The efficiency of nanowire solar cells is particularly sensitive to device parameters including the nanowire height, diameter, doping levels, and passivation, requiring careful optimization to enable the highest efficiencies. We present a coupled opto-electronic model of an array of passivated axial-junction GaAs nanowire solar cells on silicon substrates. For the optical model we utilize a modified formulation of rigorous coupled wave analysis (RCWA), which we call the continuous variable formulation (CVF). The CVF is designed to reduce the Gibbs phenomenon and yield more accurate local fields relative to conventional RCWA implementations. From the results of the optical model, we extract carrier generation rates, which are fed into the industry-standard self-consistent coupled Poisson and drift-diffusion solver, Synopsys Sentaurus. We use this combined wave-optics and electrical model to perform fully automated, global optimization of device parameters. We show the efficiency gains that are possible by optimizing the nanowire diameter, array period,
Silicon nanowires and fibers are conventionally prepared through chemical vapor deposition growth off of a metal catalyst at elevated substrate temperature. Such structures are especially of interest for lithium ion battery anodes and may also be useful for chemical sensing, in both cases due to their very high surface area. In this report we present on the fabrication of nanoscale silicon fibers grown under highly unusual conditions. We find that, following nanosecond laser ablation of a silicon surface in SF6 gas, an extended soak in the chamber for several months at room temperature results in the formation of a dense “spaghetti”-like network of silicon nanofibers all over the exposed surface of the wafer, including outside of the laser-irradiated areas. These fibers contain oxygen and fluorine, and show evidence of aluminum-containing spherical particles at their tips. Removal of the wafer shortly after irradiation shows no evidence of fibers, indicating that the structures are not formed during the laser irradiation. Moreover, other specific conditions must be met: the experiment must be performed in an aluminum chamber, the specimen must sit in the same environment the entire time, and the total irradiation must be sufficiently long. We posit a mechanism whereby the laser ablation forms a long-lived radial containing silicon and fluorine, which etches aluminum from the chamber walls. This then deposits on the silicon surface and acts as a catalyst for nanowire growth. We report on experimental support for this model obtained from gas-phase measurements at several post-ablation intervals.

Highly Stable Copper Nanowire Network Transparent Electrodes Sevinç Polat Genlik1, Dogançan Tigan1, Sahin Coskun1, Kerem E. Ercan2, Yusuf Kocak3, Emrah Ozensoy4 and Huseu E. Unalan1; 1Department of Metallurgical and Materials Engineering, Middle East Technical University, Ankara, Turkey; 2Department of Chemistry, Bilkent University, Ankara, Turkey.

Silver nanowires (Cu NWs), on the other hand, are not far behind the silver nanowires and hold great promise due to their lower cost and comparable electrical conductivity in the network form. Oxidation is the biggest barrier in front of the large scale utilization of Cu NWs. Bulk copper itself is also susceptible to oxidation and several methods have been proposed for its protection. Inspired from bulk copper, in this work, we utilized benzotriazole (BTA) as an organic corrosion inhibitor to improve the stability of Cu NWs. High aspect ratio Cu NWs are synthesized by an environmentally benign hydrothermal method and highly transparent and conducting Cu NW networks (20 ohm/sq sheet resistance at a transmittance of 88%) are fabricated through spray deposition. Following the deposition of Cu NW networks, they are spin coated with a solution of BTA for passivation. Long term stability of the passivated electrodes under ambient and severe humidity conditions are systematically investigated and compared to that of bare control samples. It is found that BTA inhibits the formation of an oxide layer on Cu NWs for at least one year of storage under ambient conditions. In addition, no significant change in sheet resistance of passivated Cu NW networks is observed (R/R0 < 1.1). High humidity conditions accelerated the degradation of bare Cu NW network electrodes and they become insulating after 2 days under 70% RH condition, while they become insulating after a day under 90% RH. On the other hand, initial sheet resistance of BTA protected samples is maintained up to 10 days under 70% RH condition, while it is maintained for 7 days under 90% RH. Moreover, attenuated total reflectance infrared spectroscopy (ATR-IR) is used to monitor the thermal stability of BTA for the protection of Cu NW networks and BTA is found to be thermally stable up to 125 °C. All in all, this highly effective and simple strategy to improve the stability of Cu NW networks will certainly open new avenues for their large scale utilization in various optoelectronic devices.
To summarize, we successfully fabricated type-II p-GaAsSb/n-InAs NWs with high uniformity. These results are promising to develop high-performance NW devices. This work was supported by JST CREST Grant Number JPMJCR16Q3, Japan.

Ultralight Gold Nanowire Aerogels Fang Gai, Alyssa L. Troksa, Tyler M. Fears, Tom Braun, Michael Nielsen, Sergei Kucheyev, Theodore Baumann, T. Yong Han and Michael Bagge-Hansen; Lawrence Livermore National Laboratory, Livermore, California, United States.

We report the first ultralight gold aerogel monoliths with tunable densities down to single-digit mg/cc. Free-standing aerogels are fabricated by freeze-casting of gold nanowire suspensions to produce gold aerogels with densities between 6 to 40 mg/cc. Electron microscope studies revealed that the aerogels consist of interconnected, high-aspect ratio gold nanowires, with diameters of ~5 nm, forming a robust percolated network. Energy-dispersive X-ray spectroscopy together with X-ray photoelectron spectroscopy confirm that the aerogels are comprised of high-purity gold. We further investigated the effect of altering the initial solvent composition on the resulting pore structures of gold aerogels, as exemplified by aqueous and water/tert-butanol solutions. The results show an abrupt transition from hierarchical porosity across different length scales to a uniform, nanosized pore geometry. We also measured distinct mechanical properties between the two structures. Compared to previous methods of gold foam fabrication, our method does not involve the use of foreign organic scaffolds or metal alloys to achieve structural robustness, and therefore enables potential applications where high-purity, ultralight gold materials are required such as catalysis, electrode materials and sensors. This work was performed under the auspices of the U.S. Department of Energy Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

The Effect of Misfit Strain on Phase Transition Behaviors and Electron Transport Properties in Vanadium Dioxide Low-Dimensional Structures Yangping Zhang1, 2, Weiming Xiong1, 2 and Yue Zheng1, 2; 1State Key Laboratory of Optoelectronic Materials and Technologies, Sun Yat-sen University, Guangzhou, China; 2Micro and Nano Physics and Mechanics Research Laboratory, Sun Yat-sen University, Guangzhou, China.

Vanadium dioxide (VO₂), as a typical metal-insulator transition (MIT) material, exhibits a transition from insulating (M1, M2 and T) to metallic (R) phase. The transition accompanied by the great changes in conductance, optical transmittance and mechanical properties, which make it has potential applications in electrical and optical switches, etc. When the structure of VO₂ reduces into low dimension, (e.g., nanowire (NW), nanobelt (NB), nanodot (ND), etc.), some novel physical properties different from its bulk material could be observed because of the size and surface/interface effects. However, the MIT behavior and electron transport properties of VO₂ low-dimensional structures (LDSs), especially the LDSs grown on the substrate and affected by the mismatch strain, are still lack and should have further investigations. In this work, abundant VO₂ LDSs (i.e., zero-dimensional NDs, one-dimensional NWs, NBs and two-dimensional nanoplatelets (NPs)) were fabricated by pulsed laser deposition. The effects of each deposition factor, i.e., substrates, deposition temperature, oxygen pressure, pulse number and annealing process, on the growth of VO₂ LDSs were systematically investigated. The results demonstrate that the NWs and NBs favor to grow on <0001> Al₂O₃ and <0001> SiO₂ substrates, respectively. By adjusting the oxygen pressure, the length/diameter ratio of NW can be conveniently controlled. Interestingly, vertically-grown NWs and NPs were also fabricated by controlling the pulse number and annealing process. High resolution transmission electron microscopy images and selected area electron diffraction patterns confirm the high crystallinity of the NW, vertically-grown NW and NP. Importantly, the MIT behaviors and electron transport characteristics were studied by temperature-dependent X-ray diffraction and current-voltage measurement, respectively. The results clearly reveal that the properties of VO₂ LDSs are strongly correlated to the mismatch strain between LDSs and substrate lattice. Under the strong effect of substrate, LDS (i.e., NW) transforms from an insulating T phase to another insulating M2 phase without the coexistence of these two phases. Under the relative weaker effect of substrate, two insulating (i.e., M1 and M2) phases could coexist in LDSs (i.e., NB, vertically-grown NW and NP) during the phase transition process, and the transition temperature could also be affected. Intriguingly, the discrepant electron transport properties corresponded to the MIT behaviors were also observed in NW and NB. The results show that the M1 and M2 phases compete with each other in the NB during the phase transition owing to the interaction of VO₂ and substrate lattice. This work provides a simple and controllable technique for fabricating VO₂ LDSs, and an efficient method for controlling the transition temperature and electron transport properties through the morphology of VO₂ as well as the misfit strain from the substrate.

Understanding the Composition of Ternary III-V Nanowires Forming from Quaternary Au-Based Liquid Melts Egor Leshchenko1, Masoomeh Ghasemi1, 2, Vladimir Dubrovskii3 and Jonas Johansson1; 1Solid State Physics and NanoLund, Lund University, Lund, Sweden; 2Physics Department, Persian Gulf University, Booshehr, Iran (the Islamic Republic of); 3ITMO University, St. Petersburg, Russian Federation.

Semiconducting nanowires are a promising class of nanoscale objects whose properties are dramatically different from the bulk counterparts. Thanks to their unique properties, nanowires hold great promise for nanotechnology with many nanoelectronic, optoelectronic and energy harvesting applications. Such versatility is explained by the possibility of modulating nanowire physical properties by tuning their structure, size, morphology, and chemical composition [1]. The majority of research on nanowire growth technology is devoted to binary systems, especially to GaAs nanowires, while ternary nanowires are less studied. To fully realize the NW potential prospects and expand their functionality, the construction of more complex materials with precise composition control is required. So, the ability to control the composition of ternary nanowires enables almost unlimited bandgap engineering. However, it is near to impossible to control the composition of ternary nanowires without understanding of underlying growth mechanisms and modeling. In this perspective, we present an analytical approach for understanding and tuning the composition of a ternary solid material nucleating from a quaternary liquid melt. The calculations are based on the two-component nucleation theory with realistic descriptions of all the considered phases. We apply this theory to a nucleation-limited regime of the vapor-liquid-solid Au-catalyzed and self-catalyzed growth. Within the model, the solid composition is obtained as a function of the liquid composition for the In-Ga-As-Au, Al-Ga-As-Au, In-Ga-Sb-Au and In-Sb-As-Au systems. The results show that the ternary nanowire composition can be controlled over a wide range by modulating the composition of the catalyst droplet and temperature except for systems with high pseudobinary interaction parameters. For such systems (In, Ga, Sb and In, Ga, As), formation of ternary NWs is thermodynamically forbidden in a wide range of solid compositions at relevant temperatures due to the miscibility gaps. The current contribution presents an important step for the fundamental understanding of the ternary NW formation. However, a direct comparison between the obtained results and experimental data is seriously hampered because of unknown liquid composition during the growth. That is why we developed a simple kinetic model which gives a relationship between the vapor and liquid phases. Combination of this kinetic vapor-liquid model with the thermodynamic liquid-solid model allows us to skip the liquid phase and model growth of ternary nanowires using available experimental data such as the flux ratios and the nanowire composition.

Platforms for Synthesizing Scalable Nanowire Networks by Molecular Beam Epitaxy Sabbir A. Khan, Joachim E. Sestoft, Filip Krizek, Yu Liu, Tomaš Stankevič and Peter Krogstrup; Center For Quantum Devices and Station Q Copenhagen, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark.

III-V semiconductor nanowire networks are promising candidates for high speed electronics and quantum applications. In this study, we investigate a suitable platform for epitaxial growth of scalable semiconductor nanowire networks. We consider two possible directions for nanowire networking, firstly, bottom up free-standing nanowire networks grown via the vapor-liquid-solid (VLS) method and secondly, selective area grown (SAG) nanowire networks from lithography defined patterns in dielectric masks. For InAs/InSb VLS nanowire networks, we engineer an InAs (100) substrate by making (111) B faceted trenches or (111) B faceted SAG and later use this (111) B faceted platform for growing VLS nanowire networks with high yield and scalability using molecular beam epitaxy (MBE). We also show SAG nanowire junctions with different directions and structures, in a lithography defined windows, which is certainly another promising route for scalability. Both directions are appropriate platforms for quantum transport measurements using in-situ epitaxial growth of superconductors (aluminum in our case) on the semiconductor nanowires.

Synthesis and Characterization of NiO/SnO2 Heterostructures María Taeho, David Maestre and Ana Cremades; Física de Materiales, Facultad de CC. Físicas, Universidad Complutense de Madrid, Madrid, Spain.

Combining nano- and microstructures of different semiconducting oxides in order to synergize their properties is gaining increasing attention in recent years [1-3]. In particular, fabrication of p-n heterojunctions in 1-dimensional structures has been attested as one of the most promising strategies to develop optoelectronic devices with enhanced applicability in photocatalysis and solar cells, the fabrication of which is still a challenging task in material science. Different approaches have been used in the fabrication of heterostructures, usually involving subsequent growth stages based in the bottom-up paradigm. In this work, NiO/SnO2 heterostructures have been fabricated in a single step following a catalysis free vapor-solid process which avoids the use of catalyst or external substrates. Individual SnO2 and NiO micro- and nanostructures have been also fabricated as a reference. SnO2 is a well-known n-type material with demonstrated applications in gas sensing, catalysis or optoelectronics. On the other hand, NiO is one of the very few p-type wide bandgap semiconducting oxides with potential applicability in electrochromic devices, sensors, magnetic devices, batteries, catalysis and supercapacitors. NiO/SnO2 heterostructures can overcome the limitations of the original binary oxides and broaden their applicability, which motivates this study. In the vapor-solid process used in this work, a controlled mix of metallic Sn and Ni pressed into a pellet is used as precursor, and thermal treatments were performed at 800°C during 10 hours under a controlled Ar flow. Following this method, a large concentration of nanowires, some microns length, grow on the surface of the treated pellet. X-ray diffraction (XRD) and Raman spectroscopy, in combination with energy dispersive x-ray spectroscopy (EDS) and scanning electron microscopy (SEM) confirm the presence of rutile SnO2 nanowires grown on NiO micrograins with cubic rock-salt structure. The luminescence of these heterostructures is dominated by the characteristic emission of SnO2, which consists of bands at 1.94 and 2.25 eV, related to the presence of oxygen vacancies, and a band at 2.58 eV associated with surface defects. NiO presents emissions at 1.45 eV and a complex emission at 2.45 eV due to Ni vacancies. Variation of the precursors, mixture ratio and parameters of the thermal treatment lead to changes in the growth of the heterostructures.

Study of Medium Influence in Solvothermal Synthesis of BiSI Nanorods and the Challenges in Their Application in Ionising Radiation Detection María Membrí Frutu1, Ivana Aguiar2, Maria E. Perez Barthabaru2 and Laura Formaro2; Grupo de Desarrollo de Materiales y Estudios Ambientales, Area Radioquímica, Facultad de Química, Universidad de la Republica, Montevideo, Uruguay; 2Grupo de Desarrollo de Materiales y Estudios Ambientales, Departamento de Desarrollo Tecnológico, CURE, Universidad de la República, Rocha, Uruguay.

BiSI is a ternary semiconductor which can be employed in X and gamma ray detection at room temperature due to the following properties: band gap of 1.57 eV, density of 6.4g/cm³, and absorption coefficient for 60keV radiation of 5.6cm⁻¹g. This work deals with the synthesis mechanism of BiSI nanorods by the solvothermal method, followed by the study of the fabrication conditions to obtain BiSI pellets, and finally it determines the response to ionizing radiation of prototype detectors built with the pellets. The solvothermal synthesis uses Bi2S3 and I2 as precursors, 180°C temperature, and 20 h reaction time. The media used was either H2O or ethylene glycol (EG). The pellets were fabricated using the synthesized BiSI, varying the applied pressure and heat treatment (HT) conditions. Prototype detectors were built with the pellets by evaporating Au as contacts and attaching Pt wires with Aquadag and encapsulating them with acrylic. X-ray diffraction was used to identify the products phase and study the preferred orientation of the nanorods in the pellets. The morphology and size of the BiSI nanorods were studied under a transmission electron microscope, while the micro structural properties of the pellets were studied by scanning electron microscopy. For the detectors the dark current density (j0) and response to different doses of a 241Am source were studied with j-V curves with forward biasing. The electrical properties were related to the microstructure of the pellets. The solvothermal method yielded pure crystalline BiSI when EG was the medium, while with H2O remnant Bi2S3 was found. The decreasing of reaction times proved that Bi2S3 is not dissolved either in EG nor H2O, indicating that Bi2S3 works as a self-sacrificing template in the formation of BiSI. Furthermore, the Bi2S3 employed has a nanorod morphology, and in both cases BiSI grew in nanorod shape, although for BiSI with EG, amorphous carbon particles were also observed. The pressure seems to induce a preferred orientation of the nanorods within the pellet, but no difference was observed between the fabrication conditions. Alternatively,
HT of pellets produced a change in morphology only for BiSI with EG. The $j_{m}$ measured for BiSI with H$_2$O was in the order of mA, and no further characterizations were made, for these detectors were not suitable for room-temperature detection. For BiSI with EG, the $j_{m}$ of the HT pellet was one order of magnitude lower than for the pellets without it, and its response to the $^{241}$Am source, linear, with a signal to noise ratio of 7 for 20V. Finally, resistivities were calculated, and the best value obtained was in the order of 10$^9$$\Omega$-cm for HT sample. While carbon particles appeared to be a disadvantage for detector performance, they lowered $j_{m}$, allowing for ionizing radiation detection at room temperature. Further work is to be conducted to orient nanorods parallel to the electric field, which would improve charge carrier transport and hence detector performance.

NM03.10.10
Axially Modulation of Metal-Insulator Phase Transition of VO$_2$ Nanowires by Graded Doping Engineering for Optically Readable Thermometers
Pai Geng, Dejun Kong, Pengcheng Chen, Run Shi and Chun Cheng; Southern University of Science and Technology, Guangdong, China.

Temperature measurement is essential to a variety of scientific experiments and technological application. Quantities of thermometers which were used for thermal sensing at macroscopic length scales have been developed and produced. However, it's still challenging to do the in situ and quantitative temperature measurement of nanoscale objects with a convenient and simple approach. In this work, we demonstrate a new type of optically-readable VO$_2$ nanowire-based thermometer. By changing the conditions of reaction, the hydrothermal synthesis of intrinsic H-doping VO$_2$ (M) nanowires has been achieved. During the hydrothermal reactions, the concentration of hydrogen doping can be adjusted by changing the concentration of reductive agent and fusing ratio. After annealing treatment, the dopants or vacancies in as-grown hydric VO$_2$ nanowires can be redistributed or eliminated. Because of the hydrogen doping through hydrothermal fabrication and the hydrogen engineering via a post-annealing process, the single-domain VO$_2$ nanowires obtains a unique axially-gradient phase transition behavior, which makes the advanced thermometer possible. The optically-readable VO$_2$ nanowire-based thermometer is user-friendly and appropriate to microscopic size. What's more, it also has ultra-high relative sensitivity (>17.4% K) and temperature resolution(<0.026K) via optical microscope. It can even achieve an extremely high resolution of (>10-5K) when combining with transmission electron microscope (TEM). The advanced thermometer we demonstrated enables the sensitive monitoring of the thermal environment of small space or the temperature of even nanoscale structure which greatly facilitates the nanoscale scientific experiments and technological application.

Hydrothermal Synthesis of Highly Ordered Monoclinic Phase VO$_2$ Nanowire Array and Research of Microactuator Application
Pengcheng Chen, Pai Geng, Run Shi and Chun Cheng; Southern University of Science and Technology, Shenzhen, China.

Since 1975, the vanadium dioxide has gradually attracted intensive attention for its special metal-insulator transition (MIT), which is followed by amazing applications in electrical, optical and mechanical properties. Based on the change of volume along the structure, Armando Rua in 2010 used polycrystalline thin film of VO$_2$ and Si to produce the double-layer chip, which will occur significant bending when it reaches the phase transition temperature [1]. Besides, Wu also carried out outstanding works based on VO$_2$ bimorph micro-actuator in recent years, like micro-actuator with large amplitude and high power density [2]. These results show that the double-layer chip has a good prospect on the micro-actuator with large displacement, high speed, and large strength, revealing the potential applications on the micro flow valve, micromanipulator, and shape memory structure. However, the application and development of VO$_2$ micro-actuator encountered some obstacles. Polycrystalline films due to grain boundaries, strain-stress and composition ratio will lead to unstable performance of the micro-actuator and the difficulty to further improve it [3]. In comparison, super-aligned VO$_2$ nanowires can effectively improve that [4]. While the current high temperature thermal evaporation method has many disadvantages, such as high power consumption, low yield, and not easy transfer of products from the substrate. To overcome these problems, we propose an approach that using V$_2$O$_5$-H$_2$C$_2$O$_5$ aqueous system to produce the precursor solution under the hydrothermal reaction. Then a layer of antimony is deposited on the smooth surface of quartz substrate by PVD method, next the substrate is inverted into the precursor solution to make the nanowire array growing. In a conclusion, this method could make a large-scale preparation of super-aligned VO$_2$ nanowire arrays. The average length of the array is about 30 μm with 100 nm of diameter, and the density is very large with very high purity. It also solves the transfer problem due to the array growing on the smooth surface, then we use the special polymer to take off the array from the substrate to make films with consistent orientation. Thereby, we could assemble an actuator with the films to do further research.

Small Channel-Length SiC Nanowire Field-Effect Transistors
Ali Uzun and Kasif Teker; Electrical and Electronics Engineering, Istanbul Sehir University, Istanbul, Turkey.

Low-dimensional semiconductor materials offer new ways to develop nanoscale electronic and optoelectronic devices and components. From the class of wide band gap semiconductor nanomaterials, SiC nanowires combine the unique properties of one-dimensional materials with that of superior intrinsic SiC characteristics and offer great opportunities for high power and high frequency electronic devices as well as in sensors capable of operating at high temperatures or hostile environments.

This study presents a systematic investigation of electronic transport properties of p-type SiC nanowire field effect transistors (SiC/NW-FET) with multiple channel lengths (smallest channel length SiC/NW-FET reported). The investigation has focused on the parameters including transconductance ($g_{m}$), carrier mobility ($\mu_{c}$), ON-OFF current ratio (gating effect - $I_{ON}/I_{OFF}$). Further, a comprehensive comparison of our experimental measurements with the previously reported theoretical and experimental studies is presented.

MOCVD-grown long SiC/NWs with diameters about 60 nm are placed on a highly doped SiO$_2$/Si substrate. The electrodes (Cr/Au: 3nm/100nm) are defined by the e-beam lithography (EBL) with varying channel lengths of 120 nm, 220 nm and 1.5 μm followed by metal deposition through e-beam evaporation. The initial electrical measurements from the fabricated p-type SiC NWs-FETs exhibited transconductance of 6.9x10$^{-9}$ A/V (@ $V_{ds}$ = 0.05V),
carrier mobility of $1.7 \text{ cm}^2/\text{V} \cdot \text{s}$, carrier concentration ($n_a$) of $3.72 \times 10^{20} \text{ cm}^{-3}$, and $f_{20}/f_{90}$ ratio more than $10^6$ for a device with 120nm channel length. The gate effect achieved in this study is the highest value reported in the literature for a SiCNW-FET, to the best of our knowledge. As a consequence, this study shows the great potential of SiCNW-FETs to be utilized in nanoelectronic and nanophotonic applications.

Fully Transparent and Printable Thin-Film Transistor Devices Based on Si Nanowires Chan Zhao1,2, Cezhou Zhao1,2 and Li Yang1,2; 1Xi’an Jiaotong-Liverpool University, Suzhou, China; 2University of Liverpool, Liverpool, United Kingdom.

