers makes the fundamental understanding of the ion-to-electron conversion extremely important for the design of new materials and devices. One crucial aspect that has been so far disregarded is the water taken up by the film during device operation. Here we show the influence of water taken up by a p-type organic semiconductor film on the efficiency, reversibility and speed of charge generation induced by electrolyte anions, penetrating inside the film. The efficiency of ion-to-electron transduction is linked to the performance of the accumulation mode OECTs comprising the polymer in the channel. We find that when less water is incorporated into the polymer film alongside the dopant anions, the OECT ON current is higher, the device is more reversible, stable and switches faster. This work gives insights into the impact of a swollen channel material on the performance of OECTs and lays the foundation for future materials design for efficient ion-to-electron transduction.

9:30 AM BM07.10.06
Low Voltage Current-Driven Organic Electrochemical Transistor for Biomedical Applications Leona V. Lingstedt1, Matteo Ghittorelli2, Fabrizio Torricelli2, N. Irina Craciun1, Paschalis Gkoupidenis1 and Paul W. Blom1; 1Max Planck Institute for Polymer Research, Mainz, Germany; 2Information Engineering, University of Brescia, Brescia, Italy.

Detection of ion concentrations plays a fundamental role in biomedical diagnostics, health and environmental monitoring, water and food controlling, as well in the security and agriculture industry. Here we show an organic electrochemical transistor (OECT) in a current-driven configuration providing highly sensitive ion detection at low voltages. The ion sensitivity normalized to the supply voltage is larger than 1200 mV V⁻¹ dec⁻¹, which is the highest value ever reported for ion-selective transistors. The bias current determines the range of ion concentration and the sensitivity is not limited by the supply voltage, thus overcoming the fundamental limit. A potential application is demonstrated by the integration of the current-driven OECT with an ion-selective membrane, exhibiting a sensitivity of 1035 mV V⁻¹ dec⁻¹, normalized to the supply voltage.

We were able to extend this concept by interfacing organic electronics with biological systems. The integration of OECTs with human cells, enables the assessment of barrier tissue layer properties in a non-invasive and label-free method. Measuring the paracellular transport provides information about the integrity and function of the barrier tissue as disruption or dysfunction can be an indicator for disease or toxicity. The OECT, resembled in the inverter-like topology, is sensitive to cell coverage and shows minute-respons to toxins due to barrier rupture. Pushing this technology to greater sensitivity, this proposed approach may open opportunities in toxicology, drug delivery, disease diagnostics and fundamental research in molecular biology.

9:45 AM BM07.10.07
Polymer OFET Biosensors with High Performance and Stability Mark Nikolka1, 2, Amir Foudeh1 and Zhenan Bao1; 1Stanford University, Stanford, California, United States; 2University of Cambridge, Cambridge, United Kingdom.

Due to their ease of processing, conjugated polymers are promising candidates for a range of optoelectronic applications ranging from flexible displays and light emitting diodes (OLEDs) to organic photovoltaics (OPV). Recently, surprisingly high levels of performance and stability have been demonstrated especially for low disorder conjugated polymers exhibiting charge carrier mobilities well above 1cm²/Vs and operational stability compatible with demanding state-of-the art OLED displays [1,2]. However, these advancements so far have not been translated into the emerging field of biosensors where similar performance and stability requirements prevail. Here we demonstrate how high mobility, low disorder polymers can be utilized in platforms for PH-sensing and bio-sensing. In particular, we demonstrate a highly stable sensors platform based on the dual-gate mechanism. In this architecture a sensing signal is transduced and amplified by the capacitive coupling between a low-k bottom-dielectric and a high-k ionic elastomer top-dielectric that is in contact with an analyte solution. We show that our platform design exhibits a high stability in various aqueous environments of different salt concentrations making it particularly interesting for biosensing applications where high selectivity is desired.

10:30 AM *BM07.11.01
Physical Biology at the Semiconductor-Based Biointerfaces Boshil Tian; University of Chicago, Chicago, Illinois, United States.

Although there are numerous studies on either semiconductors or biological components, our understanding of the fundamentals at the semiconductor-based biointerfaces has been limited. As different types of energy (such as electrostatic, mechanical, thermal, and chemical energies) display diverse scaling behaviors and can converge, an appropriate selection of the length scale is critical for promoting new scientific discoveries. My group integrates material science with biophysics to study several semiconductor-based biointerfaces. We synthesize new forms of semiconductor materials and use them to probe biological dynamics, with particular focus at the sub-micrometer and sub-cellular length scales. In particular, we have recently identified a biology-
of these devices is unique and therefore outperforms other OECTs despite the absence of an electron mediator. We show that by tuning the device operation parameters, the sensitivity and dynamic range of the device is controlled, demonstrating possible applications for biosensing.

Nanoparticles for Improving Performance of Enzymatic Electrodes

Organic Electrochemical Transistors (OECTs) are devices which find growing interest in the field of biological and chemical sensing. Although the OECT transduction is based on electrochemical reactions, the transistor architecture offers several advantages with respect to amperometric sensors, such as signal amplification, the use of easy and cheap readout electronics, low supply voltage (usually < 1 V), low power operation (< 100 μW), bio-compatibility. Moreover, OECT configuration does not require freestanding reference electrodes used in conventional electrochemical setups and offers design freedom in terms of device geometries and substrates (flexible). In addition to their inherent robustness, versatility and ease of integration, OECTs can be miniaturized and fabricated with low-cost materials [1], on any kind of substrate, including textile and plastic. Our research group has reported the fabrication of OECTs wherein the channel and all the electrodes are made by PEDOT:PSS (polystyrene sulfonate) and their use as chemical sensors for a wide class of analytes. The selectivity and sensitivity to the target analyte can be given by a proper functionalization of the gate material and/or acting on the transistor operation mode. This contribution describes our most recent results on OECT based chemical sensors exploiting the functionalization of the gate PEDOT electrode, as assessed by the following two applications:

1. The first application is the use of PEDOT doped with pH dyes (BTB and MO, i.e. Bromothymol Blue and Methyl Orange, respectively), as the gate electrode to develop an OECT sensor for pH monitoring. The developed sensor can reliably operate with a super-Nernstian sensitivity, that can be reached thanks to the amplification offered by the transistor architecture. The optimised configuration was realised on a PET substrate and the performance of the resulting flexible OECT was assessed in artificial sweat within a medically relevant pH range.

2. The second application is the design and synthesis of a new composite material based on Ag/AgCl nanoparticles (NPs) and PEDOT:PSS that allowed us to fabricate a novel kind of OECT-inspired sensor, integrating an Ag/AgCl gate electrode into the semiconductor polymer in the form of NPs. Such sensor combines an intrinsically amplified response associated to the transistor design with a simple two terminal electrical connection, which offers great advantages in terms of read-out electronics, adaptability to new and unconventional geometries and faster response time. The efficacy of such a simple connection has been demonstrated through the development of a textile sensor for real-time sweat monitoring.

Direct Metabolite Detection with an Accumulation Mode Organic Electrochemical Transistor

We describe the influence of gold nanoparticles (AuNPs) and nanoclusters (AuNCs) on the mechanism of bioelectrocatalytic reactions. Below a certain size the monolayer-protected AuNPs show a series of oxidation states and a clear HOMO-LUMO gap [1]. We propose that AuNPs can change their role in the bioelectrocatalytic processes when their size decreases below 2nm. Fructose dehydrogenase (FDH) used here is a heterotrimERIC membrane-bound enzyme complex, insensitive to oxygen, consisting of three domains. Subunit I is the catalytic dehydrogenase domain containing FAD as the cofactor. Subunit II contains 3 paramagnetic heme C moieties acts as an electron acceptor to subunit I [2].

We show that AuNCs ca. 1nm in size lead to larger FDH catalyzed currents of fructose oxidation and smaller overpotentials which reflects improved electronic communication between the electrode and the active sites [3]. The catalytic wave appears at a potential close to that of the beginning of clusters.
HOMO-LUMO gap. The effect of the smallest gold clusters is of special interest and features such as low-coordination sites, adsorptive properties of the AuNC surfaces, thiol monolayer organization have to be considered in the discussion of the improved catalytic current densities and lower overpotentials. Such behavior may be also understood as mediation of the enzymatic processes by the AuNCs as opposed to larger, plasmonic AuNPs, for which direct ET process (DET) is observed. Controlled switch from DET to mediated MET mechanism of electron transfer by decreasing AuNPs to cluster sizes might be considered for other oxidoreductases as well.

We also show that under influence of magnetic field superparamagnetic iron oxide NPs interact with paramagnetic heme centers of FDH subunit II leading to suitable orientation of the enzyme molecule and enhancement of DET. Closer approach of heme sites to the support results in the decreased fructose oxidation overpotential and Michaelis–Menten constant. Improved performance of enzymatic electrodes achieved through use of Au clusters or magnetic NPs holds great promise for third generation biosensors and biofuel cells.

Thus, by establishing a direct relation between presence of adhered cells and electrical output, we demonstrate that carbon-based electrolyte-gated transistors constitute a promising technology to perform large-scale and cost-effective monitoring for toxicology and drug development. Real time monitoring for toxicology and drug development applications, able to perform measurements with enhanced sensitivity and temporal resolution compared to standard electrochemical cell-substrate impedance spectroscopy and other well-established optical probes. Although this approach has proved to be useful in different applications, it does require complex read-out electronics, as well as non-trivial signal processing and analysis for data interpretation, being based on impedance spectroscopy techniques.

In this work, we propose carbon-nanotube based electrolyte-gated transistors as a novel tool to electrically monitor cell adherence and proliferation, able to operate consistently in aqueous environment and in conjunction with more established optical techniques. By exploiting the changes in the capacitive coupling occurring at the electrolyte/semiconductor interface as cells adhere on the active material, information on proliferation and detachment can be easily extracted from the quasi-static variation of the drain-source current in time, without any need for electrochemical spectroscopy or other frequency-dependent techniques. This particular sensing approach is validated by monitoring over a time span of three days the adhesion and growth of several cell lines via quasi-static measurements, and corroborated by means of standard and fluorescence optical microscopy. Indeed, in all instances the behaviour of the output current follows the expected changes in interfacial impedance that result from cell-proliferation on the active layer, corresponded by a full recovery of the initial currents upon inducing cell detachment from the device.

By establishing a direct relation between presence of adhered cells and electrical output, we demonstrate that carbon-based electrolyte-gated transistors constitute a promising technology to perform large-scale and cost-effective in vitro monitoring for toxicology and drug development applications, able to operate complementarily to state-of-the-art optical and electrochemical techniques.

Integrating Native Cellular Membranes with Organic Transistors Anna-Maria Pappas1, Han-Yuan Liu2, Charalampos Pitsalidis1, Rohit Singh2, Alberto Salles1, Susan Daniel1 and Roisin Owens1; 1Cambridge University, Cambridge, United Kingdom; 2Cornell University, Ithaca, New York, United States; 3Stanford University, Palo Alto, California, United States.

Cellular membranes represent an obvious, yet relatively neglected target for developing new drugs. Using membrane models (e.g., supported lipid bilayers, SLBs) for sensing and drug screening is limited by incompatibility at the biotic/abiotic interface, lack of molecular complexity, and lack of integrated functionality to transduce at the molecular level. We have recently demonstrated that SLBs are compatible with electroactive materials able to transduce molecular interactions of toxins with a model membrane. In parallel our teams have developed methods to assemble complex (native) membrane structures into planar supported bilayers on solid supports, using materials directly harvested from live cells. By using hydrated polymer-based transducers, instead of solid supports one can achieve a fluid environment- close to the physiologically relevant environment- i.e., facilitating mobility of the transmembrane proteins, which is essential for such native plasma membrane systems. These features enhance the native structural and functional properties of the membrane and ensure the credibility of our platform to be physiologically relevant and predictive of membrane molecular interactions. In this work, we demonstrate the formation of native SLBs on top of the conducting polymer poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) transistors. We characterize the native SLBs using both optical and electronic methods. Real time monitoring of the native SLB formation reveals useful information regarding dynamics of membrane fusion and allows for sensitive detection of minute changes on the membrane properties. This work is a first step towards the use of native plasma membranes with highly-sensitive, label-free and fast electrical readout to transduce membrane-compound interactions, essential for diagnostics and drug discovery applications.

Biosensor Prototype Based on Carbon Nanotubes for Detection and Hyperthermia Treatment of Cervical Cancer Cells Giovanni S. Caro1, André Marra1, Darinel Ortiz2, Ismael Jiménez2, Javier Avalos2, Gerardo Morell2 and Brad R. Weiner2; 1University of Puerto Rico at Rio Piedras, San Juan, Puerto Rico, United States; 2University of Puerto Rico, Bayamón, Puerto Rico, United States.

Current treatments for cancer include surgery, chemotherapy, and radiation, as well as combinations of these. Although widely utilized, these treatments are not entirely effective. Our primary aim is to develop a non-invasive radiofrequency-based biosensor that is able to detect cancerous cells as well as provide therapy using localized heat with the aid of nanotechnology. This wireless radiofrequency (RF) sensor employs carbon nanotubes (CNTs) to enable the detection of cancer cells and the selective treatment via hyperthermia. The sensor is a gold resonant coil LRC circuit for wireless transmission and in its capacitive component contains CNTs that were deposited and functionalized. The detection relies on the phase change of the RF signal in the presence of...
Organic Electrochemical Transistors for Electrical Cell-Substrate Impedance Sensing with Single Cell Resolution
Sven Ingebrandt1, Felix Hempel2, Jessica Ka Yan Law3, Fabian Brings1 and Xuan Thang Vu1; 1Institute for Materials in Electrical Engineering, RWTH Aachen University, Aachen, Germany; 2Informatics and Microsystems Technology, University of Applied Sciences Kaiserslautern, Zweibrücken, Germany.

Electrical Cell-substrate Impedance Sensing (ECIS) is a well-established technique in the field of bioelectronics and several commercial platform technologies are available. We developed a similar technique, which is using ion-sensitive field-effect transistors (ISFETs) as transducer elements and we coined the term Field-Effect Transistor Cell-substrate Impedance Sensing (FETCIS) [1]. In early works we utilized different designs of silicon ISFET arrays. However, they are very tedious to fabricate and devices are opaque. Nevertheless, we applied our ISFETs in practical cell assays such as adhesion, migration, wound healing, apoptosis and toxicological influences with single cell resolution [2-4].

Recent years organic thin-film transistors (OTFT) gained a lot of attention in the field of biosensing. Their versatility, easy fabrication and their biocompatibility make those devices a new and exciting alternative for cell-sensing applications [5]. We developed arrays of electrochemically-gated OTFTs (OECTs) out of poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) scaffold. OECTs offer a completely novel, ionic gating mechanism compared to the classical, purely capacitive coupling to silicon ISFETs. We realized a wafer-scale fabrication protocol for OECTs. Devices out of PEDOT:PSS scaffold, coined the term Field-Effect Transistor Cell-substrate Impedance Sensing (FETCIS) [1]. In early works we utilized different designs of silicon ISFET arrays. However, they are very tedious to fabricate and devices are opaque. Nevertheless, we applied our ISFETs in practical cell assays such as adhesion, migration, wound healing, apoptosis and toxicological influences with single cell resolution [2-4].

In recent years organic thin-film transistors (OTFT) gained a lot of attention in the field of biosensing. Their versatility, easy fabrication and their biocompatibility make those devices a new and exciting alternative for cell-sensing applications [5]. We developed arrays of electrochemically-gated OTFTs (OECTs) out of poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS). OECTs offer a completely novel, ionic gating mechanism compared to the classical, purely capacitive coupling to silicon ISFETs. We realized a wafer-scale fabrication protocol for OECTs. Devices exhibited excellent sensor characteristics with transconductance values exceeding those of our silicon ISFETs [2]. Sensors were optimized to a frequency level of 1-10 kHz. We present FETCIS assays with individual HEK 293 cells and with tight junctions forming MDCK cells [6]. An extended FETCIS model including the ionic gating mechanism of OECTs can explain the recorded frequency spectra and can be utilized to extract cell-related parameters from the bioassays. In future OECTs could be produced such cheap that sensing in disposable standard plastic dishes would be possible. This could be a very interesting alternative to the classical sensor types in ECIS.

3:00 PM BM07.13.01
Integrated Biosensor for Point-of-Care Sepsis Diagnosis
Joaha Min1, Maria Nothing2, Georg F. Weber3, Cesar Castro1, Filip K. Swinarski1, Hakho Lee4, and Ralph Weissleder1,2, 4
1Center for Systems Biology, Massachusetts General Hospital, Boston, Massachusetts, United States; 2Systems Biology, Harvard University, Boston, Massachusetts, United States; 3Cancer Center, Massachusetts General Hospital, Boston, Massachusetts, United States; 4Radiology, Massachusetts General Hospital, Boston, Massachusetts, United States; 5Surgery, University of Erlangen-Nuremberg, Erlangen, Germany.

Sepsis is an often fatal condition that arises when the immune response to an infection causes widespread systemic organ injury. A critical unmet need in combating sepsis is the lack of accurate early biomarkers that produce actionable results in busy clinical settings. Here, we report the development of a point-of-care platform for rapid sepsis detection. Terned IBS (integrated biosensor for sepsis), our approach leverages i) the pathophysiological role of cytokine interleukin-3 (IL-3) in early sepsis, and ii) a hybrid magneto-electrochemical sensor for IL-3 detection. The developed platform produces test results within 1 hour from native blood samples, and detects IL-3 at a sensitivity of <10 pg/mL, this performance is >5-times faster and >10-times more sensitive than conventional enzyme-linked immunoassorbent assays, the current gold standard. Using clinical samples, we show that high plasma IL-3 levels are associated with high organ failure rate and thus greater risk of mortality, confirming the potential of IL-3 as a sepsis diagnostic biomarker. With
further system development (e.g., full automation, data security measures) and rigorous validation studies, the compact and fast IBS could become a practical clinical tool for timely diagnosis and proactive treatment of sepsis.

3:15 PM BM07.13.02 Nanopatterned Bulk Metallic Glass Biosensors. *Emily Kinser*, 1, 2, 3 and Themis Kyriakides1; 1Yale University, New Haven, Connecticut, United States; 2IBM T.J. Watson Research Center, Yorktown Heights, New York, United States; 3IBM Corporate Research Lab, Maple Grove, Minnesota, United States.

Nanopatterning as a surface area enhancement method has the potential to increase signal and sensitivity of biosensors. Platinum-based bulk metallic glass (Pt-BMG) is a bio-compatible material with electrical properties conducive for biosensor electrode applications, which can be processed in air at comparably low temperatures to produce nonrandom topography at the nanoscale. Work presented here employs nanopatterned Pt-BMG electrodes functionalized with glucose oxidase enzyme to explore the impact of nonrandom and highly reproducible nanoscale surface area enhancement on glucose biosensor performance. Electrochemical measurements including cyclic voltammetry (CV) and amperometric voltammetry (AV) were completed to compare the performance of 200 nm Pt-BMG electrodes vs Flat Pt-BMG control electrodes. Glucose dosing response was studied in a range of 2 mM to 10 mM. Effective current density dynamic range for the 200 nm Pt-BMG was 10-12 times greater than that of the Flat BMG control. Nanopatterned electrode sensitivity was measured to be 3.28 µA/cm²/mM, which was also an order of magnitude greater than the flat electrode. These results suggest that nonrandom nanopatterography is a scalable and customizable engineering tool which can be integrated with Pt-BMGs to produce biocompatible biosensors with enhanced signal and sensitivity.

3:30 PM BM07.13.03 Stimuli-Responsive Polymer-Graded Gate Field-Effect Transistor for Bioanalytical Sensor. *Akeo Fujita*, 1 Tsukuru Masuda1, Aya M. Aikimoto2, Taira Kajisa1, Ryo Yoshida1 and Toshiya Sakata2; 1School of Life Science and Technology, Tokyo Inst. of Tech., Tokyo, Japan; 2School of Engineering, The University of Tokyo, Tokyo, Japan; 3PROVIGATE Inc., Tokyo, Japan.

Bioanalytical tools such as biosensors are being developed for in situ monitoring of biological phenomena. As one of them, a biologically coupled gate field-effect transistor (FET) is based on a potentiometric detection of the changes in ionic charges induced by biomolecular recognition events and cellular activities in a real-time, label-free, and noninvasive manner. Meanwhile, poly(N-isopropylacrylamide) (PNIPAAm) is one of the most widely studied thermoresponsive polymers, and exhibits hydrophilic/hydrophobic phase transition in aqueous media across the lower critical solution temperature (LCST). Thanks to the thermo-responsivity, PNIPAAm-modified surfaces can exhibit hydrophilic/hydrophobic changes in response to temperature, and they have been studied for various applications including flow control, bioseparation, and cell culture dishes. Here, we hypothesized that the PNIPAAm-modified surface would be useful as a signal transduction interface in the semiconductor-based biosensor. In this study, we clarified the dynamic electrical behavior of a thermoresponsive PNIPAAm film on the gate of FET device [1]. Our findings will be useful for the application of semiconductor-based biosensors.

PNIPAAm was modified by atom transfer radical polymerization (ATRP) on the Ta2O5 gate of FET devices. At first, the ATRP initiators were modified on the Ta2O5 surfaces with hydroxyl groups by silane coupling method, and then the PNIPAAm chains were grafted on them by surface-initiated ATRP. The phase transition behavior of the grafted-PNIPAAm film induced by the temperature change from 25 °C to 40 °C was analyzed from the electrical properties of the FET device. Moreover, the phase transition time of the grafted-PNIPAAm film was measured in real time using the PNIPAAm-grafted FET device. The surface potential of the PNIPAAm-grafted FET became more negative than that of the non-grafted FET, as the temperature increased from 30 °C to 35 °C. This is because the phase transition of the grafted-PNIPAAm film from a hydrated state to a dehydrated state occurs across LCST, which is 32 °C in aqueous media. In this case, the capacitance of the grafted-PNIPAAm film should be altered because water has high permittivity. Thus, the change in the electrical characteristic of FET device can exhibit hydrophilic/hydrophobic changes in response to temperature, and they have been studied for various applications including flow control, bioseparation, and cell culture dishes. Here, we hypothesized that the PNIPAAm-modified surface would be useful as a signal transduction interface in the semiconductor-based biosensor. Moreover, we have found that the surface-modified polymer needed several hours to complete the phase transition using the PNIPAAm-grafted FET. Our work suggests a new strategy of bio-interface based on a stimuli-responsive polymer for the semiconductor-based biosensor.

3:45 PM BM07.13.04 Mechanism of Label-Free, Potentiometric Sensing of Neuropeptide-Y in Artificial Skin Using Graphene Field Effect Transistors. *Ahmad E. Ismail*, 1, 2, 3, Rhett Martineau1, 2, Cameron M. Crasto1, 2, Hyunil Kim3, 4, Michael Brothers3, 4, Rahul Rao5, 6, Ariana Nicolini1, 2, Cameron M. Crasto1, 2, Hyunil Kim6, 7, Benji Maruyama1 and Lawrence F. Drummy1; 1Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States; 2UES, Inc., Dayton, Ohio, United States.

Label-free, potentiometric bio-sensing is an emerging method for rapid, specific and sensitive detection of biomarkers to probe a wide range of physiological conditions. Neuropeptide Y (NPY) is one such biomarker, which is involved in regulation of important biological and pathophysiological functions such as food uptake, energy homeostasis, circadian rhythm and cognition. NPY is also an indicator of susceptibility to stressful or threat-related events. We have recently shown PM sensitivity for NPY detection in artificial sweat using graphene field effect transistor (GFET) functionalized with a peptide-based bio-recognition element (BRE). We used in-operando Transmission Electron Microscopy (TEM) imaging to examine the structure of NPY and its interfacing with BRE and graphene. We visualized the operation of the sensors in real-time to optimize their performance.

Here, we expand our understanding of NPY sensing by thoroughly analyzing the electrical and optical responses of graphene using electrolyte-gate GFET and Raman spectroscopy measurements. In particular, we study the GFET responses in an artificial sweat environment formulated using a range of salt concentration (~ 10-100 mM) and pH (~ 4.5-7.0), as measured in sweat [1]. In these pH ranges, the charged states of BRE and NPY are away from their isoelectric points (as calculated using Henderson-Hasselbalch equation). This charged states result consistent changes in the Dirac point and mobility of graphene after the BRE functionalization and after adding NPY at different concentrations (~ 1 pM - 10 µM); this covers the range of NPY measured in depressive disorder patients [2]. In addition, a two-dimensional plot of the shifts in the graphitic G and G' peaks (generally observed at ~ 1600 cm⁻¹ and ~ 2700 cm⁻¹, respectively) obtained from Raman spectroscopy [3] confirms the magnitude of the Dirac point shift measured electrically and suggests changes in strain on the graphene layer after attachments of BRE and NPY. Overall, these complimentary electrical and optical measurements reveal the mechanism of NPY sensing using graphene through potentiometric sensing and suggest pathways for sensing of other biomarkers that have similar charged states and isoelectric points.

The latest Zika virus (ZIKV) pandemic caused great international concern from explosively proliferating throughout the Americas. This arbovirus is primarily transmitted through the bite from an infected mosquito, but infection has also been spread through perinatal transmission, sexual contact, blood transfusion, and physical contact. Although asymptomatic, ZIKV became a major health crisis due to the link with the steep rise in cases of microcephaly and Guillain-Barré syndrome with infection. With no viable vaccine or reliable and economically feasible diagnosis in sight, the World Health Organization has called for rapid development of flavivirus diagnostics. Unfortunately, antibody-based detection systems can result in false positive results and RNA-based detection systems are costly, time-consuming, and impractical for testing in remote regions. In this study, a potential point-of-care (POC) diagnostic system was developed using a chip-based potentiometric sensor to detect flaviviruses using a 3D molecular imprinting technique. The co-adsorption of ZIKV and alkanethiols formed a crystalline self-assembled monolayer (SAM) on the surface of the gold chips. The crystalline SAM was verified using cyclic voltammetry. The removal and re-adsorption of the targeted virus was verified using electrochemical impedance spectroscopy supporting the molecularly wired mechanism. This chip-based potentiometric sensor system was able to detect 10^3 PFU/mL ZIKV in a buffered solution under 20 minutes without any sample manipulation. This sensor was tested against Dengue virus at clinical viral loads and showed no sign of cross-reactivity. When tested against human saliva samples containing clinical viral loads, this sensor was able to detect 10 PFU/mL ZIKV among the pool of bio-macromolecules. The high sensitivity and high selectivity demonstrated here proved that this lab-on-a-chip diagnostic has the potential to become a POC detection system for rapid and accurate screening of flaviviruses. This work was supported by the NSF. Inspire #1344267. This work was performed in part at the Advanced Science Research Center NanoFabrication Facility of the Graduate Center at the City University of New York.

The need for rapid, sensitive, and reliable pathogen detection is of utmost importance on the global scale from food safety, biomedical diagnostics, homeland security to environmental monitoring. With the emerging technology of Internet of things/everything and flexible/wearable electronics, thin film transistor-based bacterial biosensors employing conducting polymer materials could hold promise to offer ubiquitous bacteria detection with low-cost and high-performance. Organic electrochemical transistors (OECTs) represent a very promising class of organic thin film transistors (OTFTs) that have recently fueled scientific interest as performing transducers in sensing applications. OECTs offer the advantages of simple electrical readout, low operation voltage, inherent signal amplification, straightforward miniaturization, and ease of fabrication on flexible substrates including paper. Therefore, they are excellent candidates for disposable biosensors. However, the commonly used conducting polymer poly(3,4-ethylenedioxythiophene) doped with poly(styrenesulfonate) PEDOT:PSS lacks of functionality and non-fouling properties, which limits the application as the active layer for OECT biosensors. In this work, we develop the presentation of zwitterionic carbobxyatene PEDOT conducting polymers (PEDOT-CB) and print it on paper or PET substrate to form a planar OECT. PEDOT-CB offers both functionality to chemically link antibody to the sensor surface and non-fouling properties to allow direct detection in complex media. We synthesized EDOT-CB monomer and chemically polymerized to PEDOT-CB. The UV-Vis absorption spectroscopy and electron spin resonance (ESR) spectroscopy measurements were conducted to determine polaron and bipolaron populations in the oxidized PEDOT-CB. The conductivity of the PEDOT-CB:PEDOT thin films was measured using the four-probe approach. We printed planar OECTs on paper and PET substrate using inkjet printing method. Small molecules were added to further increase the conductivity and to improve the microstructure to allow efficient link antibody. Surfactant was added to improve the adhesion of PEDOT-CB:PEDOT on paper (or PET) substrates. The dimension of channel length/width and gate length were optimized to achieve high transconductance under certain gate voltage (V_G) and source-drain voltage (V_DS). The anti-E-coli antibody was immobilized on PEDOT-CB:PSS gate via the NHS/EDC chemistry. The drain current (I_D) was recorded with time after a certain concentration of targeted ZIKV to the cavities yielded surface charging on the chips which was measured in real-time potentiometrically. The formation of these crystalline SAM was verified using cyclic voltammetry. The removal and re-adsorption of the targeted virus was verified using electrochemical impedance spectroscopy supporting the molecularly wired mechanism. This chip-based potentiometric sensor system was able to detect 10^3 PFU/mL ZIKV in a buffered solution under 20 minutes without any sample manipulation. This sensor was tested against Dengue virus at clinical viral loads and showed no sign of cross-reactivity. When tested against human saliva samples containing clinical viral loads, this sensor was able to detect 10 PFU/mL ZIKV among the pool of bio-macromolecules. The high sensitivity and high selectivity demonstrated here proved that this lab-on-a-chip diagnostic has the potential to become a POC detection system for rapid and accurate screening of flaviviruses. Fully Organic, Flexible and Biodegradable Components for Bioinspired Electronics Meng Xu, Ramendra Pal, Sayantan Pradhan and Vamsi K. Yadavalli; Chemical and Life Science Engineering, Virginia Commonwealth Univ, Richmond, Virginia, United States.

The integration of naturally derived and synthetic polymers provides exciting opportunities to develop physiologically compliant bioelectronic systems and functional scaffolds for tissue regeneration. The combination of protein biomaterials and intrinsically conducting polymers enables the formation of functional bio-composites with properties different from conventional silicon or metal-based paradigms. In particular, silk proteins can provide mechanically strong, optically transparent, bio-compatible, and biodegradable matrix materials. Conducting polymers such as poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT: PSS) can provide electrical/ionic conductivity, electrochemical properties and chemical stability in biological environments. Coupled together, our group has demonstrated photopatternable, water-based conductive inks comprising PEDOT: PSS and in-house synthesized photoactive silk proteins that can be used in facile, room-temperature, aqueous techniques to form flexible substrates and sensors.[1, 2] Here we will discuss recent results that show how these composite inks can function as the starting point to develop diverse components of flexible, fully organic bioinspired electronics. These include electroactive coating materials for conventional electrodes, flexible electrodes, biosensors, and energy storage devices.[3-5] These systems in multiple formats are formed without the use of metals or other charge collector support materials, making them programmably, and completely biodegradable. The use of proteins as the matrix of the composite improves interfacing with biological surfaces. Electroactive biomolecules such as ascorbic acid and dopamine, and analytes such as glucose can be detected sensitively and selectively using enzymes. For the first time, we demonstrate how even large biologically relevant macromolecules such as vascular endothelial growth factor (VEGF) can be detected \textit{in situ} in a flexible, conformable format [6]. We discuss the mechanical, biochemical and electrochemical characterization and microfabrication. Such systems can provide applications towards real-time health monitoring of disease in addition to the measurement of biophysical parameters. Utility of these elements as bio-sensors, opto-electronic devices and flexible energy storage systems are envisioned.

The extracellular domain of Human epidermal growth factor receptor type 2 (ECD-HER2) is a well-known biomarker to prognosis various kind of metastatic cancer such as breast, ovarian, and gastric cancer. Investigating the ECD-HER2 in serum has been used antibody-based detection method called the enzyme-linked immunosorbent (ELISA), which is using costly many processing steps such as adding a binding buffer, exchanging washing buffer, and dilution steps for quantitative analysis the ECD HER2 protein level in serum. Also, antibody-based ELISA should be conducted in certain conditions due to its denaturation property depending on heating and pH in the buffer.

Oligonucleotide-based recognized aptamers have been widely studied for substituent molecules of antibody because the aptamers have not only highly specific binding property to target molecules but also thermal and pH stability [3]. Gold nanorods (GNRs) have been widely used as optical sensors which retain its unique extinction spectrum within the visible range. This is because the electrons at the surface of gold nanorods oscillate collectively corresponding to light injection named localized surface plasmon resonance. Furthermore, this extinction spectrum is easily tunable in dealing with the morphological transformation of GNRs, chemical coatings and refractive index changing around the vicinity. In here, we developed anti-HER2 aptamer-based surface plasmon resonance sensors (HER2-APlaS) with robustness by a simple drop-coating method to detect ECD-HER2 in serum. To immobilize the GNRs on substrates with homogeneously, we introduced surface microscale grooved patterning on a polymeric substrate for controlling the dispersivity. Also, dopamine, well-known chemically adhesive materials, was used as inhibiting the aggregation of GNRs, enhancing immobility on the substrate, and giving the covalently binding available site to anti-HER2 aptamers. We used as pyrimidine modified third generation aptamers which have high stability in serum. Assembled all these advantages of described materials, HER2-APlaS was conducted real-time binding kinetic experiments in a

Testing the Viability and Reusability of Hemoglobin Biosensors Utilizing SAM Surface Molecular Imprinting and Natural Surface Roughness Indices Yehoshua Auerbach1, Nicholas Clayton2, Miguel Hulyalkar3, Andrew Todt4, Rebecca Isseroff2, 1, Vincent Ricotta2 and Miriam Rafaelovich1; 1Lawrence High School, Cedarhurst, New York, United States; 2Dept. of Materials Sciences and Chemical Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States; 3South Side high School, Rockville Centre, New York, United States; 4Lake Oswego High School, Lake Oswego, New York, United States.

We have shown that molecular imprinting (MI) technology, together with potentiometric detection, can be used to produce sensitive, yet robust, biosensing systems with real-time electrochemical readout that can be utilized for point of care diagnostics. Real time detection of biomarkers is essential when rapid, critical decisions need to be made, such as during medical procedures when cancer is suspected, or when public health is threatened, as in the recent Zika virus epidemic or in dealing with a suspected attack by biological agents. The biosensor that we developed was tested against standard methods, such as ELISA, and was found to have comparable or better sensitivity, with sample sizes which were at least an order of magnitude smaller. Furthermore, the results from the technique are obtained within minutes, using inexpensive potentiometric readout technology which can even be wirelessly transmitted. These biosensors utilize surface molecular imprinting of a self-assembling monolayer (SAM) of hydroxyl-terminated alkanethiol chains that are able to form a crystalline ‘lock-and-key’ structure around a target analyte; this allows the sensors to detect and differentiate between bio-macromolecules of similar size and shape with high selectivity and sensitivity. Therefore, they can be used as a quick yet accurate analysis of many chemical and biological processes, such as stem cell differentiation. The sensors are also very versatile, and can be used to detect molecules with sizes ranging over several orders of magnitude, and of widely varied chemical composition and structure.

In order to fully exploit the advantages of these biosensors, especially in remote, economically disadvantaged areas, it is important to understand and quantify the durability and reusability of the sensors. Polished and unpolished biosensor chips were created to A) test the viability of hemoglobin detection using molecular imprinting techniques, and B) to test if these sensors can be washed and reused after adsorption testing. The successful readsoption of hemoglobin even after washing indicates that these biosensors can be reused, extending the life and usefulness of the device. Further work is in progress to determine the number of uses for the device, and the optimal method for storage. Preliminary work seems to show that vacuum sealing of the sensors with a commercial device is adequate, indicating that convenient long-term packaging of the sensor can be achieved, in turn enabling shipping and storage.

Magnetic Nanodiscs for Simultaneous Mechanical and Thermal Neuronal Stimulation Daniela Gregorec1, Alexander W. Senko1, Andrey Chuvilin2, Pooja Reddy1, Ashwin Sankarakaram1, Po-Han Chiang1, Dekel Rosenfeld1, Francisco Garcia1 and George Varnavides1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2CIC nanoGUNE, San Sebastian, Spain.

Wireless schemes based on hysteretic heating of magnetic isotropic nanoparticles in high-frequency alternating magnetic fields (AMFs) have already permitted modulation of neural activity. We present a novel approach for neuronal modulation based on magnetite nanodiscs (MNDs). These anisotropic iron oxide nanoparticles exhibit a characteristic vortex alignment of magnetic spin with zero net magnetization in the absence of external magnetic field.
Such magnetic configuration fosters the colloidal stability in physiological solutions essential for applications in biomedicine. We synthesize a geometric palette of MNDs from 40 nm to 250 nm in diameter. Consistent with geometry, MNDs exhibit direction-dependent hysteresis loops and their specific loss power (SLP) at frequencies of 75-150 kHz up to 1000 W/g is comparable to the spherical magnetite nanoparticles, but at 5-10 times lower particle count owing it to the size of MNDs. Targeted activation of heat-gated channels is thus permitted at high frequency AMFs.

Furthermore, the magnetization in the presence of weak magnetic fields assumes an “in-plane” orientation revealing a large magnetic moment that allows MNDs to transduce magnetic fields to mechanical torques at slow-varying magnetic fields. We show how the mechanical torques are further transduced to the mechanical stimuli of neuronal cells. These stable, biocompatible MNDs robustly mediate calcium influx in mechanosensitive sensory neurons from rat dorsal root ganglia (DRGs) upon application of weak (23 mT), slow-varying (1-5 Hz) magnetic fields.

Finally, MNDs allow for multiplexed stimulation of neurons by selectively activating mechanoreceptors at 1-5 Hz magnetic fields, while heat dissipation and consequent activation of heat-gated ion channels is allowed at frequencies of around 100 kHz.

Nanostraw Platform for Intracellular Delivery into Fungal Cell
Exyam Souihel and Nicholas A. Melosh; Stanford University, Stanford, California, United States.

Major advances in nanotechnology have facilitated the development of powerful tools to study biology at the cellular level. Here, we report a nanostraw platform providing an intracellular access to introduce exogenous components such as nucleic acids, proteins and synthetic molecules directly into the cell. This platform is composed of a cargo reservoir, a polymer membrane with protruding nanostraw and a cell culture reservoir. Cargo delivery is performed by electrical pulse allowing the cargo diffusion through the nanostraw to reach the intracellular compartment. This technology allow an access into the cell without perturbing vital functions and promise high transfection efficiency of mammalian cell. Nanostraws with different dimensions i.e. length and diameter can be optimized to interface with different cell types. In this study we evaluate the ability of the nanostraw platform to delivery of exogenous components into fungal cells.

Fungi are described to be responsive of human and plants diseases and also widely used in industrial process to produce antibiotic compounds, enzymes and recombinant proteins. In all of these research areas, genetic modification using exogenous DNA is widely used to study these organisms. However fungal cells are different from mammalian cells as they are surrounded by cell walls which serve as barriers reducing the delivery of exogenous compounds into the cell. The most commonly used techniques to delivery DNA into fungal cells require the production of protoplasts (cell whose cell wall has been removed) and result in low transformation efficiency in many strains. In this context, nanostraw technology is a promising tool to increase fungal transformation efficiency and develop genetic engineering of fungi.

Surface-Initiated Hydrogel Adhesives for Seamless Cell-Electronics Integration
Han N. Nguyen, Huan-Hsuan H. Hsu and Xiaocheng Jiang; Tufts University, Medford, Massachusetts, United States.

The electronic detection and interpretation of cell-derived signals represents an important approach to understanding, interrogating, and directing many biologically significant processes. The intrinsic mismatch in biophysical and biochemical properties between living systems and artificial electronics, however, has made it challenging to establish a compatible bioelectric interface for effective signal coupling and transducing, thus limiting many potential applications. Here, we report the use of biocompatible and photo-crosslinkable hydrogels as surface-initiated “adhesives” for seamless cell-electronics integration, where nanometer-thick hydrogels are grown directly from device surface to immobilize living cells with intimate proximity and minimal invasiveness. A custom-built projection stereolithography system is used to spatially control the visible light irradiation and precisely program cell “placement” with diffraction-limited resolution. In particular, we have demonstrated the technique’s capability to incorporate living cells with different nano-electronic platforms, including both passive (microelectrode arrays) and active (field-effect transistors) type of transducers. By designing and modulating the hydrogel structure at the device interface, highly-localized, device-specific microenvironment can be created, allowing real-time, ultrasensitive bioelectrical and biochemical detection at single-cell level. A variety of cell types, including adherent (HL175 and HL1), floating (Jurkat and human white blood cells) and bacterial cells, have been reliably immobilized without compromising cell viability and functionality. Additionally, a broad range of biomaterials, including photo-crosslinkable polyethylene glycol, gelatin, hyaluronic acid, and silk have been tested and optimized as cell adhesives, which helps module interface biochemical/biological properties to overcome limitations posed by challenging material requirements of many applications. Lastly, we have demonstrated the possibility to integrate multiplex cells with large-scale, addressable device arrays, which enables high-spatiotemporal resolution studies of signal propagation at network levels. The current work represents a strategic approach to overcome the intrinsic mismatch at traditional bioelectronic interfaces and is expected to open up new opportunities for a wide range of applications in biomedical sensing, prosthetics, and hybrid information processing.

Organic Bioelectronics—Addressing the Interface Challenge
Dania Mawad; School of Materials Science and Engineering, Centre for Advanced Macromolecular Design, Australian Centre for NanoMedicine and ARC Centre of Excellence in Convergent Bio-Nano Science and Technology, University of New South Wales, Sydney, New South Wales, Australia.

Bioelectronics is considered the future of medicine as it is not only contributing to the basic understanding of biological systems but also to clinical diagnostics and therapeutics through tissue-electronics interfaces. A major challenge facing their successful medical applications is the development of compatible and functional interface technologies that enable biological to electronic signal transduction. This central consideration is driving the “rise of organic bioelectronics” [1]. Critical to this rise has been the incorporation of conducting polymers (CPs) as the electrically active component. CPs are soft, flexible and mechanically tunable; thus more compatible with tissue than inorganic electronics. The attractive properties of CPs have largely been demonstrated in in vitro applications while their in vivo application is limited to coatings for inorganic electrodes to allow for more intimate electronic contact between the device and the tissue [2]. Examples of the challenges that have been hindering the translation into the complex physiological environment include electronic stability and integration with the host tissue. A lack of versatile chemistries for functional CPs underpin these challenges. By manipulating the chemistry of CPs and employing controlled design strategies, we develop novel bioelectronics that address the aforementioned
limitations. New generation CPs are synthesized with demonstrated biocompatibility and ease of processability [3-6]. Conductive constructs such as a hydrogel doped with large polyelectrolyte or free standing patch dopel with small anion were fabricated. Functionized CPs allowed the fabrication of conductive hydrogels that not only possessed tailored physical properties, such as swelling ratios and mechanical properties, but also displayed electroactivity dependent on the chemical composition of the network. Incorporated as the active material in organic electrochemical transistor, these functional CPs exhibited good transconductance and provided surface functionalization with relevant biomolecules. In simple fabrication processes, we introduced porosity in a conductive patch and demonstrated its electronic stability in response to cyclic stretching mimicking the contraction cycle of the heart as well as its stability in the oxidized form after 2 weeks implantation in vivo. By modifying the chemistry of CPs, these macromolecules could be fine-tuned into functional materials opening the way for the development of novel multifunctional bioelectronics capable of effectively electro-coupling with biological tissues.

Molecularly Engineered Conducting Polymers with Biomimetic Properties Jadranka Travas-Sejdic1, 2; 1Polymer Electronics Research Centre, The University of Auckland, Auckland, New Zealand; 2MacDiarmid Institute for Advanced Materials and Nanotechnology, Wellington, New Zealand.

With the vision of mimicking the many functions found in nature, such as stretchability, healing and sensing, the next-generation applications including organic electronics, tissue engineering and bioensors will require new electronic materials with biomimetic features. The main challenges in developing biomimetic materials for such applications concern mechanical compliance of such material with soft biological interfaces. Organic electronic materials, notably conjugated polymers, offer many advantageous properties - the most valuable being versatile synthesis by molecular design, ease of chemical functionalisation and solution processability.

Herein, we demonstrate that the valuable biomimetic properties can be expressed through molecular design and side chain functionalisation of conjugated polymers. The simple yet versatile synthetic procedure we present enables one to fine-tune the electrical and mechanical properties without disrupting the electronic properties of the conjugated polymer. We exemplify various biomimetic properties, including stimuli-responsiveness,1 bio-sensing,2 anti-fouling,3 intrinsic stretchability and self-healing,4 by grafting polymeric side chains that affords such properties.

Dimensionality Explored at the Nanoscale in Bioelectronics Francesca Santoro, Fabrizio A. Pennacchio, Leonardo Garma and Laura Mattino; Istituto Italiano di Tecnologia, Napoli, Italy.

The interface between biological cells and non-biological materials has profound influences on cellular activities, chronic tissue responses, and ultimately the success of medical implants and bioelectronic devices. For instance, electroactive materials in contact with cells can have very different composition, surface topography and dimensionality. Dimensionality defines the possibility to have planar (2D), pseudo-3D (planar with nano-micropatterned surface) and 3D conductive materials (i.e. scaffolds) in bioelectronics devices. Their success for both in vivo and in vitro applications lies in the effective coupling/adsorption of cells/tissues with the devices’ surfaces. It is known how a large cleft between the cellular membrane and the electrode surface massively affects the quality of the recorded signals or ultimately the stimulation efficiency of a device. However, this field is hindered by lack of effective means to directly visualize in 3D cell-material interface at the relevant length scale of nanometers. In this work, we explored the use of ultra-thin plasticization technique to cells for the first time on materials which differ in dimensionality, particularly those with biological tissue.

Characterising Material Properties and Biological–Material Interactions for Conducting Polymer Biomaterials Paul J. Molino1, 2, Michael Higgins1, 2 and Gordon Wallace1; 1ARC Centre of Excellence for Electromaterials Science, University of Wollongong, Wollongong, New South Wales, Australia; 2ARC Research Hub for Australian Steel Manufacturing, University of Wollongong, Wollongong, New South Wales, Australia.

Conducting polymer materials have attracted considerable interest for a suite of biological applications due not only to their ability to transfer charge, but the ability to tailor a suite of material properties that mediate biological interactions. Polymer morphological, chemical, electrochemical and mechanical properties can easily be tuned by varying the monomer, dopant species, and polymerisation conditions and method, providing an avenue to adapt and optimise polymer properties for particular applications. This presentation will focus on the ability to use quartz crystal microbalance (QCM-D) and atomic force microscopy (AFM) to not only characterise the polymer physical and mechanical properties, but to also provide critical information on the nature of protein and cell interactions with the nanostructured conducting polymer surfaces.

QCM-D provides a highly sensitive measurement of the mass and viscoelastic properties of protein in real-time, providing a temporal study of the dynamic process of protein binding and organisation on nanostructure conducting polymer surfaces. This approach has been used to identify variations in protein mass and viscoelastic properties on conducting polymers as a function of surface nanoroughness, the identity and loading of the dopant anion in the polymeric film, and the redox state of the polymer film. More recently advances in high speed atomic force microscopy (HS-AFM) has enabled the dynamic interactions of individual protein molecules on nanorough conducting polymer films and in aqueous buffer to be studied at near video rate.
imaging speeds (i.e. 10 images/s). This approach is now being used to obtain new information relating to dynamic protein interactions with surfaces and nanoparticles, providing structural details not possible using other optical techniques. Finally the ability to use QCM-D to study cell – surface interactions will be discussed, demonstrating its ability to present information relating to the physical interaction between the cell and surface, which provides complimentary information to optical microscopy methodologies.

Precise Control of ERK Activation in Epithelial Cells by Local AC Electric Fields

Quan Qiong1, Houpu Li1, Liang Guo2, Yuan Wang1, Min Zhao2 and John Albeck1,2; Arizona State Univ, Tempe, Arizona, United States; 2University of California, Davis, Davis, California, United States.

Different types of electric fields (EF) have demonstrated great potential to trigger the extracellular-signal-regulated kinase (ERK) signaling pathway. However, it remains difficult to precisely modulate both the amplitude and frequency of the ERK activities by EF with high spatial and temporal resolution. In addition, to date the mechanism of how EF couples with ERK has been generally complicated by EF induced change of membrane potential, permeability of ions such as Ca2+, or exogenous chemical signals such as pH, and reactive oxygen species (ROS). Here we used customized planar microelectrode arrays and a dynamic single-cell reporter of ERK to demonstrate non-invasive ERK activation with precise timing by bipolar symmetric AC EF pulses with no Faradic processes involved. The ERK activities can be repeatedly synchronized and modulated in localized region close to the electrodes. We show that the ERK activation was initiated directly by EF-induced EGFP-independent phosphorylation of epidermal growth factor receptor (EGFR), and did not involve changes in pH, Ca2+ or ROS. Our results on EF coupling to ERK signaling pathway enable precise synchronization and modulation of ERK activities with single-cell resolution, and can serve as a new platform for a wide range of biomedical applications.

10:45 AM BM07.15.08
Biological Model Membranes Supported on Organic Electrochemical Surfaces

Han-Yuan Liu1, Anna-Maria Pappa2, Charalampos Pitsalidis3, Rohit Singh2, Alberto Salles3, Rosin Owens1 and Susan Daniel2; 1University of Cambridge, Cambridge, United Kingdom; 2Cornell University, Ithaca, New York, United States; 3Stanford University, Palo Alto, California, United States.

Supported lipid bilayers (SLB) are emerging as a model system for investigating the function of membrane proteins, and protein-lipid interactions, and for developing new biotechnology for biosensing applications. So far, most of them have been shown on hydrophilic and smooth surfaces, such as silica based surfaces, due to the ease of vesicle fusion and SLB formation. Even though silica based surfaces serve well for SLB assembly, they have several drawbacks, as the material is electronically insulating, inflexible, and causes protein denaturation because of the interactions with the surface. Poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), is a promising surface for SLB formation because it possess electronic transducer properties, which is unlike the typical inorganic substrate. PEDOT:PSS can not only allow the transduction of signal, but also preserve transmembrane protein function. However, it is challenging to induce vesicle fusion because of surface structures and physicochemical properties. There are a variety of stimuli for triggering the vesicle fusion (pH, osmotic shock, temperature) even under unfavorable circumstances. In this work, we systematically investigated lipid vesicle interactions with conductive polymer, PEDOT:PSS. Recently, we further leveraged native cell membrane vesicles derived directly from live cells as an intermediate to incorporate native membrane species (lipid, membrane protein, etc.) into a SLB on PEDOT:PSS. The platform presented here, which is a biological model membrane supported on an organic electrochemical material with functional proteins, can be applied towards a myriad of technological purposes from drug discovery to pathogen detecting. This study is likely to pave the way for the next generation of bioanalytical sensor interfaces.

Engineering M13 Bacteriophage Platforms for Synthesis of Nanotheranostics and Novel Materials

Uyanga Tsedev, Fred C. Lam, Ching-Wei Lin, Alan Ransil and Angela Belcher; MIT Koch Institute, Cambridge, Massachusetts, United States.

Here, we are expanding on the functionality of M13 bacteriophage as an engineerable biomaterial. M13 bacteriophage, a naturally monodisperse, multifunctional nanostructure, is especially well-suited for active material templating and assembly. The phage consists of thousands of distinct protein subunits organized in a high aspect ratio, filamentous viral capsid; approximately 900nm in length and 6nm in diameter. Both the major and minor coat proteins are amenable to mutation, and thus can be chemically tuned for such capabilities as programmable assembly; the binding, nucleation, and capping of inorganic nanoparticles; chelation of metal ions; and expression of targeting ligands or even enzymes. All of these characteristics have made the M13 bacteriophage a competitive biomaterial—we have previously demonstrated its versatility in the formulation of nanofoams, aerogels, and hydrogels for novel inorganic material synthesis as well as its use as a tumor specific vehicle for the delivery of imaging agents to ovarian cancer models. Now, to further improve on the medical and material applicability of M13, we first describe the blood brain barrier (BBB) crossing of M13 with peptide display on the capsid of M13; and second, the assembly of M13 of smaller sizes, termed ‘inho’ phages.

BBB targeting optimizes for the in vivo trafficking properties of the phage nanoparticles and allows delivery past the BBB; functionalizing the phage as a nanotheranostic for medical imaging and therapy applications, particularly in the case of difficult to reach disease sites associated with glioblastoma and neurodegenerative illnesses. Second window near infrared (NIR-II) imaging of glioma targeted phage, complexed with single walled carbon nanotubes (SWNT) or small molecule NIR-II dyes such as IR1050, reveals localization of the phage to glioma, and opens up the possibility for phage based shutting of high drug loads to the tumor cells and simultaneous, inexpensive NIR-II tracking of the therapy progression. Metal nanofoams can also be synthesized using an M13 bacteriophage template. For the first time, we demonstrate that the properties of metal nanofoams can be tuned by altering the length of M13 with inho-phage of sizes ranging from 50nm to 980nm. The morphology of metallized foams made from differing inho-phage struts reveals optimal lengths and concentrations for the crosslinking of the foam material and the resulting porosity. Batteries made using these foams can vary in ion transport capability, giving us biological control over their electrochemical properties. This can be extended to catalysis and other fields where nano-structured materials could provide significant impact including filtration and desalination, tissue or antimicrobial scaffolds, electromagnetic composites, hydrogen storage, wearable energy devices, and more.

Mola1, Marco Caprin2, Michelle Muccini3, Luigi Ambrosio1, Roberto Zamboni1, Vincenzo Guarino1, Annalisa Convertito1, Valentina Benfenati3 and Guglielmo Fortunato1; 1CNR-Consiglio Nazionale delle Ricerche, Bologna, Italy; 2FABIT, University of Bologna, Bologna, Italy; 3Bioscience, Biotecnologie e Biofarmaceutica, University of Bari, Bari, Italy.