Recently, 1-D nanomaterials, such as semiconductor nanowires (SiNWs), have emerged as interesting materials for the fabrication of high-performance transistors with electronic performance comparable to and in some cases exceeding that of the highest quality single-crystal materials. Preparation of crystalline SiNWs is the use of metal-assisted chemical etching, where solution-nucleated metal plays the important role of a nanoscale electrode in the electrochemical etching of a single-crystalline Si wafer. The metal nanoparticles, such as Ag, oxidize Si that is in contact with them by taking electrons from Si. The oxidized Si, or SiO2, is then etched away by HF in the etching solution, leaving a pit or hole on the Si surface. Finally, Si nanowires result from areas where no metal is present. This can be done even at room temperature without involving high temperature, low pressure, or costly equipment and hazardous materials, which makes metal-assisted chemical etching simple, easy, and economical. Here, we report on studies of transparent and printable thin-film transistor (TFT) devices based on SiNWs. The NW-based devices exhibit uniform characteristics with average field-effect mobilities exceeding 100 cm²/Vs. The nanowires can be aligned and selectively deposited via spray gun under air pressure as a result of evaporation-induced polar solvent flow. Prototype nanowire-based TFTs (NW-TFT) devices on glass substrates showed excellent optical transparency and transistor performance in terms of transconductance, threshold voltage range, and on/off ratio. High on-currents and field-effect mobilities were obtained from the NW-TFT devices even at low nanowire coverage. The SiNW-based TFT approach offers a number of desirable properties such as low growth temperature, high electron mobility, and optical transparency and low operation voltage, and may lead to large-scale applications of transparent electronics on diverse substrates.

Homoeptaxial Growth of GaN Nanorods via Irregular Masks Chang Hsun Huang, Wei I Lee and Yi-Chia Chou; Department of Electrophysics, National Chiao Tung University, Hsinchu, Taiwan.

Gallium nitride (GaN) is widely explored for applications in optoelectronics and high-power electronic devices [1]. For GaN nanomaterials, the high-aspect ratio characteristic combined with quantum confinement reveal the feasibility for light-emitting diodes and lasers to control light extraction with tunable bandgap [2]. Among several nanomaterials of GaN, the rods of it grown without metal catalyst have shown strain relaxation and are more suitable for nanofabrication process without metal contamination. Moreover, GaN nanorods (NRs) with c-orientation provide non-polar and semi-polar facets for reducing the quantum-confined Stark effect (QCES) and thus increase the emission efficiency and intensity of optical devices [3].

In this work, we propose an uncomplex and low cost approach using an irregular mask for GaN NR fabrication on GaN substrate via hydride vapor phase epitaxy (HVPE). The grown GaN NRs are isolated by uncoalesced SiO2 islands, served as irregular mask, and they grew along c-orientation with high aspect ratio. The maximum growth rate of GaN NRs can be achieved of ~1 µm/min. Furthermore, we demonstrate the growth mechanism of GaN NRs under various growth parameters. In addition, in-situ etching effect during the growth of GaN NRs is also discovered. The structural and optical properties of the GaN NRs will be demonstrated in the paper.

Highly Luminescent Double-Heterojunction Nanorods Gryphon Drake and Moonsub Shim; University of Illinois Urbana-Champaign, Urbana, Illinois, United States.

Colloidal semiconductor double-heterojunction nanorods are promising materials for electroluminescent applications due to their favorable band structure and enhanced light coupling efficiency compared to core/shell quantum dots. However, their photoluminescence quantum yield is less than half of the best core/shell structures. However it has been shown previously that Zn-oleate used to grow the ZnSe shell on CdS-CdSe nanorod seed as well as the rate of ZnSe growth in competition with the etching process. We demonstrate significant improvements in ensemble emission linewidth and photoluminescence quantum yield while retaining the advantageous structure and functionality of double-heterojunction nanorods as emitting materials in light emitting diodes with low turn-on voltage and high brightness.

NM03.10.16

Tunable Morphology and Doping of ZnO Nanowires by Chemical Bath Deposition Using Metal Nitrate Pierre Gaffuri1,2; Estelle Appert1; Odette Chaix-Pluchery1, Laetitia Rapenne1, Mathieu Salaün2 and Vincent Consonni1; 1Univ Grenoble Alpes, CNRS, Grenoble INP, LMGP, Grenoble, France; 2Univ Grenoble Alpes, CNRS, Institut Néel, Grenoble, France.

Over the last decade, ZnO nanowires (NWs) have been used for a wide variety of optoelectronic devices, including UV photodetectors and solar cells. For all these applications, their electrical properties, such as their conductivity and mobility, should be controlled as much as possible. ZnO is intrinsically n-type owing to the high density of oxygen vacancies and hydrogen and can intentionally be n-doped, for example, by aluminium. The doping of ZnO NWs has however been mainly performed by vapor deposition techniques. In the present work, ZnO NWs are doped with different metals by using the low-cost, low-temperature, and easily implemented chemical bath deposition (CBD) technique. Metal nitrate is added in various concentrations to the standard precursors (i.e. zinc nitrate and HMTA [1]) in deionized water. It is shown by scanning and transmission electron microscopy (TEM) that this addition completely modifies the structural morphology of ZnO NWs. The formation mechanisms are thoroughly investigated and supported by thermodynamic simulations. The incorporation of metal dopants is further investigated by energy dispersive x-ray spectrometry using scanning TEM. In particular, temperature-dependent Raman spectroscopy measurements show the occurrence of additional modes, indicating the presence of the related dopants [2].

Controlling the growth and properties of ZnO nanowires (NWs) is critical for their efficient integration into nanoscale engineering devices [1]. Owing to the nature of the wurtzite structure, ZnO exhibits a spontaneous polarization along the c-axis. The resulting polarity is known to affect the growth and properties of ZnO single crystals and epiplex films [2], but the polarity-induced effects are mostly unknown in NWs. While ZnO NWs grown by vapor phase techniques are Zn-polar, ZnO NWs grown by chemical bath deposition (CBD) can be of either O- or Zn-polarity [3], which opens the way for more deeply investigating these effects. In this context, we thoroughly address the issue of the polarity-dependent growth and properties of ZnO NWs by CBD following the selective area growth approach [4]. To leave polarity as the only varying parameter, ZnO NWs are grown under identical conditions, during the same run of experiment on O- and Zn-polar ZnO single crystals patterned by electron beam lithography with the same pattern consisting of fifteen different domains combining a wide range of hole diameters and periods. Well-ordered O- and Zn-polar ZnO NW arrays with high structural uniformity are grown on all the domains. The comparison of their typical dimensions unambiguously reveals that Zn-polar ZnO NWs have significantly higher growth rates than O-polar ZnO NWs for all the fifteen domains [4]. The origin of the difference is discussed in the light of surface configurations and interactions in aqueous solution at the top polar c-faces of the ZnO NWs. Additional electrical characterizations of the NWs using four-point probe resistivity measurements are performed on single O- and Zn-polar ZnO NWs [5]. These findings show the relevance of considering polarity as an important quantity to control the growth and physical properties of ZnO NWs by CBD.

We find that the rate of droplet consumption depends on the local environment of each nanowire. In the patterns with small pitch (< 500 nm), where each nanowire is surrounded by other nanowires, the rate of droplet consumption is higher than in patterns with larger pitch. This is due to the increased interfacial area between the nanowires and the droplet, which facilitates the consumption of the droplet. In contrast, in patterns with large pitch, the droplet consumption rate is lower due to the reduced interfacial area.

One way of obtaining a high yield of thin III-V nanowires is to interrupt and resume the growth during standard epitaxy process. This technique leads to a higher yield of thin III-V nanowires than continuous growth. In this study, we investigated the crystalization of Ga droplets on the top of self-catalyzed GaP nanowires. The nanowires were grown on patterned SiOx/Si(111) substrates. The substrates contain patterns with different pitches and hole size. After 2 minutes of Ga deposition without As flux and 20 minutes of nanowire growth at a nominal V/III ratio ~1.2 and temperature ~600°C, we have performed a crystalization step under various P and Ga fluxes. We find that the rate of droplet consumption depends on the local environment of each nanowire. In the patterns with small pitch (< 500 nm), where each nanowire is closely surrounded by other nanowires, the droplet is consumed faster than for patterns with bigger pitches (as well as droplet on nanowires at the border on the patterned area with small pitch).

We propose a simple model describing the evolution of droplet contact angle and radius during crystallization. This model can be used for predicting the geometry of the final crystallized droplet for given III-V fluxes and crystallization time. This data are important for developing the strategy for growing thin nanowires with controlled diameter and length on the top on a thicker stem. The understanding of the processes occurring during crystallization should also allow us to fabricate diameter-modulated nanowires and axial compositional and crystal-phase heterostructures within.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 722176.

This paper discusses the interaction and effect of different atomic layer deposition (ALD) parameters on the properties of a seed layer used to grow zinc oxide (ZnO) nanowires (NWs) by chemical bath deposition (CBD). Independent ALD thin film deposition parameters and their effects on the growth of ZnO NWs are available in the literature. However, to the best of our knowledge, there is little known about the combined influence of these parameters on the NW growth.

ZnO is a direct wide bandgap semiconductor (3.37 eV) with a high exciton binding energy (60 meV). It can be synthesized in many different one-dimensional morphologies. ZnO NWs are one of the most attractive due to some of their intrinsic properties, e.g. their high surface area and aspect ratio. The combination of electrical properties and 1D morphology makes ZnO NWs a very promising material for a wide variety of applications such as field effect transistors, water treatment, sensors or solar cells.
ALD is a thin film deposition technique based on the stacking of deposited atomic or molecular layers from the precursors, which yields thin films (around 30 nm in this work) with conformal surface coverage and compositional control. In ALD, different precursors (diluted zinc and water in this case) are dosed alternately under a constant flow of nitrogen gas with a purge time when only nitrogen flows. Each precursor chemisorbs to the previous layer of the film, forming atomic layers. Thus, an ALD cycle consists of the sequence of pulses and purges of the precursors. It is essential to have control over the different properties of the film such as composition, crystallite size, roughness or thickness as they have a direct effect on the properties of the as-grown NWs (orientation, size and crystallography). These properties are controlled by tuning the deposition parameters, e.g. temperature, number of cycles or the pulse and purge times.

The CBD process involves two chemicals, the zinc source (Zn(NO3)2*6H2O) and the reducing agent, hexamethylenetetramine. These reagents are dissolved in DI water before the substrate with the seed layer is submerged in the solution. Various characterization techniques such as scanning and transmission electron microscopy (SEM & TEM), x-ray diffraction (XRD), x-ray photon spectroscopy (XPS) and photoluminescence (PL) were utilized to investigate the properties of the NWs and to study the changes resulting from the thin film deposition parameters. This investigation thus demonstrates the controlled growth of single crystal wurtzite phase ZnO NWs using this low-cost process.

NM03.10.20 Nanowire Network Based Multifunctional All-Optical Logic Gates Vladislav Khayrudinov1, He Yang1, Veer Dhaka1, Hui Jiang2, Anton Autere3, Harri Lipsanen1, Ziyou Sun1 and Henri Jussila1; 1Department of Electronics and Nanoeengineering, Aalto University, Espoo, Finland; 2Department of Applied Physics and Nanomicroscopy Center, Aalto University, Espoo, Finland; 3QTF Centre of Excellence, Department of Applied Physics, Aalto University, Espoo, Finland.

All-optical nanoscale logic components are highly desired for various applications because light may enable logic functions to be performed extremely quickly without the generation of heat and crosstalk. All-optical computing at nanoscale is therefore a promising alternative but yet requires the development of a complete toolbox capable of various logic functionalities. Herein, we demonstrate nanoscale all-optical switches by exploiting the polarization dependent light emission property of crossbar InP and AlGaAs nanowire networks. These networks can perform various logic operations, such as AND, OR, NAND, and NOR binary logic functions. Furthermore, based on these logic operations, our networks successfully enable all-optical arithmetic binary calculations, such as n-bit addition. Our results underscore the promise of assembled semiconductor nanowire networks as a building block of on-chip all-optical logic components for future nanophotonics.

NM03.10.21 Development of Hybrid Structures for the Electrodynamic Screen (EDS) Films to Mitigate Energy Yield Loss Incurred by Solar Collectors Due to Soiling Annie Rabi Bernard, Ryan Eriksen and Malay Mazumder; Boston University, Brookline, Massachusetts, United States.

Over the last few years, silver nanowire (AgNW) has gained prominence as the ideal material for transparent electrodes owing to its high conductivity, transmission efficiency and availability over other transparent conductive electrode materials. Enhancement of the stability of AgNW in an outdoor environment is currently widely researched, since the nanowires prove to be short-lived when exposed to harsh on-field conditions over an extended period of time. This study aims at establishing environmentally stable and viable AgNW electrodes of an Electrodynamic Screen (EDS) film, by the inclusion of one or more protective layers of zinc Oxide (ZnO) prepared in lab in a 1) stacked structure where the AgNW electrode has a layer of ZnO on top for protection or a 2) sandwiched structure wherein the AgNW electrode is covered by ZnO layers, protecting it from the top and bottom. A second experiment to include a protective polymer based overcoat layer atop the AgNW electrodes of the EDS film is also discussed here. The EDS film technology consists of an ultrathin glass layer on which rows of parallel electrodes are deposited. The EDS film, when retrofitted on solar collectors, has proved to be a viable solution to mitigate the energy yield loss caused by soiling. Concerns regarding the presence of electrodes that could block a section of the incoming light to the solar collector and thereby potentially decreasing the output of the solar cell are addressed by using AgNW as it is a transparent conducting ink material. When dust particles are in contact with the optical surface, the EDS film charges the dust particles electrostatically, applies an electrostatic repulsion force to levitate the dust layer and removes it with a sweeping action by an electromagnetic traveling wave. Measurements of the dust removal efficiency of the EDS film will be performed after extended/accelerated exposure to UV light, high humidity, and moisture. Testing procedures of the hybrid AgNW electrode structures consist of calculated UV exposure measurements in lab as well as field testing setup, while checking the conductivity and performance of the electrodes of the EDS in terms of its efficiency in removing dust. The electrodes will be activated by a three phase voltage ranging up to 1.2 kilo volts and tests will be done to ensure the viability of the electrodes when subjected to such high voltage. EDS film thus developed will also be subjected to high temperature and humidity conditions simulated in an environmental chamber installed in lab. A complete water immersion test will also be performed in order to ensure functionality and efficiency of the EDS film in the case of rain.

NM03.10.22 Electrodeposition of Nanowires into Silica and Alumina Templates with Pore Sizes Down to 2 nm Andrew L. Hector; University of Southampton, Southampton, United Kingdom.

Supercritical fluids have low surface tension and viscosity, so provide high mass transport rates in nanoporous structures. However, due to low dielectric constants and the need to work at elevated temperature and pressure there is little published work on electrodeposition from supercritical systems. The deposition of tin nanowires from supercritical difluoromethane into 13 and 55 nm anodic alumina templates will be described. The size limits of the technique have also been tested with tin deposition into ~2 nm pore mesoporous silica templates, and the evidence for deposition into these very small pore systems will also be described.

NM03.10.23 Synthesis of Folate Receptor Targeting Coaxial PDA-F-A/P(MAA-co-EGDMA) Nanotubes for Drug Delivery Sezin Sayin1, Ali Turfani1 and Gozde Ozaydin Inci2,3; 1Materials Science and Nano Engineering, Sabanci University, Istanbul, Turkey; 2Sabanci University Nanotechnology Research and Application Center (SUNUM), Istanbul, Turkey; 3Center of Excellence for Functional Surfaces and Interfaces (EFSUN), Istanbul, Turkey.

Nanotubes have an important role in drug delivery application. Biocompatible and biodegradable nature makes polymeric nanocarriers preferable. Functional and responsive polymers can be loaded without degradation of drug molecules. Polymeric nanotubes result in longer residence time and greater activity due to cylindrical shapes. The scope of this study is to synthesize pH responsive coaxial nanotubes with folate receptor targeting for cancer.
treatment applications. Coaxial nanotubes are fabricated with the outer side of polydopamine-folic acid and inner side of p(MAA-co-EGDMA). Initiated chemical vapor deposition (iCVD) technique involving free radical polymerization is used for H response, non-soluble poly(methacrylic acid-co-ethylene glycol dimethacrylate) p(MAA-co-EGDMA) nanotubes fabrication. Conformal deposition is achieved by anodized aluminum oxide (AAO) template. Due to vapor phase synthesis, disadvantages of solution-based fabrication methods as solvent toxicity can be prevented in iCVD fabrication. Structures and compositions of nanotubes are characterized by scanning electron microscopy and Fourier transform infrared spectroscopy. Thickness measurements and swelling behavior are investigated by ellipsometry. Drug loading and release mechanisms are studied using model drug molecule.

NM03.10.24
Microstructural Properties of ZnO Nanowires Grown by Hydrothermal Synthesis on GAZO Thin Films Edigar Muchuwe1,1, , Thangiah S. Sathiraj2 and Huggins Nyakotyo1,1, 1Botswana International University of Science and Technology, Palapye, Botswana; 2Bindura University of Science Education, Bindura, Zimbabwe.

ZnO nanowires have gained significant research attention in recent years due to their novel properties which make them suitable for use as transparent electrodes in optoelectronic devices such as solar cells, touch screens and light emitting diodes. ZnO nanowires exhibit a single crystalline structure which has few grain boundaries and defects, leading to better optoelectronic properties than those of bulk and thin film forms of ZnO. In addition, ZnO nanowires have large surface-to-volume ratios and efficient charge transport along the wire axis which makes them more attractive for transparent electrode fabrication and light harvesting in solar cell structures. In the present work, we present the morphological characterization of ZnO nanowires grown by hydrothermal synthesis on glass substrates seeded with GAZO thin films.

The GAZO thin films were prepared by radio frequency magnetron sputtering using a 99.99% purity Ga/Al/ZnO (1.14:0.62/98.24 wt%) target (HHV, UK) of diameter, 76.2 mm and thickness, 3 mm. The sputtering conditions included, target to substrate distance of 130 mm, base pressure of 1.13 x 10^-5 mbar, working pressure of 1.20 x 10^-2 mbar, argon flow rate of 12 sccm, substrate temperature of 100 °C, rf power of 150 W and seed layer thickness of 385 nm. The ZnO nanowires were subsequently grown by suspending the GAZO thin film substrate upside-down in a mixture of equimolar 25 mM zinc nitrate hexahydrate (Zn(NO3)_2.6H2O, 99% purity, Sigma-Aldrich, USA) and hexamethylenetetramine (HMTA, C6H12N4, Sigma-Aldrich, 99% purity, USA) aqueous solutions at 90 °C for 2 h. After the growth process, the samples were rinsed thoroughly with deionized water to remove any residual zinc salts and dried in air at room temperature. Surface morphology of the GAZO seed layer and ZnO nanowires was characterized by atomic force microscopy (AFM) using a Bruker Dimension Edge AFM and field-emission scanning electron microscopy (FE-SEM, JEOL JSM-7100F, Japan), respectively. Elemental compositions were studied by energy dispersive spectroscopy (EDS) equipped in the FE-SEM.

AFM microscopy revealed that the GAZO seed layer had a root mean square surface roughness of 6.1 nm and was uniformly covered with particles of mean size 77.8 nm. These nanoparticles acted as nucleation centres for nanowire growth. The ZnO nanowires were well-aligned with hexagonal prism shapes and uniform diameters (100-200 nm) along their entire lengths. EDS spectrum confirmed that the ZnO nanowires were closer to stoichiometric ZnO (1:1).

NM03.10.25
Template-Free Synthesis of Highly Luminescent Organic Nanorods by Air Oxidation of para-Substituted Anilines Yoonsang Park1 and Woosung Kwon2; 1Chemical Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of); 2Chemical and Biological Engineering, Sookmyung Women's University, Seoul, Korea (the Republic of).

Oxidation of aniline provides useful multi-dimensional organic nanostructures with a wide variety of morphologies and sizes ranging from the nanometer scale to the micrometer scale. In this study, novel one-dimensional luminescent organic nanorods (ONs) were synthesized through air oxidation of para-substituted anilines without any shape-guiding surfactants. These ONs show highly crystalline rod-like structures due to π-π interactions between the phenazine-like structures which are formed by air oxidation of para-substituted aniline. Also, ONs show bright, photostable, deep-red luminescence with high quantum efficiency (up to 46%). From photoluminescence spectroscopy, absorption spectroscopy, time-correlated single photon counting, and time-dependent density functional theory calculation, it is revealed that their luminescence are originated from the phenazine-like structures. Finally, we demonstrate the potential application of our ONs as a freestanding color filter for deep-red-light-emitting devices that could be applied for color pixels of future displays. Our study provide a new strategy for the synthesis of luminescent organic nanomaterials, and show their potential for optoelectronic applications.

NM03.10.26
Rational Design of Hierarchical Nanosheet-Based SnO2 Nanotubes Functionalized with Pt Catalyst for Application in Exhaled Breath Sensor Hee-Jin Cho, Ji-Soo Jang, Won-Tae Koo, Dong-Ha Kim and Il Doo Kim; KAIST, Daejeon, Korea (the Republic of).

Tailoring of semiconducting metal oxides (SMOs) with hierarchical nanostructures is of importance to accurately detect sub-ppm concentrations of biomarkers for easy diagnosis of specific diseases through exhaled breath analysis. Therefore, several researches have been reported to maximize the surface area and porosity of gas sensing layers since the pore size and pore distribution significantly affect the penetration of biomarker molecules into the sensing layers, whereas a large surface area provides more reactive sites, thereby enhancing the sensitivity. In this work, efforts were made to improve the sensitivity and the selectivity toward acetonol detection using one-dimensional (1-D) SnO2 nanotubes. First, we prepared hierarchical SnO2 nanostructures, which consisted of hollow nanotubes in the core and the two-dimensional (2-D) nanosheets on the shell. The nanosheet-based hollow SnO2 nanotubes were synthesized by a combination of electrospinning approach and hydrothermal method. The carbon nanofibers were fabricated as a scaffold for the 1-D structure. Then the growth of SnO2 nanosheets and the removal of core carbon nanofibers were achieved by the hydrothermal route followed by high temperature calcination. The nanosheet-based pure hollow SnO2 nanotubes exhibited highly sensitive acetonol sensing property (R_0/R_Acetone = 25 at 5 ppm). Secondly, to further improve the sensitivity and selectivity, the catalytic functionalization was performed. The Pt functionalized nanosheet-based SnO2 nanotubes exhibited superior acetonol detection capability under highly humid condition similar to that of exhaled breath (95% RH). The enhanced sensing characteristics suggested a significant potential for precise detection of acetonol in exhaled breath using the Pt functionalized nanosheet-based SnO2 nanotubes.

NM03.10.27
Surface-Engineering of Zinc Oxide Nanowires Encapsulated with Zeolitic Imidazolate Framework-8 for Gas Sensors Jin Su Jeon1,1, 1, Woosook Song1, Sung Myung1, Sun Sook Lee1, Jongsun Lim2, Jinha Hwang2 and Ki-Seok An1; 1Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Hongik University, Seoul, Korea (the Republic of).

Recently, hybridization of metal oxide nanostructures with functional materials has been gaining a lot of attention for enhancing gas sensing performance. Especially, zeolitic imidazolate framework-8 (ZIF-8), a subclass of metal organic frameworks (MOF), is an adoptable material for integrating ZnO-based gas sensors owing to its high internal surface area, subnanometer-sized cavities, thermal stability, and chemical controllability. It is well-established that
the hybridization of ZnO with ZIF-8 allows the improvement of gas selectivity owing to molecular sieving capability induced by well-defined porous structures. Core-shell size = 3.4 Å. Here, we focused on the effects of preconcentration of ZIF-8 hybridized with ZnO nanowires in terms of NO2, NH3, and H2 gas sensitivity as well as gas selectivity. Hydrothermally-grown ZnO NWs are employed as a support material for the nucleation and growth of ZIF-8 nanocrystals, in which their morphological features were optimized by adjusting growth conditions including solution concentration, reaction time, and temperature. The thickness of encapsulated ZIF-8 can be effectively manipulated by the concentration of HmIM, which strongly affects to gas sensitivity of ZIF-8/ZnO NWs-based gas sensors because of a variation in gas diffusion path. For ZIF-8/ZnO NWs synthesized using 8 mM HmIM solution, NO2, NH3, H2 gas sensitivity was improved significantly compared to that of pristine ZnO NWs. Based on these results, two effects are anticipated to improve both gas sensitivity and selectivity after the hybridization of ZnO NWs with ZIF-8 nanocrystals.