Nanostructured interface capable to modulate structural, molecular and functional properties of brain cells has a huge potential to improve our understanding of the central nervous system. Astrocytes, that are the majority of non neuronal brain cells, are key players in brain physiology and pathology. Nonetheless, the astrocytes/material interaction needs to be considered in engineering implants targeting the brain, as they are the first cells
reacting to brain injury. Here we define and validate the use of innovative nanostructured materials interface based on gold coated silicon nanowires (Au/SiNws) and electrospun nanofibers made of biodegradable polymers such as polycaprolactone (PCL), as substrates where to culture and to study astrocytes physiology in an in-vivo-like morphological and functional phenotype. Nonetheless, the possibility to modulate and record astrocytes electrophysiological properties by Au/SiNws and PCL interface based device. We performed cell viability assays, fluorescent and confocal imaging, revealing that astrocytes adhere and grow on Au/SiNws and PCL nanofibers without need of additional coating. Au/SiNws mashed nanowires induce morphological stellation of astrocytes and arborisation of processes. PCL nanofibers substrate topography promotes elongation of process sprouting from astrocytes cell body. Analyses of gliotic markers indicates that both substrates are not inducing inflammatory reactions. The functional properties of cells grown on Au/SiNws and PCL nanofibers were defined. Notably, Au/SiNws based device enable recording extracellular signals from astrocytes unreported previously and not recordable on Au/Si flat device. Our results validate PCL nanofibers and Au/SiNws as novel glial interfaces that enable the growth, differentiation and recording of astrocytes in vitro. These glial interfaces are representing the first class of devices enabling to dialogue with non excitable brain cells. This work is supported by AFOSR projects ASTROMAT, FA9550 16 1 0502 and ASTRONIR, FA9550-17-1-0502 and 3D NEUROGLIA.

Organic Field-Effect Transistors Based on Polymeric Semiconductors Yunqi Liu, Institute of Chemistry, Chinese Academy of Sciences, Beijing, China.

Great interests have been aroused in flexible functional electronics and photoelectronics, such as artificial skin, non-volatile memories, photosensors and health monitoring systems. Packed up through van der Waals interactions, organic/polymeric materials have advantages of intrinsic mechanical flexibility. During the past several years, impressive progresses have been made in organic field-effect transistors (OFETs), particularly in conjugated polymer-based FETs. A few high-performance polymers-based FETs have been developed with a remarkable mobility of more than 10 cm² V⁻¹ s⁻¹, which provides a promising opportunity for applications in flexible displays and wearable devices.

In this presentation, we report an organic photosensor by three-component integration: an organic light-dependant resistor (OLDR), an organic resistor (OR) as a load resistor, and an OFET as readout element. The photosensor is transconductance type instead of conductance, thus giving a higher photo to dark on/off ratio. In addition, as a mimicry and spectral extension of human visual system, we present an integrated, retina-like optoelectronic device for filter-free near-infrared (NIR) imaging and memory purposes. The device transforms NIR signals into grey scale nonvolatile resistance states, enabling a NIR-to-memory capability. We also demonstrate color differentiation between NIR and visible incidents with preferred NIR selectivity. Due to circuit design, our retinal system accommodates a bi-modal operation with respect to incident wavelengths. It functions as nonvolatile memory under NIR (850 nm) with a dynamic range of 62 dB and 86 dB photoswitch under green light (550 nm). On the other hand, we report the design and synthesis of some copolymers with D-A structures exhibiting p-type, n-type and ambipolar behavior as well.

Highly Sensitive Flexible Pressure Sensors Based on Printed Organic Transistors with Three-Dimensionally Self-Organized Organic Semiconductor Microstructures June Ah Lim; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Highly sensitive flexible pressure sensors are at the forefront of the development of future mobile applications, such as rollable touch displays, health monitoring, and electronic skin. Recently, monolithic organic field-effect transistors (OFETs) combined directly with pressure-sensitive components have been demonstrated as actively workable pressure sensors due to cost-effectiveness, good flexibility, and large-area solution processing, which effectively enables conformal large-area contact with a surface. Despite many pioneering efforts, the low cost and easy fabrication of OFET devices cannot be fully exploited without the development of OFET-based pressure sensor printing processes. In this presentation, we will introduce a highly sensitive pressure sensor based on a printed OFET with centro-aperically self-organized organic semiconductor microstructures. Unlike previously reported OFET-based pressure sensors prepared with a top microstructured dielectric layer, we designed a unique OFET bottom layer consisting of semiconductor channels positioned at the highest summit of printed cylindrical microstructures, referred as “3D OSC”. This unique microstructure was achieved simply by printing an organic semiconductor and a polymer blend, which self-organized after deposition without additional process. The proposed 3D OSC OFET pressure sensors demonstrated a high pressure sensitivity of 1.07 kPa⁻¹ and a rapid response time of <20 ms with a high reliability over 1000 cycles. We demonstrated that our sensors are applicable to the real-time monitoring of radial artery pulse waves and as touch sensors for use in realistic prosthetic hands.

8:45 AM BM08.01.03
Colloidal Dispersion Supported Ionic Liquid Gels for New Transistor Geometries Rachel E. Owyeung, Matthew J. Panzer and Sameer Sonkusale; Tufts University, Medford, Massachusetts, United States.

Intimate monitoring of physical and chemical patient data is changing the health industry. Real-time monitoring devices, such as implantable and wearable tools for diagnostics, need truly flexible transistors for advanced electronics and elegant sensors. Previous reports have realized flexibility through geometric patterning[1] or intrinsically stretchable semiconductors[2]. For gate dielectric insulators, researchers have utilized elastomeric matrices and polygon electrolyte systems to achieve flexibility. Ionic liquid-based gel electrolytes offer high capacitance, a large electrochemical stability window, and are nonvolatile. Typical demonstrations of these ion gels use block copolymers[3] or chemically crosslinked in situ polymerization to add support, though some have demonstrated that colloidal particles dispersed in ionic liquids can result in gels[4].

In this work, we differ from previous reports of ionic liquid-based transistors (IL-OFETs) by using a colloidal dispersion of silica nanoparticles to support the ionic liquid. This scaffold is advantageous over existing triloblock copolymers or chemically crosslinked gels because of its facile fabrication for conformal gel formation. Specifically, triloblock copolymers have complex chemistry and in situ methods require additional crosslinking steps, such as UV treatment to form a gel, which could be difficult to apply to certain substrate types and geometries. Contrarily, these silica dispersion gels are easily applied after gelation for a conformal coating.

We employ 1-Ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide as the ionic liquid and poly(3-hexylthiophene) as the organic semiconductor, both well studied materials in regards to IL-OFETs[5]. We achieve OFET performance assessed by output and transfer characteristics. Use of this ion gel results in an on-off ratio of 10⁶, threshold voltage of -1.65V, an operating window of 0 to -2.7V, and allows for transistor development on softer, more flexible substrates than typical silicon or glass. For demonstration, we employ our transistor on a linen thread, which could offer a route to 3D monitoring of health in the form of smart sutures and transdermal implantations. These transistor systems have shown an on-off ratio of 10⁴, threshold voltage of -2.8V, and an operating window of 0 to -4V. These preliminary results validate this proposed material selection and design as ideal for electronics and sensors on both 2D and 3D flexible substrates.

9:00 AM BM08.01.04
High ON-Current Vertical Quantum Dot Transistors as a Novel Platform for Flexible and Wearable Electronics Jeongkyun Roh, Hyeong Jin Yun and Victor I. Klimov; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Colloidal quantum dots (QDs) have gained tremendous attention as a new class of nanomaterials that can potentially enable the next-generation solution-processible electronic and optoelectronic devices (Science 353, aa5523, 2016). Owing to their superior optical properties, intense studies on QD-based color converters, light-emitting diodes (Nature 515, 96, 2014, Nat. Photon. 12, 159, 2018) and solar cells (Nat. Nanotechnol. 13, 456, 2018) have been underway leading to successful commercialization of the QD-display technology. The next frontier is exploration of electronically coupled QD solids in the context of prospective applications in solution-processable flexible electronics toward wearable electronic and sensing systems. One existing challenge in this area is low mobility of QD films, which limits performance characteristics of QD-based field-effect transistors (FETs) that represent basic building blocks of electronic circuits. Low mobilities lead to low ON-currents of typical QD-FETs. Increase in the current is possible by reducing the FET channel length, however, this would require the use of expensive and nonscalable patterning methods such as e-beam lithography. Here, we demonstrate high ON-current QD p-type FETs by employing a vertical architecture, which is a vertical stack of a gate electrode, a gate insulator, a source electrode, semiconducting transport layer, and a drain electrode. Using this approach, we reduce a channel length down to submicron-meter scale, and as a result, achieve an unprecedented ON-current of ~0.1 A/cm², which is three orders of magnitude higher than in standard lateral FETs. This notably increases the performance of an electric semiconductor and a polymer blend, which self-organized after deposition without additional process. The proposed 3D OSC OFET pressure sensors demonstrated a high pressure sensitivity of 1.07 kPa⁻¹ and a rapid response time of <20 ms with a high reliability over 1000 cycles. We demonstrated that our sensors are applicable to the real-time monitoring of radial artery pulse waves and as touch sensors for use in realistic prosthetic hands.

9:15 AM BM08.01.05
Towards Low-Cost Electronics on Three-Dimensional Substrates Tong Yang1, Jeremy S. Mehta2, Alexander M. Haruk3, Jiayi Xu, Shan Yan3, Jin Luo1, Chuan-Jian Zhong4 and Jeffrey M. Mativetsky1, 2; 1Materials Science and Engineering, Binghamton University, Binghamton, New York, United States; 2Department of Physics, Applied Physics and Astronomy, Binghamton University, The State University of New York, Binghamton, New York, United States; 3Department of Chemistry, Binghamton University, The State University of New York, Binghamton, New York, United States.

Solution-based electronic material deposition holds promise to enable the low-cost fabrication of wearable electronics, soft robotics, and energy harvesting technologies. Conventional deposition and patterning processes for electrically-active materials, however, are only compatible with flat substrates, while
future technologies will integrate circuitry into three dimensional platforms, such as prosthetics, car windshields, or contact lenses. In this presentation, we will introduce methodologies for depositing and patterning functional materials on three-dimensional substrates. The processes are simple, scalable, and use minimal quantities of starting material, opening new possibilities for device integration.

Decanethiolate-capped gold nanoparticles were deposited and laser-sintered to pattern micron-resolution electrodes on cylindrical substrates with diameters as small as a human hair. We will show how this platform enables new approaches to local pressure and chemical sensing, while balancing the need for simple processing and high performance. In addition, stripes of high-performance organic semiconductor crystallites (6,13-Bis(trisopropylsilylethynyl)pentacene,TIPS-pentacene) were deposited at targeted locations on folded flexible substrates and complex three-dimensional objects. Preferential crystallite alignment led to anisotropic charge transport, with a hole mobility of up to 0.83 cm²V⁻¹s⁻¹ along the crystallite axis. These experiments lay the groundwork for the low-cost integration of electronic function into arbitrary non-planar substrates for sensing, energy harvesting, and display applications.

9:30 AM BREAK

10:00 AM BM08.01.06
Flexible Organic Sensors for Biomechanical Measurements Zhenghui Wu, Moran Amit and Tse Nga Ng; University of California, San Diego, La Jolla, California, United States.

Photosensors responsive to the short wavelength infrared (SWIR) spectra are used in a variety of applications including environmental monitoring and medical diagnosis. However, conventional SWIR sensors are limited by complex die transfer and bonding processing. Here we are advancing SWIR photodiodes by using a new generation of narrow bandgap conjugated polymers that are processed by solution processing techniques and allow simple direct deposition. The polymers are processed into bulk heterojunction photodiodes with photoresponse up to wavelength of 1.8 micron. The performances of devices with different polymer structures were compared through metrics including detectivity, quantum efficiency, response time and rectification ratio. Example applications including blood pulse measurements and spectroscopic identification will be demonstrated.

In addition to optoelectronics, I will also show an example of an instrumented glove for augmenting movement disorder assessments. The system is based on capacitive pressure sensing, and the validation allows an objective, repeatable metric that improve resolution over the current best practices. The glove measures the power required to move a patient’s arm and shows reduced inter- and intra-rater variability. Our approach using wearable sensors offers an objective route for the characterization of movement patterns, which would permit the effective evaluation of intervention outcomes, as well as provide a platform for novel motor interventions in the future.

10:30 AM BM08.01.07
Enhancing the Sensitivity in Capacitive-Type Strain Sensors Using Thin Au Film Electrodes Roka Nur, Naoji Matsuhisa, Zhi Jiang, Md Osman Goni Nayeen, Tomoyuki Yokota and Takao Someya; The University of Tokyo, Tokyo, Japan.

Wearable sensors are a vital component in wearable electronics, since they are responsible for transducing external stimuli into electronic signals. In particular, strain sensors are needed for applications involving motion detection and the monitoring of vital bio-signals. Capacitive-type strain sensors are excellent candidates for practical applications due to their excellent linearity, high stretchability, and low hysteresis. However, a huge limitation of this sensor is its low sensitivity due to the constraints of the parallel-plate capacitor structure under applied strain operations. At best due to theoretical limitations, this structure can achieve a gauge factor (sensitivity) of 1. Here, we present a design technique to enhance the sensitivity in capacitive-type strain sensors through using thin Au film electrodes. We achieved a best gauge factor (GF) slightly above 3 over a high stretchability of 140% strain with great linearity and negligible hysteresis. We further found that the gauge factor of this strain sensor is tunable through varying the film thickness of the electrode. The enhanced sensitivity in capacitive-type strain sensors allows for the opportunity to distinguish subtle motions more sensitively for reliable and practical wearable applications.

10:45 AM BM08.01.08
Flecography Printing of Liquid Alloy-Based Stretchable Electronics Shuo Zhang, Bei Wang, Jiajun Jiang, Kang Wu and Zhigang Wu; Huazhong University of Science & Technology, Wuhan, China.

This work presents a rapid method to selectively print liquid alloy circuits on soft substrate at ambient environment using a laser-treated stamp, by tuning the liquid alloy wettability on different surfaces. This technology has the advantage of efficient as it only need inking and imprinting in just two steps. It can compatibility with existed industrial line equipment for complex and volume automation production easily.

Room temperature liquid alloy has been widely used in stretchable and flexible electronics because of high adaptability, fluidity and high conductivity. Numerous approaches were developed for pattern, such as injection, masked deposition, directly writing, and so on. However, these processing techniques are lack of compatibility to fit existing production lines directly. A simple way with more excellent portability is still being sought. In this work, a stamp was fabricated by selectively laser treatment on the surface of carbon filled PDMS (cPDMS). The laser processed cPDMS demonstrated an alloy-photonic behavior which could attach and then transfer liquid alloy to target substrate easily, while the left parts show an alloy-philic behavior. The difference of adhesion can be characterized quantitatively by measuring the bias of advancing and receding contact angles and calculating theoretically. After inked on stamp, the liquid alloy was printed on target substrate by gently pressing the stamp on target substrate. The liquid alloy would attach on both stamp and target substrate because of adhesion effective and surface oxide layer, and the liquid alloy would separate during lifting off because of Rayleigh-Taylor instabilities. Therefore, liquid alloy could be theoretically left on both stamp and target substrate. Since the oxide layer of liquid alloy exhibits adhesion on sorts of materials, this technique could be widely used on universal substrates, such as pure PDMS, Ecoflex, vinyl tape, glass, polyethylene glycol terephthalate (PET) and so on. Additionally, the method was proved to print arbitrary liquid alloy patterns with resolution as fine as 30 μm with excellent repeatability.

Further, a 64-LED-matrix with bistratal typography with a developable surface stamp were fabricated and demonstrated by this technique.

11:00 AM BM08.01.09
Controlling Thermoplastic Elastomer Optical Properties by Mechanical Processing—Materials for Stretchable Fiber Optic Sensors Margaret Campbell, Paramjot Singh, Kunal Kate and Cindy K. Harnett; University of Louisville, Louisville, Kentucky, United States.

We demonstrate that changing the extrusion speed of thermoplastic elastomer (TPE) fiber can modify its optical transmission by a factor of more than 100. Recently, we created stretchable fiber optic sensors from commercial urethane elastomer fibers that could detect muscle activity when sewn into textiles [1]. By extruding fiber from pellets at slow speeds, optical transmission increased beyond that of the commercial material, potentially leading to sensors that measure deformation on the meter scale instead of cm scale.
Thermoplastic elastomer pellets (Versaflex CL40, PolyOne Corp.) were dehydrated overnight at 60°C, then extruded at 190°C at rates between 0.005 and 0.3 mm/s. The 0.005 mm/s specimen appeared clear upon extrusion while successively faster speeds appeared hazier. Optical transmission was measured with a photodiode and light source. Stress-strain testing showed that the fast-extruded filaments had a greater ultimate tensile strength than filaments extruded at slower speeds.

Wavingguiding in a stretchable optical fiber requires a stretchable cladding with lower refractive index than the core. Our previous silicone coating approach worked with the new extruded cores. However, the silicone claddings peeled under extreme strain (>100%). Therefore, we investigated whether solvents could improve cladding adhesion, wavingguiding and light-coupling properties of the fibers. Soaking the fibers in NMP (n-methyl-2-pyrrolidinone), then stretching the fibers while the solvent dried, turned out to modify the cladding in a way that solvents alone did not. The clearest, slowest-extruded cores were relatively unchanged by the NMP “soak-and-stretch” treatment, while the faster-extruded cores developed a porous, textured cladding with a uniform thickness.

The differing optical properties, mechanical properties, and response to solvents are likely caused by a transition from amorphous polymer at low extrusion speeds, to crystalline at high extrusion speeds. The microstructural properties of urethane based TPEs are known to involve pseudo-crosslinks, which are not chemical bonds but rather physical connections between the monomers of the block co-polymer [2], and which may be disrupted by the soak-and-stretch process. Further investigations with differential scanning calorimetry and FTIR spectroscopy were conducted to identify changes in fiber microstructure at different extrusion speeds.

Varying extrusion speed at constant temperature may tune optical properties along the axis of a fiber, for example creating absorbent regions that are sensitive to length and diameter changes, surrounded by more transmissive segments that carry the signal over long distances. The work also has implications for 3D printing soft optical structures from thermoplastic elastomer.

11:15 AM BM08.01.10

**Inkjet-Printed Graphene/ZnO Ammonia Sensor for Personal Healthcare Monitoring**

Tien-Chun Wu1, Andrea De Luca2, Thomas Albrow-Owen1, Guohua Hu1, Florin Udrea1 and Tawfique Hasan1; 1Cambridge Graphene Centre, University of Cambridge, Cambridge, United Kingdom; 2Department of Engineering, University of Cambridge, Cambridge, United Kingdom.

Early diagnosis of diseases with smartphone/wearable devices is at the forefront of intelligent personal healthcare monitoring system. Analysis of components in exhaled breath is a practical and non-invasive approach. We focus on the detection of exhaled ammonia (NH₃) level which is a critical biomarker associated with hepatitis, kidney failure, and stomach cancer.

We present a novel and industrially scalable inkjet-printed graphene-based sensory system that is integrated onto a miniaturized CMOS MEMS platform. We inkjet-printed nano-composite sensing layer of graphene/ZnO which is synthesized by a cost-effective solution-processing approach. The approach involves liquid phase exfoliation (LPE) of graphite and mixing of ZnO nanoparticles, producing uniformly decorated nanoparticles in a network of graphene flakes.

Our device outperforms conventional metal oxide semiconductor (MOS) sensors via improved gas adsorption ability at materials interface. Moreover, thanks to precisely-controlled thin-film inkjet deposition technologies, we achieve consistent readings among the fabricated devices (<1% variation in response among four devices).

The device is ideal for implementation in smartphones due to its compact size (1mm²) and its ultralow power consumption (5mW). Coupled with rapid temperature modulation of the built-in micro-hotplate, we achieve ultrahigh response of 1600% at 10 ppm of NH₃ (compared to N₂) at a low operating temperature (150 °C) with fast rise and fall time (30s and 45s, respectively).

The versatile technologies enable multi-analyte sensors to be fabricated reliably and cost-effectively, offering new routes towards the development of multi-disease diagnostics platforms.
A Novel, Low Cost, Rapid, Disposable, Enzyme-Free and Colorimetric Paper-Based Platform for Point-of-Care Testing on Glucose Sensing in the Physiological Range Elvira Fortunato 1, 2 and Rodrigo Martins 1, 2; FCT-UNL, Caparica, Portugal; 3CEMOP-UNINOVA, Caparica, Portugal.

Diabetes mellitus is currently one of the most serious and prevalent diseases in the world, affecting million people worldwide and the rate of new cases is expected to continue increasing. Therefore, the development of cheap and simple methodologies for point-of-care glucose sensing is of paramount relevance for an effective diagnosis and management of patients, mostly in underdeveloped and developing countries where the access to medical infrastructures is limited and cost-effect and simplicity are of major concerns. Due to its properties, paper represents an alternative in the performance of point-of-care tests for colorimetric determination of glucose levels, providing simple, rapid and inexpensive means of diagnosis. In this work, we report the development of a novel, rapid, disposable, inexpensive, enzyme-free and colorimetric paper-based platform for point-of-care glucose detection. This method is based on the synthesis of gold nanoparticles (AuNPs) by reducing of a gold salt precursor in which glucose is the reducing agent. Different concentrations of glucose present during the reduction process result in the formation of AuNPs of different size, to which color changes of the sensor are associated. The developed platform was tested and calibrated using different physiological concentrations of glucose from 1.25 to 50 mM and the obtained results were examined and digitally analysed through an image analysis software. It was also compared the colorimetric results obtained with a commercial scanner and with a smartphone camera, concluding that both methods are viable alternatives in the digital analysis of the sensor. The colorimetric sensor revealed sensitivity to determination of glucose levels in samples, in a simple, rapid, inexpensive and eco-friendly way.

2:15 PM BM08.02.03
Truly Stretchable and Transparent Smart Contact Lenses for the Diagnosis of Diabetes Jihan Park, Joohye Kim, Seoyeong Ju and Jang-Ung Park; Ulsan National Institute of Science and Technology (UNIST), Ulsan, Korea (the Republic of).

Recent developments in wearable electronic devices integrated with wireless technologies, which can perform health monitoring, will help to advance the medical applications. Among the advanced wearable platforms, smart contact lenses are one of candidates to provide real-time, noninvasive medical diagnostics from the physiological information on the eye and tear fluid. Especially, the eyes always contain the tear fluid, so the smart contact lenses can monitor the physiological status continuously.

Previously reported smart contact lenses exploited opaque and rigid electronic components for the operations of electronic devices. Therefore, these devices could interfere with the user’s vision and be potentially dangerous to the eyes. Furthermore, the bulky equipment with an excessive cost to monitor the signals from the smart contact lens could restrict the user’s activities. These limitations reduce the convenience and features of the smart contact lenses. Therefore, we propose smart contact lenses which can detect the glucose concentrations in tear fluid. For the superior stretchability and transparency, the smart contact lenses are fabricated using silver nanowire (AgNW) networks and graphene which have stretchable and transparent properties. Therefore, the resulting smart contact lens can provide a clear vision. In addition, the antenna composed of AgNWs enables the wireless communication, so the results of glucose sensor in smart contact lens could be wirelessly monitored. These sensor platforms based on AgNWs and graphene can be exploited as not only smart contact lenses but also internet of things (IoTs) for the environment monitoring.

Furthermore, the smart contact lens integrated with wireless display can exhibit the sensing results through the display pixel and exclude the use of bulky measurement equipment which reduces user convenience. Therefore, we believe that the smart contact lenses suggest a promising strategy towards wearable electronics for the diagnosis of diabetes.

2:30 PM BM08.02.04
Towards a Flexible and Biocompatible Implantable Sensor for Wireless Monitoring of Human Bladder Volume Filippo Melloni, Giorgio Ernesto Bonacchini, Mario Carioni and Guglielmo Lanzani; Istituto Italiano di Tecnologia, Milan, Italy.

The incidence of pathologies related to bladder dysfunction is clinically relevant, these including spinal injuries and neurological disorders. A considerable part of these illnesses is associated to urinary incontinence, which is not only cause of severe discomfort for patients, but in cases of poor or erroneous treatment it could lead to infections and tissue lacerations, with serious threats for health. A number of therapies are currently available for micturition control, however a definitive solution for real-time and adequate monitoring of bladder volume is still not available. Such a solution would allow the continuous probing of the filling state of the organ, thus avoiding the insurgence of two complications, i.e. excessive expansion of the bladder and its incomplete evacuation. This aid could work in cooperation with a wearable unit or also as feedback for already existing systems apt to urinary stimulation.

We herein propose an innovative design for a capacitive strain gauge, fabricated with a hybrid process that exploits organic and flexible materials as scaffold, metallic conductive layer as electrodes and an electrical insulator coating as protective and dielectric layer. The main challenge for this application is the design of a strain gauge able to match the high elasticity of the sensor and the considerable elongation that the device undergoes during bladder filling and emptying. For this reason, we designed a strain gauge made up of two different dielectric layers with different dielectric constants, obtaining a stepwise varied dielectric constant that allows for a linear response of the sensor to the deformation of the bladder.

The proposed design allows for a distributed strain analysis exploiting a principle similar to a linear encoder, and embeds contactless communication through an integrated RF antenna. In our work, we operate the system on an artificial bladder model, demonstrating contactless data read-out via a passive communication system, and thus paving the way towards testing on more realistic ex vivo and in vivo models.

The sensing system proposed in this work thus aims at providing a novel approach to the long-standing issue of bladder volume measurements, by advancing a design that could in principle allow for easy and reliable monitoring, not achievable with current technologies. Further developments of this approach could lead to the coupling of such device to implantable stimulating ones, hence helping to restore the original bladder functionality in patients, as well as enable direct data communication and control though smartphones or other handheld devices.

2:45 PM BM08.02.05
Bioinspired Multifunctional Nanostructures Integrated in Micro-Optical Sensor for Translational Implants Radwanul H. Siddique1, Vinayak Narasimhan1, Jeong-Oen Lee1, Shailabh Kumar1, David Srtavan1 and Hyuck Cho1, 2; California Institute of Technology, Pasadena, California, United States; 3University of California, San Francisco, San Francisco, California, United States; 4Samsung Institute of Advanced Technology, Suwon, Korea (the Republic of).

While numerous multifunctional antifouling nanostructures on insect wings have been previously studied and replicated, their potential incorporation into implantable medical devices remains unexplored. We have demonstrated the use of multifunctional bioinspired nanostructured membrane inspired by transparent butterfly wings for intraocular pressure (IOP) sensing in vivo. [1]

We investigated the multifunctional properties of the biophotonic nanostructures found on the wings of the longtail glasswing (C. faunus) butterfly. The APM, SEM, optical, and biological characterizations have revealed that two groups of dome-shaped nanostructures with different periodicity co-exist on the transparent wings of the C. faunus: (1) angle-independent anti-reflective nanostructures with periods of 140-180 nm in the postdiscal areas; and (2) angle-independent transmissive light-scattering nanostructures with periods of 200-300 nm in the basal areas. In vitro testing has revealed both regions displayed antifouling properties based on physically-induced cell lysis. We have (1) adapted the coherence-preserving angle-independent transmissive light-scattering nanostructure as the sensing platform for the IOP sensor, and (2) fabricated the sensor as a passive and wireless micro-photonic sensor and demonstrated the ability to sense IOP in vivo. We have also validated the sensor in vivo in two different models using a standard and a custom fabricated device.
property of the basal nanostructures that could make optical sensors such as Fabry Perot (FP) resonators more angle-independent; and (2) by further engineering the basal nanostructures, created bioinspired nanostructures (BINS) that would prevent cell lysis and suppress inflammation. To produce BINS with periods of 385-505 nm on a Si$_3$N$_4$-membrane, we used a polymer-phase-separation process following the nature’s way of forming nanostructures [2,3]. Angle-resolved transmission spectroscopy showed that the light transmission of the BINS-integrated membrane was twice more angle-independent than a flat Si$_3$N$_4$-membrane. In a series of in vitro studies, the BINS-integrated Si$_3$N$_4$ surface displayed remarkable anti-biofouling properties against proteins (albumin and streptavidin, ***P ≤ 0.001), prokaryotes (E. coli, **P ≤ 0.01), and eukaryotes (HeLa cells, **P ≤ 0.001) when compared to flat Si$_3$N$_4$ and control (glass) surfaces.

Finally, we integrated BINS onto the FP-resonator-based IOP sensor that was recently developed in our lab [4]. However, its practical applications were limited by its narrow readout angle inherent to FP-resonators and infrequent but severe biofouling observed after long-term implantation. The BINS integration onto the IOP sensor led to a 2.5-fold improvement in readout angle allowing easy handheld monitoring and in a one-month in vivo study conducted in rabbits, showed a 3-fold reduction in IOP error and 12-fold reduction in tissue encapsulation and inflammation, compared to an IOP sensor without BINS.

Portable Respiration Sensor Using Nanoparticle Film for Monitoring Respiratory Condition

Shinya Kano and Minoru Fujii; Kobe University, Kobe, Japan.

Respiration is one of the important vital signs of human in daily life. Respiratory signals including the information of rates, patterns, and phase are highly related to condition of respiratory organs and activity of exercise. Monitoring respiration rates helps us to find a risk of respiratory disorders such as sleep apnea, asthma, and chronic obstructive pulmonary disease. Conventional respiratory monitoring system, such as transthoracic impedance plethysmography, mainly records respiration of subjects at rest because motion of a target person can affect the observation of respiration. Therefore, wearable respiration sensors using various sensing mechanisms have been intensively studied. In this study, for monitoring human respiratory condition during exercise, we develop a portable respiration sensor with a humidity-sensitive nanoparticle film. We adopt surface-oxidized silicon-based nanoparticle (silicon nanocrystal, silica nanoparticle) thin films as a humidity-sensitive film. The thin films are solution-processed on flexible polyimide films by using the colloidal nanoparticle solution. Interdigitated electrodes on the polyimide films have 100 μm spacing. Fabricated devices work as a respiration sensor which detects water vapor in exhaled air. Response of the respiration sensor is fast enough to fully monitor human respiration condition up to 1.7 Hz. Patterns and phase of respiration can be analyzed by using the signal of the sensor. We also demonstrate a portable sensor using a portable data logger and a humidity-sensitive film for monitoring human respiration during running. This sensor can track and assess respiratory information during exercise easily.

4:45 PM BM08.02.10
Thread-Based Wearable Multiplexed Sensor for Real-Time Sweat Monitoring
Trupti Teese, Zimple Matharu, Meera Punjia, Boyang Lyu and Sameer Sonkusale; Department of Electrical and Computer Engineering, Tufts University, Medford, Massachusetts, United States.

A wearable thread based sensor patch for continuous multiplexed analysis of sweat is reported. This sensor performs real-time, simultaneous, on-body measurements of important sweat markers such as electrolytes (sodium and ammonium ions), metabolites (glucose and lactate), sweat pH and body temperature. Low cost and flexible polyester threads coated with conductive inks were used as sensing electrodes. Selective potentiometric detection of electrolytes and pH was achieved by an ion-selective membrane and pH-sensitive polyaniline coating on threads respectively. Whereas threads functionalized with enzymes were used in the amperometric detection of glucose and lactate. The selectivity and sensitivity of these sensors in detecting the known concentration of target analyte were studied. The array of these selective thread sensors were further integrated on a patch that can be worn on the skin with readout electronics for real-time sensing. The real-time data was recorded by placing the sensor on the human volunteer during strenuous exercise condition. This sensor device can also be integrated with wireless data communication and storage for real-time data analytics. Proposed thread based sensing platform truly offers a great avenue for simple, low cost, flexible and stretchable wearable sensor development which can be sewn, woven or sutured on any substrate including body tissues.

Self-Healable, Transparent and Stretchable Pressure-Sensitive Capacitor Using Light-Induced Curable Polymer Based on Dynamic Reversible Urea Bonds
Sun Ok Kim2, Cheul-Ro Lee2, Youngmin Kim1 and Jang-woong Kim2; 1Korea Electronics Technology Institute, Seongnam Gyeonggi, Korea (the Republic of); 2School of Advanced Materials Engineering, Chonbuk National University, Jeonju, Korea (the Republic of).

Since the functionalization of the pressure sensor is basically based on contact with external objects and mechanical deformation of the sensor, efforts to render the pressure-sensitive devices robust and durable to withstand mechanical damages have led to development of various self-healable polymers. Considering that polymers are susceptible to be damaged which would severely weaken the mechanical properties and lifetime of materials, the integration of the pressure sensing functionalities with the ability to self-heal would be highly beneficial to all the domains of their application. One of the most prominent self-healing approaches is Diels–Alder (DA) reaction, which utilize reversible covalent bond formation. Previous studies have revealed that in polymeric materials based on multi-furan and multi-maleimide synthesized via the DA reaction, the inter-monomer linkages disconnect at temperatures above 120 °C (corresponding to the retro-DA reaction) and subsequently reconnect upon cooling. It was revealed that the DA adducts can be used in fabrication of self-healable and stretchable substrate due to their impressive healing performance and mechanical softness. However, DA-based elastomeric polymers are not considered to be suitable as a material for fabricating a pressure sensor because of their insufficient toughness and strength. Recently, the urea bonds with bulky substituents have drawn much attention as the linkages for the self-healing polymers because they were reversibly transformed to their starting materials of isocyanate and amine groups in the mild condition. Furthermore, the Young’s moduli of the polymers with the dynamic urea bonds can be enhanced when they were produced through the UV curing process due to the high density in crosslinking. Inspired by this, we have synthesized the UV-curable urethane acrylate and monomer featuring the dynamic urea bonds. The mechanical properties and the self-healing capabilities were adjusted by mixing the urethane acrylate and the monomer. Based on this, we fabricated a self-healable, stretchable and transparent pressure-sensitive capacitor by embedding Ag nanowire (AgNW) patterns just underneath the surface of the polymer. A simple tandem compound electrode was patterned on AgNW electrodes, allowing a capacitance to be formed between the parallel electrodes, which varies with the gap. The resulting sensor was mechanically stable to several bends or stretches, and was highly sensitive to the direct contact pressure or its deformations. Most interestingly, many artificially formed scratches by steel brushes on AgNW electrodes were instantaneously removed by irradiations of intense-pulsed-light (IPL). The scratches formed at the surface of the electrode were healed and electrical conductivity was efficiently recovered by the photo-thermal effect. The scratching and healing were repeatedly demonstrated at the same location for several times.

Multimodal Resistive Pulse Analysis
Makusu Tsutsui1, Kazumichi Yokota1, Akihide Arima1, Wataru Tonomura2, Masayoshi Tanaka2, Mina Okochi2.
Masateru Taniguchi¹, Takashi Washio³ and Tomoji Kawai¹; ¹Institute of Scientific and Industrial Research, Ibaraki, Japan; ²Tokyo Institute of Technology, Tokyo, Japan.

A nanoscale hole sculpted in a thin solid membrane, so-called nanopore, has been extensively studied as an ultrasensitive sensor device for detecting and identifying particles and molecules of variety of sizes from cells to polynucleotides. It measures temporal blockade of the ionic current flowing through the nanochannel, via an individual object passing through there. Height of the thus acquired electrical signals, which is in a form of a resistive pulse, serves as a useful index to measure the size of the object as the amount of ion exclusion scales with the size of the object. Compared to this conventional single-modal approach, I will present our recent research on multimodal resistive pulse analysis for identifications of single-particles through leveraging machine learning algorithm to pattern-analyze the single-particle signatures in a high-dimensional feature space.

Our device consists of a nanopore formed in a thin Si₃N₄ membrane. Here, the channel depth was designed to be much thinner than the diameter. This low-thickness-to-diameter aspect ratio architecture renders exceptional sensitivity of the ionic blockade to not only the size of analytes but also several other features including their shape and surface charge status (M. Tsutsui et al., ACS Nano 10, 803-809 (2016)). Using the ultrathin nanopores, we obtained resistive pulses for several kinds of bacteria and viruses. Each pulse waveform, which contains wealth of information about the detected bioparticles, was then interrogated by the ensemble learning method (M. Tsutsui et al., Sci. Rep. 7, 17371 (2017)) with multiple feature parameters such as the width and pulse bluntness. We demonstrated single-bacteria discriminations of resembling shape and size by the multimodal resistive analysis method with better accuracy than the conventional single-modal approach (M. Tsutsui et al., Sci. Rep. 7, 17371 (2017); Anal. Chem. 90, 1511-1515 (2018)). In my presentation, I will also show our recent results on a use of the machine learning based single-particle analysis for influenza typing in a functionalized nanopore.

BM08.03.03
Soft Electromagnetic Actuators
Stanley Doerger and Cindy K. Harrett; University of Louisville, Louisville, Kentucky, United States.

The prevalence of textiles in our everyday lives, from clothes to upholstery to carpets, means we are surrounded by flexible and wearable surfaces that can support functional fibers—including current-carrying wires. In this work, we use machine embroidery to embed fine, insulated copper magnet wire into flexible fabrics, producing soft electromagnetic actuators. We show that consumer-level embroidery machines are capable of making thin, flexible cm-scale electromagnets that exert forces and torques on permanent magnets. Beyond textiles, we discuss a path to transfer these electromagnetic actuator sheets into soft silicones and 3D printed robotic parts [1].

Our soft electromagnetic actuators use currents in the 100-500 mA range and voltages in the 1 V range. To produce linear motion, pairs of coils are driven by a sequenced pair of square waves that create a travelling magnetic field, driving a permanent magnet along the length of the device; alternatively the soft coils can move atop a stationary magnet array [2]. The magnets move in discrete steps related to the distance between segments of the embedded coils.

Using experiments and simulations, we examine the effect of magnet size and material, wire gauge, current, loop density and coil shape on the output force. We also investigate an embroidery-specific tradeoff: how to maximize the magnetic field gradient by creating flux overlap from multiple coils, while preventing the sewing needle from striking previously-placed wires and maintaining flexibility of the finished device. These embroidery-specific coil pattern generators are available for others to use.

Further investigations look at the maximum speed at which permanent magnets can be driven, the maximum height the magnet can be above the surface for successful actuation, and currents induced by externally moving a permanent magnet in the presence of the flexible coils. Potential applications of this technology include energy harvesting using stretchable materials, wearables with integrated actuators that can open vents, create folds and move flaps in fabrics, precision positioning on flexible surfaces, and electromagnetic actuator sheets that can be dropped into 3D printed robotic mechanisms.

BM08.03.04
Performance Optimization of Thermoelectric Measurement Based on Wearable Materials
DanHong Han, Gang Li and Shengyong Xu; Key Lab. for the Physics and Chemistry of NanoDevices Department of Electronics Peking University, Beijing, China.

Along with the development of nanotechnology, wearable devices and “Internet of Things”, substrate materials using for wearables include PET, parylene, PDMS and less conventional substrates, such as papers [1, 2]. Polyethylene terephthalate (PET) has been broadly used as the substrate for fabrication of flexible electronics owing to that its optimal thermoelectricity is beneficial to slow down the device performance degradation. Parylene has not only the well electrical properties, protective performance, but also the bio-compatibility, which is listed as a long-term implantable biological medical materials in the body. We can measure changes on physiological state like the surface and internal micro-scale temperature changes in living organisms through this flexible material. How to optimize the performance of a thin-film thermocouple array using for monitoring the body temperature at times on the flexible material is our concern.

Here we will introduce a kind of cascaded devices with a single layer of metal thin-film thermocouple (TFTC) [3]. A single layer metal thermocouple is similar to a conventional bimetalic thermocouple, but the two beams of the sensor are of different widths and composed of the same metal thin film, which leads to that the sensitivities of the single-metal TFTCs were all around 1 μV/K or less. In view of this situation, we developed the cascaded array of single metal thin film thermocouples, which consist of a 5μm narrow stripe and a 100μm wide stripe. We have got a 64-cascaded thermocouple achieved a Seebeck coefficient of up to 55.69 μV/K, which is much higher than that of a commercial type-K thermocouple, 39.60 μV/K. Furthermore, we have fabricated this cascaded array on flexible substrates - parylene-C, making it potentially useful in practical applications such as measuring arm surface temperature, as seen in Figure 1.

Due to the simple fabrication process and remarkable temperature sensing ability, the cascaded thermocouples could be integrated easily into the flexible electronics and wearable devices, as well as find potential applications in monitoring temperature of body surface and interior in real time under various conditions, which would be beneficial to public health and care.

BM08.03.05
Magnetically Actuated Hydrogels as a Remote-Controlled, Robust and Wearable Drug Delivery Platform Ayomide Perera, Richard Jackson, Mark Modownik and Marc-Olivier Coppens; University College London, London, United Kingdom.

Polymer hydrogels incorporated with magnetic nanoparticles (MNPs) have vast potential in various biomedical applications such as treatment of cancer and cardiovascular diseases, and in regenerative medicine. The advantages of having MNPs in such platforms are that they can be remotely triggered by various methods, such as hyperthermia, pH and chemical changes, to release drugs or other desired molecules. Actuation of a drug-carrying platform by an external magnetic field (i.e., magnetic actuation), is another such possible pathway to trigger drug release in a controlled manner. This technique has tremendous potential as a non-invasive, safe and precise approach to drug delivery, for both in vivo and ex vivo applications.

We have developed a novel technique to fabricate polymer hydrogels incorporated with Fe₃O₄ MNPs. These gels are biocompatible, and can be actuated via an external magnetic field. The porosity and mechanical properties of the gels can be readily customized. Various drug molecules can be mixed into the polymer-MNP solution, prior to gel formation, to generate gel patches infused with known drug quantities. Using acetaminophen as a model drug, we demonstrate that these gels can be actuated with external magnetic fields for drug release. The amount of acetaminophen released can be controlled by customizing the physicochemical properties of the gels by varying the amount of either polymer or MNP concentrations.

The macro-structure of the magnetic gels can be tailored to optimise their mechanical properties. We have used a nature-inspired approach, by utilizing the structural and functional features of mollusc nacre (i.e., the inner shell layer) to improve the compressibility and strength of the gels. 3D printed templates were employed to develop hexagonal moulds that were used to assemble the gel into various layer-by-layer structures. This technique allowed the Young’s modulus of the layered gels to be increased up to 5 times, compared to the non-layered material.

The biocompatibility, customizable properties and robustness allows for these materials to be used as wearable drug release devices for both external and sub-epidermal applications. The magnetic component allows for remote control actuation, as well as the possibility to be activated via hyperthermia. Such a platform can potentially lead to significant improvements in targeted drug delivery, with minimal invasive procedures.

BM08.03.06
Low Voltage, Core-Shell Electrospinning Patternning of Submicron Silver Fibres Wenya Wang, Xia Li and Yan Yan Shery Huang; Engineering Department, University of Cambridge, Cambridge, Cambridge, United Kingdom.

Ultrathin, meso-scaled metallic fibres possess unique mechanical, electrical and optical properties, such as high aspect ratio, transparency, and lightweight. These properties will enable a wide range of novel applications such as fibre-based circuitry, and flexible and transparent electrodes. Due to their low bending stiffness, meso-scaled metallic fibres produced by existing fabrication techniques are restricted to applications where the fibres were bound to a supporting substrate. Such a configuration inevitably compromises the unique attributes of the meso-scaled fibre structure, as the mechanical and optical properties of substrate can dominate the performance of final products. Herein, we introduce a novel one-step printing technique to synthesis and pattern conductive silver meso-fibres under mild temperatures and atmospheric conditions. We demonstrate spanning silver core-shell fibre arrays with an average diameter of ~1μm and best conductivity of 1.8×10⁶ S/m. A rapid line writing speed of 600 mm/s is achieved, where fibres can span across a distance of up to 10mm with both ends making direct electrical contact with external circuits. No post-processing such as annealing is required in this process. Based on this technique, ‘floating’ electronic structures are demonstrated with LEDs and photodiodes. Unlike traditional transparent or flexible electrodes confined to a substrate, in our work, electronics can be mechanically suspended and electrically connected by the meso-fibre array alone. Tensile test shows that the mechanical property of the fibres is similar to human skin, indicating potentials for artificial skin and wearable sensors. Overall, we demonstrate an efficient and rapid silver meso-fibre patterning technique, and its applications in facilitating facile circuitry connection for unconventional, floating electronic structures.

BM08.03.07
A Novel and Rapid Single Step Approach Toward Fabrication of Piezoelectric Sensors Chithra Parameswaran and Dipti Gupta; Indian Institute of Technology Bombay, Powai, India.

Sensors for biomedical applications have become indispensable for their signal detection and simplicity. Various fabrication techniques are being explored for fabrication of cost effective and high sensitive piezoelectric sensors, both capacitive and resistive in nature. For this purpose elastomers sponges have been targeted due to their skin conformity and bio-friendly nature. Here we introduce a leavening agent mediated process for obtaining PDMS sponges over large area. These are then realized in capacitive sensors over a wide range of pressure from finger touch to pulse sensing with better sensitivity (0.756 kPa⁻¹ to 5kPa) to the best of our knowledge. This approach is further extended in obtaining resistive pressure sensor by bringing a variant in the synthesis. The hydrophilic sponge is made resistive using a dip-and-dry method in a commercially available ink. A compression induced in the sponge decreases the resistance providing an electrical equivalent of the applied mechanical stimulus providing an efficient resistive sensor with good cyclic response and sensitivity. The approach presented here paves way for huge feasibility in obtaining desired sensitivity and porosity during the in-situ fabrication process which is a first report in literature.

Broadband LED and Piezo-Phototronics Enhanced Photodetector on CMOS Compatible Flexible Si Platforms Arijit Sarkar, Ajit K. Katiyar, Amal K. Das and Samit K. Ray; 1S.N. Bose National Centre for Basic Sciences, Kolkata, India; 2Advanced Technology Development Centre, Indian Institute of Technology Kharagpur, Kharagpur, India; 3Department of Physics, Indian Institute of Technology Kharagpur, Kharagpur, India.

Development in mechanically flexible optoelectronic devices on Si platforms, compatible with conventional CMOS technology are encouraging for future integrated wearable and flexible optical sources, detectors, displays and solar cells. Typical flexible devices based on organic semiconductors are fabricated on plastic substrates. These devices have the disadvantages of thermal and chemical degradation as well as low mobility of carriers and low efficiency compared to Si based devices. Therefore, optoelectronic devices fabricated on mechanically flexible Si substrates are very promising in this regard. Here we report the fabrication of flexible Si membranes (3-5 μm thick) acting as a substrate to develop a low power consuming broad band visible light emitting diode (LED) and a high responsive photodetector, sensitive to both UV and visible photons. The p-Si membranes are fabricated by simple and
cost effective chemical etching method followed by n-ZnO thin film (~180 nm) deposition by RF sputtering method forming a p-n heterojunction. The n-ZnO/p-Si membrane heterojunction exhibits very good rectification behaviour and broad band electroluminescence (EL) in the 400-850 nm wavelength range at room temperature under forward bias condition. The minimum operating voltage of the fabricated flexible LED is 3.19 V which is lowest on comparing with other reported results on similar device structure. The EL from the device appears to be yellowish white to naked eye in a dark room. The flexibility of the device was tested by recording EL spectra at different bending conditions, from relaxed to bend to a semi-circle. In all the cases the EL spectra exhibited no significant change in intensity or emission feature. This confirms that the fabricated flexible LED performed brilliantly under different mechanical bending conditions.

Similar n-ZnO/p-Si membrane heterojunction was also developed into a flexible and high responsive photodetector which demonstrated enhanced photosresponse in UV and visible wavelength range utilizing piezo-phototronic effect. A peak responsivity of 0.20 AW⁻¹ with detectivity of 4.8 × 10¹³ cm Hz⁻¹/₂ W⁻¹ has been obtained without applying any external bias. The high mechanical flexibility of the Si membranes and the inherent piezoelectric property of ZnO thin film have been utilized to enhance the performance of the device via piezo-phototronic effect. On application of external tensile strain, piezo-potential developed in piezoelectric ZnO thin film has been exploited to modulate the transport property of the photo generated carriers thereby enhancing the device performance. Photocurrent has increased by 22% with gradual increase in the applied tensile strain. Thus the fabricated mechanically flexible n-ZnO/p-Si membrane heterojunction based low power consuming broad band visible LED and piezo-photodetector is very promising for future wearable optoelectronic applications such as flexible displays and CCD devices.

BM08.03.09
DNA-Inspired Supercoil Fiber for Superelastic, Weavable Supercapacitors Changsoon Choi¹ and Younghoon Kim²; ¹Division of Smart Textile Convergence Research, Daegu Gyeongbuk Institute of Science and Technology (DGIST), Daegu, Korea (the Republic of); ²Convergence Research Center for Solar Energy, Daegu Gyeongbuk Institute of Science and Technology (DGIST), Daegu, Korea (the Republic of).

Stretchable and electrically conductive one dimensional fibers are important for diverse applications. Here we report the DNA supercoil structure inspired composite fibers which are highly stretchable, and electrically conductive. Carbon nanotube wrapped sheath on commercially available spandex core fibers were fabricated and giant twist was inserted for supercoiling. The resulting supercoiled composite fibers show highly ordered and compact structures along fiber direction, which enable superelasticity (up to 1300%). The supercoiled fiber exhibited stretch-invariant electrical property that very low resistance increase is observed for a fully stretch, when especially overcoated by passivation layer. Moreover, by incorporating pseudocapactive MnO₂ active materials on the supercoiled fibers, we demonstrated the superelastic supercapacitors with high linear and areal capacitances, which are highly retained when reversibly deformed in the fiber direction.

BM08.03.10
Graphene Oxide Modification for Machine Learning-Based Multisensor Systems Feder S. Fedorov, Alena Alekseeva, Stanislav Evtushin, Vladislav Kondrashov, Maxim Panov, Alexander Shafeev and Albert Nasibulin; Skolkovo Institute of Science and Technology, Moscow, Russian Federation.

Monitoring of temperature, air humidity, concentration of CO₂ and CO air pollutants (NOₓ, SOₓ), and volatile organic compounds requires new sensor systems which would combine enhanced selectivity and low detection limit. Among criteria to be fulfilled, we could outline low power consumption what requires room temperature operation, simple manufacturing protocols and long-term performance that generally determines the cost of the final product [1]. Thus, the key element of the sensor is a sensing material whose properties should be properly tuned to enable good performance. Here we propose a single material sensor platform based on graphene oxide (GO)/reduced graphene oxide (rGO) which is a unique material sensitive to humidity, pollutants and other gases [2]. The material also responds well to temperature changes. GO/rGO shows good response, stability, reversibility at ambient conditions, though, lacks the selectivity. To approach the selectivity, we combine several sensors based on GO/rGO material in an array whose vector signal is processed by pattern recognition algorithms to get a “fingerprint” of the gas mixture at defined temperature, following known multisensory concept. Sufficient variation of the sensor properties enables successful discrimination of the environment changes. Such variation we create by partial reduction GO by laser under developed treatment protocols [3]. Particularly, we will discuss the results on sensor arrays fabricated by irradiation of GO by laser to transform it to rGO tuning the ratio between GO/rGO areas what allows us to get different response for each sensor element in the array. The reconstruction of the environment changes from property variations is realized by modern machine-learning algorithms what we illustrate by successful determination of both the humidity (from 5% to 95% RH) and the temperature (up to 60 °C). The authors acknowledge MIT Skoltech Next Generation Project.

BM08.03.11
Stretchable Substrate for Body Attachable Systems Minwoo Nam, Myung Sub Lim, Young Hyun Son and Kyung Cheol Choi; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Development of stretchable electronic devices has been perceived as a key technology to meet interest in making more functional devices. Compared with recently-commercialized electronic devices, which are mechanically robust because they are based on rigid substrates such as wafers or glass slides, stretchable electronic devices that can withstand a variety of mechanical stress conditions like bending, twisting and folding can be integrated with wearable or fashionable electronic clothing and biocompatible medical devices.[1-2] The ability of stretchable electronic devices to undergo stretching and compression to various degrees will enable people to move more freely when the devices are worn or even placed on the skin. To realize stretchable electronics, the flexibility limitations of plastic and glass substrates have to be overcome and stable operation performance is needed on the substrate when elongated. Here, we have developed design and fabrication technology for stretchable substrates with structures yielding mechanical stress isolation and relief for body attachable systems.

In this study, we fabricate a stress-relief stretchable substrate by structure change of substrate with general materials and demonstrate its feasibility, with the further aim of developing a soft patch for an obstructive sleep apnea monitoring system. The stretchable substrate used in this study consists of two parts, one, PDMS, which gives elasticity to the substrate and another, SU-8 (negative photoresist), consisting of rigid planar plates on which chips and devices are operated. Patterned with bridges and plates, SU-8 can be stretched and tied up on top of the protruding PDMS pillar arrays. The PDMS column array disperses the mechanical stress applied to the SU-8 plates when the substrate is elongated and makes devices more stable. Transfer-based integration
of thinned chips onto stress-relief stretchable surface allows us to realize sensors and devices that can remain stable under tensile and compressive stress. We fabricated different colors of organic-light emitting diodes, which are applied to a sleep apnea monitoring system on stress-relief substrates using thermal evaporation without the addition of a process like pre-straining of the substrate; devices were found to work stably under stretch-release test.

In conclusion, we present stress-relief stretchable substrates essential for realization of body attachable systems applicable to non-planar and arbitrarily shaped surfaces. Integrated circuits and sensors can be operated when the patches are stretched with stress-relief substrates, reducing stress on devices. This substrate is expected to provide a key base technology for wearable electronic devices as well as medical patch systems.

BM08.03.12
Encapsulation of Single Nanoparticle in Fast-Evaporating Micro-Droplets in PDMS for Photocatalysis and Other Applications Xinjian Shi and Xiaolin Zheng; Stanford University, Stanford, California, United States.

This work describes the use of fast-evaporating micro-droplets to finely disperse nanoparticles (NPs) in a polymer matrix for the fabrication of nanocomposites. Agglomeration of particles is a key obstacle for broad applications of nanocomposites. The classical approach to ensure the dispersibility of NPs is to modify the surface chemistry of NPs with ligands. The surface properties of NPs are inevitably altered, however. To overcome the trade-off between dispersibility and surface-functionality of NPs, we develop a new approach by dispersing NPs in a volatile solvent, followed by mixing with uncured polymer precursors to form micro-droplet emulsions. Most of these micro-droplets contain no more than one NP per drop, and they evaporate rapidly to prevent the agglomeration of NPs during the polymer curing process. As a proof of concept, we demonstrate the design and fabrication of TiO2 NPs@PDMS nanocomposites for solar fuel generation reactions with high photocatalytic efficiency and recyclability arising from the fine dispersion of TiO2. Our simple method eliminates the need for surface functionalization of NPs. Our approach is applicable to prepare nanocomposites comprising a wide range of polymers embedded with NPs of different composition, sizes, and shapes. It has the potential for creating nanocomposites with novel functions.