NM03.10.28

Perovskite Nanocatalysts Sensitized SnO2 Fiber-in-Tube Scaffold Toward Superior Formaldehyde Gas Sensors Joon-Young Kang, Ji-Su Jang, Won-Tae Koo, Dong-Ha Kim and Il Doo Kim; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Sensitive and selective gas detection of low concentration (even at sub-ppm level) have been required in various fields for indoor air quality and accident prevention. Among various chemical gas sensing materials, electrospun one-dimensional semiconducting metal oxides (SMOs) are considered as ideal building blocks, due to their large surface area, high porosity, and facile synthesis process. To further enhance their sensing performances, catalytic functionalization is essential in SMOs-based gas sensors. Conventionally, noble metal catalysts, such as Pt, Pd, and Au, have been widely studied to promote the gas sensing properties of SMOs by means of electronic and/or chemical sensitization. However, nanoscale noble metals are readily agglomerated and degraded during long operation cycles at high sensing temperature. Therefore, a new catalytic material with high thermal stability and low cost is highly desired for SMOs-based chemiresistors.

In this work, highly porous SnO2 fiber-in-tubes (FITs), which are sensitized with perovskite oxides, i.e., La1.04Sn1.02Cu2.3Mn0.7O8.5 (LSCM) particles as chemical sensitizers, are used as a superior formaldehyde (CH2O) sensing layer. LSCM particles affected the morphologies of electrospun Sn precursor/polymer composite fibers during the calcination step, resulting in the fiber-in-tube (FIT) SnO2 structures with high surface area and porosity. Furthermore, LSCM particles with a high oxygen vacancies concentration and a large work function significantly provide surface oxygen species (O2-) that promote electron depletion on the surface of SnO2, leading to the dramatic resistance variation. As a result, LSCM-loaded SnO2 FITs (LSCM@SnO2; FITs) provide remarkably high response to formaldehyde (Rmax/Rmin = 26.50 to 5 ppm) and excellent selectivity against interfering gases (H2, CH4, NH3, C2H8O, C3H6, CO, and C2H2), even without using noble metal catalysts. Particularly, the role of complex composition of LSCM particles, played in the oxygen supply effect of LSCM particles, and the synergistic effect with FIT structures, were first described in this work. These observations demonstrate the potential use of LSCM@SnO2 FITs for real-time monitoring of indoor air quality, especially toward formaldehyde, which is not accurately detected by conventional metal oxide based sensors.

NM03.10.29

Templated Synthesis of Dy-BiFeO3 Nanotubes and Assessment of Its Photocatalytic Performance as Compared with Nanoparticulate Systems Carlos Ostos and Lima M. Castro, Antioquia, University of Antioquia, Medellin, Colombia.

In recent years semiconductor photocatalysis under visible light irradiation has become of great importance as an alternative technology for environmental remediation. Despite the intensive efforts on developing semiconductor materials for improving the efficiency on these tasks, there is still a shortage in the development of an efficient photocatalyst. At this point, nanostructured BiFeO3, a p-type semiconductor with a small band gap (2.2 eV) emerges as a promising material with multifunctional properties for harnessing in photocatalytic applications. Nevertheless, the good photocatalytic performance is strongly correlated with the design of the semiconductor at the nanoscale. Among various structures, one-dimensional (1D) nanostructured BiFeO3 photocatalysts are very interesting owing to their unique properties. To mention some, 1D geometry provides fast and long-distance electron transport. Furthermore, the high length-to-diameter ratio enhances the light absorption. And finally, 1D nanostructures have a larger specific surface area as compared with corresponding commonly used nanoparticulate material. The remarkable characteristics of the material make it of great significance to investigate into its potential photocatalytic activity.

For comparison purposes, in this work we present the synthesis of both 0D and 1D systems of Bi1-xDyxBiFeO3 (0 ≤ x ≤ 0.15), with structural configurations that offer important multifunctional characteristics. Moreover, the replacement of Dy3+ ions into the Bi3+ sites, has the purpose of optimizing the physical properties of the material and encouraging its performance in the degradation of organic compounds in diluted aqueous media. The synthesis of phase-pure Bi1-xDyxBiFeO3 0D systems was systematically monitored via sol-gel route and the dimensional parameters of 1D systems were regulated from their assembly in commercial and lab made anodized aluminium oxide (AAO) templates. The desired geometrical features of the lab made templates were selected by means of Box-Behnken experimental design. After selecting the best pore features, the templates were immersed into aqueous and non-aqueous precursors solutions, with the aim to assess the wettability of templates and its influence into 1D morphologies. The microstructural characterization of the as obtained Bi1-xDyxBiFeO3 (0 ≤ x ≤ 0.15) 0D and 1D systems was assessed by means of XRD, SEM, TEM and BET. Finally, the photocatalytic activity by the Rhodamine B degradation as a test molecule, demonstrates that tubular structures supported in commercial AAO with 15% of Dy substitution had the greater performance in comparison with one dimensional structures supported in lab made templates and the assessed 0D systems. The rates of degradation reported in this work are higher than the reported before for bismuth ferrite one-dimensional structures.

NM03.10.30

Coaxial Copper Nanowire Network Core—Polymer Shell Nanocomposites as Supercapacitor Electrodes Mete Batuhan Durukan1,2, Sevin Polat Genlik1, Dogancan Tigan1 and Husnu E. Ural1,2; 1Department of Metallurgical and Materials Engineering, Middle East Technical University, Ankara, Turkey; 2Energy Storage Materials and Devices Research Center (ENDAM), Middle East Technical University, Ankara, Turkey.

Metallic nanowires hold significant potential to be used in energy storage devices, such as batteries and supercapacitors due to their high surface area and electrical conductivity. Among metallic nanowires, silver nanowires so far dominated the literature due to their reproducible, controllable and large scale synthesis. Copper nanowires on the other hand are still at their infancy; but, hold strong promise to replace silver nanowires due to their comparable optoelectronic properties and low cost. In this work, hybrid nanocomposite electrodes with copper nanowire core and polypyrrole shell (Cu NW/PPy) were fabricated and electrochemically characterized. Hybrid nanocomposite electrodes were fabricated through spray deposition of Cu NW networks onto glass substrates, followed by electrochemical deposition of PPy onto Cu NW network. Electrodeposition was performed onto Cu NWs by applying a constant current in an electrolytic solution containing benzotriazole (BTA), oxalic acid and pyrrole monomer. Capacitive behavior of the hybrid coaxial nanocomposites was investigated through cyclic voltammetry, galvanostatic charge-discharge and impedance spectroscopy. Cu NWs facilitated the charge transfer and PPy behaved both as a pseudocapacitive material and as a protective shell to improve the electrochemical stability of Cu NWs. Preliminary analysis shows a specific capacitance of 0.12 mF/cm2 at a scan rate of 100 mV/s in 1 M LiClO4 in PC. Thorough analysis on the electrochemical stability and capacitive behavior of the fabricated nanocomposite electrodes will be presented in conjunction with different electrochemical coating parameters and different electrolytes.
Electrochemical Phosphate Sensors Using Silver Nanowires Treated Screen Printed Electrodes

Md Tawabur Rahman, Md Faisal Kabir, Ashim Gurung and Qiuquan Qiao; Electrical Engineering & Computer Science, South Dakota State University, Brookings, South Dakota, United States.

Essential biomolecules of the human body and plant growth depend upon the proper amount of phosphate ions. Phosphorus has critical values in both agricultural and biomedical applications. There is a need for inexpensive, portable, repeatable, highly sensitive, and field deployable sensors with wide detection range to monitor the health of water system and field soil. This paper aims to develop an electrochemical phosphate sensor using novel ammonium molybdate tetrahydrate/silver nanowires (AMT/AgNWs) modified screen printed electrode (SPE) for phosphate detection to achieve simplicity, high sensitivity, wide detection range, and high repeatability and portability. The cyclic voltammetry measurements exhibited the sensitivities of AMT modified SPE without and with AgNWs are 0.1 μA/μM and 0.71 μA/μM, respectively. The use of highly conductive AgNWs significantly increased the sensitivities of the AMT/SPE. Besides, AgNWs and AMT modified SPE (AMT/AgNWs/SPE) showed a very wide detection range of 5 μM–1 mM. The maximum relative standard deviation of around 5% confirms the repeatability of the proposed sensor. This paper suggests that AMT/AgNWs/SPE is promising for simple, low-cost, and portable phosphate ion detection.

NM03.10.32
Control the One-Dimensional Growth of PbSe Nanorods Through Dipole-Dipole Interaction
Yiteng Tang1, Zhoufeng Jiang1, Paul J. Roland2, Randy Ellington2, Wenhui Wan3, Yuguang Yao4, Fan Zhang3 and Liangfeng Sun5; 1Bowling Green State University, Bowling Green, Ohio, United States; 2University of Toledo, Toledo, Ohio, United States; 3Beijing Institute of Technology, Beijing, China; 4The University of Texas at Dallas, Dallas, Texas, United States.

Lead selenide (PbSe) represents a promising thermoelectric material owing to its high thermolectric figure of merit. This property is expected to be further enhanced in anisotropic one-dimensional structures. A few research groups have synthesized colloidal PbSe nanowires/nanorods previously, where the one-dimensional oriented attachment was identified to be the primary growth mechanism. However, the microscopic mechanism of the growth is still poorly understood.

In our experiments, we demonstrated that long nanorods could only grow in reaction solution while the PbSe quantum dots were terminated by short ligands. If the quantum dots are terminated by long ligands, few nanorods are formed. This means that the attaching process can be turned on or off by tuning the length of surface ligands on the quantum dots, i.e. the dipole-dipole interaction between them. Using the amount of surface charge obtained experimentally by another research group, we calculated the dipole-dipole interaction energy between the quantum dots in the reaction solution and compared it with the thermal energy at the reaction temperature. We found that the calculated dipole-dipole interaction energy is above/below the thermal energy when the short/long ligands were used to terminate the PbSe quantum dots, which is consistent with the experimental results. Not only it reveals that the dominant growth mechanism is the one-dimensional oriented attachment of quantum dots, but also it proves that the length of the surface ligands on the quantum dot can control the process.

The reaction temperature also has a significant effect on the growth of nanorods. At higher reaction temperature, the dominant growth mechanism shifts from kinetics (oriented attachment) to thermodynamics. In the latter case, no nanorods but large quantum dots are formed.

The synthesized nanorods have a high photoluminescence quantum yield of more than 30% and photoluminescence lifetime near 1 microsecond. Both indicate that the nanorods have low defects and a high quality.

NM03.10.33
Cadmium Telluride Nanowires Growth for Photovoltaic Application
Manuel Apollo1, Wojciech Stepniowski2, Massimo Tormen3 and Kenneth Duruse4; 1University of Liverpool, Liverpool, United Kingdom; 2Lehigh University, Bethlehem, Pennsylvania, United States; 3ThunderNIL Srl, Trieste, Italy.

There is a global drive to increasing the efficiency, performance and cost effectiveness of renewable energy sources including the photovoltaic (PV) devices. Currently the PV market is dominated by silicon (Si) solar cells technology. Although their performances, they suffer technological limitations, such as an indirect bandgap and low absorption coefficient. An alternative material like cadmium telluride (CdTe), a II-VI semiconductor, exhibits a direct bandgap of approximately 1.45eV, which enables optimal absorption of the solar radiation. Therefore high efficiency CdTe solar cells are thinner and more economically convenient than Si solar cells[1].

In addition, it is possible that nanostructures may be used to create new kinds of devices with enhanced optical performance over existing structures. It is the aim of our project to explore these opportunities, in particular the possibility of growing nanowires (NWs) in the template assisted method, using aluminum oxide membranes or nanoimprints supplied by ThunderNIL Srl.

Once obtained the templates, different techniques relating the nanostructures growth (sublimation, VLS, CSS, spattering, spin coating) will be explored. The nanostructures so obtained will be characterized via XRD, SEM, UV-UVS-IR. It is the aim to then fabricate and test working solar cell devices from the nanowire materials via impedance analysis, current-voltage, capacitance voltage, PV performance (Air Mass 1.5).

Our goal is to demonstrate that is possible to manufacture high performant and cost effective CdTe nanostructured solar cells.

Facile, Sing-Step Hydrothermally Synthesized Sb-Doped ZnO Nanorod Arrays with Highly Improved Efficient UV-Sensing Properties
Donghyung Kim, Hongsseon Song, Miniki Baek, Minseok Lee, Dokyung Kim and Kijung Yong; Chemical Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

The synthesis of electrical and optical property-modulated, low-dimensional metal oxide semiconductors has been adopted for the development of nanodevices. However, conventional modulation methods, such as doping and alloying, generally require complex and expensive processes, such as multi-step high-temperature reactions, gas-phase growth, high-vacuum processes, etc. Alternatively, in the current study, the facile and cost-effective synthesis of Sb-doped ZnO nanorod arrays (NRAs) is achieved using a simple hydrothermal growth process at 95 °C. Through a single-step reaction, Sb atoms are substitutionally doped at the Zn atom sites with control of the Sb concentration. Sb dopants and Sb-induced oxygen vacancies increase the electron concentration in the ZnO NRAs, enhancing the electrical conductivity of the ZnO NRAs and inducing the further adsorption of ambient oxygen molecules on the nanorod surface. Upon UV irradiation of the highly oxygen-adsorbed, Sb-doped ZnO NRAs, the desorption of oxygen induces greater conductivity changes compared to the undoped samples. Based on this enhanced resistivity change, UV sensor devices were fabricated, and an improved reversible UV sensing performance was observed, with a 9-fold enhancement in the photocurrent of the ZnO NRAs after Sb doping. Moreover, UV sensing is achieved...
even under an extremely low bias of 10⁻⁴ V, suggesting the promising application of this material in extremely low-power UV sensor devices.

**Polarization-Sensitive Single-Crystal Sb2Se3 Nanowire Motor** Xiaojun Zhan; The University of Hong Kong, Hong Kong, Hong Kong.

Antimony selenide (Sb2Se3), a non-toxic earth-abundant promising absorber material for light harvesting, is inherently one dimensional crystal structure, covalent band within the chain and van der waals bond out of the chain. Such anisotropy has been studied for crystal oriented solar cell device and strong in-plane asymmetry of Sb2Se3 nanosheets. However, all of recently reported light-stimulated nano/micromotor systems haven’t utilized the polarized light, potential substitutional channel to wavelength or light intensity. Here an atomic smooth axis-oriented single-crystal Sb2Se3 nanowires are successfully prepared through vapor transport deposition method (VTD) possessing higher electrical conductivity than hydrothermal synthesized and bulk film counterparts and polarized response of incident light. Furthermore, coupled with a layer of conformal N type zinc oxide (ZnO), polarized light intrigued nano/micromotors’ motion is achieved for the first time. Besides the solar cell device behaviors of single-crystal Sb2Se3 nanowire and bulk Sb2Se3 film are compared and suggest the experimental limit for crystal oriented Sb2Se3 solar cells.

**Influence of Gold Catalyst on the Growth of Titanium Nitride Nanowires** Panupong Jaipan¹, Chandra Shekar Reddy Nannuri¹, Nikhil R. Mucha¹, Adele Moatti², Jagdish Narayan², Svitlana Fialkova³ and Dhananjay Kumar³; ¹Mechanical Engineering, North Carolina Agricultural and Technical University, Greensboro, North Carolina, United States; ²Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States.

A systematic study was conducted to investigate the influence of Au catalyst thickness and Au nanodots size on the growth and morphological properties of Titanium Nitride (TiN) nanowires. The Au nanodot size has a significant influence on the diameter and length of the TiN nanowires. The fabrication of TiN nanowires induced by gold catalyst was successfully achieved at 800 °C. The nanowires were found to have their diameters in the range of 9 nm to 13 nm and their lengths from 96 nm to 430 nm. Our study has shown that Au nanodots with diameters in the range of 10-13 nm allows favorable conditions for TiN nanowire growth. On the other hand, the Au nanodots size with a diameter less than 10 nm are not able to induce the growth of TiN nanowires due to a high activation barrier to grow a nanowire with a small radius of curvature even in the presence of the catalyst. Furthermore, if the nanodot size is larger than 14 nm, the particle tends to behave as a bulk gold and loses its catalytic activity. The existence of a lower and upper threshold limit in the Au nanodots size is marked by the absence of TiN nanowire formation in both regions.

**Nano-Heterostructures Based on Oxide Nanowires—Synthesis and Characterization** Bianchi Mendez; University of Complutense, Madrid, Spain.

Oxide nanowires are an attractive family of functional materials that offer a lot of versatility in the applications: optical and mechanical resonators, lasing, sensors, photo-catalysis, solar cells, and biomedical and healthcare usages, to name a few. Besides, when it comes to the nanoscale, they can adopt a wide range of morphologies within the quasi-one dimension (nanowires, nanobelts, or nanorods). Some of the current challenges are focused on getting controllable doping, controllable luminescence or controllable architectures. In this last case, it would be worthy of attention to explore novel nano-heterostructures by making junctions of different oxides and/or even different dimensionality. We have experience on the study of physical properties of single oxides nanowires, and in particular their optical properties. Here, we report the synthesis and characterization of complex nanostructures of oxide nanowires in which Ga₂O₃ and Zn₂GeO₄ nanowires combine with SnO₂ particles, flakes or wires. The synthesis method is the thermal evaporation of the suitable chemical precursors on a catalyst-free basis via a vapor-solid mechanism. One of the key points to get the selected architectures is the presence of certain impurities, which influences the growth direction of the axis nanowire. This is important since the central oxide nanowire serves as substrate for the nano-oxides grown on it. The growth model of the nano-heterostructures will be discussed with the aid of high-resolution transmission electron microscopy.

**Bottom-up Engineering of Hematite Nanowire Heterostructures for Photoelectrochemical Water Splitting** PengYi Tang¹,², HaiBing Xie¹, LiJuan Han¹, Carles Ros², Marti Biset Peiro³, José Ramón Galán-Mascarós¹,⁴, Teresa Andreu², Juan R. Morante² and Jordi Arbiol¹,⁴; ¹Institut Català de Nanociència i Nanotecnologia (ICN2), CSIC and BIST, Barcelona, Spain; ²Catalonia Institute for Energy Research (IREC), Barcelona, Spain; ³Institute of Chemical Research of Catalonia (ICIQ), The Barcelona Institute of Science and Technology (BIST), Tarragona, Spain; ⁴ICREA, Pg. Lluís Companys 23, Barcelona, Spain.

The development of technologies for H₂ production or CO₂ reduction strongly relies on an abundant supply of protons and electrons liberated by water oxidation. [1-2] Therefore, photoelectrochemical (PEC) water oxidation is an important anodic half-cell process in the development of a sustainable artificial solar fuel system. In the PEC devices design, coupling water oxidation catalysts with active photoanode materials has become the most promising methodology, since the attachment/integration of the catalyst on the semiconductor light absorbers could kinetically facilitate interfacial charge transfer reactions.

In this contribution, we have fabricated ITO/Fe₂O₃/Fe₂TiO₅/FeNooH multi-layers nanowire heterostructures via combination of sputtering, hydrothermal, ALD, photo-electrodeposition methods for photoelectrochemical (PEC) oxygen evolution application. Structural, spectroscopic and electrochemical investigations disclose that the origin of the superior catalytic performance is owing to the interfacial coupling effect of ITO underlayer (Sn doping and conductivity promoter), ultrathin Fe₂TiO₅ coating (Ti doping, energetics and surface state density modulation) and FeNooH eletrocatalyst (varying surface state energy level). [2]

Meanwhile, an alternative earth-abundant CoFe prussian blue analogues (CoFe PBA) is incorporated in core-shell Fe₂O₃/Fe₂TiO₅ type II heterojunction nanowires as photoanodes for PEC water oxidation. The observed photocurrent is improved from 0.12 mA cm⁻² to 1.25 mA cm⁻² at 1.23 V vs. RHE under illumination by involvement of ultrathin Fe₂TiO₅ layer and CoFe PBA WOCs coating. Further investigation of the PEC mechanisms via
photoelectrochemical impedance spectroscopy unveils that the enhanced PEC performance of hematite nanowires is attributed to the enhanced charge transfer efficiency owing to the tuned energy level and density of surface state. [3-4]

Surmounting the Carrier-Transport and Stability-Bottleneck of III-Nitride Nanowire Solar-Water-Splitting Device for Efficient and Sustainable Hydrogen Generation [4] Mohammad F. Chowdhury*, Hong Guo and Zetian MI, 1, 2; 1, 2-Electrical and Computer Engineering, McGill University, Montreal, Quebec, Canada; 1, 2-Electrical Engineering and Computer Science, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 1, 2-Department of Physics, McGill University, Montreal, Quebec, Canada.

Hydrogen generation from the two of the most abundant free resources available on earth, i.e. sunlight and water via photocatalytic water splitting, is a very appealing approach for the crucial societal transition to a clean and sustainable energy resource future. High-efficiency devices for photovoltaic-assisted photoelectrochemical (PEC) water splitting and electrolysers are reported in conductive electrolytes with selective pH adjustments. However, direct splitting of pure or sea water with significantly enhanced device-longevity at concentrated sunlight holds enormous promise for hydrogen generation at pH-neutral condition without any external bias, sacrificial reagent or conductive electrolytes. Progress in this field has been limited by the low photocatalytic efficiency of conventional metal-oxide materials. We have recently demonstrated that nearly defect-free GaN-based nanostructures can meet the thermodynamics for overall water splitting (OWS) [1]; and by tuning the surface Fermi-level through controlled Mg-dopant incorporation, the apparent quantum yield for solar-to-hydrogen conversion can be enhanced by nearly two orders of magnitude under UV [2] and visible light illumination [3-4]. In this work, we demonstrate multi-band InGaN nanosheet photochemical diode (PCD) structures, which can induce spontaneous charge carrier separation and steer them toward distinct redox sites for water oxidation and proton reduction reaction. During the synthesis of InGaN PCD nanosheets, p-type dopant (Mg) concentrations are rationally tailored, which induces a large built-in electric field between the two parallel surfaces. Due to the presence of a net built-in potential (~300 meV) along the lateral dimension, the two surfaces are enriched with photo-generated holes and electrons to perform water oxidation and proton reduction reactions, respectively [5]. With spatially separated catalytic sites and reduced carrier recombination, the nanoscale PCDs exhibit stoichiometric H2 and O2 evolution, with a production rate of ~1.62 mmol h⁻¹ cm⁻² and ~0.784 mmol h⁻¹ cm⁻², respectively, which is equivalent to a solar-to-hydrogen efficiency over ~3%. We are currently developing a novel III-Nitride nanostructured device on Si wafer which, when decorated with suitable co-catalyst nanoparticles on surfaces, can demonstrate unprecedented performance-stability in photochemical water splitting reaction - the longest ever measured for any semiconductor photocatalysts or photoelectrodes without protection/passivation layers in unassisted solar water splitting with an STH >1%. With further structural and surface engineering of the nanowires, we aim to enhance the solar-to-hydrogen efficiency in the range of 5-10%.

9:30 AM NM03.11.04
GaN Nanowire Arrays for Photocatalytic Applications [5] Julia Winne1, Sabrina Armeier, Richard Hudecek and Martin Stutzmann; Walter Schottky Institut, Technische Universität München, Munich, Germany.

In recent years, group III-nitride nanowires (NWs) have attracted increasing interest for device fabrication due to their high crystal quality, large surface-to-volume ratio and their waveguide character. The favorable energy position of their bands with respect to many oxidation and reduction reactions and their chemical stability under harsh environments make them interesting candidates for photocatalytic applications, e.g. water splitting or CO2 reduction. The integration of group III-nitride NW arrays on GaN-based light emitting diodes (LEDs), serving as a platform for electrically driven NW-based photocatalytic devices, enables an efficient coupling of the light from the planar LED to the GaN NWs. Here, we present a systematic numerical study of the influence of the NW geometry, i.e. diameter, period and length, and the illumination wavelength on the coupling of the light from the LED into the GaN NW arrays. We found that for large NW periods the interaction of light with the GaN NW arrays is to the waveguide modes, providing an enhanced evanescent field around the NWs, whereas for dense NW arrays, it is additionally affected by the inter-wire coupling and the excitation of in-plane waveguide modes. Transmission measurements of GaN NW arrays on transparent sapphire substrates confirmed the coupling of light into waveguide modes. Experimental measurements of GaN NW arrays on GaN-based LED substrates verified an efficient coupling of the light from the LED to the NWs. For NW-based photocatalytic applications, we found that GaN NW arrays with diameters for which the incident light is coupled weakly to the waveguide modes, providing an enhanced evanescent field around the NWs, have to be chosen for a maximum illumination of the NW surface and, thus, a maximum excitation of photocatalytic reactions. Fluorescence measurements are performed in order to investigate the optical coupling of the evanescent field and dye molecules immobilized on the NW surface. [1]

9:45 AM NM03.11.05
Seed-Layer Free Zinc Tin Oxide Tailored Nanostructures for Nanoelectronic Applications Produced by Low-Temperature Hydrothermal Synthesis [6] Ana Rivasco, Rita Brunquinho, Jorge Martins, Elvira Fortunato, Rodrigo Martins and Pedro Harquinhã; i3N/CENIMAT, Department of Materials Science, Faculty of Science and Technology, Universidade NOVA de Lisboa and CEMOP/UNINOVA, Caparica, Portugal.

Looking at the actual technology development, we are facing an increasing demand for smart and multifunctional surfaces on all sorts of objects and shapes. With this, flexible and transparent electronics is being pushed to unprecedented performance and integration levels [1]. Thus appears the necessity for a new generation of materials combining sustainability, low dimensions and still a wide range of properties compatible with its application on transistors, memories, sensors or even energy-harvesting components. For this end, indium-free multicomponent oxide nanowires (NWs) such as zinc-tin...
oxide (ZTO) are some of the most promising material systems for an upcoming generation of sustainable yet high performing transparent nanoelectronics. Being a ternary oxide ZTO is a multifunctional material, with a wide applicability in for example photocatalysis, nanoelectronics, sensors and energy harvesting. ZTO can crystalize in Zn$_2$SnO$_4$ and ZnSnO$_3$ phase, with different types of structures possible for each phase. However its synthesis is hard to control, due to the presence of two cations. In this context, this work presents a detailed study on the influence of both chemical [2] and physical [3] parameters in the hydrothermal synthesis of seed-layer free ZTO nanostructures at temperatures of only 200 °C. The low-temperature hydrothermal methods explored here proved to be a low-cost, reproducible and highly flexible route to obtain multicomponent oxide nanostructures, namely Zn$_2$SnO$_4$ nanoparticles and ZnSnO$_3$ nanowires with length ∼ 600 nm. Optical and electrical properties close to the reported for nanostructures obtained by high temperature processes were achieved. Particularly, band gaps of 3.60 and 3.46 eV, for ZnSnO$_3$ and Zn$_2$SnO$_4$, respectively, and a resistivity of 1.42 kΩ.cm for single ZnSnO$_3$ nanowires were obtained. For electrical characterization, nanomanipulators inside SEM were used, after a localized deposition of Pt electrodes by e-beam assisted gas decomposition. The seed-layer-free nature of the developed synthesis allowed a facile application of the ZTO nanowires for photocatalytic applications and memresistive devices with very promising results being already obtained for both cases. These two illustrate how a wide array of applications can be successfully envisaged, given the flexible nature of a seed-layer free synthesis, and furthermore showing that good performance can still obtained even when considering low temperature hydrothermal methods.

10:30 AM *NM03.12.01
In Situ TEM Imaging of Semiconductor Nanowire Growth by the Electrochemical Liquid-Liquid-Solid (ec-LLS) Method Stephen Maldonado; University of Michigan, Ann Arbor, Michigan, United States.

Presently, the majority of methods for bottom-up synthesis of crystalline nanowires follow a common set of themes. First, high temperatures and/or low pressures are used to drive the thermal decomposition of vapor phase precursors to their zero-valent forms. Second, the precursors/reactants are heavily refined and often difficult to handle, and store. Third, growth reactors involve some elements of heating and/or low pressures to effect nanowire growth. New synthetic strategies that avoid these aspects, without sacrificing material quality, could enable new applications and device manufacturing opportunities for semiconductor nanowire materials. Electrodeposition is one alternative methodology that can produce nanowires with simple infrastructure and at low temperatures. Our lab has pioneered the ec-LLS concept as a particular electrodeposition tactic that blends electrochemistry with melt crystal growths. For nanowires, ec-LLS draws strong parallels from vapor-liquid-solid (VLS) growth concepts, but can be conducted in air, on the benchtop, and with unrefined (oxide) precursors. Despite the similarities with VLS, ec-LLS also introduces factors of surface charge, electrostatic fields, and precisely tunable electrochemical driving forces that can affect the nucleation and crystal growth steps. Our ongoing work highlights how these different factors can be understood and ultimately leveraged for specific target material properties. This presentation highlights data that describe our latest insights on the controlling factors in electrochemical liquid-liquid-solid (ec-LLS) growth processes for semiconductor nanowire synthesis. The presented results will include in-situ videos of ec-LLS nanowire growths that describe the conditions necessary to nucleate and grow nanowires at ambient temperatures. Additional supporting ex-situ TEM, atom probe tomography, and electrical characterization data will be presented that speak to the purity and conductivity of as-prepared Ge nanowires.

11:00 AM NM03.12.02
Epitaxy of Semiconductors on 2D Materials via Solid Phase Catalytic Growth Frances M. Rossi1, Priyanka Periwal2, Joachim Dahl Thomsen3, Dmitri N. Zakharov4, Mark C. Reuter1, Lynne Gignac1, Timothy J. Booth5 and Stephan Hofmann2; 1IBM T. J. Watson Research Center, Yorktown Heights, New York, United States; 2Department of Electrical Engineering, University of Cambridge, Cambridge, United Kingdom; 3Department of Micro- and Nanotechnology, Technical University of Denmark, Kongens Lyngby, Denmark; 4Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States.

Control of crystal growth and the integration of heterogeneous materials are central to the semiconductor industry. A key challenge is therefore to create well-defined interfaces reproducibly between materials that are lattice mismatched. Several strategies have proven successful for materials integration: catalytic crystal growth is used to self-assemble nanostructures such as nanowires that integrate lattice mismatched crystals, while van der Waals epitaxy can unify lattice mismatched 2D materials. However, forming well defined interfaces between 2D materials and standard 3D materials, such as Si and Ge, remains a challenge. Here we show that the catalytic pathways for semiconductor deposition that have been developed for nanowire growth can be exploited to grow epitaxial Ge, Si and other semiconductor nanocrystals on 2D materials such as graphene and hexagonal boron nitride. By using solid metal nanoparticle catalysts that are themselves epitaxial on the 2D materials, we show that epitaxial Si and Ge nanocrystals can be formed by a vapor-solid-solid growth mechanism. In situ transmission electron microscopy is used to explore the reaction pathways for this process, which takes place at lower temperature and with an improved degree of epitaxy compared to direct chemical vapor deposition or deposition using liquid phase catalysts. We discuss the prospects for the formation of nanostructure arrays and single crystal thin films.

11:15 AM NM03.12.03
Morphology Dependent Strain Relaxation in Horizontally Grown ZnSe@ZnTe Core-Shell Nanowires and Its Effects on Electronic Band Alignment Sara Martí-Sánchez1, Eitan Oksenberg2, Marc Botifoll2, Christian Koch3, Quintin Ramasse3, Ernesto Joselevich3 and Jordi Artisal1, 4; 1Catalan Institute of Nanoscience and Nanotechnology (ICN2), Bellaterra, Spain; 2Department of Materials and Interfaces, Weizmann Institute of Science, Rejovot,
Core-shell Ge\(_{1-x}\)Sn\(_x\) nanowires synthesized via VLS one-dimensional crystal growth have been demonstrated to exhibit desirable optical properties. The core-shell strain plays an important role in the enhanced photon emission. We characterize the strain in these nanowires using strain mapping in scanning transmission electron microscopy in 4D-STEM diffraction, a spatially resolved technique. 4D-STEM is also sensitive to lattice defects such as Sn-rich lattice plane inclusions in the GeSn shell of core-shell Ge\(_{1-x}\)Sn\(_x\) nanowires. Coupled with defect imaging, we can better understand the formation and the origin of defects in GeSn. Although characterization of strain in core-shell nanowire cross-sections is complicated by sample mechanical relaxation, choice of thinning orientation allows accurate spatially localized strain measurements. Phase field simulations of the core-shell nanowire structures provide an estimate of the expected strain, which matches well with experimental measurements from 4D-STEM, and explains the formation of six-fold symmetric Sn-poor spikes in the Ge\(_{1-x}\)Sn\(_x\) shell.

Over the recent years III-V semiconductor NWs have become widely studied nanostructures for nanophotonics, optoelectronics and advanced nanoelectronics. The ability to control the NWs’ diameters and lengths give rise to tunable quantum confinement effects [1]. For InAs NWs very strong quantum confinement effects are expected to occur for diameters well below 30 nm [2] – a regime which has hitherto been difficult to reach by conventional bottom-up growth methods. Here, we develop such ultra-confined InAs NWs with size dimensions far below 30 nm and further aim to understand their optical properties and charge carrier dynamics set by the 1D electronic subband structure. The presented InAs NWs are grown along the [111] direction on SiO\(_2\)-masked Si (111) using a completely catalyst-free vapour-solid (VS) growth mechanism [3, 4] via selective-area molecular beam epitaxy (SA-MBE).

In a first approach we show how by direct bottom-up SA-MBE the NW dimensions can be controlled by tuning both growth parameters and substrate pattern design. After optimizing V/III ratio and temperature, we illustrate that the interwire separation (growth pitch) and the growth time are critical for reaching sub-30 nm InAs NWs. In contrast, the shape and diameter of the mask opening seem less influential as the NWs grow randomly from the edge of the mask opening. This way we obtained, InAs NWs with diameters as low as ~20-25 nm.

In a second approach, we explore a so-called reverse reaction growth (RRG) mechanism to intentionally thin as-grown InAs NWs by in situ thermal annealing [1, 5]. Starting from > 1 \(\mu\)m long NWs with diameters of > 60 nm we performed various different thermal annealing experiments by varying in situ vacuum conditions, As-overpressure, annealing temperature and time. Most interestingly, under controlled As-overpressure the InAs NW sidewalls start to thermally decompose from the top in distinct hierarchical sequences. Using sacrificial NWs and specific pitch-dependent kinetics, we thereby realized so far InAs NWs with diameters < 15 nm.

Ongoing experiments are also shown which (i) identify the influence of the RRG mechanism on the microstructure using TEM (transmission electron microscopy), and which (ii) explore the level of radial quantum confinement in the ultrathin InAs NWs by \(\mu\)-photoluminescence (PL) spectroscopy. First preliminary low-temperature PL spectra of a NW-array with sub-30 nm diameter show a substantial blue-shifted peak emission (> 0.48 eV) compared to conventional unconfined NWs [5]. The data are further correlated with simulations of the optical transition energies under the influence of strong radial quantum confinement.

1 B. Loitsch et al Advanced Materials, 27 (2015), 2195
3 J. Becker et al ACS Nano, 12 (2018), 1603
The photoluminescence (PL) emission properties of group III-nitride nanowires and nanowire heterostructures sensitively respond to changes in the chemical environment in gaseous and liquid atmospheres. At the same time, the presence of photogenerated charge carriers on their surface can trigger chemical processes by charge transfer into electronic levels/molecular orbitals of adsorbed gas molecules or surrounding electrolytes, as it is also employed in photo-electrochemical water splitting. Hence, monitoring of the PL and controlling the photocurrent allows for analyzing and initiating photoactivated chemical surface processes as well as establishing new principles for opto-chemical nanosensors or chemically sensitive nanophotonic probes. We demonstrate these strategies by discussing different examples such as detection and analysis of water adsorption, optical pH-sensing or dynamic imaging of biochemical cellular processes. When coated with ultrathin oxide coatings such as TiO$_2$ or CeO$_2$, InGaN/GaN nanowires can serve as nanophotonic probes to monitor ion transport and diffusion processes in the oxide film. As examples we discuss optical in-situ monitoring of oxygen self-diffusion in CeO$_2$-coatings as well as Li$^+$-intercalation in TiO$_2$.

The concern about the presence of toxic and potentially harmful gases in outdoor and indoor environments is continuously increasing. Numerous types of gas sensor devices and systems are used to monitor the presence of these gases in the atmosphere. Among the different possibilities, solid state gas sensors are an excellent choice due to their low cost and low power consumption thanks to MEMs technology, and remarkable performances obtained with metal oxide nanowire-based gas sensors in terms of sensitivity and response time. However, metal oxides usually lack in selectivity, being only able to distinguish among oxidizing or reducing gases. A solution to this problem is the called e-nose, where pattern recognition across sensor arrays with different sensing characteristics (using different materials or operation temperatures) is applied. The present work demonstrates for the first time that site-selective growth of different materials in the form of nanowires for sensing applications is possible on a single chip in a well-defined geometry. The growth of nanowires on top of micromembranes can be easily adjusted and represents a simple and suitable fabrication process for the direct integration of different nanowire-based resistive multifunctional devices. The use of chemical vapor deposition techniques is compatible as a CMOS post-processing and, therefore, the impact of preparing gas sensors on any kind of chips for multifunctional devices is unimaginable. This proof-of-concept is exemplified by the deposition of SnO$_2$, WO$_3$ and Ge nanowires on different membranes of one single chip and their gas sensing responses towards different concentrations of CO, NO$_2$ and humidity diluted in synthetic air are shown. The devices presented here have the same gas sensing behavior as devices made on separate chips and CVD chambers. The principal component analysis (PCA) of the collected data allows gas separation and identification and, thus, it is proved that the system is a well-operating nanoelectronic nose.

Metal-oxide semiconductor gas sensors are viable alternates for highly sensitive and selective detection of different gases and air pollutants, which provide various advantages such as miniaturization, low cost gas detection, and real-time monitoring. Various strategies have been used to increase the gas response and selectivity, including modulating the sensing temperature, [1] morphological control, [2] catalyst doping/loading, [3] and catalytic filtering of interference gases [4]. Constructing heterostructures between two different oxides is an effective method to enhance gas response, via controlling the conductivity at p-p, p-n, and n-n interfaces, as well as the selectivity, through synergistic catalytic effects between different materials. In particular, reports given by the group of Miura [5] and Noh [6] show that the gas sensing properties could be enhanced by adding WO$_3$ to NiO based sensors or NiO to the WO$_3$ based sensors. Inspired by this fact, it is very essential to design NiO/WO$_3$ heterostructures for studying their gas sensing properties. WO$_3$ is an n-type semiconductor, and has been intensively studied as a gas-sensing material [7]. On the other hand, NiO is a p-type semiconductor attaining considerable attention for gas-sensing applications in the past few years [8].

The main idea behind this work is to bring together the properties of two different nanostructure materials into a single sensing platform by using a simple, low cost and high yield method. In this way, one platform with different materials properties can be used detect the variety of gases. Herein, we report the novel preparation and characterization of NiO/WO$_3$ branched 1D-1D nano-heterostructures, consisting of inner NiO nanowires [8] and outer WO$_3$ nanowires obtained through vapor-phase method. The surface morphology of the nanowires was investigated by using scanning electron microscopy (SEM). For structural characterization, instead, GI-XRD, transmission electron microscopy (TEM) and Raman spectroscopy were performed. The structural characterizations shows the presence of nickel tungstate (NiWO$_4$) phase in the nanostructures. Finally, NiO nanowire and NiO/WO$_3$ heterostructure based conductometric gas sensing devices have been fabricated and tested towards different gases spcies such as (NO$_2$, H$_2$, CO, VOC’s) and their sensing performances have been compared. Interestingly, NiO/WO$_3$ NWs heterostructure based sensing devices shows superior performance compared to NiO sensors.

Ultrafast Lights up the Nanoscale—Pushing the Limits of THz Spectroscopy to Reveal Novel Nanowire Optoelectronic Properties with fs-Temporal and nm-Spatial Resolution

By Jessica L. Boland
University of Oxford, Oxford, United Kingdom; University of Regensburg, Regensburg, Germany.

Between the microwave and infrared regions of the electromagnetic spectrum lies the so-called "terahertz gap," a band of terahertz (THz) frequencies which are difficult to access by conventional photonic or electronic technologies. Due to their high charge carrier mobilities and tunable charge carrier lifetimes, III-V semiconductor nanowires exhibit great potential for optoelectronic devices operating at these THz frequencies. For example, high performance nanowire-based photoconductive THz detectors [1] and ultrafast switchable THz polarisation modulators [2] have been recently demonstrated.

Just as III-V nanowires show great promise for THz devices, the THz spectral region is greatly promising for the development and optimisation of III-V nanowire materials. Specifically, transient THz spectroscopy provides a powerful contact-free means of measuring nanowire electrical properties. It can achieve accurate measurements of charge carrier transport and dynamics at room temperature with sub-picosecond temporal resolution, and yields key parameters such as electron mobility, ionised dopant density, charge carrier lifetime and surface recombination velocity. Being a contact-free technique, it overcomes many of the challenges associated with traditional contact-based measurements and provides fast feedback to growth experiments. This has enabled the optimisation of growth parameters for achieving nanowire heterostructures, doped nanowires and modulation-doped nanowires [3, 4]. This talk will discuss how THz spectroscopy is guiding nanowire growth, the cross-correlation of THz and contact-based measurements, and the engineering of nanowire-based devices, particularly devices operating at THz frequencies.

Studying and Exploiting the Unique Properties of III-V Nanowires in the Terahertz Gap

By Hannah J. Joyce
University of Cambridge, Cambridge, United Kingdom; University of Oxford, Oxford, United Kingdom; University of Regensburg, Regensburg, Germany.

Between the microwave and infrared regions of the electromagnetic spectrum lies the so-called "terahertz gap," a band of terahertz (THz) frequencies which are difficult to access by conventional photonic or electronic technologies. Due to their high charge carrier mobilities and tunable charge carrier lifetimes, III-V semiconductor nanowires exhibit great potential for optoelectronic devices operating at these THz frequencies. For example, high performance nanowire-based photoconductive THz detectors [1] and ultrafast switchable THz polarisation modulators [2] have been recently demonstrated.

Just as III-V nanowires show great promise for THz devices, the THz spectral region is greatly promising for the development and optimisation of III-V nanowire materials. Specifically, transient THz spectroscopy provides a powerful contact-free means of measuring nanowire electrical properties. It can achieve accurate measurements of charge carrier transport and dynamics at room temperature with sub-picosecond temporal resolution, and yields key parameters such as electron mobility, ionised dopant density, charge carrier lifetime and surface recombination velocity. Being a contact-free technique, it overcomes many of the challenges associated with traditional contact-based measurements and provides fast feedback to growth experiments. This has enabled the optimisation of growth parameters for achieving nanowire heterostructures, doped nanowires and modulation-doped nanowires [3, 4]. This talk will discuss how THz spectroscopy is guiding nanowire growth, the cross-correlation of THz and contact-based measurements, and the engineering of nanowire-based devices, particularly devices operating at THz frequencies.

Ultrafast Lights up the Nanoscale—Pushing the Limits of THz Spectroscopy to Reveal Novel Nanowire Optoelectronic Properties with fs-Temporal and nm-Spatial Resolution

By Jessica L. Boland
University of Oxford, Oxford, United Kingdom; University of Regensburg, Regensburg, Germany; Lund University, Lund, Sweden; École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

Accurate characterization of the electronic properties of semiconductor nanowires is essential for the development of novel nanowire-based devices. In order to harness the full potential of these materials, an in-depth understanding of key properties, such as charge carrier lifetimes, mobilities, doping concentrations, charge carrier recombination and scattering mechanisms, is vital. However, detailed studies still prove challenging, as the inherent quasi-one dimensional nanowire geometry impedes conventional electrical measurement techniques. Challenges in fabricating lateral Ohmic contacts for Hall effect measurements and uncertainty in the gate capacitance term for field effect measurements, render such techniques difficult. Therefore, non-contact, non-destructive techniques, such as terahertz and Raman spectroscopy, are highly desirable for obtaining the nanowire optoelectronic properties, providing a route for optimization and control of the nanowire transport properties for device optimization.

In this work, both far-field optical-pump terahertz-probe (OPTP) spectroscopy and near-field terahertz scanning optical microscopy (THz-SNOM) are presented as alternative techniques for accurate characterization of the charge carrier dynamics in semiconductor nanowires. First, OPTP spectroscopy is employed for InAs, Sb, nanowires. Photoconductivity lifetimes, carrier mobilities and scattering rates are obtained at room temperature and within the temperature range of 4 – 300K for a range of Sb contents. As Sb content is increased, the defect density within the NWs reduces, leading to an increase in electron mobility and carrier lifetime. For 35% Sb concentration, the highest ever electron mobility for III-V NWs is reported at ~7000cm²V⁻¹s⁻¹ at 300K, indicative of reduced impurity scattering in the NW due to reduced defect density offered by Sb incorporation. These results highlight the potential of OPTP as a powerful tool for characterising nanowire behaviour. Secondly, THz-SNOM is discussed as a near-field method for examining the local optoelectronic properties of a single nanowire and preliminary measurements on Bi₂Sₑ nanowires are presented. With this technique, the optoelectronic properties of semiconductor nanowires can be resolved with not only femtosecond temporal resolution but also nanometre spatial resolution. The technique is also surface-sensitive, allowing the transport and dielectric properties of the nanowire to be resolved at different depths within the nanowire, isolating contributions from the bulk and the surface to the nanowire conductivity.

Wavelength-Selective Reflection Enhancement Towards Rare-Earth Doped 1D-Nanolasers

By Maximilian Zapf
University of Jena, Jena, Germany; University of Regensburg, Regensburg, Germany.

Wavelength-selective (WS) reflection enhancement using rare-earth ions (REIs) in III-V nanowires is presented. A novel method for growth and post-growth processing to achieve WS reflection enhancement is described. WS reflection enhancement is shown to be a general method for REI activation and the realization of nano-scaled lasers. Nano-scaled lasers are essential for future optoelectronic applications in life sciences, chemistry, and physics for on-chip sensing, spectroscopy, and optical data communication. Optically one-dimensional nanolasers are currently realized using semiconductor nanowires (NWs) under intense optical excitation, as they inherently combine the required semiconductor optical gain and the beneficial NW morphology. This morphology allows efficient wave guiding and provides a nanoscale Fabry-Pérot-type cavity.
resonator structure, where the cavity is determined by reflections at the nanowire end facets due to refractive index contrast. Both the internal material gain and the end facet reflectivities strongly influence the lasing threshold. Distributed Bragg reflectors (DBRs), where the nanowire is periodically cut, have higher reflectivity than a single end facet at wavelengths pre-determined by the spacing of cuts. These wavelength-selective mirrors can be combined with gain from the semiconductor material or from dopants ion implanted into the NW to shift laser emission within a broad spectral range. Finite-difference time-domain calculations were performed to simulate the wavelength-dependent reflections occurring at an air - ZnO DBR structure. Such DBR structures were milled into ZnO nanowires using inert-gas focused ion beam providing the high refractive index contrast between the ZnO material and air. Subsequently, reflection and transmission properties of the DBR structures have been studied. Enhanced wavelength-dependent end facet reflections allow reducing laser thresholds in nanowire lasers as well as tailorable nanoscale wavelength filtering, and spectral emission tuning. This wavelength-selective reflection enhancement can be applied in order to realize sub-band gap nanolaser emission in arbitrary spectral regimes determined by the optical gain of the dopants.

GaAsSbN Based Core-Shell Nanowires with Photoluminescence Emission Reaching 1.55 μm Prithviraj Deshmukh1, Manish Sharma1, Surya Nalamati1, Lewis Reynolds2, Yang Liu2 and Shanthi Iyer1; 1Department of Electrical and Computer Engineering, North Carolina Agricultural and Technical State University, Greensboro, North Carolina, United States; 2Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; 3Nanoengineering, North Carolina Agricultural and Technical State University, Greensboro, North Carolina, United States.