BM08.03.13
Development of Electrochemical Biosensors with Alternative Inorganic Framework Structures Burcu Akata Kurc1, 2, Sergei Dzyadevych3 and Berna Ozansoy1; 1Micro and Nanotechnology Department, Middle East Technical University, Ankara, Turkey; 2Central Laboratory, Middle East Technical University, Ankara, Turkey; 3Laboratory of Biomolecular Electronics, Institute of Molecular Biology and Genetics, Kiev, Ukraine.

An electrochemical biosensor is a self-contained integrated device, which is capable of providing specific quantitative or semi-quantitative information about the composition of a liquid or gaseous sample. Nowadays the development of biosensors is an actual challenge. The biosensors characteristics essentially depend on the conditions of biomaterial immobilization on the transducer surface. Thus, the improvement of methods of immobilization is very important. Recent progress in the synthesis of nanomaterials is a ground for the development of new immobilization methods. It is expected that the application of nanoparticles for biomaterial immobilization will improve sensitivity, linear range, stability, and other analytical characteristics of biosensors. Zeolites as being potential alternative nanomaterials for immobilization are micro- and nanoparticles based on a crystalline lattice structure containing a highly ordered structure with a complex pore and canal system. They have a large surface area, on which various substances can be adsorbed, and are widely used in various fields as adsorbents. In the current work, zeolites were added to the biorecognition elements of the biosensors and served as additional components of the biomembranes or adsorbents for enzymes. Three types of biosensors (conductometric, amperometric and potentiometric) were studied and developed biosensors were compared with similar traditional biosensors without zeolites. The biosensors contained the following enzymes: urease, glucose oxidase, glutamate oxidase, and acetylcholinesterase and were intended for the detection of urea, glucose, glutamate, and acetylcholine, respectively. Furthermore, a biosensor for the sucrose determination contained a three-enzyme system (invertase/mutatorase/glucose oxidase), immobilized by a combination of adsorption on silicalite and cross-linking via glutaraldehyde; such combined immobilization demonstrated better results as compared with adsorption or cross-linking separately. The analysis of urea and sucrose concentrations in the real samples was carried out. Methods to obtain these zeolitic films on flexible substrates will be discussed. Accordingly, results obtained with biosensors were shown to have high correlation with the results of traditional analytical methods, thus the developed biosensors are promising for practical applications.

BM08.03.14
Self-Cleanable, Stretchable and Transparent Ionic Communicators Based on Triboelectricity Younghoon Lee and Jeong-Yun Sun; Seoul National University, Seoul, Korea (the Republic of).

Human-machine interfaces have been highlighted with the advent of wireless sensor networks and the internet of things; it may require wearable/attachable electronics exhibiting stretchability, biocompatibility, and even transmittance. Furthermore, due to limited weight and volume for wearability, energy efficient and even self-powered devices are required. Here, we report practical approaches for a stably self-cleanable, transparent and attachable ionic communicator based on triboelectric nanogenerators. It can be easily applied on human skin due to its softness and chemically anchored robust layers. It functions as a means of real-time communication between humans and machines. Surface functionalization on the communicator by (Heptadecafluoro-1,1,2,2-tetrahydrodecy)trichlorosilane improves sensitivity and makes the communicator electrically and optically stable due to the self-cleaning effect without sacrificing transmittance. This research will be a foundation for potential development of attachable ionics, self-powered sensor networks, and monitoring system for biomechanical motion.

BM08.03.15
Integrating Deep Learning into Wearable Stretch Sensors Ben Oldfield2, Richard Jackson1, Peter Smitham1 and Mark A. Miodownik1, 3; 1Mechanical Engineering, University College London, London, United Kingdom; 2CoMPLEX, University College London, London, United Kingdom; 3UCL Institute of Orthopaedics & Musculoskeletal Science, Royal National Orthopaedic Hospital, London, United Kingdom; 4Institute of Making, University College London, London, United Kingdom.

There is a growing need for flexible stretch sensors to monitor real time stress and strain in wearable technology. However developing stretch sensors with linear responses is difficult due to viscoelastic and strain rate dependant effects. Instead of trying to engineer the perfect linear sensor we take a deep learning approach which can cope with non-linearity and yet still deliver reliable results. We present a general method for calibrating highly hysteretic resistive stretch sensors. We show results for 1D and 2D textile and elastomeric stretch sensors however we believe the method is directly applicable to any physical choice of sensor material and fabrication, and easily adaptable to other sensing methods, such as those based on capacitance. Our algorithm does not require any a priori knowledge of the physical attributes or geometry of the sensor to be calibrated, which is a key advantage as stretchable sensors are generally applicable to highly complex geometries with integrated electronics.
requiring bespoke manufacture.

The method involves three-stages. The first stage requires a calibration step in which the strain of the sensor material is measured using a webcam while the electrical response is measured via a set of arduino-based electronics. During this data collection stage, the strain is applied manually by pulling the sensor over a range of strains and strain rates corresponding to the realistic in-use strain and strain rates. The correlated data between electrical resistance and measured strain and strain rate are stored. In the second stage the data is passed to a Long Short Term Memory Neural Network (LSTM) which is trained using part of the data set. The ability of the LSTM to predict the strain state given a stream of unseen electrical resistance data is then assessed and the maximum errors established. In the third stage the sensor is removed from the webcam calibration set-up and embedded in the wearable application where the live stream of electrical resistance is the only measure of strain - this corresponds to the proposed use case.

This rapid desktop method requires less than one hour of data collection followed by a fully automated calibration routine based on LSTM. Highly accurate stretch topology mapping (within 5-15% errors) is achieved for the sensor skins tested including three different commercially available flexible sensor materials (Medtex P130, Technitex P130B, and Adafruit conductive rubber) as well as a bespoke printed composite silicone stretch sensor.

We discuss the application of our approach to various real-world use scenarios in emerging wearable technology sectors including prosthetics and assistive technology.

BM08.03.16
Integrating MXene Electrochemical Microsupercapacitor with Triboelectric Nanogenerator as a Wearable Self-Charging Power Unit Qiu Jiang1, Changsheng Wu2, Zhengjun Wang3, Aurelia C. Wang4, Jr-Hau He5, Zhong Lin Wang6 and Husam N. Alshareef7; 1King Abdullah University of Science & Technology, Thuwal, Saudi Arabia; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

One aspect that has been poorly studied in the field of wearable electronics is the integration of energy harvesting and storage devices. By using silicone to encapsulate TENG device and solid-state microsupercapacitor into a single monolithic device, a power unit made of a single-electrode-mode TENG and 2D MXene-based solid-state microsupercapacitor can sufficiently convert and store mechanical energy of human biomechanical motions into electrochemical energy, while maintaining long life time and high mechanical flexibility.

The device can utilize and store the random energy from human activities in a standby mode and provide power to electronics when active. As a result, our microsupercapacitor delivers a capacitance of 23 mF/cm² with 95% capacitance retention after 10,000 charge-discharge cycles, while the triboelectric nanogenerator exhibits a maximum output power of 7.8 µW/cm². Given the simplicity and integrated nature, our device can be integrated with a variety of electronic devices and sensors.

BM08.03.17
Facilely Prepared Layer-by-Layer Graphene Membrane-Based Pressure Sensor with High Sensitivity and Stability to Detect Human Motions Liu Tao; City University of Hong Kong, Hong Kong, Hong Kong.

With the prospering development of artificial intelligence, medical diagnostic and electronic skins, wearable electronic devices have drawn much attention in our daily life. Flexible pressure sensors with high sensitivity, especially in a large pressure range regime are highly required in the past decades.

In this work, graphene membrane with a layer-by-layer structure has been successfully prepared via a facile self-assembly & air-drying (SAAD) method. Air-drying the graphene hydrogel contributes to the uniform and compact layer structure in the obtained membrane. Owing to the excellent electrical and mechanical properties of the prepared graphene membrane, the pressure sensor based on several layers of membranes has high sensitivity and repeatability in the pressure range of 0-20 kPa. What’s more, the pressure sensor shows desired results in wearable applications to detect human motions. We demonstrate it can be used for pulse monitoring, breathing detection as well as various intense motion recording such as walk, run and squat et al.

We hope the facilely prepared layer-by-layer graphene membrane-based pressure sensor will have great potentials in the fields of smart electronics for medical health, human movements and even artificial intelligence and robot technology development.

BM08.03.18
Flexible InO/Al2O3 Hetero-Interface Diode Using PEALD for Active-Matrix Tactile Sensor Array Platform Hye-In Yeom, Guk-Jin Jeon, Steve Park and Sang-Hye K. Park; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

With a rapid development in Internet of Things (IoT), intelligent terminals including smart wearable devices, humanoid robotics, and artificial electronic skins (E-skin) have attracted huge attention. For those advanced applications, it is necessary to develop a proper tactile sensor array system. Especially for our targeted application (E-skin), we have to consider the low-pressure regime (1-10 kPa), a common but crucial range, covering a pressure on a daily activities. Resistive type sensors are often used due to their simple structure and easy read-out system. So, they offer significant advantages over other types of pressure sensor in terms of integration with other circuit system. Also, backplane can be one of the key component for the tactile sensor array, enabling precise sensing contrast with low noise level and low power consumption. As a switching device in each pixel, organic thin-film transistor (OTFT) has usually been adopted in resistive sensor array, however, they often suffered from environmental degradation and poor electrical performance.

Herein, we demonstrate highly stable and sensitive tactile sensor array platform using flexible InO/Al2O3 hetero-interface diode using plasma-enhanced atomic layer deposition (PEALD). As a starting step, we had to carefully consider proper diode structures according to their environmental stabilities, on/off-ratio, and on-current level. Then, the metal/oxide semiconductor (OS)/insulator/metal (MSIM) structure was adopted and was successfully developed with the ultra-thin indium oxide layer(<3nm) and alumina layer(<20nm) using PEALD, showing outstanding rectifying performance as a switching device. The on-to-off ratio is over 10⁷ and off-current density is lower than 100 nA/cm². There could be several reasons for the fairly stable current flowing phenomenon through the interface between OS and insulator. One plausible cause is enhancement of electron injection from cathode to insulator through thin OS layer, thereby electron can easily flow to anode under forward bias. Thus, on the basis of our active-matrix sensor array platform, any kind of resistive sensor can be integrated with it. The 8x8 matrix arrays were fabricated by photolithography process and top anode was patterned as interdigitated electrode. Then, a microstructured PDMS sheets coated with MWCNT would be integrated on them. We will further discuss about electrical properties and sensing performance.

BM08.03.19
Development of Highly Stretchable Printed Circuit Board Towards Reliable Integration of Electric Components Minsong Kim1, Kyuyoung Kim2, Hyuneul Lim3 and Inkyu Park1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

We developed stretchable printed circuit board (PCB) which can easily integrate electric components with high electrical and mechanical reliability. To surely apply techniques of stretchable electronics to wearable devices, it is necessary to realize totally stretchable device including complex interconnections between electric components. Stretchable PCB is the one of the most promising solution to achieve the all-stretchable electronics. We
chose most suitable elastomeric polymer as a substrate of the PCB by conducting electromechanical tests. Also metal film and highly conductive nanomaterials were used as conductor lines, buried in the substrate. Under the stretched state, metal film was strongly-adhered to the substrate and metallic nanowire act as electrical anchor and bridge respectively. Not only this hybridization effect but serpentine patterns of conductive materials attribute to improvement of the performances of stretchable PCB in terms of stretchability and strain-insensitivity. Additionally, other electric components can be easily integrated onto the opening of substrate occurring electrical/mechanical contact with buried conductor line, which is similar with surface mount technology of conventional PCB. The integration region includes tiny parts of rigid film to minimize stress applied to the mounted components, leading reliable integration. Finally, we show electromechanical characteristics of the fabricated stretchable PCB, and demonstrate the integration performance of which additional components are negligibly affected by the strain of the PCB.

Epidermal Multiple-Stimulus Electroluminescence Sensor for Human Activity Monitoring
Eunhyuk Kim, Hyowon Han and Cheolmin Park; Yonsei University, Seoul, Korea (the Republic of).

Wearable human-interactive electronics require the stimuli-responsive sensor that can detect stimuli in human body with vital signals of health-monitoring in epidermal skin through several sensing mechanisms. Here, we describe an epidermal electronic electroluminescence based multiple-stimuli sensor that allows for both monitoring and visualization of human-readable response. This “epidermal multiple-stimulus electroluminescence sensor” (EMES) is capable of human activity monitoring including internal body information and external stimuli. Our device consists of stacked bilayers of sensing layer on two transparent electrodes separated by an in-plane air gap on single side and the epidermal skin itself pressure and conductance sensing architecture. Simultaneous sensing and visualization of human monitoring is achieved to field induced between two separated electrode and skin is controlled by the capacitance change or impedance change of the sensing layer on epidermal skin. The utility of the EMES for human activity signal has been successfully demonstrated by touch, blood pressure, respiration, motion behaviour, fingerprint recognition, heat/cold, and humidity. Our multiple-stimuli sensor devices provide potential advantages in terms of simplicity, functionality, and broad applicability compared to previous wearable sensor based highly flexible and ultrathin substrate that involve conformal attachment of active elements onto skin.

BM08.03.21
The Effect of Interfacial Interaction on the Conformational Variation of poly(vinylidene fluoride) (PVDF) Chains in PVDF/Graphene Oxide (GO) Nanocomposite Fibers
Jeong-Eun Lee, Sojeong Heo, Youngho Eom, Sang-Ha Hwang and Han Gi Chae; Ulsan National Institute of Science and Technology (UNIST) U Plan Lab, Ulsan, Korea (the Republic of).

Polymers such as poly(vinylidene fluoride) (PVDF), and its copolymers with hexafluoropropylene (HFP), trifluoroethylene (TrFE) and chlorotrifluoroethylene (CTFE) are known to possess electroactive properties and have been studied for decades, enabling them one of the most promising candidates for wearable and smart textile applications. Nonetheless, the practical applications are still limited and are in the early stage of development because of poor mechanical integrity. In the current study, we have prepared PVDF/graphene oxide (GO) nanocomposite fibers by dry-jet wet spinning method at the GO concentrations of 0, 1, and 2 wt% with respect to the polymer weight. The as-spun fibers were drawn in the draw ratio (DR) range of 2 to 6.5, and the correlation between the PVDF chain conformation and the mechanical properties of the fibers upon drawing has been studied by 2D correlation spectroscopy (COS) of Fourier-transformed infrared (FTIR), wide-angle X-ray diffraction (WAXD), differential scanning calorimetry (DSC), and tensile testing. The PVDF/GO nanocomposite fibers exhibited that the mobile PVDF crystals were nucleated because it was based on the conformational defects and kinks due to the polar interaction between PVDF chains and functional groups of GO, whereas the control PVDF fiber showed the conventional conversion of crystal polymorphs (α and γ phases to β phase). As a result, the nanocomposite fiber showed dramatically improved toughness (enhanced by 1123% at a DR of 2 and 120% at a DR of 6.5) as compared to that of the control fiber. Furthermore, the tensile strength and modulus of the PVDF/GO (2 wt%) fiber were 394 MPa and 4.6 GPa, respectively, while those of the control PVDF fiber were 295 MPa and 3.9 GPa.

BM08.03.22
Stretchable Ultrasonic Transducer Arrays for Three-Dimensional Imaging on Complex Surfaces
Hongjie Xu, Xuan Zhu, Chonghe Wang, Lin Zhang, Francesco Lanza di Scalea and Sheng Xu; University of California, San Diego, San Diego, California, United States.

Ultrasonic imaging has been implemented as a powerful tool for noninvasive subsurface inspections of both structural and biological media. Current ultrasound probes are rigid and bulky and cannot readily image through nonplanar three-dimensional surfaces. However, imaging through these complicated surfaces is vital because stress concentrations at geometrical discontinuities render these surfaces highly prone to defects. This study reports a stretchable ultrasound probe that can conform to and detect nonplanar complex surfaces. The probe consists of a 10 × 10 array of piezoelectric transducers that exploit an “island-bridge” layout with multilayer electrodes, encapsulated by thin and compliant silicone elastomers. The stretchable probe shows excellent electromechanical coupling, minimal cross-talk, and more than 50% stretchability. Its performance is demonstrated by reconstructing defects in 3D space with high spatial resolution through flat, concave, and convex surfaces. The results hold great implications for applications of ultrasound that require imaging through complex surfaces.

BM08.03.23
Strongly Correlated Oxides as Electric Field Sensors for Haptics
Zhen Zhang, Derek Schwanz and Shriram Ramanathan; Purdue University, West Lafayette, Indiana, United States.

Advancing sensing modality to monitor bio-matter and chemical signatures in water-containing environment is of great importance in emerging fields of haptics and robotics. However, sensing multiple properties with the same material is often impossible due to instability when exposed to water. On the other hand, elasmobranch marine organisms such as sharks have evolved to naturally detect their environment through various electroreceptors, positioning them as apex predators. In this work, we will discuss how perovskite nickelates such as SmNiO₃ can directly mimic the functionality of the gel-like Ampullae of Lorenzini electroreceptor organs in sharks. Such sensing behavior of nickelates is enabled by an electric-field-driven Mott phase transition in aqueous environment which is accompanied by large nonlinear electrical resistivity increase and visible color change. These unprecedented properties of metastable oxide materials introduce a new sensing modality for environmental sensing that may be adapted to wearables and autonomous systems that operate in unstructured environments.

A Novel Straightforward Wet Pulling Technique to Fabricate Carbon Nanotube Fibers
Mariia Goncharova¹, Eugene Shulga¹, Sergey Shandakov², Ivan Sergeichev¹, Evgenia Gilshteyn¹, Anton Anisimov¹ and Albert Nasibulin¹; Skolkovo Institute of Science and Technology, Moscow, Russian Federation; ¹Kemerovo State University, Kemerovo, Russian Federation; ²Canatu Ltd, Helsinki, Finland.

The growing demand for wearable electronics requires flexible and stretchable conductive materials. Among them, carbon nanotubes are recognized for their outstanding mechanical, electrical, optical properties and chemical stability. Although CNTs possess remarkable properties, the devices made of
individual CNTs are quite challenging in fabrication. CNTs are usually used in the form of fibers, arrays, or films. In this work, we introduce a novel technique of rapid fabrication of both active and passive flexible electronic components. A tactile sensor, a pulsometer and an electrical circuit are fabricated for the demonstration of their applicability. We expect this new approach to simplify the production of functional carbon nanotube fibers and to enlarge their usage in diverse applications.

This work was supported by MIT Skoltech NGP Program (Skoltech-MIT joint project).

BM08.03.25
A Bandage-Type, Wearable and Luminescent Sensor for Monitoring Transcutaneous Oxygen Pressure Changjin Lim, Soyeon Lee and Jin-Woo Park; Yonsei University, Seoul, Korea (the Republic of).

We present a new concept for a wearable oxygen (O2) sensor for transcutaneous O2 pressure (tcpO2) monitoring by combining the technologies of luminescent gas sensing and wearable devices. O2 monitoring has been exhaustively studied given its central role in diagnosing various diseases. The ability to quantify the physiological distribution and real-time dynamics of O2 from subcellular to the macroscopic level is required to fully understand mechanisms associated with both normal physiological and pathological conditions. Despite its profound biological and clinical importance, few effective methods exist for noninvasively quantifying O2 in a physiological setting. The wearable sensor developed here consists of three components: a luminescent sensing film attached onto skin, an organic light-emitting diode (OLED) as a light source, and an organic photodiode (OPD) as a light detector. The green OLED was fabricated to excite the sensing film in accordance with absorption spectrum of oxygen sensitive material, 2,7,12,13,17,18-octaeethyl-2H,3H-porphyrin, platinum(II), (PtOEP) changing the ratio of PL intensity (sensitivity, L/I30) in relation to O2 concentration. After energy excitation of luminophores by absorption from OLED, the PL emission intensity decreases by energy transfer from PtOEP molecules to surrounding O2 molecules which is called quenching effect. P3HT:PCBM bulk heterojunction based OPD precisely detects the red PL intensity change from the O2 sensing film. All the components are solution-processable and integrated on a plane in a bandage-like configuration. To verify the performance, tcpO2 variations by pressure-induced occlusion were measured in the lower arm and a thumb by the wearable sensor, and the results were comparable to those measured by a commercial instrument. Due to its noninvasive and flexible features, the wearable bandage-like O2 sensor proposed in this study can monitor the tcpO2 in any part of the body, even when a person is exercising or working, which is currently beyond the restrictions of existing commercially available monitoring systems. Our wearable, bandage-like O2 sensor opens new possibilities for the continuous monitoring of not only patients during surgery and recuperation but also out-patients suffering from Raynaud disease, diabetic ulcers and similar ailments.

BM08.03.26
Electroactive Polymer-Electrolyte-Composite Artificial Muscles of Greatly Enhanced Strength Zachary A. Goodwin1, Michael Eikerling2, Hartmut Lowen3 and Alexei Kornyshev1; 1Imperial College London, Cambridge, United Kingdom; 2Chemistry, Simon Fraser University, Vancouver, British Columbia, Canada; 3Theoretical Physics, Heinrich Heine Universität Düsseldorf, Düsseldorf, Germany.

There is great interest in developing artificial muscles for soft robotics.1 Such electroactuators, composed of polymer-electrolyte films with bulky mobile cations, confined between two electrodes, curve in response to an applied voltage between the electrodes (forward actuation). On the other hand, upon bending an output voltage or current can be generated (reverse actuation). Both of which, forward and reverse actuation, involve the redistribution of the mobile cations and solvent. To further understand and develop these much-desired devices, we present a unified theory that describes both forward and reverse actuation with flat and porous electrodes.

Forward actuation with flat electrodes has a limited response from an applied voltage because stressful regions only develop in a minor part of the hydrated fibers with desired properties. To vary by parameters of the CNT fibers, we demonstrated the possibility to control the strength of the SWCNT fibers from 300 to 700 MPa and their resistance from 60 to 300 Ohm (for 1 cm long fiber). The method is also easily adaptive to different kinds of carbon nanotubes and allows rapid fabrication of both active and passive flexible electronic components. A tactile sensor, a pulsometer and an electrical circuit are fabricated for the demonstration of their applicability. We expect this new approach to simplify the production of functional carbon nanotube fibers and to enlarge their usage in diverse applications.

This work was supported by MIT Skoltech NGP Program (Skoltech-MIT joint project).

BM08.03.27
Printed Integration of High-Performance Intrinsically Stretchable TFTs with Soft Sensors for Mass Customization of Wearable Electronics Byeongmoon Lee, Jiseok Seo, Hyeon Cho, TaeHo Kim and Yongtaek Hong; Department of Electrical and Computer Engineering, Inter-University Semiconductor Research Center, Seoul National University, Seoul, Korea (the Republic of).

Soft electronics has become the driving force of innovation in the way that the electronic systems maintain their performance under harsh deformation and are conformably attached on arbitrary-shaped surfaces, thus realizing stretchable display, skin-patch devices, and implantable biomedical electronics. As core components in electronic systems, thin film transistors (TFTs) also need to be soft, in order to give the soft electronic system sophisticated functions without hindering its softness. For this reason, intrinsically stretchable TFTs have attracted great research attention in recent years. Several leading groups have realized this soft basis by exploiting 1-dimensional materials such as single-walled carbon nanotube (SWCNT) as semiconductors and electrodes.
Another novel idea has been reported to make polymer semiconductors stretchable through forming nanoconfined morphology. In spite of these remarkable achievements, there are still many challenges in integrating stretchable TFIs with active components such as silicon-based integrated circuits into wearable electronics. Most of the previous work has focused on fabricating polymer-free devices, and the challenge is to integrate stretchable electronics into wearable systems. In this work, we report a facile and low-cost fabrication strategy based on ink-jet-printing for high-performance intrinsically stretchable TFIs. The materials are carefully selected in order to achieve both high electrical performance and stretchability. We exploit high-K elastomeric dielectrics for gate insulators, SWCNT for active layers, and highly conductive silver nanowire (AgNW)-based stretchable conductors for gate/source/drain electrodes. The components including the gate/source/drain electrodes and the active layers are ink-jet-printed so that all layers of the device are fully customizable. The fabricated devices show mobility of $5-10 \text{cm}^2\text{V}^{-1}\text{s}^{-1}$, on/off ratio over $10^4$, low operation-voltage under $5\text{V}$, and stretchability over $50\%$, which imply the feasibility of our devices for applications in wearable integrated circuits. Furthermore, our ink-jet-printing-based fabrication strategy enables not only facile integration of the soft TFIs with printing-based soft sensors, but also mass customization of the integrated wearable systems. For proof of concept, we demonstrate a series of ink-jet-printed active matrix sensor arrays with various layouts. We believe that this work contributes to the effective integration of soft components into functional wearable systems. The detailed methods and results will be discussed later.

**Principles of Multi-Layer Encapsulant Design for Wearable and Implantable Systems**

Soumen Saha, Bhaskar Mitra and Madhusudan Singh; Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India.

Wearable and implantable electronic devices are enabling in a new generation customized healthcare real-time monitoring system [1]. Some of the most sophisticated systems involve silicon MOSFETs as the basis for active sensors as well as digital and analog circuits, in a thin, flexible form [2][3]. Protecting these transistors in a harsh fluidic environment is relatively difficult because the requirement of wearability demands biocompatible encapsulation with low flexural rigidity. The charged ions (such as Na+) from the biofluids are capable of diffusing rapidly through the thin encapsulation layer and destabilize the entire system. Moisture is another problem since the water molecules could either penetrate through or dissolve the encapsulation layer at a temperature-dependent rate. The optimization of the encapsulation layer is, therefore, a critical challenge for the development of wearable/implantable system design.

In this work, we describe the design principles of stacks of encapsulation layers as biofluid barrier for flexible electronic implants. The multi-layer encapsulation can be conformally coated on both sides of a flexible electronic platform with an array of NMOS transistors. The threshold voltage shift of the NMOS ($\Delta V_{th}$) transistor indicates the level of performance degradation. Accelerated soaking experiments show that (1) thermally grown SO$_3$Se$_2$N$_6$, bilayer block the passage of ions [4][5], (2) HIO$_4$ coated thermal SiO$_2$ slows down both moisture diffusion and dissolution of the encapsulation layer by orders of magnitude [6]. Systematic theoretical investigations reveal the details associated with encapsulant material property [7]. In this context, both numerical and analytical models describe the ion penetration as well as the moisture assisted dissolution process. Coupled with the device physics of MOSFET, our model predicts that $\Delta V_{th}$ follows accelerate growth over time due to the coupled effect of ion transport and encapsulant dissolution. The predictions are well validated by results of the accelerated soaking experiment. Our physics-based model serves as the basis for lifetime projection for MOSFET-based wearable/implantable electronics under different operating conditions in a harsh biological environment. Ion and moisture penetration through encapsulant is a generic problem, therefore our results are also relevant for encapsulation of electronic, mechanical, and chemical systems.

**Compositional Dependence of Electromechanical Response in Lead-Free Piezoelectric Thin Films for Wearable Electronics**

Raininder S. Deol, Soumen Saha, Bhaskar Mitra and Madhusudan Singh; Electrical Engineering, Indian Institute of Technology Delhi, New Delhi, India.

Wearable sensors and other electronic devices require reliable autonomous power generators that are compact and can scavange mechanical vibration energy sourced from various movements of the human body. While lead zirconium titanate (PZT) and its derivatives are usable in compact piezoelectric devices, the presence of lead limits their use due to health and environmental concerns. Thus, lead-free high-performance piezoelectric materials are uniquely needed for wearable sensor applications. Further, piezoelectric materials can be used to sense human movement through time variation of stress. The highest piezoelectric response in one such material, potassium sodium niobate (KNN), is expected at the morphotropic phase boundary (MPB) systems.

This work was partly supported by Institute for Information & communications Technology Promotion (IITP) grant funded by the Korea government (MSIP) (No.2017-0-00048, Development of Core Technologies for Tactile Input/Output Panels in Skintronics (Skin Electronics)) and the Center for Advanced Soft-Electronics grant funded by the Ministry of Science, ICT and Future Planning as Global Frontier Project (CASE-2015M3A6A5065309).

**Upconversion Nanoparticles/Graphene—Opening New Windows for Highly Sensitive Photodetection**

Monika Kataria1,2, Wei-Hua Wang1,2 and Rajinder S. Deol; 1Department of Physics, National Taiwan University, Taipei, Taiwan; 2Department of Physics, National Central University, Chung-Li, Taiwan; 3Department of Physics, National Taiwan University, Taipei, Taiwan.

References:

With recent technological advancements engulfing the world and making it a better place to live, wearable transparent electronics definitely have a crucial role to play. Plentiful studies on upconversion mechanism observed in lanthanide doped core-shell upconversion nanoparticles (UCNPs) have successfully marked their presence in the ongoing research fields of displays, solar cells, etc. The lanthanides doped core-shell UCNPs are capable of sequentially absorbing two or more photons of higher wavelength leading to an emission of photons of lower wavelengths. Graphene is a 2D material which is famous for its high carrier mobility, short carrier life time, flexibility and its optical transparency. Since graphene has a low density of states around the Dirac point therefore its conductance is influenced by external perturbations from allied materials. Therefore placing core-shell UCNPs in close vicinity of graphene opens a new window for highly sensitive photodetector. In this work we demonstrate a very novel approach towards lanthanide doped core-shell UCNPs and graphene hybrid rippled structure photodetector. The 4th electronic configuration of lanthanides contributes for a multi-energy sublevels which eventually results in longer excited state lifetime for photogenerated charge carriers due to the presence of metastable states when subjected to laser illumination. This unlocks a new regime for ultrahigh sensitivity in lanthanide doped core-shell UCNPs (NaYF4:Yb:Er:Nd@NaYF4:Nd) and graphene hybrid rippled structure photodetector. The device fabrication process includes the usage of core-shell structured UCNPs and monolayer graphene on pre-strained poly(dimethylsiloxane) (PDMS) substrate which was later released to get a core-shell UCNPs/rippled graphene structure hybrid wearable photodetector. Under 808nm laser illumination, core-shell UCNPs/rippled graphene hybrid structure exhibits the highest responsivity of the order of ~31 AW⁻¹ among core-shell UCNPs based hybrid photodetectors based on the upconversion transitions of the several energy sublevels of core-shell UCNPs. Also, the rippled graphene structure helps to increase the optical absorption of photons for core-shell UCNPs. The graphene ripples accelerate light trapping due to multiple scattering, which adds on to increase the responsivity for the hybrid rippled structure photodetector. Also, we have demonstrated that the core-shell UCNPs and graphene hybrid rippled structure photodetector works effectively under 100 % longitudinal strain. The rippled graphene and UCNPs hybrid photodetector on PDMS substrate exhibits superb wearability and durability. This innovative design, nominal low cost fabrication, large-area, and its ability to function at lower powers of illumination makes this highly flexible, stretchable, transparent hybrid rippled structure photodetector most suitable for our day to day optoelectronics applications for.

Starch-Cellulose-Based Triboelectric Nanogenerator Obtained by a Low-Cost Cleanroom-Free Processing Method
Robert Ccorahua, Alexandra Cordero, Juan Huaroto, Maria Quintana and Emir Vela; Universidad Peruana Cayetano Heredia, Lima, Peru.

Triboelectric nanogenerators (TENGs) have become one of the most sustainable ways to scavenge blue energy from mechanical movements. However, fabrication of TENGs often requires use of expensive instruments. Some attempts to reduce costs, using biomaterials of cellulose and chitosan, were reported. Nevertheless, to date only few low-cost bio-based materials have been reported to be useful as TENGs but they still keep employing costly nanofabrication techniques. Herein, we report on a new bio-based starch-cellulose TENG fabricated without using complex equipment is reported for the first time. Chopped samples of peruvian potato (Solanum tuberosum: yellow variety) were homogenized in a blender, sieved and left for decantation. After 4 h, supernatant was discarded and the precipitate was degreased by resuspension in a solution of 1:1 metanol/water. The obtained starch was dried at 60°C for 24 h. Starch films were prepared by casting. Dried starch was diluted in distilled water to form a 5% (w/w) starch solution. This solution was partially hydrolyzed in dilute hydrochloric acid (0.1 N) adjusting pH to 2.0. Glycerol was added at ratio of 2:5 (glycerol:starch (dry basis)). The starch solution was homogenized by stirring for 15 min at 95°C. Then, the solution was neutralized in dilute sodium hydroxide (0.1 N) adjusting the pH to 10 to stop hydrolysis. Finally, the starch solution (7% (w/w)) was poured on Petri dishes containing substrates of sand paper (grit #400) and placed in an oven at 40°C. After 48 h of drying, films of about 50 to 200 μm in thickness were obtained. For the complementary dielectric film, a microfiltration membrane of 47 μm of pore size was used. The surfaces open to the air (upper part) of the films were covered with a thin layer of commercial aluminum foil by using double sided adhesive tape. The resulted TENG was electrically characterized by using a linear motor as a vibrating external source at forces up to 6 N. Surprisingly, despite both dielectric films inside the TENG were made of biomaterials, the electrical output was considerably higher than other biomaterial-based TENGs reported to date. Our results showed that, depending on the film thickness, electric outputs varied from 60 mV to 300 mV per 4 cm² area. The thicker the film, the lower the electrical outputs, and vice versa. Moreover, FTIR-ATR analysis also showed that no chemical modification was made on the surface of starch after casting. Therefore, starch remained unmodified at the time of characterization, being this performance proper of a pristine starch. In addition, though organic starch isolation, fabrication of the proposed TENG was entirely handmade, thus avoiding use of complex equipment of nano- and micro-fabrication which resulted in the development of an eco-friendly TENG with very good performance according to the state-of-the-art.

BM08.03.32

Development of a Sheet-Like pH Imaging Sensor with Polyelectrolyte Multilayered Thin Films
Shinji Takeoka, Daichi Someya, Satoshi Araiz and Toshihito Fujie; Waseda University, Tokyo, Japan.

We developed flexible and physically adhesive polymer thin films (nanosheets) for biomedical or bioelectronic applications. Recently, we reported a temperature sensor nanosheet responding to the external NaCl stress. The pH sensor nanosheet will be useful for biology or medicine if it is combined with the apoplastic ion milieu of plants. Here we report a new pH sensor nanosheet to be used for biosensing applications. We developed flexible and physically adhesive polymer thin films (nanosheets) for biomedical or bioelectronic applications. Recently, we reported a temperature sensor nanosheet of peruvian potato (Solanum tuberosum: yellow variety) was homogenized in a blender, sieved and left for decantation. patient’s everyday life remains an open challenge. We have successfully screen-printed piezoelectric P(VDF-TrFE) sensors with versatile geometries on 25 µm thin, stretchable substrates suitable for a skin conformal attachment. The stretchable piezoelectric transducer allows for a versatile sensing, ranging from whole body motion down to tiny pressure variations originating from the human blood flow or heartbeat. Additionally, vibro-acoustic sensing allows for the detection of various physiological signals such as speech, snoring, or respiratory auscultation. Rigid islands for the incorporation and connection of read-out electronics, as well as electrical shielding for signal improvement were all fabricated by means of screen-printing. We thus present a printed, entirely stretchable, low-cost sensor patch for various medical applications.

**Triboelectric Nanogenerators for Powering Portable, Wearable and Body-Implantable Devices**

Sung-Woo Kim; Department of Advanced Material Science and Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of).

Energy harvesting systems based on piezoelectric and triboelectric nanomaterials are in great demand, as they can provide routes for the development of self-powered devices which are highly flexible, stretchable, mechanically durable, and can be used in a wide range of applications. Our recent research interest mainly focuses on the fabrication of piezoelectric and triboelectric power generators based on various kinds of nanomaterials. Flexible generators exhibit good performances and are easy to integrate which make it the perfect candidate for many applications, and therefore crucial to develop. In this presentation, I firstly introduce the fundamentals and possible device applications of triboelectric power generators, including their basic operation modes. Then the different improvement parameters will be discussed. As main topics, I will present a couple of recent achievements transparent flexible graphene triboelectric generators, textile-based wearable triboelectric power generators, etc. The recent research and design efforts for enhancing power generation performance of generators to realize self powering of portable and wearable sensors and electronics will also be discussed in this talk. In addition, I will address a high performance inertia driven triboelectric nanogenerator based on body motion and gravity. The packaged device has successfully harvested around 144 mW during day time in preclinical test, and real-time output voltage data is monitored via Bluetooth low energy information transmit system.\[1\]

**Soft, Stretchable, Conductive Metal-Polymer Composites as Nonlinear Springs for Broadband Vibration Energy Harvesting**

Zining Yang and Seek Kim; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Energy harvesting from ambient vibrations is widely considered as a solution for the most prominent obstacle towards the commercialization of internet of things (IoT), which is the expenses and human efforts invested in battery replacement for millions of wireless sensor nodes. Unfortunately, ambient vibrations are generally distributed over a low-frequency domain with wide bandwidth, which renders most microscale vibration energy harvesters unpractical for real-world applications. Here, a vibration energy harvester with both low operation frequency and a broadband response is achieved by using a resonator with soft and nonlinear springs. A soft, deformable, and electrically conductive metal-polymer composite is employed as the spring material, not only to obtain a low spring constant using a compact clamped-clamped beam design but also to trigger the broadband behavior by harnessing the geometric nonlinearity of the doubly clamped beam at large deflection. A highly miniaturized (footprint < 1 cm2) capacitive vibration energy harvester with low operation frequency (resonant frequency 73Hz), broad bandwidth (28% of the resonant frequency), and high power density (171 μW/cm3 at resonant frequency) is realized using the soft spring resonator. The energy harvesting device is also used as a wearable, self-powered acceleration sensor with a voltage sensitivity of around 0.78 V/g.

9:15 AM BM08.04.05

**Textile Based Triboelectric Nanogenerator with Fully Stretchable Knitted Fabrics**

Sung Soo Kwak, Jihye Kim and Sang-Woo Kim; Sungkyunkwan Univ, Suwon-si, Korea (the Republic of).

Harvesting human-motion energy for power-integrated wearable electronics could be a promising way to extend the battery-operation time of small low-power-consumption electronics such as various sensors. For this purpose, a fully stretchable triboelectric nanogenerator (S-TENG) that has been fabricated with knitted fabrics and has been integrated with the directly available materials and techniques of the textile industry is introduced. This device has been adapted to cloth movement and can generate electricity under compression and stretching. We investigated plain-, double-, and rib-fabric structures and analyzed their potentials for textile-based energy harvesting. The superior stretchable property of the rib-knitted fabric contributed to a dramatic enhancement of the triboelectric power-generation performance owing to the increased contact surface. The present study shows that, under stretching motions of up to 30 %, the S-TENG generates a maximum voltage and a current of 23.50 V and 1.05 µA, respectively, depending on the fabric structures. Under compressions at 3.3 Hz, the S-TENG generated a constant average root-mean square power of up to 60 µW. The results of this work show the feasibility of a cloth-integrated and industrial-ready TENG for the harvest of energy from human biomechanical movements in cloth and garments.

9:30 AM BM08.04.06

**Super-Stretchable and Mechanically-Durable Triboelectric Nanogenerator for Wearable Energy Harvesting and Self-Powered Tactile Sensing**

Ying-Chih Lai and Zhong Lin Wang; 1Materials Science and Engineering, National Chung Hsing University, Taichung City, Taiwan; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

In this presentation, we demonstrate a mechanically durable and resilient triboelectric nanogenerator (MDTENG) with unprecedented features of ultrahigh omnidirectional stretchability and capability to produce energy in different extreme mechanical deformations. The innovative nanogenerator can be adaptive on various desired non-planar and irregular objects, including human bodies, spheres, and tubes, etc., and act as power sources for other electronic components. The MDTENG was realized through composed of intrinsic stretchable and durable components that enable the device to generate electricity from tapping or skin touching despite under various deformations. Based on the durable materials, the triboelectric nanogenerator is omnidirectionally stretchable over 300% strain. Even experiencing severe tearing damages, the device can still function as an effective power source for the load. Moreover, the energy produced has been demonstrated to be able to sustainably power a commercial smart watch. Based on the stretchable and durable nanogenerators, we further demonstrated the first fully autonomous and self-powered adaptive e-skin system that can map touch by responding to visual light-emitting diode (LED) signals without the need of external power supply. The work presented here are timely and beneficial for the development of wearable, deformable electronics and self-powered electronic and sensing systems.

**Triboelectric Nanogenerator as a Power Source and Self-Powered Sensor**

Zhong Lin Wang; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States.
United States; 2Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

Triboelectrification is an effect that is known to each and every one probably ever since the ancient Greek time, but it is usually taken as a negative effect and is avoided in many technologies. We have recently invented a triboelectric nanogenerator (TENG) that is used to convert mechanical energy into electricity by a conjunction of triboelectrification and electrostatic induction. As for this power generation unit, in the inner circuit, a potential is created by the triboelectric effect due to the charge transfer between two thin organic/inorganic films that exhibit opposite tribo-polarity; in the outer circuit, electrons are driven to flow between two electrodes attached on the back sides of the films in order to balance the potential. Ever since the first report of the TENG in January 2012, the output power density of TENG has been improved for five orders of magnitude within 12 months. The area power density reaches 500 W/m², volume density reaches 490 kW/m³, and a conversion efficiency of ~50% has been demonstrated. The TENG can be applied to harvest all kind of mechanical energy that is available but wasted in our daily life, such as human motion, walking, vibration, mechanical triggering, rotating tire, wind, flowing water and more. Alternatively, TENG can also be used as a self-powered sensor for actively detecting the static and dynamic processes arising from mechanical agitation using the voltage and current output signals of the TENG, respectively, with potential applications for touch pad and smart skin technologies. This presentation will focus on TENG for wearable electronics.

10:45 AM BM08.04.08
Body Implantable Triboelectric Nanogenerator Driven by Inertia for Powering Implantable Medical Device Hanjun Ryu and Sang-Woo Kim; Sungkyunkwan University, Suwon (the Republic of Korea).

Body-implantable bioelectronics devices that monitor and modulate abnormalities in patients are highly sophisticated technologies, and long-term operation of such in vivo devices has faced a major technological challenge. Currently, medical implant devices require high-risk repeat surgery to replace used devices; permanent operation of body-implantable bioelectronics devices will reduce the patient’s risk of surgery, including device removal and replacement. Notwithstanding that a variety of in vivo energy harvesters using near-field or mid-field electromagnetics, thermal gradient, and mechanical movements of organ have been proposed, in vivo power generators are still limited, which are lack of power to charge storage device as energy sources for bioelectronics devices. Especially, the metal package of in vivo devices interferes with energy transfer, resulting in low energy conversion. In addition, in vivo energy transfer systems require external energy transmitters that can be inconvenient for the user. Thus, while the only possible and promised energy source for implantable medical devices is batteries, batteries with limited dimensions, capacity, or stability have a finite lifespan.

We demonstrate a high-performance inertia-driven triboelectric nanogenerator (I-TENG) based on body motion and gravity. We also successfully operated the in vivo I-TENG in a preclinical test and collected real-time output-voltage data via a Bluetooth low-energy (BLE) information-transmitting system. A synchronous shock structure, which achieves current waveform superposition, can step the peak current value up without additional components, so that, the I-TENG generated 7.3 mWpeak and 90 μWRMS in laboratory experiment, and harvested around 144 mW during the daytime in the preclinical testing in a synchronous stack structure, which achieves current waveform superposition, can step the peak current value up without additional components, so that, the source for implantable medical devices is batteries, batteries with limited dimensions, capacity, or stability have a finite lifespan.

11:00 AM BM08.04.09
Adding a Stretchable Deep-Trap Interlayer for High-Performance Stretchable Triboelectric Nanogenerators Dong Wook Kim, Ju Hyun Lee, Insang You, Jin Kon Kim and Unyong Jeong; Pohang University of Science and Technology, Pohang, Korea (the Republic of). The main approach to enhancing the electrical output performance of triboelectric nanogenerators (TENGs) has been focused to increase of triboelectric charge generation. However, there have been few studies on achieving effective electrostatic induction and conserving the triboelectric charges. This study reports that an interlayer containing deep charge traps of large trap density can conserve the surface charges for long period of time and increase the surface potential that can be obtained. This study suggests polydimethylsiloxane (PDMS) added between a charge generation layer and an electrode as an effective material candidate for the interlayer. The PDMS interlayer greatly enhanced the output power density of TENGs (20.8 W/m² by gentle tapping), which is 173-fold increase compared to TENGs without the interlayer. Surprisingly, the PDMS interlayer resulted in triboelectric performance even between identical surfaces, which is owing to the enhanced charge conservation by the interlayer. This study demonstrates a high-performance stretchable single-electrode TENG (S-TENG) which shows stable high performance at 50% uniaxial strain during repeated stretch cycles. The results in this study provide insight to material design for achieving high-performance stretchable self-powered electronic systems.

11:15 AM BM08.04.10
Increasing Surface Charge Density by Intrinsic Charge Layer Inclusion for High-Performance Triboelectric Nanogenerator Devices Aravind Ravichandran and Marc Ramuz; EMSE-CMP, Gurdanne, France.

With the rapid development of wearable electronics and sensor networks, batteries cannot meet the sustainable energy requirement due to their limited lifetime, size and degradation. With miniaturization leading to high-power and robustness, triboelectric nanogenerators(TENGs) have been conceived as a promising technology by harvesting mechanical energy to power small electronics and wearables. The main issues associated with TENGs are their very low output power leading to low output charge density and high impedance matching.

In this work, a state of the art multilayer flexible structure is devised which not only increases the charge density but also provides a high average(RMS) power output. Thin-film organic flexible materials are deposited to trap the charges from the triboelectrification process, allowing the acceptance of more charges from an electrode and thereby increasing the power output. Material work function provides better understanding towards charge transfer process.

A proof of concept wearable device is conceptualized for use in a highly efficient self-powered sensor network system, converting ambient mechanical energy to electricity with a 1.2kV peak amplitude and a charge density of 1000 μC/m². This device structure makes the TENGs attractive to charging applications for wearables and large-scale harvesting without massive volume. By this technique, we have overcome numerous friction-based operation challenges including lack of uniform contact, material loss through wear, high sensitivity to humidity, and output power storage.

By considering these merits of simple fabrication, outstanding performance, robust characteristic and low-cost technology, we believe that TENGs can
open up great opportunities not only for powering small electronics but can contribute to large-scale energy harvesting through engineering design being complementary to existing energy sources.

SESSION BM08.05: Circuits, Integration and Communications

Session Chairs: Seunghyun Baik and Unyong Jeong
Tuesday Afternoon, November 27, 2018
Sheraton, 2nd Floor, Grand Ballroom

1:30 PM *BM08.05.01
Thermoplastic Elastomer-Based Stretchable Devices Unyong Jeong; Pohang University of Science and Technology, Pohang, Korea (the Republic of)

The Folding and stretching will be the key characteristics in the next-generation electronic devices. The stretchable electronics have motivated scientists to develop deformable materials for use in electrodes, semiconductors, bio-interfaces, and sensors. To realize fully stretchable electronic devices, each component of the device must maintain its performance up to a critical strain. This talk will present recent developments of stretchable polymeric conductors and semiconductors, and stretchable devices that are based on thermoplastic elastomers. Special focuses will be put on the thermoplastic block copolymer composites for their uses as substrates, electrodes, interfacial adhesives, and circuits. This talk presents a generalized platform that can be used for a variety of stretchable devices and several stretchable devices will be demonstrated including real-time a long-term use heart sensor, haptic device, display, energy harvesting, and stretchable transistors.

2:00 PM BM08.05.02
High-Performance Flexible Carbon Nanotube Complementary Electronics for Integrated Sensor Systems Li Xiang, Heng Zhang, Lian-Mao Peng and Youfan Hu; Peking University, Beijing, China.

The long-time vacuum of high-performance complementary metal-oxide-semiconductor (CMOS) technology on plastics is a non-negligible obstacle to the applications of flexible electronics with advanced functions, such as continuous health monitoring with in situ signal processing and wireless communication capabilities, in which high speed, low power consumption, and complex functionality are desired for integrated circuits (ICs). Here, we report the implementation of carbon nanotube (CNT)-based high-performance CMOS technology and its application for signal processing in an integrated sensor system for human body monitoring on ultrathin plastic foil with a thickness of 2.5 μm. The performances of both the p- and n-type CNT field-effect transistors (FETs) are excellent and symmetric on plastic foil with a low operation voltage of 2 V: width-normalized transconductances (gm/W) as high as 4.69 μS/μm and 5.45 μS/μm, width-normalized on-state currents reaching 5.85 μA/μm and 6.05 μA/μm, and mobilities up to 80.2 cm²V⁻¹s⁻¹ and 97.1 cm²V⁻¹s⁻¹, respectively, together with a current on/off ratio of approximately 10⁵. The devices were mechanically robust, withstanding a curvature radius down to 124 μm. Utilizing these transistors, various high-performance CMOS digital ICs with rail-to-rail output and a ring oscillator on plastic surface with an oscillation frequency of 5 MHz were demonstrated. Furthermore, an ultrathin skin-mounted humidity sensor system with in situ frequency modulation signal processing capability was realized to monitor human body sweating.

2:15 PM BM08.05.03
Super-Elastic Electronic and Photonic Fiber Devices via Thermal Drawing Fabien Sorin1, Yunpeng Qu1, Dang Tung Nguyen1, Alexis Page1, Wei Yan1, Tapajyoti Dasgupta1, Rene M. Rossi2 and Nicola Bartolomei1; 1Ecole Polytechnique Federale de Lausanne, Switzerland, Lausanne, Switzerland, 2Empa-Swiss Federal Laboratories for Materials Science and Technology, Saint-Gallen, Switzerland.

Stretchable optical and electronic fibers constitute increasingly important building blocks for a myriad of emerging applications, such as in robotics or medical implants. They are particularly suitable for wearables and smart textiles as seamlessly integrated devices that can bring high added values in monitoring and energy harvesting. Fibers can indeed integrate complex sensing and actuating functionalities such as light, heat, chemicals or pressure sensing, as well as piezoelectric actuation. They can also be used for energy harvesting from heat, light or mechanical movement. Yet, it remains challenging to fabricate efficient and advanced soft fiber-base devices that can undergo significant mechanical deformation in a simple and scalable way. Conventional fiber manufacturing methods, such as wet and dry spinning, or extrusion, are not well adapted to fabricate multi-material functional fibers. The preform-to-fiber thermal drawing technique on the other hand is an emerging powerful platform to fabricate multi-material fibers with complex architectures and functionalities. Thus far however, this fabrication approach has been restricted to rigid thermoplastic or glass fibers, preventing their use for mechanical sensing or actuation, and rendering difficult their use in wearable approaches or within textiles.

In this contribution we will show how we could revisit the selection criteria for cladding materials compatible with the thermal drawing process, and fabricate super-elastic fibers with advanced optical and electronic functionalities. We will demonstrate how, thanks to a deeper rheological characterization, we could identify thermoplastic elastomers that could be drawn from a solid preform at high viscosity. Subsequently, we will demonstrate that thermoplastics, liquid metals, and conductive polymer composites could be co-drawn with prescribed architectures within thermoplastic elastomer cladding. This allowed us to successfully fabricate stretchable optical and electronic fibers that are used as precise and robust pressure, strain or more generally deformation sensors, as well as soft and stretchable waveguides. This work was just published (Advanced Materials, 2018, 201707251) and highlighted in several news media (here is a video highlighting this recent breakthrough: https://actu.epfl.ch/news/an-elastic-fiber-set-to-revolutionize-smart-clothes/). As we will show via concrete examples, the ability to thermally draw soft multi-material fibers open new opportunities in robotics as well as fiber integrated devices and wearable technologies. These results open opportunities not only for exploring new academic research directions, but also in industrializing fiber-based flexible and stretchable devices for applications in sensing, health care, robotics, wearable devices and smart textiles.

2:30 PM BM08.05.04
Integrated Wearable Electronic System with Stretchability, Modularity and Self-Healability Jiheong Kang and Zhenan Bao; Stanford University, Stanford, California, United States.

Electronic skin devices capable of monitoring physiological signals and displaying feedback information through closed-loop communication between user and electronics are being considered for next-generation wearables and Internet-of-Things. Such devices need to be ultrathin to achieve seamless and conformal contact with our human body, to accommodate strains from repeated movement such as bending, and, more importantly, be comfortable to wear. However, ultrathin materials are inevitably more susceptible to our daily wear and tear processes. Recently, self-healing chemistry has driven important advances in deformable and reconfigurable electronics, particularly with self-healable electrodes as the key enabler. Although polymer substrates are self-healable due to its dynamic nature, the disrupted conducting network is unable to recover its stretchability after damage. In addition, commonly used self-
constructing p-n junctions in a single planar polymer film

Hong Wang; Frontier Institute of Science and Technology, Xi'an, China.

Constructing p-n junctions with a single planar polymer film will not only largely reduce the fabrication cost but also largely increase the integration density of organic electronic devices. However, it is very challenging to build Schottky barriers or p-n junctions in only one organic material because diffusion of the counter-ion dopants renders such structures very unstable. Here we show a rectifying curve obtained from a single planar polymer film with a high current density of 2-3 orders higher than conventional organic rectifiers. The structure was built by converting half of the film from p-type into n-type using a chemical reaction other than a doping method. This approach is expected to be extended into other polymers. We hope our work could open the door for designing flexible and portable organic devices with high integration level.

Constructing p-n junctions will not only largely reduce the fabrication cost but also largely increase the integration density of organic electronic devices. We hope our work could open the door for designing flexible and portable organic devices with high integration level.
Organic light-emitting devices have become a big topic in modern research and are often discussed as a future leading technology because of their light weight, flexibility and solution-processability. Here we refer to a further advantage of this technology, namely the possibility of producing biodegradable/biocompatible devices, which will open the pathway to a whole new field of future applications ranging from healthcare and medicine to smart packaging, disposable and wearable electronics.

In this work we present the fabrication of light-emitting electrochemical cells (LECs) comprising a non-halogenated bio-friendly solid-polymer electrolyte (poly-(ε-caprolactone-co-trimethylene carbonate) plus tetrabutylammonium bis-oxalato borate) on biodegradable cellulose di-acetate substrates by industrially relevant printing techniques. [1] By using a biocompatible electrode system consisting of PEDOT:PSS and ZnO we could produce functional devices comprising up to 99 vol% of biocompatible materials. The devices are semi-transparent and flexible even under operation. A maximum luminance of over 200 cd m\(^{-2}\) is achieved significant for display and lightning applications. The relatively short lifetime on the timescale of some minutes can be compensated by a fully-printed production process utilizing inkjet printing and blade coating, relevant for an industrially cost-efficient production of biodegradable-transparent electronics.

Binder Jetting Fabrication of Graphene Composite Structures for Printed 3D Electronic Devices

Xuechen Shen and Hani E. Naguib; University of Toronto, Toronto, Ontario, Canada.