Incorporation of nitrogen in the GaAsSb shell is studied to reduce the bandgap energy for realizing nanoscale optoelectronic devices in the telecommunication wavelength region. Bandgap tuning up to 1.55 μm in GaAsSbN nanowires (NWs) can be achieved using dilute amounts of nitrogen in the shell. Engineering the material composition and structure of the core-shell NW for bandgap reduction has not been fully explored in this quaternary system. Previous work on GaAsSb [1] and GaAsSbN [2] shell utilizes a GaAs NW as the core, which limits the amount of Sb to 10 at. % in the shell, due to NW bending and rough surface morphology. [2] In this work, we report on high density of vertical GaAsSb/GaAsSbN core-shell configured nanowires, with smooth surface morphology and Sb compositions exceeding 10 at. %, in the shell, grown on Si (111) substrates using plasma assisted molecular beam epitaxy. Nitrogen incorporation in the dilute nitride shell was optimized to produce high photoluminescence (PL) intensity. Effects of N incorporation on the morphology of NWs were studied to optimize a closely lattice-matched core-shell material configuration. Study of variation in shell thickness and V/III ratio are carried out to achieve NWs with reduced bandgap energy and smooth morphology. Room temperature PL emission of 1.55 μm has been achieved. Annealing in dilute nitrides is essential for annihilation of N-induced point defects and band tail states. [3] We have carried out rapid thermal annealing in N2 ambient at varying temperatures in order to eliminate point defects and to enhance the PL intensity. Changes in peak positions and spectral lineshapes in the Raman spectra of annealed samples have been used to ascertain the nature of the defects being annihilated. Study of structural quality of dilute nitride NWs using transmission electron microscopy will also be presented. We successfully demonstrate significant bandgap reduction in the core-shell NWs by engineering appropriate reduction in the lattice strain with the non-nitride core.

GeSn Mid-Infrared Nanophotonic Resonant Absorbers Siying Peng, Michael Braun, Andrew C. Meng, Zhengrong Shang, Alberto Salleo and Paul C. McIntyre; Geballe Laboratory of Advanced Materials, Stanford University, Stanford, California, United States.

Mid-IR wavelengths are technologically crucial for chemical sensing, thermal imaging and LIDAR communications. Having been shown to exhibit a direct bandgap, GeSn alloys hold great promise as a mid-IR light emitting and absorbing material, with the potential to be monolithically compatible with existing silicon technologies. Therefore GeSn can open pathways for miniaturization of mid-IR devices such as on-chip molecular sensors, optical interconnect and thermal cloaking. Previous research on GeSn films has shown mid-IR lasing at T<90K. It has also been shown that GeSn nanowires with high-Sn content exhibit strong direct-gap PL at room temperature. In principle, GeSn nanowires have several advantages over thin films. GeSn film suffers the inherent compressive misfit strain from coherency with a silicon growth substrate, while GeSn nanowires are not constrained to lattice match with the substrate. In addition, epilayer film growth of metastable Sn alloy compositions (~10%) required to modify the conduction band structure of Ge so to achieve a direct band gap is likely to produce defects due local Sn surface segregation and/or phase separation. In comparison, GeSn nanowires grown by catalyzed low-temperature methods may be able to achieve unusually high Sn contents by solute trapping. Therefore, GeSn nanowires may constitute a superior laser gain medium compared to GeSn thin films, whose emission characteristics are limited by substrate-induced strain and non-radiative combination centers from defects. We have synthesized and characterized mid-IR photonic crystals consisting of GeSn/Ge core-shell nanowires. FDTD simulations reveal Mie resonances of the high refractive index (n>4) GeSn/Ge structures can be tuned to the desired wavelength by varying radius and height of individual nanowires. GeSn/Ge nanowires arranged in hexagonal photonic crystal arrays can be designed to be highly absorbing, by varying periodicity and filling factor of the photonic crystal. Ebeam lithography was utilized to pattern Au catalyst arrays on [111] Ge substrate, followed by two step VLS growth to synthesize GeSn nanowire arrays, with periodicity of 1000 nm and radius from 60 nm to 300 nm, and yielding 90% vertical growth. We then spin coat PMMA to insulate the Ge substrate from the nanowires, followed by ITO spattering for top contact. At bottom contact was then evaporated onto the n-type Ge substrate. Room temperature PL characterization reveals emission peaks from 1600nm to 2100nm. Mid-IR reflectance of the GeSn photonic crystal arrays was measured with FTIR, showing 40% reflectance from photonic crystal arrays, with the reflectance peak tunable with radius of the nanowires. We also performed photocurrent characterization with a FTIR spectrometer. Room temperature photocurrent was observed at wavelengths from 1.2μm to 2μm, generated from a non-coherent mid-infrared source. Nanophotonics tuning of the wavelength and widths of the photocurrent peak will be discussed.
Single crystalline metal oxide nanowires are interesting nanostructures due to their abundant resources and robustness in air and water. In addition, metal oxides exhibit many fascinating physical properties, including high-Tc superconductors, ferromagnetism, ferroelectrics, memristive properties, photocatalytic properties, transparent conductors and others, which are not attainable to conventional semiconducting materials (group IV and III-V).

However, fabricating single crystalline metal oxide nanowires has been based on a rule of thumb, there has been no general principle to design metal oxide nanowires. The feasibility of functional oxide nanowires, whose physical properties are hardly attainable to other materials, has been also strongly limited. Here I demonstrate i) a fundamental design concept for creating single crystalline oxide nanowires via vapor-liquid-solid (VLS) pathway, and ii) a development to measure the physical properties of a single nanowire, including electrical and thermal transport properties. By comparing experimental VLS nanowire growth to MD simulations, we found that the difference between LS interface and VS interface on the critical nucleation size essentially allows us to perform VLS nanowire growth. This knowledge can be expanded to discover novel metal oxide nanowires via VLS mechanisms. In addition, we have shown the impact of crystal growth interface on the electrical properties of metal oxide nanowires. I believe that the presented approaches by utilizing meal oxide nanowires offers an important platform for investigating not only nanoscale physical properties of transition metal oxides but also exploring novel nanodevices with other materials, which had not been possible to be integrated onto Si and/or plastic substrate.

Next, vanadium dioxide (VO₂) has attracted much attention due to its distinct change of physical properties across the metal-insulator transition (MIT). Specifically, VO₂ will experience a dramatic strain up to 1% along the c-axis as a result of MIT, which is hundreds of times larger than the other material such as piezoelectric ceramics and bimetal actuators, which could only have strain of 10⁻³-10⁻⁴ more importantly. Young’s modulus of VO₂ can approach 140 GPa, which is rather lower than steel. These distinctive characteristics make VO₂ a promising material in actuator applications. As previously reported, most of micro-sized VO₂ bimorph actuators are fabricated by pulsed laser deposition (PLD). However, the equipment required for PLD process is complex and expensive, and the preparation is time consuming and results in micro-scale VO₂ films, largely restricting its developing. In addition, the obtained VO₂ films demonstrated a severely limited output work density of 0.63 J/cm², compared with the theoretical value of 7 J/cm², which was caused by the disordered polycrystalline structures of VO₂ in PLD process. Therefore, a novel synthesis method is urgently required.

To break these limitations, we propose a facile and scalable method to fabricate large-scale and high-performance actuator films. In this work, we firstly synthesized ultra-long VO₂ nanowires (>100nm) via a scalable hydrothermal process, then successfully assembled the nanowires into super-aligned arrays in the water-oil-vapor interface. Subsequently, carbon nanotube (CNT) thin films were combined with the VO₂ super-aligned arrays to obtain VO₂/CNT actuator in a macro scale (1-5cm², much larger than that fabricated by PLD method). The synthesized actuator demonstrated excellent performance close to single crystal with the ratio of actuation displacement/length up to 0.83 and work density up to 5.67 J/cm³. Furthermore, VO₂/CNT actuator exhibited strong anisotropy characteristics, namely, its actuation direction would significantly change with the orientation of VO₂ nanowires. Besides, several biomimetic devices based on VO₂/CNT actuator are developed, and these devices have the advantages of superior performance, long-time durability and multiple excitation sources. Overall, we have fabricated high-performance VO₂/CNT actuator and biomimetic devices based on super-aligned VO₂ nanowire arrays for the first time, which will definitely pay a way for research on actuators and biometrical devices.

9:15 AM NM03.15.03 Oxidation-Enhanced Si Self-Diffusion in Isotopically Modulated Nanopillars Ryotaro Kiga1, Sayaka Hayashi1, Satoru Miyamoto1, Yasuo Shimizu2, Tetsuo Endoh3, Yasushi Nagai2 and Kohei M. Itoh1; 1School of Fundamental Science and Technology, Keio University, Yokohama, Japan; 2Institute for Materials Research, Tohoku University, Sendai, Japan; 3JST-ACCEL, Sendai, Japan.

In advanced Si-MOSFETs, current leakage issues have been pronounced as a result of approaching downsizing limit. A vertical gate-all-around architecture offers great advantages for both low-power consumption and high-density integration [1]. While gate-oxide formation surrounding nanoscale Si pillars involves a high-degree controllability, substantial modifications from conventional planar oxidation may be required for a precise process modeling of surface-oxidized nanopillar geometry. Recently, taking the geometrical and stress effects into account, several paths of Si atomic transport are theoretically predicted for the inner Si and outer SiO₂ regions, respectively [2]. In this work, we present experimental investigation of Si self-diffusion in the oxidized nanopillars by means of atom probe tomography (APT).

Here, a periodic Si isostructure heterostructure composed of naturally abundant ⁵²Si and isotopically enriched ⁵⁷Si (99.92%) was epitaxially grown on a Si(100) substrate, which was followed by a top-down metal-assisted chemical etching for obtaining isotopically modulated Si nanopillars. The resulting nanopillars having a diameter of ~200 nm were subject to dry oxidation at 900 °C for 4 hours. For reference, a nanopillar sample annealed in an Ar ambient was also prepared. Individual nanopillars were then picked up from each sample and sharpened into needle-shaped APT specimens by focused ion beam technique. In order to acquire ⁵⁷Si concentration profile along a pillar or depth axis, 3D mapping of Si isotopes was carried out using a laser-assisted atom probe (LEAP4000XHR, Cameca). In parallel, second ion mass spectrometry (SIMS) was performed only for an unetched bulk region outside nanopillars. The comparison of isostructure layer thickness with the SIMS profile enabled APT-based evaluation of Si self-diffusivity on a calibrated depth scale [3]. For a bulk region of the Ar-annealed sample, the Si self-diffusivity obtained from the APT analysis indeed represented good agreement with the SIMS result. In addition, whereas the Si self-diffusion was obviously enhanced for both nanopillar and bulk under dry oxidation, the self-diffusivity in nanopillar was found to remain comparable with the result for the bulk Si. Although oxidation-enhanced diffusion is known to take place via Si interstitials created at the Si/SiO₂ interface, they are most likely to diffuse out of the pillar core into the deep bulk region. However, the oxidation-enhanced diffusion holds irrespective of the nanosized structures since more Si interstitials can be injected into the pillar core due to high interface-volume ratio.

This work was supported by JST ACCEL Grant Number JPMJAC1301, Japan, and in part by JSPS KAKENHI (No. 15H05413).

Like GaAs and GaSb, GaAsSb ternary alloys are not expected to show hot carrier effects. We use femtosecond pump-probe measurements (TRS: transient Rayleigh scattering) in single zinc-blende GaAsSb nanowires at both 10 K and 300 K to monitor the photoexcited carrier density and temperature as a function of time and so determine directly the energy loss rate. We confirm that hot carriers quickly thermalize to the lattice predominantly through optic phonon emission as expected. Similar measurements were performed on GaAsSb-InP core-shell nanowires. While the growth of the InP shell results in substantially longer lifetimes through passivation of surface defects, we found, surprisingly, that the growth of the shell had a dramatic impact on the thermalization of the photoexcited carriers. Using TRS measurements, we monitor the density and temperature of carriers to determine the energy loss rate. At both 10 K and 300 K the optic phonon emission rate is strongly suppressed resulting in strong hot carrier effects. This is surprising since the GaAsSb nanowire core is the same in both cases. The presence of the InP shell is impacting directly the thermalization dynamics of carriers confined to the GaAsSb core.

Adjusting the Surface Band Structure of Bottom-up Grown Silicon Nanowires
Tobias Dlugosch, Tanja Sandner, Ahmed Chnani and Steffen Strehle
Ulm University, Ulm, Germany.

Silicon nanowire ion-sensitive field-effect-transistors were highlighted within the last decade as nanoscale transducers for label-free molecule detection owing to their large surface to volume ratio. Hence, a reliable and well-controlled transducer response is intimately linked to the electronic surface band structure, but which is still insufficiently explored. Here, we discuss the electronic surface band structure of bottom-up grown silicon nanowires as well as strategies that allow to rationally adjust the position of the surface valence and conduction band edge as well as the surface Fermi-level position. The studies were carried out by using a Kelvin probe, ambient photoelectron spectroscopy, and ambient surface photovoltage spectroscopy allowing an absolute reconstruction of the electronic surface band structure as well as an estimation of the charge carrier lifetime. In principle, as-grown silicon nanowires showed frequently the well-known mid-band gap Fermi-level pinning, governed by surface states, which significantly limits the transducer sensitivity. Nevertheless, the surface band structure can be effectively controlled by suitable surface state passivation layers. Besides a hydrogen termination, a common surface functionalization, e.g. by (3-aminopropyl)trimethoxysilane and (3-mercaptopropyl)trimethoxysilane, is already sufficient to alter the surface states effectively. Furthermore, ultra-thin field-effect passivation layers such as thermal SiO2 and atomic layer deposited Al2O3 were intensively studied and allow to rationally adjust the surface band structure and therefore, the surface charge carrier concentration. In result, silicon nanowire surfaces exhibiting a charge carrier accumulation, depletion, inversion and even a degeneration can be created in this manner, which is highly relevant for any reliable and controlled nanowire device usage. The silicon nanowires for our study were synthesized bottom-up by using a SiH4-based and gold-catalyzed vapor-liquid-solid process. Besides unintentionally doped nanowires, p- and n-type doping of varying concentration were realized by admixture of either B2H6 or PH3, respectively.

Epitaxy of Nanostructures for Device Integration
Heinz Schmid1, Johannes Gooth2, Stephan Wirths1, Philipp Staudinger1, Benedikt Mayer3, Siegfried F. Karg4, Heike Riel1, Svenja Mauthe1 and Kirsten Moselund1; 1IBM Research Zurich, Rueschlikon, Switzerland; 2MPI Dresden, Dresden, Germany; 3ABB, Baden Daetwil, Switzerland; 4MPI Berlin, Berlin, Germany.

Over the last 20 years many approaches for nanostructure synthesis have been pursued [1] which often resulted in exotic geometries from a wide range of materials, and triggered huge interest across many scientific disciplines. Translating these promising nano-structuring methods into a powerful device technology remains challenging up to now, also with competing technologies steadily improving. Here, we show our efforts on nanostructure synthesis specifically targeted towards device integration and illustrate challenges and opportunities. We focus on III-V compound semiconductors as these materials are well known, have outstanding properties, are universally used, but still face unsolved integration issues when combined with silicon. The device examples were all fabricated by local epitaxy in templates on Si substrates [2]. Epitaxy and resulting structural and electrical material properties are discussed in detail. Selected device results on field effect transistors and optical excited disk lasers [3] are shown and their integration potential addressed. Finally, devices targeted for 1D transport measurements [4] are discussed which are of interest in more fundamental oriented research.

Oriented Semiconductor Nanostructure Generation with Phototropic Growth Control
Madeline Meier; California Institute of Technology, Pasadena, California, United States.

Photosynthetic plants, including palm trees and sunflowers, exhibit a phenomenon known as phototropic growth wherein the physical extension of the
biological system proceeds preferentially towards the time-averaged position of the sun. By capitalizing on anisotropies intrinsic to light-material interactions, a natural phototropism can be mimicked using photoelectrochemical deposition to effect the template-free generation of semiconductor nanoarrays. Photocatalytic electrochemical growth of semiconducting chalcogen films without any lithographic pre-processing or photomask yielded films comprised of highly anisotropic and ordered nanostructures. By controlling the angle of incidence of the light during deposition, the orientation and growth direction of the structures with respect to the substrate could be defined without relying on epitaxial growth. This manner of morphological evolution was observed as the growth was dictated by light capture: mass was spontaneously added most preferentially to the localized regions capturing the maximal light flux. Morphological complexity was generated by combining the use of inclined illumination with a series of defined polarization and wavelength inputs which allowed in-plane and out-of-plane orientation, spacing, and periodicity. Growth was simulated using a finite-difference time domain method to model the light-matter interactions and a Monte Carlo method for mass addition. The results of the simulation successfully reproduced the experimentally observed morphologies. The underlying optical basis was further investigated using a simplified light scattering model that corroborated the magnitude and direction of the empirically-observed phototropic responses.

Effects of Growth Conditions on the Preferential Orientation of Al-Catalyzed Silicon Nanowires
Mel Haine1, Xiaotian Zhang1, Ke Wang1 and Joan M. Redwing1; 1Pennsylvania State University, University Park, Pennsylvania, United States; 2Materials Process Engineering, Nagoya University, Nagoya, Japan.

Silicon nanowires grown in high energy growth direction such as <110>- and <100>- are of scientific interest because of their predicted improved conductivity and hole mobilities relative to <111>- wires. However, large-scale, controllable growth of these wires remains a challenge, limiting not only their potential application, but even attempts to experimentally verify their predicted properties. Additionally, the use of an aluminum catalyst is desirable because the incorporated Al acts as a p-type dopant instead of forming deep-level traps as with an Au catalyst.

In this report, we demonstrate the effect that hydrogen partial pressure, reactor temperature, and particularly precursor (SiH4) depletion have on the preferential growth direction of aluminum-catalyzed silicon nanowires grown by chemical vapor deposition (CVD) in a hot wall quartz tube reactor. The substrates used for growth consisted of Si (110) wafers coated with a 10 nm Al catalyst film. Previously, we have demonstrated that sub-eutectic growth temperatures and high hydrogen partial pressures promoted <110>- wire growth from Si (110) substrates. However, prior reports of Al-catalyzed <111>- wire growth suggested that these same temperatures and pressures should promote growth in the lower energy <111>- direction. To better understand how the same growth conditions can promote different preferential growth directions, long (~3 cm) Si (110) substrates were placed in the reactor using the previously described preferential <110>- growth conditions. At the front of the sample, closer to the gas inlet, nanowires grew exclusively in the <111>- direction. Moving further downstream in the reactor, a clear transition from preferential <111>- to preferential <110>- growth was observed without significant change in the nanowire growth rate.

Computational fluid dynamic simulations combined with a simplified gas phase and surface chemistry model of SiH4-decomposition and reaction along the length of the reactor tube suggests that the transition from <111>- to <110>- corresponds with gas phase depletion of SiH4. The transition from preferential growth in high-energy growth directions under SiH4-depleted conditions agrees with previous observations from Ge <110> nanowire growth, where decreased Ge flux to the catalyst droplet changed the preferential growth direction from <111>- to <110>-.

Finally, by using silane-depleted growth conditions, we demonstrate that <100>- wires can also be fabricated from Si (100) substrates. These results suggest that silane-depletion conditions can be used to fabricate wires in previously inaccessible growth directions.

11:30 AM NM30.16.04
Realization of Vertical GaN NW Static Induction Transistors
Matthew Hartensveld1, Cheng Liu1, Yu Kee Ooi1 and Jing Zhang2; 1Microsystems, Rochester Institute of Technology, Rochester, New York, United States; 2Electrical and Microelectronic Engineering, Rochester Institute of Technology, Rochester, New York, United States.

Nanowire (NW) transistors are emerging as replacement technology to planar devices due to better scaling and gate control. Vertical NWs, as opposed to planar NWs, allow for conventional fabrication techniques to be utilized to build the device once the NWs are formed. The gate length in these devices is defined by the metal thickness on the sidewalls which allows better scaling of those transistors. In addition, vertical NWs support higher transistor densities and allow for separate source and drain metalization engineering. Specifically, GaN has been explored to use in vertical NW transistors due to the wide bandgap along with high carrier mobility, which are important in high power applications. Several studies have explored GaN vertical NW transistors recently, which are mostly Metal Oxide Semiconductor Field Effect Transistors (MOSFETs). Those MOSFETs typically make use of a surface channel combined with a unique growth structure, which are difficult to implement. Alternatively, Static Induction Transistors (SITs) have a buried channel, straightforward vertical structure, and ability to support high voltages. Therefore, in this work, GaN-based NW vertical SITs have been realized in order to capitalize on these properties. Instead of a custom n-i-n structure from most GaN NW MOSFETs, this GaN NW SIT is fabricated from unintentionally doped GaN with a background doping concentration of 1×1016 cm-3. A top-down NW formation and a bottom-up fabrication process are utilized to fabricate the SIT. The NWs are formed through nanoscale lithography and Reactive Ion Etch (RIE), followed by KOH wet etch to crystal graphically shrink the diameter and to smooth the sidewalls of the NWs. Layers of metal are deposited to form the source, gate, and drain with Polydimethylsiloxane (PDMS) as the supporting insulating layers. In this study, a small gate length of 30 nm of aluminum is achieved solely through metal deposition. 20 nm of titanium is deposited as the source and drain contacts, followed by annealing in an N2 environment to produce nitrogen vacancies. These vacancies then act as donors that create an n-i-n structure through the wire. Both simulations and experimental results are obtained in order to electrically characterize the vertical SIT. The experimental results include the on/off ratio and the family of curves, recording six orders of magnitude difference for the on/off ratio. The effects of Drain Induced Barrier Lowering (DIBL) on the device are also electrically measured and show a shift to higher pinch-off values as the source to drain bias is increased. As the drain bias increases from 1 V to 1.5 V, the current level increases by 188 times. Device simulations have also been performed using Silvaco’s Athena, showing similar findings in experimental performance and DIBL. Due to the feasibility of the vertical GaN NW SITs, these power transistors can open the door to a number of new integration opportunities.

11:45 AM NM30.16.05
Optically Directed Bottom-Up Growth of Anisotropic Semiconductor Nanostructure Arrays
Azhar I. Carim1, Nicolas Bataara2, Anjali Premkumar2, Harry A. Atwater2 and Nathan S. Lewis1; 1Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, California, United States; 2Engineering and Applied Sciences, California Institute of Technology, Pasadena, California, United States.

Bottom-up growth of macroscale arrays of highly anisotropic nanoscale elements with significant periodic order was effected via photoelectrochemical deposition of a semiconducting chalcogen film. The exact nature of the optical excitation was the determinant of the features sizes, periodicities, anisotropies, and orientations of the arrays. Use of linearly polarized light resulted in the development of an array of highly-anisotropic components with a single set of extended axes that aligned along the E-field vector. The nanoscale component size and pitch was encoded by the illumination spectral profile.
A single pitch was observed regardless of the use of broadband and multimodal spectral profiles. The void space between the array elements could be tuned and this value could be tuned between ca. 20 nm to 100 nm by using ultraviolet to near-infrared wavelengths. Intersecting arrays with nonequal periodicities in the two orthogonal in-plane directions could also be generated and both periodicities could be independently controlled by orthogonally polarized inputs. “Stacked” arrays could be generated by using temporally-varying polarization and/or wavelength inputs.

The nanopatterning process occurred without the use of any type of physical or chemical templating agents: no photomask, patterned substrate nor surfactants/ligands were used to influence the morphology. Modeling of the growth using a combination of full-wave electromagnetic simulations of light absorption and scattering coupled with probabilistic simulations of mass addition successfully reproduced the experimentally observed morphologies and indicated that morphology development was a consequence of the fundamental light-matter interactions during growth.

Structural Analysis of Stable Defects in III-V Semiconductor Nanowire
Ana M. Sanchez1, James A Gott1, H Aruni Fonseka1, Yunyan Zhang2, Huiyuan Liu2 and Richard Beanland1, 2
University of Warwick, Coventry, United Kingdom; 3University College London, London, United Kingdom.

The rapid improvement in semiconductor growth and new processing techniques has produced novel materials/structures with unique functionalities. Nevertheless, persistent obstacles, such as the constraints on lattice parameter and thermal expansion mismatch, have prevented the growth of a wide range of epitaxial layers on bulk substrates. These constraints cause dislocations and cracks making the devices unviable. Nanowires (NWs) avoid both of these problems, since they are only attached to the substrate at one small region – their base. Moreover, mobile defects with long-range strain field – i.e. dislocations – are unstable and get expelled from the NW by surface image forces.

Electron microscopy plays a key role in understanding the structure of these novel materials. In fact, aberration-corrected scanning transmission electron microscopy (ac-STEM) has provided some beautiful images and valuable insights into many materials, with resolution and analysis capability now truly at the atomic scale.