Carbon-based nanomaterials see ubiquitous usage in research and industry as structural reinforcement in composites. Aside from excellent mechanical properties, carbon-based nanomaterials also demonstrate desirable electrical properties. Graphene has current carrying capacity several magnitudes higher than copper, able to achieve a current density on the scale of 10\(^9\) Acm\(^{-2}\), compared to the current density of copper at 10\(^6\) Acm\(^{-2}\). The improved current density of graphene over traditional conductive materials is significant for reducing the size of electronic devices to meet demands for higher device density. Furthermore, graphene has high affinity for compositing with polymer materials, enabling the fabrication of flexible and conductive composites. Such graphene-polymer composites are highly suitable for wearable electronics and soft robotics applications. Developing additive manufacturing techniques for 3D carbon nanomaterial structures could lead to manufacturing processes that facilitate rapid prototyping and promote more ubiquitous usage of nanomaterials in flexible sensors, actuators, and energy devices.

Graphene oxide (GO) is a popular material choice in 2D circuit printing due to its ease of processability. As GO, the material disperses well in water, and aligns readily when extruded from thin micronozzles, which enhances mechanical and electrical properties over bulk material. GO inks need to be reduced to graphene after printing to recover conductive properties.

In an ongoing study, we investigate the use of principles from 2D inkjet printing of GO in a binder jetting process to additively manufacture 3D electronics including actuators, sensors, energy storage, and integrated electronic systems. In this system, a GO/water dispersion is used as binder. The dispersion is jetted onto a polymer or metal powder to temporarily bind adjacent particles. Dropping binder to define 2D patterns over stacked layers of powder builds a...
3D object. Following post-processing procedures, the final product is a 3D printed composite material of graphene and the polymer or metal powder.

Our first study investigates Polyvinyl alcohol (PVA) as powder because it dissolves in water and forms a flexible plastic when dried. This property gives PVA powder high affinity with a graphene oxide/water binder, which is a well-studied material. The effect of adding Intrinsically Conductive Polymers (ICP) such as poly(pyrrole)s or polyanilines mixed with PVA is investigated to increase conductivity of the graphene composite without significant increase in cost.

Our second study investigates Copper as powder to fabricate PVA to increase conductivity. The resulting structure is significantly less flexible compared to a polymer composite, but it exhibits high electrical conductivity and density, forming a metal-graphene composite with exceptional electrical properties.

BM08.06.02
Integrated Energy Devices for Smart Textiles and Electronic Skins Xiong Pu; Beijing Institute of Nanoenergy and Nanosystems, Beijing, China.

Rapid advancements in wearable smart textiles and stretchable/multifunctional electronics impose the challenge on corresponding power devices that they should possess comparable flexibility, stretchability and functionalities. Here, we briefly summarize our recent progresses on wearable energy storage and harvesting devices, especially energy devices aiming to power smart textiles and artificial electronic skins. Both yarn or textile-based electrochemical energy storage devices and textile-based triboelectric nanogenerators (TENGs) have been developed; meantime, self-charging systems have been achieved by integrating them so that energies harvested from daily human motions can be stored simultaneously. It is even more challenging to provide power sources for electronic skins or soft electronics/robotics. We report a soft skin-like triboelectric nanogenerator that enables both biomechanical energy harvesting and tactile sensing by hybridizing elastomer and ionic hydrogel as the electrification layer and electrode, respectively. Ultra-high stretchability and transparency are achieved simultaneously for an energy-harvesting device. Our work provides new opportunities for soft power sources and potential applications in soft/wearable electronics.

BM08.06.03
Flexible Drug Delivery Device for Controlled Administration Sang Hyun Sung and Keon Jae Lee; KAIST, Daejeon, Korea (the Republic of).

We report flexible drug delivery microdevices (f-DDM) that are capable of controlled administration. The unique structure of the f-DDM consisting of freestanding gold membranes over the microreservoirs was enabled by reversing the fabrication order of the reservoir and sealing membrane. We optimized the design of the f-DDM by a finite element analysis (FEA) to prevent thermal damage during the laser transfer process. The required current density for reliable drug release operation was determined through an electrochemical analysis. The f-DDM was conformally implanted on the curved cerebral cortex, and localized drug delivery was confirmed by the diffusion of two different types of fluorescent neurotracers. Finally, in vivo therapeutic treatment using the f-DDM was demonstrated by the controlled release of an anti-epileptic drug into the mice.

BM08.06.04
Study of Long-Term Biocompatibility and Bio-Safety of Implantable Nanogenerators Jun Li, Lei Kang, Yanhao Yu, Yin Long, Justin Jeffery, Weibo Cai and Xudong Wang; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Since the first demonstration of ZnO nanowire-based implantable nanogenerator (i-NG) in 2010,[1] i-NGs have been consistently investigated and developed as self-sustainable implantable power sources and real-time healthcare monitoring sensors.[2,3] One of the most essential requirements for i-NG development is the long-term bio-compatibility and bio-safety considering years-long lifespan of most implantable medical devices (IMDs). Although earlier work on NG development has demonstrated extensively long working cycles of the piezoelectric functional components which is sufficient for in vivo operation of NG over 5-10 years in theory,[4, 5] long-term assessment of i-NG in biological systems has not been investigated. Meanwhile, considering the potential risks of immune reactions and infections over a long period of time, biological influence of i-NG also needs to be fully evaluated to justify their implantation feasibility. To fill the gap and address this critical issue, herein we present a systematic study of polydimethylsiloxane (PDMS) and PDMS/Parylene-C packaged polyvinylidene fluoride (PVDF) NGs implanted inside female ICR (Institute of Cancer Research) mice for up to six months.

The packaged PVDF NG had a stable in vitro output of 0.3 V when bended for 7200 cycles. After i-NGs were implanted between the skin and muscle of mice at lower right back, multiple advanced imaging techniques, including computed tomography (CT), ultrasound, and photoacoustic were used to characterize the embedded i-NGs in vivo. These techniques not only demonstrated that the i-NGs kept excellent adhesion to the adjacent muscle surface and exhibited intactness without damage but also observed the real-time motion of packaged i-NGs in response to muscle movements. While no signs of toxicity or incompatibility were found from the surrounding tissues based on complete pathological analyses, the whole body functions of mice kept normal evidenced by the blood and serum test. Moreover, all devices exhibited stable electrical output during the entire examine period and packages were also able to effectively insulate the i-NG in biological environment with negligible stray currents at a pA scale.

These series of in-vivo and in-vitro studies confirmed the high biological feasibility of using i-NG in vivo for biomechanical energy harvesting, and thereby further enables self-powered capability of practical IMDs bypassing the requirement of batteries. This research provided the first cornerstone for the future intelligent self-powered IMD system implantation.

Sensitivity Controllable, Printed Flexible Vibration Sensor Daisuke Yamamoto1, Takayuki Arie1, Seiji Akita1 and Kuni Takei1, 2; 1Osaka Prefecture University, Sakai, Japan; 2JST PRESTO, Chiyoda, Japan.

Trillion sensor concept requires many sensors on everywhere including humans and infrastructures to monitor a lot of information. One of the important
information is to monitor infrastructures such as strain and vibration. Vibration can be often monitored by inflexible acceleration sensor. Although few demonstrations about flexible acceleration sensor have been reported, the detail study of the printed flexible acceleration sensor has yet to be conducted. This study printed flexible acceleration sensors to control the sensitivity and demonstrates a vibration monitoring. By optimizing the device size and materials, we successfully monitored small vibrations. This technique can be monitored infrastructure vibration mapping by attaching the sensor sheet on the objects.

The flexible acceleration sensor consists of 4 beam structure with various beam length (L) and width (W). Strain sensors formed by Ag nanoparticles and carbon nanotube inks were printed on three beams, and Ag ground electrode was printed on another beam on PET film. The strain sensor is resistive-change sensor. First, real-time resistive change of a sensor was monitored by applying different acceleration directions. The results explain that resistance change is different depending on the acceleration directions, which are in good agreement with simulation results. To observe the size dependence, acceleration dependences of different beam length and width were characterized. The results show that the sensor with longer length and narrower width has lower threshold acceleration. Based on the results, threshold acceleration is proportional to $-L^{-2.7}$ and $-W$. To support these experimental results, finite element method simulation to extract the force for 1 mm displacement with three different beam lengths and widths was conducted. These suggest that the trends of length and width dependences were well matched between them. Based on the results, it can be concluded that mechanism of strain distribution for flexible acceleration sensor is explained by the standard spring mechanism. For mechanical flexibility of the acceleration sensor, the normalised sensitivity change as a function of bending radius is studied. At smaller bending radius, the sensitivity increases (decreases) when the bending direction is along (perpendicular to) the beam. This is most likely due to spring constant change depending on the bending directions. For reliability of long time use, this can be withstood for more than 500 times strong acceleration ($\approx 29\ m/s^2$). As the first proof-of-concept of vibration detection, the sensor sheet was attached on a smartphone and applied a vibration by calling the phone. The results clearly show the vibration detection, which is also good agreement with a commercially available acceleration sensor.

In summary, we studied the device size dependence of the printed flexible vibration sensor, and the results may be good advances for the future flexible electronics.

BM08.06.06 Enhanced Polarization of CaCu$_3$Ti$_4$O$_{12}$ Composite Layer Induced by Triboelectric Field for High-Performance Triboelectric Nanogenerator Ilhye Kim and Sang-Woo Kim; School of Advanced Materials Science and Engineering, Sungkyunkwan University, Suwon-Si, Korea (the Republic of).

Triboelectric nanogenerator (TENG), which can harvest energy from various resources in our living environment such as wind, wave, raindrops, and human motions, has gained great attention thanks to their relatively high output power and simple device structures by comparison to other energy harvesting devices. To date, numerous studies are being conducted to control and design the inside of the dielectric layer for sustainable and high triboelectric output power. For instance, performance enhancements of TENGs have been reported by aligning the dielectric polarization by applying an external electric field to the dielectric composite structure. However, this research also has the limitation that the external electric field is needed and the stability of polarization and output power over time is significantly reduced.

In this work, we utilized a high dielectric constant material, CaCu$_3$Ti$_4$O$_{12}$ (CCTO), to improve the triboelectric output power of the Butylated Melamine Formaldehyde (BMF) resin based composite layer by enhancing the polarization of dielectric layer induced by the triboelectric field, which always occurs during friction. We investigated the triboelectric output performance depends on the dielectric constant of the composite layer by using Al$_2$O$_3$, TiO$_2$, and CCTO particles. Evidently, the triboelectric output enhanced as the dielectric constant of dielectric layer increased; BMF-CCTO based TENG produced higher RMS output voltage (270 V) and current (26 mAm$^{-2}$) than those of pure BMF, BMF-Al$_2$O$_3$, and BMF-TiO$_2$ based TENG. And the Polarization-electric field (P-E) curves show that a larger polarization is formed in the BMF-CCTO composite layer than in the pure BMF layer, when the same strength electric field is applied. In addition, we found that the triboelectric output increases until the concentration of CCTO reached 1 wt%, and decreased with larger CCTO concentration above 1 wt% due to the charge concentration effect. The introduction of particles in the polymer matrix generally introduces defects in the system causing centers of charge concentration leading to the leakage current. Furthermore, there is no limit to the dielectric matrix material because the high dielectric constant particles, CCTO, always enhances the triboelectric output regardless of the direction of the triboelectric field that changes depending on whether the dielectric matrix material is positive or negative. Since CCTO increases the triboelectric output without an external electric field, BMF-CCTO composite based TENG has the output sustainability and stability, which is always maintained over time.

BM08.06.07 Nanomaterial-Based Wearable Electrochemical Sensor for Glucose and pH Monitoring in Human Sweat Seungyoon Oh and Jeong Sook Ha; Korea University, Seoul, Korea (the Republic of).

Along with the increased efforts in developing wearable healthcare devices for monitoring and managing physiological and metabolic information, electrochemical sensors have been also extensively investigated. Especially, electrochemical sweat sensor capable of measurements of the glucose level and pH in sweat can serve as disease diagnosis device because glucose level and pH in human sweat provide rich information about our health condition. To apply a sweat sensor to human skin, it should be stretchable, and patchable onto a non-planar skin surface so that it can keep the stable performance even under body movement.

In this work, we report on a facile fabrication of a nanomaterial-based wearable electrochemical sensor for detecting glucose and pH in sweat. Our conductive electrode is fabricated via filtration of gold nanosheet (AuNS), and the AuNS forms the percolation network on a stretchable polymer substrate to make intrinsically stretchable sensor without serpentine or island-bridge structure. Our working electrodes for glucose and pH detection are based on CoWO$_3$/CNT and polyaniline/CNT nanocomposite coated on CNT-AuNS electrode, respectively. Also, solid-state stretchable reference electrode is prepared via chlorination of silver nanowires. Encapsulation of the stretchable sensor with silbione as sticky polymer leads to a conformally skin-attachable sensor. Our wearable glucose and pH sensors were evaluated using real human sweat samples, and we confirmed that the sensors can measure glucose and pH in real human sweat with good linearity ($R^2 = 0.999$).

The work demonstrates the high potential for the application of our wearable electrochemical sensor to health management as a healthcare wearable device.

BM08.06.08 Control of Mouse Behavior via Flexible Vertical Light-Emitting Diodes on the Cortical Surface Jung Ho Shin, Seung Hyun Lee, Han Eol Lee and Keon Jae Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

The stimulation of targeted neural regions in the brain is one of the attractive technology in neuroscience for controlling physical movement, and long-range interactions. Recently biomedical implants now employ flexible light-emitting-diodes combined with optogenetic mouse models to generate the neural signals in high resolution. However, most conventional devices are fabricated to stimulate functional regions through blue-light driven channelrhodopsin. In this report, we introduce flexible AlGaInP vertical light-emitting diodes (VLEDs) for the stimulation of functional cortical regions in the mouse brain. Micro-sized VLED chips effectively captured the conductive particles in anisotropic conductive film (ACF) inducing red light emissions with high optical
power density, which are high enough to modulate motor neurons deep below layer III from the cortical surface. Stable operation of pulsed red light from f-VEGs produces strong body movements and electromyogram (EMG) signal changes. The expression of chrimson, red-shifted channelrhodopsin, enables red-light excitation of targeted functional cortical regions. This demonstration opens new opportunities for sophisticated cortical mapping, analyzing the interactions between different motor regions in the mouse brain.

**BM08.06.09**

**Thermally Invisible Optoelectronic Patch for the Skin**

Han Hee Jung and Kyung In Jang; DGIST (Daegu Gyeongbuk Institute of Science and Technology), Daegu, Korea (the Republic of).

Nowadays, as wearable sensor technologies have surpassed the limits of technologies such as electronics, healthcare system and medical devices, which have been in the past, the interest of necessity measuring the physiological signal actively and accurately is critical for prophylaxis and prediagnosis. There are many devices that can easily check the conditions of the body, and pulse oximetry is the most commonly used in daily life and clinics for monitoring the vital signal. By virtue of pulse oximetry, it is convenient to check and readily predict health condition by observing cardiac and cerebral activities by monitoring heartrate and dynamics of blood flow. Although the applications of modern optoelectronic devices have been extended and provided practical tools for seamless real-time monitoring of blood flow dynamics, there are still prominent challenges in thermal management for optoelectronic devices due to undesired thermal energy originated from light source. The optoelectronic device exhibits very high surface temperature compared to that of neighboring biological epidemris layer, which resulting skin integrity issues and deterioration of the light-emitting diode functionality. In this study, we propose heterogeneous integration of the light-emitting diode, photodetector and thin metallic heatsink element embedded in the optoelectronic module which can provide an attractive architecture for sustainable in-situ spatiotemporal measurement of blood flow dynamics with excellent thermal management. Experimental and computational analysis clearly explain that the proposed optoelectronic device with heatsink element has excellent heat dissipation and long-term usability with thermally safe operating condition to the skin in virtue of high thermal conductivity and thin film geometrical design of the embedded heatsink. The biomedical demonstration envisions that the proposed optoelectronic device with metallic heatsink is an ideal blood flow monitoring system, which is mechanically and thermally compliant to the skin and offer opportunities for long-term clinical applications, such as sleep study for insomnia patients.

**Structural Design and Optimization of Wearable Thermoelectric Generator System**

Jeong Hun Kim¹, Junsoo Kim², Jong-Pil Im¹, Jaewoo Lee¹, Solye Im¹ and Seungeon Moon¹; ¹Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); ²Harvard University, Boston, Massachusetts, United States.

A thermoelectric generator (TEG) is promising energy harvesting device that can convert heat generated from power plant, furnace and combustion engine to electric energy. A TEG can use various heat sources not affected by weather, interests are growing by its stable energy generation property. In this paper, we not only have measured heat resistance of human body also optimized the structure of the thermoelectric element (TE) and TEG. From this result, we fabricated wearable TEG system and show the application using electrical energy converted from body heat. As a TE for fabrication of TEG, we used BiTe-based material which is most widely used for TEG system. The surface area and height were fixed as 1 mm² and 3 mm respectively from our previous research and the module size was 22 mm x 36 mm. Then the numerical simulation about the temperature difference of hot and cold side, open circuit voltage (OCV) and output power of the module have been conducted as the number of TE pairs are increased. For the TEG module fabrication, we assembled 31 pair of TE on the PCB substrate using metal jig. Because the general PCB substrates for fabrication of TEG are rigid, though metal PCB is facile material to make high performance TEG, but it cannot suitable for the wearable energy harvesting system. To solve this problem, we adopted two kinds of flexible PCBs which are made from polyimide and epoxy/silica composite. The polyimide PCB (PI-PCB) is very promising platform because of its flexibility, thin structure and thermal resistance. But in the TEG system, the temperature difference between hot and cold side that concludes the output power decreases from its low thermal conductivity, therefore, other materials have to be considered. The composite PCB consists of epoxy/silica shows higher thermal conductivity, and we could make up for the weakness of the PI-PCB. As over time, the temperature difference would decrease if heat dissipation at the cold side is not sufficient. Though metal fin is most widely used structure for the heat sink, but it is not suitable for wearable system because of the rigidity and bulky structure. We proposed novel bio-inspired heat sink system composed of polymer micro structures. Our heat sink is not only flexible also able to change structures by temperature modulation by the characteristic of Poly(N-isopropylacrylamide) (PNIPAm) that can shrink under 32 °C and expands over 32 °C. Likewise sweat gland of human body, this bio-inspired heat sink can prevent evaporation of water in low temperature via structural expansion, but in the high temperature, heat sink releases the heat of the TEG through water evaporation opened region by shrinkage of the active polymer. The TEG module using our heat sink show two times higher output power than using the metal fin. The optimized TEG module components were integrated for wearable energy harvesting system and we could demonstrate turning on a light emitting diode via body heat.

**Functionalised Nanoporous Gold as a New Biosensor for Quantitative Detection in Ultra-Low Concentrations**

Paola Rizzi; Federico Scaglione, Eugenio Alladio, Francesco Turci, Cristina Giovanni, Silvia Bordiga and Livio Battezzati; Università di Torino, Torino, Italy.

The development of a new generation of ultra-sensitive sensors for analytical and bio-diagnostic devices requires a strong signal in front of a very small quantities of material. Taking advantage of peculiar plasmonic properties of nanoporous gold (NPG), a promising sensor for selective detection of Human Serum Albumin (HSA), as a proof of concept, has been prepared by a proper functionalization of the substrate. NPG has been synthesized by chemical de-alloying an amorphous precursor, Au₅₅Cu₄₅Ag₉. Pd₁₀S₂₅, starting from melt spun ribbons. A fully de-alloyed ribbon with ligaments of around 60 nm was obtained after 4 h of de-alloying in proper conditions of temperature and concentration of the electrolyte. This material is self-standing and mechanical resistant and then well-versed for applications. At this stage, NPG is SERS active toward probe molecules (i.e. pyridine, bi-pyridine, rhodamine) even in very low concentration, but not specific for other complex molecule of interest such as HSA. Ad hoc functionalization is then required for this purpose. Bare NPG has been bound with a selective ligand i.e. a target-directed antibody (anti-Human Serum Albumin, Ab anti-HSA) covalently grafted onto the gold surface and then tested by Surface Enhanced Raman Spectroscopy (SERS) measurements as a function of HSA concentration. Data analyses in junction with a chemometric approach have successfully demonstrated that the NPG sensor is able to perform HSA quantitative detection in ultra-low concentrations.

**BM08.06.13**

**Non-Invasive Monitoring of Ketosis for Improved Therapy of Epilepsy with Breath Acetone Sensors**

Julia F. Kompalla, Andreas T. Günther and Sofinis E. Pratsinis; ETH Zurich, Zurich, Switzerland.

By implementing healthcare sensors into portable or even wearable devices, continuous monitoring of the patient’s physiological state is possible. Chemo-
resistive gas sensors based on semi-conductive metal-oxides could give such continuous feedback by analyzing exhaled breath. This could enable routine and personalized dietary monitoring needed for the treatment of drug-resistant epilepsy affecting 15 million people worldwide. More specifically, breath acetone detection could be a non-invasive and cost-effective way to monitor ketogenic diets (KD; high fat at low carbohydrate and protein intake). Here, a portable breath acetone sensor based on flame-made Si-doped WO3 was used for non-invasive ketosis monitoring of 20 volunteers following a 36-hour KD. This sensor could accurately follow the ketosis level over a wide acetone concentration range (0.4 – 30 ppm) relevant for this application. Furthermore, the individual metabolic responses of the volunteers could be easily distinguished by this sensor as validated by parallel capillary blood BOHB. As a result, this portable non-invasive sensor embodies a reliable device for non-invasive monitoring of enhanced ketosis during KDs enabling routine and personalized dietary monitoring and epilepsy treatment. With the potential for compact size and low power consumption of this sensor fabrication technology, this sensor could be readily incorporated into integrated health monitors.

BM08.06.14
Metabolic Monitoring from Breath with Portable Acetone Sensors Stéphanie Schon, Andreas T. Güntner and Sotiris E. Pratsinis; ETH Zurich, Zurich, Switzerland.

Wearable health devices enable cost-effective, user-friendly and continuous personalized healthcare at any time and place. For this, biological fluids such as sweat or breath are attractive as they are readily accessible providing a non-invasive insight into human metabolism. For instance, tracing exhaled acetone, a volatile by-product of ketosis, could enable close monitoring of the interplay between fat and glucose metabolism thus enabling individual customization of physical activity and dietary regimes towards optimal performance and fat loss. Chemo-resistive gas sensors are appealing for breath acetone sensing as they feature high miniaturization potential, low power consumption. When based on Si-doped WO3 nanoparticles, acetone can be detected down to 20 ppb with high selectivity to interfering analytes. Such sensors have been applied already successfully on 20 volunteers to measure their individual fat burn rates during and post exercise. As current technologies to monitor the interplay between fat and glucose metabolism are either invasive (e.g. blood assay) and/or too expensive for widespread application (e.g. indirect calorimetry) such sensors might be ideal for personalized metabolic monitoring. Here, a portable breath acetone sensor consisting flame-made Si-doped WO3 films is presented that can follow individual changes between fat and glucose metabolism in real-time. We applied this sensor on 11 healthy volunteers in a test course first stimulating ketogenesis by exercise (i.e. 3 × 30 min of cycling) and thereafter rapidly inhibiting fat metabolism by an oral glucose tolerance test (i.e. intake of 75 g glucose). The sensor clearly followed breath acetone concentrations during the test course in good agreement to bench-top mass spectrometry. Thereby, the sensor correctly identifying a shift from fat to glucose metabolism for all volunteers even recognizing individual dynamics between the subjects, as validated by parallel capillary blood β-hydroxybutyrate (BOHB) and glucose measurements. In the long run, this sensor is highly promising for integration into wearable devices to guide daily diet and exercise routines towards optimal performance or fat loss.

BM08.06.15
A Bio-Inspired Mineral Hydrogel as a Mechanically Adaptable Ionic Skin for Highly Sensitive Pressure Sensing Zhuyue Lei1 and Peiyi Wu1,2. 1Department of Macromolecular Science, Fudan University, Shanghai, China; 2Chemistry, Chemical Engineering and Biotechnology, Donghua University, Shanghai, China.

Human skin is soft, robust, self-healable and able to sense subtle environmental differences like a gentle breeze, which has stimulated numerous studies of artificial skin-like materials, especially electronic skins or soft sensor devices. However, profound challenges remain in terms of imitating natural skins because of their unique combination of mechanical and sensory properties. Currently, there are three major approaches to stretchable electronic skins: (1) buckling flexible electronic devices, (2) patterning discontinuous stiff components, and (3) developing intrinsically stretchable materials. While for the purpose of biomimetic and medical applications, materials that are flexible and/or stretchable are not sufficient. A soft artificial skin needs to be mechanically compliant and durable for practical applications, i.e., plastically deformable to fully match curved and dynamic surfaces and autonomously self-healable, mechanically compliant to curved and dynamic surfaces, and exhibit relatively high sensitivity. The hydrogel-based ionic skin can sense subtle pressure changes, such as a gentle finger touch, human motion or even small water droplets. This work may not only show the great potential of physically-crosslinked hydrogels as novel intelligent skins, but also enrich the design of artificial skins for future large-scale Internet of Things applications.

BM08.06.16
Highly Stretchable, Transparent and Biocompatible Gelatin-Supported Deep Eutectic Solvent Gels for Strain and Pressure Sensors Huan Qin and Matthew J. Panzer; Tufts Univ, Medford, Massachusetts, United States.

There is a growing demand for flexible and soft electronic devices in the past two decades because of their broad applications in personal healthcare, human motion detection, and soft robotics. Hydrogels have been intensively investigated and utilized for multiple sensing applications due to their high ionic conductivity, good biocompatibility and tunable stretchability and toughness. However, the long-term use of hydrogel-based devices is limited by the dehydration of most hydrogels in ambient conditions. Ionogels based on ionic liquids with relatively lower ionic conductivity and nonvolatility have attracted considerable attention in sensing applications, but their high cost and toxicity make them unlikely to replace hydrogels. Deep eutectic solvents
(DESs) with similar physical properties (e.g. moderate ionic conductivity and low volatility) are generally low cost and environmentally-friendly, which could be scaled up with a great potential for sensor applications. Herein, we present the first example of DES gels as ionic conductors for multiple capacitive-type sensor prototypes. A DES based on choline chloride and ethylene glycol has been prepared and transparent DES gels have been synthesized in a facile manner using the coil-helix transition process of gelatin. AC impedance spectroscopy and tensile tests are used to characterize the ionic conductivity and stretchability of DES gels containing different amount of gelatin. A DES gel containing 22 wt.% gelatin could be stretched up to 400% without breaking while retaining a decent room temperature ionic conductivity of 2.5 mS/cm. Further stress-strain and strain cycling tests have been performed on the 22 wt.% gelatin gel. There is no obvious hysteresis response up to a strain of ~130% and the elastic modulus decreased slightly (27 kPa to 23 kPa) over 10 cycles at a strain of ~130%, indicating its excellent durability. Therefore, the DES gel with 22 wt.% gelatin was selected to be incorporated into capacitive-type sensor prototypes, where a stretchable tape was inserted as an insulator between two layers of DES gel. A relative capacitance change of 33% was obtained via bending a finger attached to a sensor. Tensile testing has also been carried out for the device and a good linearity between capacitance vs. strain was obtained over ~130% strain with a gauge factor close to 1, which is the theoretical limit of capacitive-type strain sensors. A pressure sensor prototype has also been fabricated and could measure pressures as low as 1 kPa. These promising device results and the low volatility of the DES gel prove that these materials could be an ideal alternative to hydrogels in multiple sensing applications and offer a novel solution to the development of soft electronics.