This work demonstrates that the nanopore defect microstructure is very different from bulk material. We analysed defects present in semiconductor nanowires in regions of imperfect crystal growth, i.e., at the nanowire tip formed during consumption of the droplet in self-catalyzed vapor–liquid–solid growth and subsequent vapor–solid shell growth. Various line defects have been observed either (i) trapped by locks or other defects (ii) arranged as dipoles or groups with a zero total Burgers vector and (iii) have a zero Burgers vector. We find two new line defects with a null Burgers vector, formed from the combination of partial dislocations in twinned material.

The most common defect is the three-monolayer high twin facet with a zero Burgers vector. These defects are \( \Sigma 3 \) (11-2) boundaries, having topological properties similar to those of dislocations, but no long-range strain field are stable and act as non-radiative recombination centers. Interestingly, if NW polarity is maintained across the (111) boundaries on either side of the step, i.e. an ortho-twin, the material on opposite sides of the \( \Sigma 3 \) (11-2) boundary is related by a mirror, and it must be a para twin. These interfaces are constituted by 5- and 7-membered rings that contain under-bonded and over-bonded atoms. Density functional theory calculations demonstrate that these \( \Sigma 3 \) (11-2) facets produce a shift in the band edge and a closing of the band gap. So they will act as non-radiative recombination centres, causing problems for minority carrier devices and deleterious effects on nanowire properties.

In Situ Studies on Layer-by-Layer Growth Kinetics of GaAs Nanowires
Carina Baba Maliakkal1, 2, Daniel Jacobsson1, 3, Marcus Tornberg1, 2, Axel R. Persson1, 3, Jonas Johansson1, 2, Reine Wallenberg1, 3 and Kimberly A. Dick1, 2, 3
1NanoLund, Lund University, Lund, Sweden; 2Solid State Physics, Lund University, Lund, Sweden; 3nCHREM and CAS, Lund University, Lund, Sweden.

Semiconductor nanowires (NWs) have emerged as a highly promising technology for next-generation electronics and photonics. Although the potential of these structures lies in the possibility to control and design their properties on an atomic scale, the current mechanistic understanding of the synthesis process is clearly insufficient for achieving the promised level of control. Semiconductor nanowires are mostly grown via vapor-liquid-solid mechanism using a catalytic liquid metal nanoparticle (typically Au). The process is broadly understood to occur by dissolution of semiconductor precursor species in the liquid metal followed by precipitation of the solid semiconductor once the precursor becomes supersaturated. NW growth occurs in two steps: formation of a critical nucleus followed by step-flow across the liquid-solid interface. Most theoretical models explaining NW growth assume the step-flow to be effectively instantaneous and the NW growth rate to be limited by the slow nucleation. In-situ imaging of nanowire growth demonstrated that the step-flow can also limit the overall growth rate.[1] We study, using in-situ TEM imaging combined with in-situ compositional analysis, the layer-by-layer growth kinetics of III-V NWs.

We have grown GaAs nanowires in a Hitachi HF3300S aberration-corrected environmental TEM connected to a CVD system. A SiNx-based MEMS heating chip was mounted on a holder with two separate microtubes running to the holder tip for supplying gases. We used trimethylgallium (TMGa) and arsine as the Ga and As precursors respectively. High resolution, high-frame-rate videos (20 fps) enable us to determine the growth rate for each bilayer (step flow time) as well as incubation times between layers. We studied the elemental composition of the catalyst by energy dispersive X-ray spectroscopy as a function of the growth parameters.

When growth temperature is increased for Ga-limited growth, the average Ga content in the droplet increases along with the incubation time. However, the step flow time is rather insensitive to temperature. When varying the TMGa flux, we identify two regimes: For TMGa flux below a critical value, the average concentration of Ga in the droplet is constant and Ga limits the average growth rate, while for TMGa flux above this value, the Ga content increases in the catalyst. The concentration of As in the catalyst droplet is small and below our detection limit. For the Ga-limited regime the long incubation time between bilayers limits the average growth rate. The incubation time decreases significantly with increasing Ga precursor flux. However, the step flow time is independent of Ga and we propose that this is limited by the arrival of As species in both regimes. For sufficiently high TMGa flux, the incubation time becomes shorter than the step flow time, and the arsine flux will limit the overall growth rate.

2:15 PM NM03.17.03
Semiconductor nanowires with high carrier mobility and controlled chemical composition, morphology, and size distribution offer great promise in designing novel electronic, thermoelectric, and photovoltaic applications. It is well known that III-V nanowires can grow in the wurtzite crystal structure, even if the bulk crystal structure of the same material is zinc blende. There is currently a lot of research about controlling the crystal structure of nanowires by fine-tuning the growth conditions and this is known as crystal phase engineering. The breakthroughs in this area open new horizons allowing the fabrication of nanowires with well controlled or modulated crystal structure along the growth direction. Previous attempts to control crystal structure control are mainly devoted to binary III-V nanowires. Crystal structure control in ternary nanowires is, on the other hand, poorly studied.

The aim of the current investigation is therefore to understand and predict the crystal structure of ternary nanowires. Among the various ternary material systems which are relevant for nanowire fabrication, the greatest attention has been paid to InGaAs [1] due to its excellent materials properties. We present an approach to understanding the zinc blende and wurtzite crystal structure formation in InGaAs nanowires growing from a quaternary gold-based liquid alloy. The model we have developed is based on two-component nucleation theory using realistic chemical potentials, calculated from an assessed thermodynamic database [2]. Using the model we calculate the probabilities of zinc blende and wurtzite phase formation in this materials system for different growth conditions. We compare our results with available experimental data and special attention is paid to analysis of the main trends in crystal phase control and the impact of the liquid composition on the final crystal structure. The developed model may help in optimization of the growth conditions for InGaAs nanowires with tailored crystal structure.

Finally, an interesting theoretical result of our analysis is that the wurtzite and zinc blende phases have different compositions, even if they are nucleated from identical conditions of the catalyst particle. We will show that this could open up for the possibility to fabricate nanowires with zinc blende and wurtzite segments having significantly different compositions even if the growth conditions are almost identical.

Light Trapping in Nanowire Geometric Superlattices Seokhyeun Kim1, Kyoung-Ho Kim1, David J. Hill1, Hong-Gyu Park2 and James F. Cahoon3; 1University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States; 2Physics, Korea University, Seoul, Korea (the Republic of).

All-optical operation holds promise as the future of computing technology, and key components will include miniaturized waveguides (WGs) and optical switches that control narrow bandwidths for logic operations and wavelength multiplexing. Nanowires (NWs) offer an ideal platform for nanoscale WGs, but their utility has been limited by the lack of a comprehensive coupling scheme with band selectivity. Controlled in-coupling of light to NW WGs thus still is problematic and has relied on scattering at NW end facets or end-on parallel coupling to the NWs. Mie resonances of NWs have been considered as a potential route to enable controlled coupling into guided modes, but the interplay of the two orthogonal modes remains yet unclear. Here, we introduce a NW geometric superlattice (GSL) that allows controlled, narrow-band guiding in Si NWs through direct coupling of a Mie resonance with a bound guided state (BGS) under normal incidence illumination with transverse-magnetic (TM) polarization. Periodic diameter modulation in a GSL creates a Mie-BGS coupled-excitation that manifests as a scattering dark state with a pronounced scattering dip in the Mie resonance envelope. We analyze scattering characteristics of NW GSLs using Temporal Coupled-Mode Theory (TCMT) and compare with numerical finite-element modeling. The coupling strength between the Mie and BGS modes, which is zero in the absence of the GSL geometry, becomes non-zero with periodic modulation and increases with an increasing modulation depth. Experimental extinction spectra of individual NW GSLs are measured by a home-built laser microscope and presented with numerically simulated spectra. The frequency of the coupled mode, tunable from the visible to near-infrared, is determined by the pitch of the GSL and exhibits a Fourier-transform limited bandwidth. Using a combined GSL-WG system, we demonstrate spectrally-selective guiding at telecommunication wavelengths with bandwidths of ~50 nm, which aligns with the spectral positions of the dips observed in extinction spectra. We also present optical switching characteristics of a GSL with an index change of the surrounding medium, highlighting the potential to use NW GSLs for the design of on-chip optical components.

2:45 PM NM03.17.05
2D to 1D Growth of Layered SnSe2—Morphological Control of CVD Grown Nanostructures Fionán Davitt1, 2, Samantha Hawkens1, Subhajit Biswas1, Gillian Reid1 and Justin Holmes1, 2; 1Materials Chemistry and Analysis Group, University College Cork and the Tyndall National Institute, Cork, Ireland; 2AMBER, CRANN, Trinity College Dublin, Dublin, Ireland; 3School of Chemistry, University of Southampton, Southampton, United Kingdom.

Bottom-up growth strategies offer the potential for precise control over the crystallinity, structure, composition, and morphology of nanomaterials. In this research, a liquid injection chemical vapour deposition method has been utilized to grow crystalline tin diselenide (SnSe2) nanostructures, from a distorted octahedral [SnCl4{BuSe(CH2)3SenBu}] single source diselenoether precursor.1 Most notably, careful adjustment of the growth parameters yielded great morphological control of the grown nanostructures; yielding structures from large 2D flakes, to large branched wire networks, and individual one-dimensional (1-D) nanostructures. With the custom designed single source precursor, SnSe2 nanostructures of only a few layers thickness were achievable, as well as 1-D growth with diameters between 60-240nm. The Sn:Se stoichiometric ratio of ~1:2 in all of the different morphologies was confirmed by energy dispersive X-ray analysis and Raman spectroscopy. The presence of the SnSe2 A1g Raman mode was clearly observed for all synthesized nanostructures.2 The Sn:Se stoichiometric ratio of ~1:2 in all of the different morphologies was confirmed by energy dispersive X-ray analysis and Raman spectroscopy.

The presence of the SnSe2 A1g Raman mode was clearly observed for all synthesized nanostructures.2 The morphology and crystal structure of the SnSe2 nanostructures was investigated through X-ray diffraction, atomic force microscopy, electron diffraction, and transmission electron microscopy. SnSe2 nanostructures demonstrate potential applications in phase change memory devices (PRAM), with films of SrTiO3 being previously reported as showing the reversible amorphous to crystalline switching needed in phase change memory applications.3,4
Electroluminescence from Photonic Crystal Cavities Based on III-V Nanowire Array on Silicon-on-Insulator

Conventionally, nanowire characterization with a high spatial resolution relies on electron microscopy techniques, which can provide a large variety of structural and compositional information with atomic resolution. Energetic electrons interact quite strongly with condensed matter so that the analyzing depth is limited and the Bremsstrahlung-background allows only a moderate detection limit of elements. Compared to electrons, X-rays interact less strongly with matter and are thus less invasive and have a higher penetration depth, enabling analysis even at ambient conditions of operating and/or functional devices. Even if the spatial resolution of X-ray based methods is clearly lagging behind the one obtained by electron based techniques, today one can focus X-rays below 30 nm at several synchrotron facilities. In addition to their high brilliance, third generation synchrotron radiation sources have wide energy tunability, a high degree of polarization, fast temporal structure, coherence and more. This opens up the possibility of studies at length scales relevant for the characterization of semiconductor nano-devices with energy dependent X-ray studies, such as X-ray absorption near edge structure (XANES) or extended X-ray absorption fine structure (EXAFS). In this presentation, we will show several combinatorial studies [1,2] demonstrating the beneficial use of X-ray nano probes for the characterization of single semiconductor nanowires and in-operando studies on devices thereof.

Electrical and Optical Characterization of GaN-Based Hybrid Nanowire and Microrod LEDs

Linus Kriegl, Stefan Leis, Angelina Jaros, Joergen Jungclaus, Florian Meierhofer and Tobias Voss; Braunschweig University of Technology, Braunschweig, Germany.

The oxidative chemical vapor deposition (oCVD) of ultrathin (<100nm) and highly transparent p-conductive polymer layers on arrays of vertically aligned semiconductor nanowires or microrods is a very powerful method for the fabrication of hybrid three-dimensional (3D) LEDs. In these hybrid LEDs, the p-doped part of the diode consists of a conformal layer of highly p-conductive poly(3,4-ethylenedioxythiophene) (PEDOT) for which literature values >3000 S/cm of the lateral conductivity have been reported. We have used oCVD of PEDOT for the fabrication of hybrid GaN-based nanowire and microrod LEDs. The inorganic part of the LED consists of n-type GaN rods grown by selective-area MOVPE on sapphire substrates. The active region is formed by a radial InGaN-based multi-quantum-well structure. Using the gaseous monomer EDOT and FeCl3 as oxidant, thin p-conductive polymer layers have been deposited on planar and 3D GaN structures to form full hybrid LEDs. Stable, blue electroluminescence is observed from the devices at ambient conditions for an applied voltage ~3V. We have studied the electronic properties of the hybrid pn-junction in temperature-dependent IV-measurements. The results are modelled in the frame of a thermionic emission model based on a bipolar Schottky junction yielding barrier heights of ~0.7-1.0 eV, breakdown voltages of ~-8 V, ideality factors of ~1.8-2 at room temperature and rectification ratios at ±4 V in the order of 106.

Our results demonstrate that oCVD of conductive polymer layers is about to become a powerful technique for the fabrication of highly p-conductive transparent polymer layers on nanowire devices with the layer thickness and doping level of the polymer being controlled by the deposition parameters.

Electroluminescence from Photonic Crystal Cavities Based on III-V Nanowire Array on Silicon-on-Insulator

Ting-Yuan Chang1, Hyunseok Kim1, Wook-Jae Lee2 and Diana Huffaker2; 1University of California, Los Angeles, Los Angeles, California, United States; 2Cardiff University, Cardiff, United Kingdom.

Epitaxial growth and heterogeneous integration of III-V optoelectronic devices on silicon photonic platform have been a potential building block for optical interconnect. Here, we demonstrate III-V arrayed nanowires (NWs) light emitting diodes (LEDs) monolithically integrated on silicon-on-insulator (SOI) substrate by selective area epitaxy (SAE) using MOCVD. This presentation will include the NWs LED design, growth and characterization in detail. NWs with axial p-GaAs / i-InGaAs heterostructure and in-situ InGaP passivation shell are directly grown on lattice mismatched n-type silicon substrate, while maintaining more than 98% yield and remarkable uniformity in NW dimensions. Due to small footprint, lateral strain releasing leads to lack of threading dislocation in NWs. Electroluminescence at photonic band edge in near infrared (NIR) region is observed, which can be utilized in in-plane waveguide coupling and low-loss propagation in silicon optical interconnect. It is worth noting that altering the design of NW array allows tunable emission wavelength for on-chip multi-wavelength optical network communication. Lastly, we show an advanced NW heterostructure in which diffusion barriers are incorporated to improve electrical confinement, enabling high carrier densities in the gain medium. These results provide great opportunities for achieving electrically injected NW-based photonic band edge lasers on silicon photonic platforms.
subsequently fluorescence-tagged with live-cell compatible labels targeting the cell membrane and filamentous Actin, respectively.

Within the cell, the nanowires form nanoscale ring structures of about 100 nm diameter, wrapping tightly around the nanostraws. On the other hand, the Actin cytoskeleton forms intricate, coil-like nanometric structures around the nanostraws; these structures strongly vary in diameters between 250-600 nm and appear to widen with increasing distance from the nanostraw substrate.

In addition, STED images of living cells stained for both membrane and Actin signal reveal a significant degree of co-localization at the apical cell membrane, i.e. further away from the nanostraws. This co-localization is almost entirely lost at the basal membrane close to the nanostraws which is due to a strongly reduced Actin signal on that side of the cell.

In conclusion, our sub-diffraction STED imaging based investigations of the behavior of single living cells cultured on nanostraws reveals a strong response of the cellular membrane and the Actin cytoskeleton – two of the main structure-giving features of the cell. In a next step, we will extend our studies to additional scaffolding proteins to arrive at a more detailed map of the topology of living cells at the interface to nanostructures of different geometries.

4:45 PM NM03.18.05
Preparation of 2D Bar Code Labeled Substrates for Nanowire Devices Yuki Hanamura, Grace G. Redivyk, Ryo Yamada and Hirokazu Tada; Engineering Science, Osaka University, Osaka, Japan.

Nanowire materials have been intensively studied in recent years because of the quantum confinement effect in one-dimensional structures of superconductor, metal, semiconductor, organic materials, and so on [1-4]. Their typical length to width ratio is greater than 10, which makes it possible for nanowire materials to connect with other macroscopic structures towards a functional device. There have been several works on the position control of nanowire structures, such as in-situ growth, electrophoresis alignment, and flow-induced shear force [5]. Preparation of an individual nanowire device using such methods requires a precise control of the position of the selected nanowire. However, direct observation of the nanowire position during electron beam lithography may cause structural deformation [6]. Therefore, atomic force microscopy (AFM) observation is typically used prior to the electron beam lithography to locate the individual nanowire. Here we report the development of 2-dimensional (2D) bar code as a position marker to determine the exact location of the nanowire and ensure the successful lithography of the electrode contact. The 2D bar code was made of Au thin film, with a thickness of 30 nm. One bar code was constituted by orientation markers and binary markers. The binary markers represent the coordinate of the 2D bar code relative to the alignment marker. We will show how we can utilize the 2D bar code from the AFM image to determine the nanowire position and create electrode contact successfully to the nanowire.

Pinning Down the Structure/Performance Interplay in Nanowires with Electron Microscopy Sonia Conesa-Boj; Quantum Nanoscience, Delft University of Technology, Delft, Netherlands.

In the last decade, a significant progress has been made in controlling the growth and properties of low-dimensional systems such as nanowires. Their small radial dimension enables more freedom for the combination of different materials. The ability of nanowire systems to overcome existing limitations of heterostructures is one of the key ingredients for the design of next-generation devices. In turn, this requires a detailed understanding of the crystalline structure and the mechanisms for strain relaxation in these systems, in order to eliminate defect formation and thus to boost optical and electronic properties. Therefore, the characterization of their structure and chemical composition with atomic resolution is essential to achieve a full understanding of how their physical properties are correlated. In this context, transmission electron microscopy (TEM) provides a unique toolbox to achieve this goal. TEM is extremely versatile, combining within a single instrument the complementary capabilities of imaging, diffraction and spectroscopy. In this talk I discuss the crucial role that electron microscopy plays in mapping the structure, properties, and performance of nanomaterials and their mutual interplay, and then present the results of recent studies illustrating this important role for the specific case of core-shell nanowires. Finally, I motivate the impressive physics potential that can be exploited by pushing the boundaries of electron microscopy analysis for novel quantum materials.

9:00 AM NM03.19.02
Helium Ion Microscopy as a Novel High-Resolution Probe for Complex Quantum Heterostructures in Core-Shell Nanowires Christian Pöpsel1, Jonathan Becker1, Nari Jeon2, Markus Dixbinger3, Thomas Stettner1, Alexander Holleitner1, Jonathan Finley1, Lincoln J. Lauhon2 and Gregor Koblmueller1; 1Walter Schottky Institut, Technical University of Munich, Garching, Germany; 2Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 3Department of Chemistry, Ludwig-Maximilians-Universität München, Munich, Germany.

Over the years semiconductor nanowires (NW) have emerged as promising systems for many unique device applications in nano- and quantum-electronics, --photons and energy conversion. Simultaneously, they also became an excellent testbed for advancing ultrahigh-resolution imaging methods due to their rich palette of integrated quantum heterostructures, defined by either intentional polypeptide crystal phases or by accurately controlled modulations in alloy composition along their axial or radial dimensions. Ideally, the ultrahigh-resolution imaging techniques should enable examination of the specimens’ structure and material contrast at the sub- or few-nanometer scale with minimal damage and sample preparation.

Here, we demonstrate that scanning helium ion microscopy (ShelM) provides a powerful and straightforward method to map the unique material contrast of quantum heterostructures embedded in complex III-V semiconductor nanowires (NW) with an accuracy at the ~1-nm resolution level. By probing the

9:15 AM NM03.19.03 Growth and Characterization of Epitaxial, Anisotropic Ge$_x$Sn$_{(1-x)}$, Nanostructures as Direct Bandgap Materials Michael S. Seifner and Sven Barth; Institute of Materials Chemistry, TU Wien, Vienna, Austria.

Germanium can be converted into a purely group IV-based direct bandgap material with high light-emitting efficiency in the mid-IR range. However, the required and thus targeted Sn content of > 9 at% to convert Ge to a direct bandgap material exceeds the solid solubility limit of < 1% according to the binary phase diagram. [1,2] Conventional high-temperature approaches will therefore not lead to the desired metastable compound and alternative synthesis strategies using kinetically controlled growth conditions have to be established. We demonstrate that solution-grown Ge$_x$Sn$_{(1-x)}$ NWs show low resistivity values in single nanowire devices and determined the thermal stability for different chemical compositions of these germanium-tin nanowires. [3,4,5] The knowledge gained by these solution processes has been used to establish a strategy for the epitaxial growth of anisotropic, metastable Ge$_x$Sn$_{(1-x)}$, nanostructures with high Sn content in a vapor-phase process at very low temperatures. This procedure does not rely on a Ge nanowire support structure acting as a template. Independent and complementary methods including X-ray diffraction and STEM-EDX elemental mapping are used to determine the Sn content, while TEM confirms the single crystalline nature of the obtained products. We demonstrate a size and synthesis parameter dependence of the Sn content in the composition range of 8-15 at% Sn. Optical measurements confirm the formation of a low bandgap material without strain effects of the substrate material used for these metastable Ge$_x$Sn$_{(1-x)}$, nanostructures with Sn concentrations above the threshold of the indirect-to-direct bandgap material transition. [6] The results of this study will help to push the implementation of group 14-based direct band gap materials for novel optoelectronic devices.

9:30 AM NM03.19.04 Self-Assembled Ultrathin Gold Nanowires—Modeling to Reveal Their Structure and Reactivity Jorge Vargas1, Valeri Petkov1 and Guillaume Viau1; 1Physics, Central Michigan University, Mt. Pleasant, Michigan, United States; 2LPCNO, Université de Toulouse, Toulouse, France.

Ultrathin metallic nanowires and metallic nanorods exhibit unique structural and electronic properties due to their very small diameter and one-dimensional (1D) feature. In particular, ultrathin gold nanowires (Au NWs) are promising candidates for nanoelectronics, optics, electro-catalysts or as active materials in chemical sensors. Their synthesis and several measurements have been intensively reported over the last decade. In this contribution, Au NWs are studied using the atomic Pair Distribution Function (PDF) obtained from analysis of the ternary AlGaAs shell layers and of compositionally non-uniform GaAs/AlAs SLs reveals distinct alloy composition fluctuations in the form of Al-rich clusters with size distributions between ~1-10 nm. In the GaAs/AlAs SLs the alloy vanishing with increasing SL-period (> ~5-10 nm GaAs/4-5nm AlAs), providing insights into critical size dimensions for atomic intermixing effects in short-period SLs within a single NW [3]. The small-size alloy clusters correspond to previously identified sources of quantum-dot-like emitters in AlGaNAs-based NW shell layers that are otherwise only detectable by advanced, yet destructive APT methods [4]. Moreover, our SHEIM data also evidences first indications of atomic segregation at twin-plane defects in the AlGaNAs alloy shell system, illustrating excellent image contrast in the single monolayer level [3].

9:45 AM NM03.19.05 Atomic-Level Imaging and Structure Identification of Mo$_5$O$_{14}$ Nanowires by Advanced Electron Microscope Yi-Hsin Ting1, Ping-Hung Yeh1 and Wen-Wei Wu1; 1Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2Department of Physics, Tamkang University, New Taipei City, Taiwan.

The Mo$_5$O$_{14}$-type structure is a very important and representative to the complex oxide in the selective oxidation of heterogeneous catalyst. However, the spatial resolution in the conventional technique of transmission electron microscopy (TEM) was insufficient to distinguish the real position of atoms. In this work, we aim at systematically analyzing and identifying the needle-like Mo$_5$O$_{14}$ nanowires fabricated by chemical vapor deposition (CVD) process. Utilizing high-angle annular dark-field (HAADF), annular bright-field (ABF) and enhanced annular bright-field (E-ABF) within scanning transmission electron microscope (STEM) revealed the real atomic-level images and large-scale special arrangement. Importantly, E-ABF could enhance the intensity of light atoms like oxygen atom, so the image demonstrated the overall structure of Mo$_5$O$_{14}$. We presented the ultra-high resolution images consistent with the network of MoO$_6$ octahedral and MoO$_7$ pentagonal bipyramids in theoretical model. Electron energy loss spectroscopy (EELS) analysis would also provide the information about binding energy of Mo$_5$O$_{14}$ and the element distribution through atomic-scale mapping. Besides, the ultra-high resolution images have provided the new insights to the [001] growth direction of needle-like Mo$_5$O$_{14}$ nanowires with quasi-2D structure and tunnel structure. The cross-section images showed the unique close-packed plane and highly periodic atomic arrangement with repeating pentagonal structure. Details of the atomic structure were analyzed. In addition, we used in-situ TEM to investigate electron beam radiation effect. It revealed that Mo$_5$O$_{14}$ structure transferred from crystal to amorphous. These results would benefit to the catalytic selective oxidation related with Mo$_5$O$_{14}$-type structure.

10:00 AM BREAK
In order to translate 1-D nanostructures from the laboratory into viable technologies, there is a need for efficient characterization tools, particularly for semiconductor nanowires with complex dopant profiles or heterostructures. Traditional measurement methods, because they require each nanowire to be electrically contacted, are laborious. Thus, they are unsuitable for statistically analyzing process – structure – property relationships of nanowire ensembles. Here, we advance electro-orientation spectroscopy (EOS) to characterize individual, vapor-liquid-solid-grown Si nanowires with axially programmed dopant profiles. EOS is a non-contact technique that can determine the structure and properties of individual nanowires based on their transient alignment under applied AC electric fields when suspended in a fluid. We demonstrate an ability to measure the length ratio of two segments of distinct carrier density in individual nanowires. We find that nanowire segment-length ratios exhibit much less variation than the segment conductivity, which can differ by more than an order of magnitude within an ensemble. We also show that nanowire carrier densities are strongly surface-dependent, with Al2O3 passivation via atomic layer deposition (ALD) able to increase nanowire conductivity by more than 4 orders of magnitude. Notably, the relative variation of the conductivity decreases with surface passivation. This advancement in EOS enables, for the first time, the high-throughput characterization of nanowires with structural heterogeneity, and serves as an important step toward the characterization of full devices.

**11:00 AM NM03.20.02**

**Properties, Challenges and Limits of Metallic Nanowire Networks—A Brief Overview**

Daniel Bellet; LMGP - Grenoble INP, Grenoble, France.

In recent years there has been a growing interest for metallic nanowire (MNW) networks as they exhibit very promising properties: high optical transparency, very good electrical properties and mechanical flexibility [1]. Such networks are mostly targeted to be used as transparent electrodes for many applications [1] such as solar cells, OLEDs, displays, transparent heaters [2] or smart windows. They could replace the currently well-known transparent electrode indium tin oxide (ITO) since indium scarcity and the lack of flexibility of ITO have prompted the search for alternative low cost and flexible materials.

Many researches worldwide deal with the optimization of the properties of MNW networks and the enhancement of their stability. Research focuses on i) the fundamental understanding of the physical phenomena taking place both at the network scale (macroscale) and at the nanowires scale (nanoscale); and ii) the integration of MNW networks as transparent electrodes in many devices. Our research mainly concerns Ag nanowires. In-situ electrical measurements performed during either thermal annealing [3] or voltage ramps [4] provide useful information regarding the evolution of AgNW networks properties. We have extensively investigated the influence of both length and diameter of AgNWs, as well as network density, on the physical properties of the networks [4]. At the network scale, the ability to distinguish the nanowires taking part in the electrical conduction (“electrical percolating pathways”) from the inactive nanowires is a critical issue for the application. By combining in situ experimental a discrete activation process of efficient percolating pathways through the network was evidenced [5]. We have lately reported that the electrical degradation of AgNW network is associated with crack occurrence and propagation that was observed in-situ [6]. We will address as well the stability issue associated to AgNW networks and will propose a solution for enhancing it thanks to Spatial Atomic Layer Deposition (SALD), an low cost, high throughput deposition technique which allows the deposition of very thin oxide layers onto AgNWs for preventing silver atomic surface diffusion and therefore the network degradation [7]. We will conclude by highlighting what appears to be the future most promising and innovative research directions in the field of transparent electrodes based on MNW networks.

**Exploring Pure and Mixed Metal Phases as Catalysts for Wurzite InP Nanowire Growth**

Mariana Zavarize, Murilo H. Moreira, Varlei Rodrigues and Monica A. Cotta; UNICAMP, Campinas SP, Brazil.

Free-standing semiconductor nanowires are currently under intense investigation, both as basic science, to understand the nanostructure formation dynamics, and for technological applications in areas such as optoelectronics and energy harvesting, among many others. However, their integration into current device processing technologies still poses a few challenges. Planar nanowires, on the other hand, show similar advantages with yet a more straightforward integration capability. For this reason, efforts to control and characterize planar nanowires have grown in the last few years. Also, most of the studies use Au catalysts in Vapor-Liquid-Solid (VLS) growth mode for semiconductor nanowire synthesis; however, some characteristics of this type of synthesis limit nanowire potential applications, such as integration with silicon, for example. So in order to find an alternative to gold, many other metals have been explored in nanowire synthesis the last few years, such as Cu, Sn, Ag and Pd.

In this work we explore Ag, Au and Ag/Au alloy nanoparticles as catalysts for planar and vertical InP nanowire growth. Both metals present many similar properties, such as crystal structure, melting point and ductility. The InP nanowires were grown by Chemical Beam Epitaxy in VLS growth mode. The metal nanoparticles were obtained by the gas aggregation method, which allows size and composition control (in case of alloys). These nanoparticles show a pure metal-phase, with no passivating cap layer from the colloidal chemistry. Substrates of InP and GaAs with different crystallographic orientations and polarity were used for each of the growth conditions. Scanning electron microscopy provided nanowire shape statistics while transmission electron microscopy was used to investigate chemical and structural properties of the nanowires. We observe that nanowires tend to grow in planar or vertical mode depending on the polarity and orientation of the substrate, for each type of catalyst used. Au-catalyzed InP nanowires tend to grow in planar mode on GaAs(111)A and vertically on GaAs(111)B. For Ag catalyzed nanowires, however, we observe the opposite behavior, i.e., nanowires grow in planar mode on GaAs(111)B and vertically on GaAs(111)A. GaAs(100) substrates exhibit mixed populations. Similar behavior was observed with InP substrates. When Ag/Au alloy nanoparticles are used, however, planar and vertical nanowire populations are present on both GaAs(111)A and GaAs(111)B substrates, but with different densities in each case. These results indicate the importance of the surface-chemistry mediated substrate-metal nanoparticle interaction to
determine nanowire growth mode.

**11:30 AM NM03.20.04 Earth-Abundant Semiconductor Nanowires for Energy Harvesting** Simon Escobar Steinwall, Luca Francaviglia, Mahdi Zamani, Elias Stutz, Jean-Baptiste Leran and Anna Fontcuberta i Morral; Laboratory of Semiconductor Materials, Institute of Materials, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

Nanotechnology has allowed the utilisation of materials with limitations in their bulk form by utilising the processing and enhancing functionalisation. Nanowires in particular facilitate defect free epitaxial growth of systems with relatively large lattice mismatch through radial strain relaxation, and avoidance of mismatch dislocations at the interface if the diameter is small enough [1].

One material benefitting from this is zinc phosphate (Zn₃P₂). Despite exhibiting optoelectronic properties ideal for photovoltaic applications, such as a direct band gap at 1.5 eV, carrier diffusion lengths in the order of 5-10 um, and high absorption in the solar spectrum, it has found negligible use in modern photovoltaics [2-3]. The factors inhibiting its successful application are the lack of availability of lattice-matched substrates, impedes epitaxial growth, its high expansion coefficient compared to other semiconductors, causing strain and crack formation after processing, and doping, due to intrinsic p-doping by phosphorus interstitials and difficulty of homogeneously introducing extrinsic dopants.

Zn₃P₂ nanowires have been successfully grown on InP (001) substrates through the vapour-liquid-solid method using molecular beam epitaxy. It is observed that the zinc reacts with the InP substrate, generating In-Zn-P droplets, which act as the growth catalyst. Transmission electron microscopy (TEM) shows that the resulting wire is single crystalline and free of defects, and compositional analysis confirms that it is indeed composed of Zn₃P₂. It also shows that indium, proposed as an n-type dopant in Zn₃P₂, is incorporated throughout the wire. [4] This has the effect of doping the nanowire and slowly consuming the droplet, resulting in a tapered shape. Further studies also show how varying the zinc pre-deposition alters the size of the formed droplets, consequently determining the diameter of the nanowires. Micro-photoluminescence studies of these nanowires indicate an optical band gap at 1.40 eV, which is lower than the bulk value and closer to the maximum of the Shockley-Queisser limit. Power dependent measurements also indicate that the recombination is through acceptor-donor pair transitions rather than band gap transitions. Electrical measurements carried out in the 4-point configuration and back-gated transistor measurements will also be included, showing the electrical characteristics of the wires and their dominant charge carrier type.

**11:45 AM NM03.20.05 Synthesis and Characterization of Tellurium Nanowires Using Both Chemical and Green Routes and Their Comparison in Terms of Biocompatibility and Anticancer Properties** Ada Vernet Crua, David Medina and Thomas Webster; Northeastern University, Boston, Massachusetts, United States.

Traditional chemistry has undoubtedly enhanced the quality of life, but a price of the threat of the environment and the health of humans. Chemical processes are responsible for the contamination of all the known ecosystems all over the planet, to more or less extent. The traditional physics-chemical approaches for the synthesis of compounds are easy-to-get and straightforward. Nevertheless, there is a cost associated with the limitations that should be overcome from these approaches, such as the production of toxic by-products or the biocompatibility of the products. Therefore, new methods are needed, and the green chemistry offers a suitable answer.

Tellurium nanowires (TeNWs) were prepared using both chemical and green chemistry approaches. For the first one, sodium tellurite was dissolved in an aqueous solution of polyvinylpyrrolidone (PVP), hydrazine monohydrate and ammonia, and kept inside a hydrothermal reactor for several hours. The environmentally-friendly approach led to the use of telluric acid and starch as a unique reducing agent and kept inside a hydrothermal reactor for several hours. Both structures were characterized in terms of morphology and composition using TEM, SEM and EDX. Once purified, TeNWs were used as a template for the growth of metallic nanoparticles in a quick method with no need of additional reducing agent at room temperature. Besides, biocompatibility tests of the TeNWs with human tissue were accomplished, growing human dermal fibroblast (HDF) cells in media in the presence of both chemical and green-synthesized nanowires. Furthermore, anticancer studies were done using the tellurium nanowires with melanoma cells for 5 days.

It is demonstrated that green TeNWs can be used as a template for the in-situ preparation of nanoparticles. In vitro cytotoxicity assays were performed with human dermal fibroblasts (HDF) cells. The experiments showed that green-synthesized nanowires showed a higher cell proliferation of the cells than the experiments carried out with chemically-synthesized structures. Furthermore, after the incubation period, the growth of the cells was enhanced in comparison with the control and the chemically-synthesized nanowires. Anticancer studies showed an enhanced anticancer activity of green nanowires compared to the chemically-synthesized structures over a period of 5 days, causing a higher depletion of cell viability. Anticancer properties were examined: the presence of nanoparticles was able to delay the cell proliferation over the same range of nanoparticle concentration. Starch was able to synthesize tellurium nanoparticles in a rapid, cost-effective and entirely green approach that showed both antimicrobial and anticancer effect with low cytotoxicity for healthy cells.

Therefore, green TeNWs were compared with chemically-synthesized structures to show that the first ones have an enhanced biocompatibility and anticancer properties over the ones synthesized using traditional methods.

**SYMPOSIUM NM04/B101/ET14**
Environmental issues keep steadily increasing, thus there is a strong urge to discuss how materials scientists could more rapidly respond to the worldwide concerns. This joint tutorial effort would be organized by the three symposia together. To ensure the success of such synergistic efforts it is also urged a close dialogue with society so to establish guidelines for policymakers, thus this tutorial will incorporate both the societal and the engineering aspects of life cycle analysis (LCA) would be covered. The main objective of this tutorial is to explore communications pathways between companies and materials researchers that further elevate the profile and challenges of sustainability that represents a societal necessity and a viable and critical topic for research.

1:30 PM  
**Societal Aspect of LCA** Jean-Pierre Birat; ArcelorMittal

Materials are not simply the product of an engineering discipline, Materials Science, but also "social constructs" that have entertained a close relationship with society all through the historical timeline and remain a core element of our modern world, what is called a Key Enabling Technology. How this can be analyzed by parallel approaches of hard and soft sciences will be explained in the class as well as the trinity of economic, environmental and social values of materials. Examples reported in the 13 past SAM conferences will be used as examples.

2:45 PM BREAK

3:15 PM  
**Engineering Aspect of LCA** Alan Rae; IncubatorWorks, USA

The instructor will provide an overview on all the aspects considered in a life cycle analysis aimed to the engineering design of an industrial process. A part of the tutorial will involve the interaction with the audience in order to apply some of the concepts described in the first part of the tutorials to common objects.

4:15 PM **Sustainability Challenge** Alan Rae, IncubatorWorks

The symposia organizers will divide the participants into groups and a sustainability challenge will integrate the concepts presented by the instructors so to review and facilitate networking among participants and instructors

4:45 PM  
**Final Remarks**

higher than reported data in the literature. Therefore, the current study reported a type of highly electrocatalytic efficient IrO2 nanostructures, but also a specific capacitance, total charge, most accessible charge, electrochemically active surface area, and roughness factor. Our IrO2 NRs demonstrated enhanced electrocatalytic OER activity in 0.5 M H2SO4 compared to the commercial IrO2 NPs. Moreover, compared to commercial IrO2 NPs and previous reports, our IrO2 NRs showed enhanced electrocatalytic activity for both OER and HER after passing either N2 or O2 gas in a 0.5 M KOH electrolyte, as confirmed by cyclic voltammetry, chronoamperometry and electrochemical impedance spectroscopy. Our results are comparable with, and in most cases, higher than reported data in the literature. Therefore, the current study reported a type of highly electrocatalytic efficient IrO2 nanostructures, but also a simplistic, reliable and scalable synthetic process for them. It is expected that these IrO2 NRs can serve as a benchmark in the development of active OER and HER (photo)electrocatalysts for various applications in the near future.

Electrocatalytic water splitting has been considered as a viable strategy to convert and store energy renewably, but has been hampered by the slow kinetics of the oxygen evolution reaction (OER). Hence there is an urgent need to improve the performance of currently used materials and/or develop new materials. Iridium oxide is an effective stable electrocatalyst with low over-potential and high current for efficient fuel generation technologies. To further improve its activity, we developed a facile one-step molten salt synthesis process to generate ultrafine iridium oxide nanorods (IrO2 NRs). The electrocatalytic performance of these IrO2 NCs for OER in acidic media was compared with that of commercial IrO2 nanoparticles (NPs) in terms of specific capacitance, total charge, most accessible charge, electrochemically active surface area, and roughness factor. Our IrO2 NRs demonstrated enhanced electrocatalytic OER activity in 0.5 M H2SO4 compared to the commercial IrO2 NPs. Moreover, compared to commercial IrO2 NPs and previous reports, our IrO2 NRs showed enhanced electrocatalytic activity for both OER and HER after passing either N2 or O2 gas in a 0.5 M KOH electrolyte, as confirmed by cyclic voltammetry, chronoamperometry, and electrochemical impedance spectroscopy. Our results are comparable with, and in most cases, higher than reported data in the literature. Therefore, the current study reported a type of highly electrocatalytic efficient IrO2 nanostructures, but also a simplistic, reliable and scalable synthetic process for them. It is expected that these IrO2 NRs can serve as a benchmark in the development of active OER and HER (photo)electrocatalysts for various applications in the near future.

Gamma-radiation-induced synthesis of metal and metal oxide nanoparticles involves reactions of dissolved precursor metal salts with products of water radiolysis. When exposed to ionizing radiation water decomposes to form chemically reactive radicals and molecular species. The products of water radiolysis range from highly oxidizing, e.g. hydroxyl radicals to highly reducing, e.g. hydrogen radicals and solvated electrons. The oxidants and reductants produced upon radiolysis react then with solutes and change their oxidation state. These chemical changes lead to the formation and subsequent precipitation of insoluble species, since the solubility and reactivity of metal ions depend on their oxidation states. Synthesis of nanomaterials can be done by using either reductive or oxidative routes. To reach the controlled redox conditions and avoid the unwanted reactions one can add other organic or inorganic compounds which act as scavengers of the radicals. The amount of material obtained by gamma-radiation-induced synthesis can be controlled by the yield of reductive/oxidative radiolysis products formed in solution. Radiation-induced synthesis is a powerful tool to produce the materials of complex shape and compositions. It has the following advantages as compared to the other methods: The nanoparticles with very narrow size distribution and uniform shape can be synthesized; there are possibilities to synthesize the nanostructure in confined media, such as porous materials, nanotubes etc. The formation of radicals stops immediately when the solution is removed from the radioactive source. Therefore the amount of reacting radicals and thus the amount of obtained precipitate is controlled by the total radiation dose with a high accuracy. Moreover, the radiation-induced method is cost-effective processing, since it implies direct energy transfer without intervening media. It has low energy consumptions, since the radiation source does not require external energy supply. It requires minimal use of potentially harmful chemicals (initiators, crosslinking agents, acids etc.). Thus, radiation-induced synthesis can be considered as a green method.
In the current work we demonstrate how gamma radiation induced synthesis can be implemented to produce metal (Ag, Cu, Ni) and metal oxide (Cu2O, Co3O4, CuO) nanoparticles having narrow size distribution for different applications. The nanomaterials are produced both free standing and on solid supports. Metal nanoparticles are synthesized using the reductive route while metal oxide particles are produced using both oxidative and reductive routes [1, 2].

Photoelectron Spectroscopy Investigation of GaN/Si Heterostructures for Photocatalytic Water Splitting Srinivas Vankel1,2, Elisabetta Arca3, Glenn Teeter1 and Zeitian Mi4; McGill University, Montreal, Quebec, Canada; 2University of Michigan, Ann Arbor, Michigan, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States.

Surface, interface, and bandgap engineering play a pivotal role for designing tandem photoelectrodes for photocatalytic water splitting to potentially realize solar-to-hydrogen efficiencies >20%. III-nitride semiconductors, e.g. GaInN, have emerged as one of the most promising materials to realize high efficiency photocatalysts: their fundamental bandgap can be varied across nearly the entire solar spectrum by changing the alloy compositions and the band edge positions straddle water oxidation and reduction potentials under visible light irradiation. In this context, we have performed, both theoretically and experimentally, a detailed investigation of the structural, electronic, and photocatalytic properties of Ga(In)N/Si heterostructures. Detailed X-ray photoelectron spectroscopy (XPS) measurements reveal that the conduction band edge of GaN and Si are nearly-perfectly aligned, which enables efficient extraction of photo-generated electrons from the underlying Si wafer to GaN nanowires. Band diagrams were constructed from the measured valence band minimum (VBM) and the observed core-level shifts between different thickness GaN/Si samples. Deposition of 2-3 nm of GaN evidently passivates the Si surface and induces a small amount of upward band bending (BB). The interfacial valence-band-offset calculated from measured VBMs and core-level shifts was 2.52±0.1 eV. This value, in combination with the individual band gaps of Si and GaN, leads to a conduction band offset of 0.22±0.1 eV, where the negative sign indicates that the CBM of GaN is lower than that of Si. It is to be noted that in GaN acts like a hole blocking layer which helps in charge carrier separation and thereby reduce the surface recombination of the photo-generated carriers. With the incorporation of Pt co-catalyst nanoparticles on Ga(In)N surface, we have demonstrated solar water splitting on Ga(In)N/Si photocathode with a maximum current density of >35 mA/cm² and an applied bias photon-to-current efficiency >10% in 0.5 M H2SO4 under AM1.5G one-sun illumination. This work shows the use of GaN nanowires as a multi-functional protection layer as well as excellent charge extraction of the photogenerated electrons from the underlying Si wafer.

9:45 AM NM04.01.05
Structure and Reactivity of Zinc Oxide Nanoparticles—A DFT Study Takat B. Rawal1, 2 and Loukas Petridis1, 2; 1Department of Biochemistry and Cellular and Molecular Biology, University of Tennessee, Knoxville, Tennessee, United States; 2UT/DOE Center for Molecular Biophysics, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Zinc oxide (ZnO) nanoparticle, an active ingredient of bactericides, has potential applications in treating citrus greening disease owing to its unique properties. Here, employing density functional theory we study the structures and reactivity of sub-nanometer-sized ZnO nanoparticles. Examination on the propensity of binding of water, urea, salicylic acid and citric acid molecules to the surface of ZnO nanoparticle (diameter ~14Å), indicates that the molecules bind strongly at Zn atoms at the nanoparticle edges. Strikingly, the binding of urea, salicylic acid and citric acid through their O (O=C) atoms at the Zn sites can be traced to the electronic structures. We also investigate the solvation effects on the binding characteristics of these molecules. Finally, we compare the structures and energetics of molecules adsorbed on the nanoparticle with those on extended ZnO(10-10) surface, and find that the edge Zn sites of the nanoparticles are more active than the surface Zn sites of the extended surface. Overall, our results provide insights into the reactivity of ZnO nanoparticle in different local environments, and may offer guidelines to design the ZnO-nanoparticle-based material as an antibacterial agent for agricultural applications.

Hybrid Nanomaterials and Their Applications in Energy and Water Areas Pei Dong1, Yongjie Zhan3 and Jun Lou2; 1George Mason University, Fairfax, Virginia, United States; 2University of Texas, Texas, United States; 3Northwest University, Xi’an, China.

Water and energy are two of the world’s most valuable resources. In the near future, as the industrial sector expands, demand for water and energy will be even greater than it is today. Recently, advanced nanomaterials have been widely implemented in energy and water areas. Here, hybrid nanostructures composing of graphene-like film and bamboo-like carbon nanotubes have been synthesized in a simple, one-pot, catalyst-free chemical vapor deposition process. Pre-sputtered carbon coating on a copper substrate is considered as the key factor contributing to the final morphology. Furthermore, this hybrid nanostructure product has been shown to be a potential alternative material in solar cell and water desalination applications for sustainability.

Nanostructured Devices and Catalysts for the Solar-Driven Reduction of CO2 to Fuels

CO2-derived fuels present an attractive way towards a sustainable energy system. Mimicking natural photosynthesis by synthesizing carbon-based energy carriers using renewable energy allows for closing the anthropogenic carbon cycle and therefore represents an attractive way to store intermittent power, a challenge that has not yet found a satisfying solution. Using solar power as the energy source for fuel synthesis will require large surfaces of absorbers and efficient catalysts, which should be fabricated from abundant materials. In this context, we show the application of cheap and scalable CuO photocathodes in combination with molecular rhenium catalysts, both in solution and covalently bound to the nanostructured photoelectrode surface. Both systems feature substantial photocurrents and photovoltages, demonstrating protected CuO photocathodes as viable candidates for solar-driven CO2 reduction processes.

Moving from organic solvents into aqueous systems, we demonstrate the unassisted and sustainable splitting of CO2 into CO and O2 using perovskite demonstrating protected Cu2O photocathodes as viable candidates for solar-driven CO2 reduction processes.

Going beyond the production of CO, a novel approach was used to gain insight into the mechanism of hydrocarbon formation at copper electrocatalysts. Studying this process in nonaqueous electrolytes at low temperatures allows for fine-tuned control of the proton donor and the CO binding strength, enabling activation-controlled kinetic studies over an extended parameter range. From these measurements, we are able to show that the rate of methane and hydrogen formation is governed by the competition of CO and H for surface sites while ethylene formation remains weakly impacted by this effect.

Microkinetics on these electrodes indicate that the selectivity change is due to the suppression of H2 evolution, while the rate of CO production remains similar. Together with the use of a bipolar membrane, allowing for separating product gases while maintaining a sustained pH gradient, we used these electrodes demonstrate long-term solar CO production at an efficiency of 13.4 %, driven by a single 3-junction photovoltaic. Going beyond the production of CO, a novel approach was used to gain insight into the mechanism of hydrocarbon formation at copper electrocatalysts.

The presentation illustrates the pathway to ever more insight and to efficient catalysts and devices for the reduction of CO2, first to CO and subsequently to hydrocarbon fuels such as methane and ethylene.