BM08.06.17

Gold Nanoparticles Decorated on Single Layer Graphene Applied for Electrochemical Ultrasensitive Glucose Biosensor Shifeng Hou; Shandong University, Jinan, China.

A glucose biosensor was fabricated by glucose oxidase (GOD) immobilized on gold nanoparticles decorated on single layer graphene (Au/SLG) modified glassy carbon electrode, with 6-(ferrocenyl)hexanethiol (Fc-C6H12-SH) as electron transfer medium (Fc/GOD/Au/SLG/GCE). The free-standing Au/SLG was obtained by sputtered gold nanoparticles on CVD-generated monolayer graphene. The good dispersion and clean surface of gold nanoparticles on graphene promote immobilization of GOD. The synergistic effect of graphene and electron mediator facilitates electron transfer process which account for the enhanced electrochemical performance with the detection limit of 0.1 nM (S/N = 3). The CVD-generated monolayer graphene has lower background current and good ductility, with free polymer transfer process bring clean surface, which is suit as platform for ultrasensitive detection of glucose. The biosensor was further studied for real perspiration test with attractive feasibility, which has potential application in large-scale production and perspiration-based wearable glucose detection.

BM08.06.18

Development of Biocompatible Microbatteries Aimed at Ingestible Sensors Using MEMS-Fabrication Processes Sven Staube1, Shinya Yoshida2,3, Tsutomu Nakamura4, and Itaru Honma1; 1Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Sendai, Japan; 2Graduate School of Engineering, Tohoku University, Sendai, Japan; 3Innovation Center for Creation of a Resilient Society, Tohoku University, Sendai, Japan.

Biocompatible microbatteries hold promise for a wide range of applications, especially for health care devices and environmental sensors. One specific example where biocompatible batteries can be employed is in ingestible devices, which can be used for regular monitoring of vital body functions, drug release, or for controlling medication adherence. Currently, ingestible sensor devices are often powered by large batteries that contain electrode materials that are toxic, requiring special encapsulation to ensure their safe use. This leads to bulky systems that are difficult to swallow and also expensive. Moreover, fabrication processes of the batteries are based on conventional methods and therefore possess only limited potential for miniaturization and eventually mass production, to lower the cost of the devices. We have developed biocompatible microbatteries that use gastric fluid as an electrolyte and which can be realized using existing microfabrication processes.

The microbatteries consisted of essentially two main parts: An Si substrate, that contained microstructures acting as passive, biomimetic capillary pumps, and electrodes of the microbatteries which were deposited on glass wafers containing W-vias for connecting front and backside electrodes. Microfluidic reservoirs containing the capillary pumps were realized in Si by standard photolithography and deep reactive ion etching, to depths ranging between 100–200 μm. The capillary pumps enabled more controlled filling of the microreservoir with electroyte, reducing the risk of trapping gas bubbles which could prevent operation of the microbatteries.

For the microbatteries, electrodes with nominal footprints of 0.7 x 3.2 mm² and consisting of about 3 μm thick AgCl cathodes and Zn anodes were fabricated by sputtering using shadow masks. The AgCl cathodes were then formed by electrochemical oxidation of the sputtered Ag films in 0.1 M KCl solutions.

Finally, the Si and glass wafers were bonded together and diced to chips of 5 x 5 mm². The microbatteries were characterized by galvanostatic testing in simulated gastric fluid at current levels ranging from 1 to 100 μA. The cell output reached values of the order of 0.9V, close to the theoretical value 0.984 V of the AgCl/Zn redox couple. The operation time of the microbatteries was limited to about 5–8 minutes, but it is expected that by using thick film techniques, that the operation time can be increased.

It is also anticipated that the use of Si-compatible MEMS fabrication will enable further size reduction of the microbatteries and thereby facilitate their integration in future sensor devices aimed at medical and environmental applications.

BM08.06.19

Interfacial Adhesion Improvement Between Stretchable PDMS and EcoFlex Layers with Nanoparticles for Electrodeposition Robot Gripper Application Lim Hanhuyu1,2 and Baejin Kim1; 1Yonsei University, Seoul, Korea (the Republic of); 2Green Chemistry and Materials Group, Korea institute of Industrial Technology, Cheonan, Korea (the Republic of).

The polymer layers could be easily deformed by external force because of its intrinsic elasticity. In the case of multi-layered polymer thin films, however, it could bring a certain problem. If the adhesion between the interfaces isn't sufficient, slip may be occurred. Particularly, the nanoparticles such as TiO₂, SiO₂, Al₂O₃ and BaTiO₃ dispersed polymers are further modified and affects to the adhesive force. Therefore, it is necessary to predict the relationship among deformation, composisites and interfacial adhesion. In this study, the modulus and interfacial strength of whole layers were measured by Universal Test Machine (UTM) in the ASTM-638. Based on this result, the maximized interfacial adhesion value was confirmed less than 10 N with 200 μm thickness. For the test, the pristine polymer and NP embedded polymer were spin coated to form bilayer shape with single layer tail. As a result, the NP coated polymer showed similar mechanical strength with double error range 1 N compared to the pristine polymer's modulus. Furthermore, we also introduced an adhesive layer such as primer and polyethylene imine (PEI) added PDMS to improve the interfacial adhesion. With NP/PDMS composites, we applied to electrodeposition (EA) robot gripper. NPs have higher dielectric constant than polymer so that it can increase EA force in the same potentials. Furthermore, the critical parts of robot gripper are skin layer and EA layer. Both of skin and EA layers are composed of stretchable polymers so that our achievement could be used for it. As a result, highly adhesive EA gripper was investigated by solving interfacial adhesive problem.

BM08.06.20
High-Performance Energy Devices Based on Amphiphilic Core-Sheath Structured Fibers Xuemei Fu, Hao Sun, Songlin Xie, Limin Xu, Zhuoer Li and Huisheng Peng; State Key Laboratory of Molecular Engineering of Polymers, Department of Macromolecular Science and Laboratory of Advanced Materials, Fudan University, Shanghai, China.

Owing to the lightweight, flexibility and adaptation to various curved surfaces like our bodies, fibrous energy devices are widely studied to revolutionize electronic fields. Numerous efforts have been made to develop high-performance fibrous electrodes which demonstrate high mechanical strength, electrical conductivity and electrochemical activity. As a candidate, carbon nanotube (CNT) fibers have attracted extensive attention but the poor electrochemical activities need addressed. Plasma treatment has been thus adopted to obtain hydrophilic oxygenated CNT (OCNT) followed by introducing active materials. However, the defects formed during treatment largely decrease the mechanical strength and electrical conductivity. The balance between these two aspects requires to be struck for realizing high-performance fibrous energy devices.

Herein, a novel family of amphiphilic core-sheath structured fiber is developed as high-performance fibrous electrode. The hydrophobic CNT core provides high mechanical strength and electrical conductivity while the hydrophilic OCNT sheath acts as platform depositing electrochemically active materials. When the core-sheath fiber used as counter electrode for fibrous dye-sensitized solar cell, a power conversion efficiency of 10% has been achieved, representing the highest power conversion efficiency among all kinds of fibrous solar cells. Further, upgraded core-sheath fibers are applied to fibrous supercapacitors which show excellent capacitance of 324 F/cm² retained at 79% as current density up to 50 A/cm². The structure design can be generalized to other high-performance energy devices.

Highly Sensitive Crack Based Strain Sensor Using Microsphere Expansion Young Jung1,2 and Hanchul Cho1; 1Korea Institute of Industrial Technology, Seoul, Korea (the Republic of); 2Mechanical Engineering, Pusan National University, Buan, Korea (the Republic of).

In recent years, the needs for flexible and wearable electronics have rapidly increased. Among them, strain sensors based on polymer such as PDMS, Ecoflex, Dragon Skin play an important role in the human motion monitoring, electronic skin, etc. Most of these strain sensors with high sensitivity have cracks on the conductive layer, which maximizes the sensitivity of the sensors. However, there is a limitation that the process of making such micro/nano cracks is difficult to manufacture in a large area and the productivity is low. In this work, we suggest new crack fabrication method on the conductive layer using thermal expandable microsphere (THEM). The microsphere is consists of thermoplastic resin and hydrocarbon like a balloon. THEM expands 5~7 times at operating temperature. The cracks are formed by expanding of microsphere in the PDMS/Microsphere composite. Owing to its unique structure and mechanism, strain sensors can have high sensitivity in the 10 percent strain range, good mechanical property, fast response time and high durability in the cyclic tests. We verified the crack propagation using in-situ scanning electron microscopy (SEM) when microsphere was expanded and the sensors were strained. We compared with experimental results and theoretical strain range. Furthermore, we confirmed the expansion ratio of thermal expandable microsphere by adjusting the temperature, which affected the size and total length of cracks. Sensitivity of the fabricated sensor could be tuned by controlling the temperature for the various strain range. The sensors showed significant performance to detect very tiny human body motion like a finger, wrist and neck.

BM08.06.23

Development of a GaN Based Liquid Sensor Using FIB Milling Technique Inas Tahar1,2, Nitu Rajput1, Tomas Palacios2, Mustapha Jouidi1 and Daniel Choi1; 1Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Gallium nitride (GaN) has the advantage over many other semiconductor materials in sensor applications at high temperature environment because of its high temperature stability. Moreover, it has potential capability in sensing polar liquids due to its high internal piezoelectric polarization and chemical stability. Water adsorbs dissociatively on the GaN surface with a sticking coefficient ≥ 0.45 [1]. Dissociation of the water molecules is an exothermic reaction (-44 kcal/mole); therefore, it is thermodynamically favored. Through a reaction chain, oxygen can eventually bound to Ga, and hydrogen desorbs into the gas phase in the form of H₂. High activation energies are achieved by hydrogen desorption from Ga-H bonds and breaking of hydroxyl groups (Ga-OH). Thus, these processes are expected to occur only at higher temperatures [1]. In this work, we report the fabrication of single crystal p-type GaN lamella using focused ion-beam (FIB) milling technique for liquid sensing applications. Two-terminal metal contact geometry was fabricated by depositing Ti/Al on a Si/SiO₂ substrate using electron-beam evaporation. The effect of polar molecules was monitored using Agilent B1505A curve tracer and 2-terminal metal contact geometry was fabricated by depositing Ti/Al on a Si/SiO₂ substrate using electron-beam evaporation. The effect of polar molecules was monitored using Agilent B1505A curve tracer and Agilent B1505A curve tracer by adjusting the temperature, which affected the size and total length of cracks. Sensitivity of the fabricated sensor could be tuned by controlling the temperature for the various strain range. The sensors showed significant performance to detect very tiny human body motion like a finger, wrist and neck.

Interconnection of Flexible NAND Flash Memory via Roll-to-Plate Transfer Method Taelin Kim, Do Hyun Kim and Keon Jae Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Roll-based fabrication has received large attention for the mass production of unconventional soft electronics. Recently, a number of research groups have shown innovative methods in roll-to-roll (R2R) processing such as graphene fabrication, nanotexturing, nanoimprint lithography, and transfer of oxide thin-film transistors (TFTs). However, fully packaged flexible large-scale integrated circuits (LSI) for the computational application should be accomplished in roll-based technology to utilize fully operational roll-based flexible electronic systems. In this work, our group demonstrated the ultrathin silicon-based flexible NAND flash memory (f-NAND) fabricated by highly-productive roll-based flip-chip packaging technology. The roll-to-plate thermo-compression bonding enables the interconnection of the f-NAND on a flexible printed circuit board (FPCB), realized by non-linear elastic deformation of the anisotropic conductive film (ACF). The ACF packaging materials exhibits high compatibility with the continuous roll-transfer process and excellent flexibility even after the interconnection. To confirm non-linear deformation during the roll-based ACF transfer bonding, finite element analysis (FEA) was carried out. The reliable circuitry operation of the 16×16 f-NAND is observed through addressing and bending tests, enabled by the high flexibility of ACF.
interconnections. This work suggests a significant breakthrough toward the mass commercialization of roll-based advanced f-LSI integration technology.

BM08.06.25

All-Soft and Liquid-Phase Supercapacitors Based on CNT-Integrated Liquid Metal Electrodes Min-su Kim1,2, Byeongyong Lee1, Seung Woo Lee1 and Oliver Brand1,2; 1School of Electrical and Computer Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2Institute for Electronics and Nanotechnology, Georgia Institute of Technology, Atlanta, Georgia, United States; 3George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Soft energy storage systems are a core technology for powering wearable and skin-mountable electronics. Supercapacitors are considered promising energy storage components for these applications because of their ultrafast power supply and long cycle life; however, their relatively low energy density compared to Li-ion batteries is the major limitation. Moreover, conventional supercapacitors are manufactured from hard and brittle materials, which fail at less than 2% strain. Therefore, interfacing failure between soft skin and rigid electronics is the major limiting factor for wearable and skin-mountable electronics. As a result, a key consideration for realizing all-soft supercapacitors is that each electrode component must be soft and conductive without sacrificing electrochemical performance. The use of liquid-phase conducting materials, such as eutectic Ga-In alloy (EGaIn), can open a new path for all-soft, deformable, and self-healing electronics because of its low melting temperature (<15°C), non-toxicity, favorable electrical conductivity (~3.4×10⁶ S/m), and unlimited mechanical stretchability. In addition, nanocarbon materials, such as carbon nanotubes (CNT), have been actively investigated for improving the energy density.

This paper presents all-soft and liquid-phase supercapacitors based on CNT integrated with EGaIn electrodes. Soft and stretchable CNT-integrated liquid metal electrodes are enabled by i) large area EGaIn thin-film patterning on polydimethylsiloxane (PDMS) substrates using an additive stamping process and ii) functionalization of EGaIn with CNT via a layer-by-layer (LbL) adsorption technique. The additive stamping approach provides large area (~cm²) and uniform EGaIn patterning with a lateral resolution of 500 μm at film thicknesses of ~1.5 μm. The EGaIn patterns will serve as the electron transport channel and support for CNT adsorption. The oxygen functional groups on the CNT enhance the energy density of the electrodes as well as interaction with native oxide (Ga₂O₃) on the surface of EGaIn, resulting in a 3D network on the EGaIn surface with strong adhesion even at 50% applied strain. To demonstrate supercapacitors with a parallel-plate configuration, CNT-integrated EGaIn electrodes were vertically integrated with a soft separator, comprising a porous PDMS structure filled with ionic liquid. The ionic-liquid-filled soft separator enables physical separation between the two electrodes for all-soft and liquid-phase supercapacitors. Our preliminary data show that the areal capacitance increases almost linearly with the number of LbL adsorption steps with a measured areal capacitance ≈15 mF/cm² with 30 LbL steps. Moreover, the specific capacitances remain nearly unchanged for >2000 cycles, which indicates excellent electrochemical stability. The demonstrated all-soft and liquid-phase supercapacitors overcome the limitation of rigid supercapacitor configuration and could enable fully-integrated wearable and skin-mountable electronics.

BM08.06.26

Advanced MEMS Vibrating Ring Gyroscope for Miniaturized Space Attitude Control System Daniel Choi1,2, Boo Hyun An1, Mariam S. Mansouri1, Wajih Syed1, Zakriya Mohammed1 and Ibrahim Elfadel1; 1Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 2UAE Space Agency, Abu Dhabi, United Arab Emirates.

Extremely miniaturized, very low power, navigation-grade attitude control systems are an enabling technology for a number of civilian and defense systems, including miniature, autonomous sensors, navigation systems for satellites and unmanned air vehicles (UAV), ground and underwater robotic systems, and defense and law-enforcement systems for widely dispersed surveillance and precision targets. Space systems employing an attitude control system should include the control and processing appropriate electronics to provide the most direct method for sensing inertial angular velocity. While micro-electromechanical systems (MEMS) are playing a growing role in safety critical applications, in the harsh and remote environment of space, reliability is still the crucial issue, and the absence of an accepted qualification methodology is holding back MEMS from wider use.

In this study, we develop an innovative, affordable, miniature, low-power, navigation-grade integrated gyroscope for the attitude control system that applies MEMS technology to achieve the performance, size, power, sensitivity, and cost objectives of space and other commercial applications. We have designed physical model of MEMS gyroscope investigated using Finite Elements Method (FEM) simulation by improving previous developed vibrating ring gyroscope (VRG) designs. Design parameters and elements are modified to narrow down bandwidth and improve shock resistance. To meet the requirements of MEMS gyroscopes for space application, the proposed model of MEMS VRG is designed with shock resistive dual spring structure and multiple ring structure for increasing shock resistance and Q factor. The MEMS VRG is designed in 5 x 5 mm device with 3 mm diameter of the vibrating structure.

BM08.06.27

MEMS Accelerometer Based on GaN for Harsh Environment Daniel Choi1,2, Boo Hyun An1, Menguang Yuan2, Tomas Palacios2, Inas Taha1, Nitu Rajput1, Hamad Al Yass1, Mihai Sanduleanu1, Tawaddod Alkindi1, Mariam S. Mansouri1 and Maryam Almuhayyan1; 1Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Inertial sensing technologies in high temperature environments over 500°C are in great demand in aerospace, power plants and material processing applications. However, conventional micro-electromechanical systems (MEMS) sensors still cannot be operated at such high temperature and need to be isolated in controlled environment.

Gallium nitride (GaN) is very promising for high power devices, high temperature electronics and microsystems due to their wide energy bandgap with low intrinsic carrier density at high temperature over 500°C. Capacitive inertial sensors which consist of two separated electrodes can be operated by detecting capacitance changes between the electrodes upon applied stress. Capacitive inertial sensors have lower thermal drift, high resolution and good noise performance compare to piezoresistive sensors.

In this study, we develop MEMS accelerometer as part of the smart sensor system that will be utilized for monitoring the catalysts inside of the high temperature furnace for the oil refining process. We will discuss a design of MEMS accelerometer using GaN as structure layer, grown epitaxially on aluminum nitride/silicon substrate. The resonance frequency of the designed accelerometer is found to be 2.235 kHz and bandwidth is around 1.2 kHz. Modeling and simulation results of the GaN accelerometer will be discussed and characterization of the fabricated devices would be presented.

The chainmail fabric is made by selective laser sintering (SLS) nylon. These 3D prints have high inherent porosity, and easily take up a fluid containing magnetic nanoparticles through capillary action in post-processing. When dried, the magnetic nanoparticles coat the interior of the porous material, such that it becomes uniformly magnetically functionalised. We show that the location and strength of magnetic actuation can be controlled at the scale of individual links in the chainmail. Therefore, our chainmail fabric can be regarded as a functional chainmail mesh for the swine heart. The mesh monitors cardiac activation signals from ventricles and stimulates at any sites in the ventricles without being hindered by anatomical obstacles.

Intrinsically stretchable conductors form a vital component of advanced bioelectronics. And novel nanocomposites based on conductive nanomaterials have been used in diverse areas including wearable and implantable bioelectronics. Among many nanomaterials for the composites, silver (Ag) nanowires are popular because they are highly conductive and the ultralong nanowires form highly percolated conductive networks in the elastomeric media. However, achieving highly conductive and soft composites is challenging because current methods produce materials that are either highly conductive or soft but never both. Furthermore, because bioelectronics is necessarily exposed to biofluids, preventing Ag nanowire oxidation and Ag ion leaching are significant challenges. And we have achieved a highly conductive, biocompatible, and soft nanocomposite by using silver-gold (Ag-Au) core-sheath nanowires and polystyrene-butadiene-styrene (SBS) elastomer. We synthesized ultralong Ag nanowires encapsulated with a smooth and uniform Au sheath and then mixed them with the polymer. Phase separation of Ag-Au NWs and SBS occurs, which forms microstructures in the composite, reduces Young’s modulus, and increase softness and conductivity of the composite, allowing it to be stretched up to ~266% whilst maintaining a conductivity of 41,850 S/cm. By increasing the content of Ag-Au nanowires, the nanocomposite can achieve conductivity up to ~72,600 S/cm. Using the heat-rolling-press, stretchability of the nanocomposite can be further increased up to 840%. We used the Ag-Au nanocomposite to develop a wearable device for recording electrophysiological signals through the human skin and delivering electrical and thermal stimulations that respond to sensor signals. We also designed and fabricated a customized multi-channel soft cardiac mesh for the swine heart. The mesh monitors cardiac activation signals from ventricles and stimulates at any sites in the ventricles without being hindered by anatomical obstacles.

At some point in our lives, many of us, either through injury, chronic disease or old age, will have to rely on technologies to mechanically assist and support our bodies. Current solutions tend to rely on robotics which often involve cumbersome electronics and heavy power packs. One new approach is the use of soft robotics using pneumatic actuators, which is proving fruitful but usually requires the provision of compressed air through a tether. Actuating smart materials are a potential lightweight and low-power alternative but until recently, their reliable integration into wearable technology has proved difficult. However, recent advances in the field of 3D printing of smart materials (so-called 4D printing), has led to growth of both the hardware and software available for successful integration of these materials into biomedical devices. Here we report on our progress using 4D printing to create active chainmail fabrics for use as wearable exoskeleton supports.

This paper describes the characterisation and processing parameters of magnetically functionalised chainmail fabric that can be used as a biomedical device with controllable stiffness. The use of 3D printing techniques to fabricate the device allows it to be digitally designed by clinicians to exactly fit a patient’s needs. The magnetic actuation results in an on/off state for each controllable link in the chainmail making stiffness a tailored metaproperty of the device, which can be controlled by the clinician.

The chainmail fabric is made by selective laser sintering (SLS) nylon. These 3D prints have high inherent porosity, and easily take up a fluid containing magnetic nanoparticles through capillary action in post-processing. When dried, the magnetic nanoparticles coat the interior of the porous material, such that it becomes uniformly magnetically functionalised. We show that the location and strength of magnetic actuation can be controlled at the scale of individual links in the chainmail. SLS printing is well-suited to making the complex geometries required for wearable fabrics. The functional chainmail reported can be regarded as a mechanical metamaterial, since its design at the macroscale directly influences its mechanical properties. The smallest elements of mechanical metamaterials have become known as melexs (mechanical pixels). In this case, our melexs are individual links in the chainmail. Through our 4D fabrication process they can be designed to be in one of two states – locked or unlocked – and a magnet can be used to flip between them. We show that when all melexs are in the locked state this corresponds to an overall rigid fabric, whereas melexs in the unlocked states renders the material flexible. By design, there are a large number of states in-between fully rigid and fully flexible which is what gives this approach so much potential for wearable exoskeleton support garments.

Monitoring of central blood pressure (CBP) waveform from deeply embedded vessels, such as the carotid artery and jugular vein, has significant clinical values due to their proximity to the heart. The CBP waveform has a direct relationship with the cardiovascular status such as the atrial, ventricular, and valvar activities on both left and right sides. The most accurate method for measuring CBP, namely cannulation, is too invasive to allow frequent measurements, even though it is crucial for many conditions related to all-cause cardiovascular mortality prediction. Existing non-invasive solutions, including photoplethysmography (PPG) and tonometry, have significant challenges to provide accurate and reliable measurements on blood vessels that are deep underneath the skin. Here, we demonstrate a skin-integrated conformal ultrasonic device that overcomes all these limitations by combined strategies of material design and advanced microfabrication. This conformal probe has an ultrathin profile (240 μm in thickness), a high reversible stretchability (60%), and a comparable axial resolution (400 μm) with commercial transducers. This study demonstrates the first conformal electronics capable of launching ultrasonic waves that penetrate into deep biological tissues (~4 cm) in a gel-free manner, and acquiring accurate CBP waveforms at deeply embedded arterial and venous sites to monitor cardiovascular events. Also, this is the first conformal device that enables observing the prominent pressure amplification caused by progressive increase in vessel stiffness along the arterial tree, by comparing the captured peripheral blood pressure (PPB) with the CBP waveforms. Additionally, this device allows correlating the blood pressure (BP) waveforms at different locations of the body with a simultaneous electrocardiogram (ECG) to evaluate arterial stiffness along conduit arteries. Collectively, this opens up extensive opportunities for continuous and accurate deep tissue diagnosis and prognosis using non-invasive wearable electronics.
This talk describes materials and device designs for soft, skin-compatible, battery-free platforms that offer unique capabilities in quantitative capture, storage and in situ chemical analysis of microfluidic volumes of sweat. These systems have options in integration of enzymatic biofuel cells, microfluidic networks, colorimetric chemical reagents and near-field communication (NFC) electronics for readout. A demonstrator includes a reusable NFC electronic module with reversible magnetic connection to a single-use soft, flexible microfluidic component for simultaneous tracking of sweat rate, total sweat loss and pH and of concentrations of lactate, glucose and chloride using biofuel cell and colorimetric approaches. Detailed benchtop studies and field tests on human subjects establish quantitative correlation of data collected using these devices with those obtained by nuclear magnetic resonance spectroscopy, chloridometry and pH measurements.

Highly Sensitive and Robust Soft Pressure Sensor Using 3D-structured Microchannel and Liquid Metal for Wearable Applications 

Kim1, Yongrok Jeong1, Jacho Park1, Minseong Kim1, Yong Suk Oh2 and Inkyu Park1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Northwestern University, Chicago, Illinois, United States.

In this study, we have developed a highly sensitive and robust soft pressure sensor for wearable applications using 3D-structured microchannel and liquid metal. Liquid metal is used as a stretchable conductor because of its high conductivity and high adaptability to the mechanical deformation. First, the 3D-structured microchannel was fabricated using 3D-printed dissolvable molds. Using fused deposition modeling (FDM) 3D printing, 3D-printed molds with micro-bumps were fabricated and removed after casting into an elastomer. Then, the liquid metal was inserted into the prepared microchannel using vacuum filling method. It is a competitive fabrication method for its simplicity and cost-effectiveness for not using conventional photolithography. When the pressure is applied, the cross-sectional area of the microchannel decrease draws the resistance of the sensor increases. The high sensitivity of the pressure sensor is achieved by two strategies. First, conventional microchannels fabricated with photolithography were not able to have different thickness of the channel in Z-direction. Using 3D printing technology, we fabricated the 3D-structured microchannel. It is more advantageous for them to close the channel against the small pressure compared with those with uniform thickness. Second, liquid metal reservoirs fabricated at the ends of the sensor acted as a buffer zone for liquid metal flow. Since there was enough room for liquid metal flow, the sectional area of the microchannel could change in respect to the given pressure.

In our study, the pressure sensors with different styles were tested with corresponding finite element method (FEM) simulation results. The geometry and the stiffness of the bumps were controlled. On the other hand, it is ideal for the pressure sensor signal not to be disturbed by other external inputs such as strain. Also, the initial signal level has to be maintained after the deformation. To demonstrate the robustness of the proposed sensor, we performed various complex deformation modes including stretching, folding, twisting, stretching + folding, stretching + twisting, and so on and observed the change of the signal. As wearable applications, we implemented five pressure sensors into the textile and monitored the pressure distribution during sitting and lying. For the real-life wearable applications, it is important for the sensor to be robust and reliable. The proposed pressure sensor has a high sensitivity and robustness having a long life cycle and a simple and cost-effective fabrication process. It is expected to be applied to various applications such as wearable devices, electronic skins, and soft robotics.