Etched Metal Superhydrophobic Surfaces for Enhanced Condensation
Soumyadip Sengupta, Kalyan Boyina, Kazi Fazle Rabbi, Bassel Abu Jabal, Justin Olson, Longnan Li and Nenad Miljkovic, University of Illinois, Urbana, Illinois, United States.

Inspired from natural surfaces such as lotus leaves, water strider legs, the Namib desert beetle, and geckos’ feet, the past few decades have seen significant research and development in the design and manufacturing of water repellent or superhydrophobic surfaces. For superhydrophobicity, surfaces need to be fabricated in two steps, initially creating micro/nanostructures, thereby providing roughness to the primary substrate, followed by the deposition of a low energy surfactant coating. The low surface energy leads to higher advancing and receding contact angles with water droplets, lower contact angle hysteresis, and hence easy droplet removal, promoting dropwise condensation and enhancing heat transfer. Recent studies have focused on chemical oxidation of metallic surfaces to form conformal micro/nanoscale structured metal oxide layers at the solid-air interface. The process is usually self-limiting, with both the oxide layer thickness and structure length scale ranging from 10 nm to 100 µm. Despite efficient dropwise condensation, the metal oxide layers create a significant conduction parasitic thermal resistance due to their lower thermal conductivities (around 10 W/m.K) when compared to their pure metal counterparts (around 100 W/m.K). Furthermore, the application of metal oxide structures for industrial applications remains a challenge due to their poor durability. Here, we develop micro/nanostructured surfaces via direct electrolytic etching of metals. Different length scale surface structures and roughness are obtained by controlling the etching time and supply voltage of the electrolytic process. The etched metallic structures are made of the base metal, enabling higher thermal conductivity and lower parasitic resistance. Furthermore, the uniform metallic composition of the base metal and etched structure minimizes the thermal-mechanical stresses. Linear abrasion tests revealed greater durability of our etched metal structures when compared to metal oxides. After coating the developed surfaces with a low energy self-assembled monolayer using vapor deposition, these surfaces show water droplet contact angles greater than 160°. Our work not only develops metal etched structured surfaces for durable condensation of steam and enhancement of condensation heat transfer coefficient, it enables a scalable manufacturing technique for durable superhydrophobicity.

Periodic Step Nanostructure Evolution at the Thin Film Gold/Substrate Interface
Linfeng Chen, Maria Koifman Khristosov, Cecile Saguy, Alex
Nanoscale step structures have attracted recent interest owing to their importance in both fundamental and applied research, for example in adsorption, in catalysis, and in directing nanowire growth. In this in situ study, self-ordered vicinal-like surface structures were obtained by annealing of thin films of gold deposited on ultraflat Si/SiO$_2$ substrate. Annealing at temperatures ≥200 °C efficiently promoted the formation of vicinal-like structures on the inner gold/substrate interface. Gold grains near the inner surface exhibited an orientation with the [111] direction very close to the substrate normal. Furthermore, the step periodicity depended on the grain/substrate orientation angle. Smaller misorientation resulted in a larger average step periodicity, similar to that seen in regular vicinal surfaces of gold single crystals. Formation of low-index terraces and atomic steps at the inner gold interface (while the silica surface remains ultraflat) can be considered as a kind of solid–solid dewetting. We suggest that the formation of vicinal-like structures could be attributed to the thermally activated surface reconstruction by minimization of the total surface energy, which includes the gold/substrate cohesion energy and the GB energies. The process is controlled by diffusion of gold from the inner gold/substrate interface, most probably to the grain boundaries and then to the outer surface of the film. Substantial bulk diffusion across the film during annealing at 400 °C for 4 h can also provide a required mass transport from the inner to the outer surface. This work contributes to the understanding of the atomic step structure formation at the gold/substrate interface, which will be helpful in the use of vicinal-like surfaces as templates for growing of regularly spaced nanostructures. It also offers a method for the in situ investigation of both the grain orientation and the grain interface step periodicity in a given grain, and then can be utilized for further explorations of vicinal-like surfaces.

2:15 PM *NM04.02.04
Sustainable Hydrogen Solution Enabled Through Hydrolysis with Water-Reactive Nanoporous Metals

Eric Detsi, John S. Corsi and Jintao Fu; University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Water-reactive nanostructured materials and metalloids such as nano-Mg, nano-Al, nano-Zn and nano-Si with minimum surface oxide coverage have a broad range of potential applications. They can serve as catalysts for combustion, as active materials in hydro-powered spaceship engines, and as materials for onboard hydrogen production to power portable devices and hydrogen fuel-cell vehicles. The degree of reactivity of this class of materials with water is linked directly to their nanoscale size and to the extent in which the surface of these nanomaterials is covered with oxide. For example, smaller nanostuctures exhibit faster kinetics in their reaction with water to produce hydrogen. Nearly oxide-free, ultrafine nanoscale structures with characteristic sizes in the range of 10-20 nm are commonly required for effective reactivity with water. Nanofabrication of these highly-reactive materials with such ultrafine structure sizes and minimum surface oxide coverage is still a fundamental challenge due to their high chemical reactivity. In this talk, I will present a novel, cost-effective, and scalable route to sustainable hydrogen for on-board application. Our new route involves: (i) the hydrolysis of neutral water with nanoporous aluminum to produce hydrogen and aluminum oxide without the typical use of catalysts, and (ii) the recycling of aluminum hydroxide back to aluminum metal without any CO$_2$ footprint. While over 95% of hydrogen used worldwide is produced by steam reforming of natural gas, this method is not sustainable because CO$_2$ is co-produced during the process. Sustainable hydrogen can be generated by electrolysis of water into hydrogen and oxygen, but this method is relatively expensive (~40-53 kWh of energy is needed to produce 1 kg of H$_2$) and not very efficient (40-60% yield). The new method presented in this talk requires only 24-47 kWh of energy to produce enough nanoporous aluminum to generate 1 kg of hydrogen with 50-85% yield by hydrolysis in neutral water. [1,2]

High Temperature Nanomanufacturing for Emerging Technologies

Yonggang Yao; University of Maryland, College Park, Maryland, United States.

High temperature processing can provide sufficient activation energy for materials’ compositional, structural, and morphological evolutions, and is essential for various kinds of reactions, synthesis, and post-treatment. However, the current high temperature heating sources, mostly furnaces, are far from satisfying for nanomaterials processing owing to their bulky size and limited temperature and ramp range (~1300 K, ~10 K/min). Here we have focused on the study of electrical triggered Joule heating as a new route for high temperature engineering of nanomaterials toward nanomanufacturing. We developed facile, highly stable and controllable heating strategies for micro/nanoscale high temperature engineering. Ultrahigh temperature annealing (~2500 K) is applied to carbon nanomaterials to address the defects and poor interfacial problems. Ultrafast thermal shock (~2000 K in 55 ms) is applied to metal salt loaded carbon substrates for in-situ synthesis of ultrasmall, well-dispersed nanoparticles. The high temperature engineering on nanomaterials is highly facile, energy-efficient, and reliable toward scalable nanomanufacturing. More exciting results and products are expected for various nanomaterials during/after the unique high temperature engineering.

3:00 PM BREAK

3:30 PM OPEN DISCUSSION

3:45 PM NM04.02.07
Additive Manufacturing of Gold Nano-Dimers Under Ambient Conditions

Chenpling Zhao; University of Dayton, Dayton, Ohio, United States.

The terms “nanomanufacturing” and “nanofabrication” are often used interchangeably. Recently, Liddle et al. have distinguished between nanomanufacturing and nanofabrication by using the criterion of economic viability. Nanomanufacturing, which utilizes efficient and cost-effective nanofabrication methods to manufacture nanostructures and functional devices, has the characteristic of being a source of money, while nanofabrication is often a sink. Nanomanufacturing is indispensable in today’s “nano-world” as the devices keep shrinking in size. The functional devices with internal bond lengths of 10-20 nm scales have intriguing and extraordinary properties for many applications. For example, the color of gold nanoparticles distributed in a material does not appear yellow its familiar color for bulk gold, instead, the color of nano-gold changed to ruby red. The melting point of gold at the nanoscale is also significantly lower than its bulk counterparts.

There are a large number of nanofabrication approaches available, but only a few are suitable for large-scale nanomanufacturing. Therefore, the exploration of new technology is desperately needed to expand the nanomanufacturing toolbox. Here, we demonstrate a method that can be used for affordable nanomanufacturing at the ambient conditions. A low-cost continuous-wave (cw) laser is used to directly kick and transfer nanostructures from one substrate
to another in ambient conditions. Unlike the direct laser ablation method, where expensive pulsed lasers are typically used to ablate the materials disruptively, the method demonstrated here has no damage on the nanostructures, therefore, this method can maintain the geometry of nanostructures and transfer them selectively in an additive manner.

4:00 PM °NM04.02.08
Sustainable Nanomanufacturing Research at NSF* Khershed Cooper; Advanced Manufacturing, National Science Foundation, Alexandria, Virginia, United States.

Nanomanufacturing is the fabrication of nano-scale building-blocks (nanomaterials, nanostructures), their assembly into higher-order structures, and the integration of these into larger scale systems with manipulation and control at nano-scale. Typically, the scale ranges from 1-100 nm. Processes can be top-down (additive/subtractive) or bottom-up (self- and directed-assembly) or an integration of the two. Manufacturing processes need to be scalable, controllable, reproducible, efficient and low cost. The combination of large-scale production and nano-scale products raises environmental and sustainability issues. Questions needing answers are: 1) How can industry develop new nanotechnologies in a responsible and sustainable manner; 2) How can it be ensured that nanomanufacturing processes are safe for producers and products are safe for consumers and the environment. This talk discusses NSF-supported projects in sustainable nanomanufacturing that address life-cycle analysis, recycling, environmentally-benign nanomaterials and processing, green nanomanufacturing, clean energy, wastewater treatment, among others. It will conclude with a discussion on future directions and their implications.

4:30 PM RAPID FIRE PRESENTATION
efficient pathways for ion and electron transportation, as potential successor of current filtration membranes. While the pressure driven transport data on highly ordered continuous, thin films of multi-layered graphene oxide and holey graphene is expected to demonstrate faster transport for salt water, higher retention for charged and uncharged organic probe molecules with hydrated radii above 5 Å as well as modest retention of mono- and di-valent salts for ~150 nm thick membranes. The highly ordered graphene nanosheets and nanoscaled porous graphene in the plane of the membrane make organized, molecule-hugging cylindrical and spherical channels, respectively, thus enhance the permeability and hydrodynamic conductivity. The results illustrate that both the mesoscale and nanoscale pores are favorable for enhancing CDI performance by reducing the diffusion distance from external electrolyte to the interior surfaces and enlarging surface area analogous to electrochemical double-layer supercapacitors where in electrical energy storage is through concurrent surface ion adsorption and electron transfer. We determined the salt ion species rejection by composite CDI electrodes by > 65% for actual seawater in one cycle which can be further improved by use of nanoparticles for ion selectivity. This work is supported in parts by KY NSF EPSCoR and WKU Research Foundation internal grant.

NM04.03.04
3D Hierarchical Structure for Water Splitting with Extraordinarily Enhanced Photocactivity
Junho Jun, Sucheol Ju, Seungho Baek, Minseop Byun and Heon Lee; Korea University, Seoul, Korea (the Republic of).

As the need for renewable energy continues to increase, hydrogen, the most promising clean energy source, is receiving a great deal of attention. Solar water splitting, which is the most efficient way to produce hydrogen without any pollutants, has been actively studied since the discovery of the TiO2 photocatalyst by Fujishima in 1972. Nevertheless, the production efficiency of this method is still very low, making it impractical for commercial use, and many studies are underway to improve the efficiency of solar water splitting. The mechanism of the reaction at the photoelectrode can be roughly divided into three sub-categories: absorption (Eabs), electron separation (Esep), and surface reaction (Etrans), each with its own efficiency. In order to produce an efficient optical electrode, the material used for solar water splitting must be efficient for all three reactions. Especially, it is challenging to decouple the efficiency between light absorption and charge separation (Eabs x Esep). Nanostructuring is one of the most efficient method to overcome this coupling issue. By nanostructuring with one or more materials, nanostructured layer can have increased light absorption with even a thin layer, which is good condition for short carrier diffusion length of oxide materials such as BiVO4, Fe2O3.

Herein, We fabricate Au/BiVO4 3D nanostructured photoelectrode via nanoimprint lithography(NIL) and various deposition method. NIL has advantages on fabrication of nanostructure in large area. Using NIL, we can fabricate uniform nanostructure such as nanocone or high-aspect ratio pillar. After that, we deposit various materials on nanostructured template by Atomic layer deposition(ALD) or photo assisted electrodeposition (PED). This 3D hierarchical structure has an optical effects that can enhance light-matter interaction including anti-reflection and light-scattering, and also help generated electron-hole deposit various materials on nanostructured template by Atomic layer deposition(ALD) or photo assisted electrodeposion (PED). This 3D hierarchical structure has an optical effects that can enhance light-matter interaction including anti-reflection and light-scattering, and also help generated electron-hole.

One-step Flame Synthesis of W/Mo/N-Doped Titanium Dioxide Nanoparticles for Enhanced Photocatalytic Activity
Yujuan Zhang, Zhizhong Dong, Bernard Kear and Husnu E. Unalan; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

W/Mo/N-doped titanium dioxide (W/TiO2) nanoparticles are synthesized using a multiple diffusion flames setup, where tungsten mesh, molybdenum wire, and CNH2 is utilized as doping source and titanium isoproxopropoxide (TTIP) serves as precursor for TiO2. At relatively lower tungsten loading rates, nanoparticles are produced in W-TiO2 form with an obvious shift angle (0.15°) in the XRD pattern. However, at high tungsten loading rates, homogenous nucleation of WO3 occurs concurrently with homogeneous nucleation of TiO2, thereby leaving less tungsten ions to be doped into the TiO2 matrix. Molybdenum wire is placed on top of the tungsten mesh to achieve W-Mo co-doping of TiO2. Cyanamide solution is injected into the central flame to produce N-doped TiO2. UV-Vis spectroscopy shows that the as-synthesized doped nanoparticles possess enhanced absorbing ability in the visible light wavelength range compared with that for non-doped TiO2 nanoparticles. Photocatalytic activity of the doped nanoparticles are tested via batch phase water reduction with methanol as a sacrificial agent. As-synthesized samples having a higher H2 evolution meanwhile are more active under dark and UV illumination comparing to that for Pt25.

NM04.03.06
Ultra-Fast Additive Nano-Patterning Process and Its Applications with Large Area and Flexible Form-Factors
Hanul Moon1, Hyeonho Jeong1, Han-Jung Kim1, Min Yoon1, Chang-Goo Park2, Yong Suk Oh1, Dae-Geun Choi2 and Seunghyup Yoo1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

Nano-scale patterns have been intensively studied in wide range of fields because they provide enhanced performance or new functions that cannot be observed in macro- or micro-scale patterns. However, conventional nano-patterning process based on lithographic methods has limited wide-spread of nano-patterns due to complex process steps requiring expensive equipment. To fully open the possibility of nano-patterns in various fields, an alternative method is required to fabricate nano-patterns in a facile way that secures significantly improved cost-effectiveness, and versatility allowing large-area fabrication or various form-factors such as flexibility. Here, we proposed an additive nano-patterning process from solution route using selective-wetting phenomenon in response to such requirements.

The proposed process proceeds to 1) nano-imprinting on to hydrophobic/hydrophilic bilayers and 2) solution dragging. Appropriate post-processes such as annealing can be followed. The former step results in 3D structures consisting of nano-scale engraved hydrophilic parts and embossed hydrophobic parts. Then, by dragging a solution on top of the surface, the solution is automatically confined in the engraved hydrophilic parts without residue on the embossed hydrophobic top surface by selective-wetting phenomenon. The 3D engraved structure is also essential to cause nano-patterns with sufficient amount of target materials. The results verified that the yield of the nano-patterning process is almost perfect once the imprinting onto the bilayer is successful. 150 nm-diameter dot arrays of Ag over the area of 10 cm × 10 cm were successfully fabricated with high yield, and was served as a plasmonic color filter of uniform magenta color. The mechanism of the proposed nano-patterning process was analyzed using fluid-dynamics simulation, and verified control parameters aiming at higher process speed and smaller pattern size.

Virtually, any kind of solutions can be applied to the process, and nano-patterns of Ag, metal-oxide, and organic materials could be fabricated by using a metal-nano-particle ink, a sol-gel solution, and organic solvent. In terms of throughput, the dragging speed of solution could be over 4.5 m/min. The selectivity-wetting phenomenon also enables self-aligned multiple deposition of nano-patterns, thus allows thickness controllability and multi-layer nano-patterns assembly of different materials. Thanks to the simple fabrication steps, the proposed method could open an access to make various substrates including plastics and papers. According to the aforementioned advantages, we believe the proposed process significantly improves the usefulness of nano-patterns in wide range of fields, especially if they require nano-patterns over large-area with various form-factors fabricated by a cost-effective way.

NM04.03.07
Investigation of Magnetic Properties of Electrodeposited Cobalt Ferrite Films with Control of Grain Size and Surface Morphology
Brent
Cobalt ferrite is a material which has been researched for its applications in spintronics, magnetic sensing, and catalysis. Though synthesis methods have been established for formulating films including pulsed laser deposition, chemical vapor deposition, and rf sputtering most of these methods need high vacuum and power sources to formulate a film. Within this work a facile method for synthesizing films through electron deposition without the need of high energy appliances. The main component for the process includes an aqueous solution which can be reused with reproducible results. Through varying Co:Fe content, time, potential, and ramp rates, control over grain size and morphology of the surface was established. X-ray diffraction (XRD), energy dispersive spectroscopy (EDS), and scanning electron microscopy (SEM) were used to confirm phase, composition and surface morphology. Variations in magnetic properties such as transition temperatures, magnetic saturation, coercivity, were observed from grain size ad surface morphology. The current research seeks to improve facile thin film methods which may be facilitated in a variety of magnetic applications.

NM04.03.08
On-Demand Band-Gap Tuning of Colloidal Perovskite Nanocrystals Enabled by Fast Anion-Exchange Reactions Kameel K. Abdel-Latif, Robert W. Epps, Michael Bowen, Corwin Kerr and Milad Abolhasani; Chemical Engineering, North Carolina State University, Raleigh, North Carolina, United States.

Since the discovery of the colloidal perovskite nanocrystals three years ago, they have rapidly grown to become one of the most promising classes of nanomaterials for large-scale applications in optoelectronic devices. Anion exchange reactions of the highly luminescent cesium lead halide perovskites (CLHPs) provide a facile post-synthetic route for the tuning of the absorption/emission band-gap of CLHPs. These post-synthetic reactions allow the utilization of CLHPs in various optoelectronic applications including third-generation photovoltaic cells and light emitting diodes. Studies of anion-exchange reactions are typically conducted using the time- and material-intensive flask-based synthesis approach. Batch scale synthesis strategies are notorious due to (a) batch-to-batch variation, (b) inefficient and irreproducible mixing timescales, (c) manual sampling and characterization at room temperature, and (d) poor size distribution of the resulting nanocrystals after scale-up. Here, we present a modular multiphase microfluidic strategy with an in situ spectral monitoring capability that enables the systematic kinetic study of anion-exchange reactions of CLHP nanocrystals. Utilizing the microfluidic nanocrystal synthesis platform, we monitor absorption and emission spectra of CLHPs, in real-time, over residence times ranging between 100 ms and 17 min. In-situ monitoring of the optoelectronic properties of CLHPs over different synthesis conditions enables fundamental and applied studies of structural tuning of CLHPs via anion-exchange reactions. The enhanced mixing feature of the multiphase flow along with the novel anion-exchange framework using ZnX2 (X=I or Cl) facilitates on-demand bandgap tuning of high-quality CLHPs (i.e., narrow size distribution with high quantum yield) via a positive feedback loop in which synthesis parameters are varied until the target optoelectronic characteristics are achieved.

Corporate Responsibility—A Green Initiative to Reduce Chlorobenzene Based Chemistries in Semiconductor Processing Monique Farrell, Kevin Frey and John Mason; Northrop Grumman, Linthicum, Maryland, United States.

Climate change and an increase in endangered species, are examples of technological advances negatively impacting the environment. As technology demands increase, an earnest effort to reduce the environmental impact of processing and manufacturing related activities is critical. From a business perspective, minimizing or removing toxic chemicals from processes, is a high impact area that can increase work environment safety and decrease waste management costs. This work presents processing considerations when transitioning to greener alternative polymer resist solvents, for applications in nanomanufacturing with sustainability considerations. Within government contracting, process modifications that change product form, fit, or function require qualification and at minimum justification. This work presents the conversion from a chlorobenzene to anisole based solvent using a 495 kMW polymethyle methacrylate polymer resin, without impacting form, fit, or function of the intended device. Resist conversion is of interest as the difference in the substrates of the two solvents, impact the effective toxicity of the materials. Specifically, the oral median lethal dose (LD50) for chlorobenzene is 1110 mg/mL, while anisole is 3700 mg/mL. Developing a process that utilizes anisole as opposed to chlorobenzene, addresses this safety concern and contributes to green initiatives worldwide. Within this work, an electron beam lithography fabricated transistor consisting of a source, drain and gate were converted from a chlorobenzene based resist to a process utilizing an anisole solvent; while maintaining process of record specifications. The purpose of this work is to provide a starting platform for individuals seeking to convert from a chlorobenzene solvent to an anisole based resist, for sub-micron lithography steps.

Approved For Public Release #18-1367; Unlimited Distribution

NM04.03.10
The Role of the Counterion on the Crystal-Shape and Photocatalytic Properties of ZnO Nanostructures Grown via Hydrothermal Route Ariadne C. Canto1, Luis F. da Silva1, Mateus Ferrer2, Osmundo F. Lopes1, Valmor R. Mastelaro3 and Elson Longo1; 1Federal University of São Carlos, São Carlos, Brazil; 2University of São Paulo State–UNESP, Bauru, Brazil; 3University of São Paulo, São Carlos, Brazil.

Nowadays, a concern over environmental problems has enhanced our awareness of the need to develop alternative and environmentally friendly process aiming at increase environmental protection. For the treatment of waste water and pollutant degradation, photocatalysis is considered one of the most promising and sustainable way due to its high-efficient, eco-friendly, low toxicity and low cost. Zinc oxide (ZnO) exhibiting different morphologies and high surface/volume ratio exhibit many favorable optical, electronic and surface properties leading it a promising candidate in field of photocatalysis as a sustainable and eco-friendly technology. Motivated by these considerations, the goal of this study consisted to investigate the influence of zinc precursor on the structural, microstructure, surface and photocatalytic properties of nanostructured ZnO films grown under hydrothermal conditions.

The nanostructured ZnO films were grown via hydrothermal method using different zinc salts, including acetate (Zn(CH3COO)2·2H2O), nitrate (Zn(NO3)2·6H2O), and sulfate (ZnSO4·7H2O) under identical conditions. The crystalline structure and morphological features were investigated by X-ray diffraction (XRD) and field-emission scanning electron microscopy (FE-SEM) measurements, while the surface properties were probed using X-ray photoelectron spectroscopy (XPS).

XRD patterns of the ZnO films were fitted to the wurtzite ZnO structure, however the sample synthesized from zinc sulfate also presented additional peaks assigned to the zinc hydroxy-sulfate-hydrate phase. FE-SEM analyses reveal that the morphology of the ZnO structures is strongly dependent on the zinc salt. The zinc nitrate provides the formation of the same morphology of the acetate, with an anisotropic growth preferentially along the (0001) direction resulting in hierarchical nanorod-like structures with an average diameter of ca. 90 nm. The average rod diameter was larger for ZnO samples synthesized using zinc acetate (ca. 2 times). Regarding the zinc sulfate, the change in microstructure was more significant, where SEM images revealed the formation of hexagonal microplate-like structures. In this case, the growth along (0001) was dramatically suppressed, producing a micrometric 2D morphology.

With respect to photocatalytic activity, the ZnO samples were studied for the degradation of methylene blue (MB), and rhodamine B (RhB) dyes under ultraviolet light. The ZnO film prepared from zinc nitrate exhibited the best photocatalytic activity compared to other samples, followed in turn by the
sample prepared with acetate, and sulfate. The enhancement of photocatalytic activity was attributed to structures size, surface morphology including the higher fraction of exposed (0001) ZnO polar facets, as well as the presence of oxygen defects.

**High Volume Manufacturing of Boron Nitride NanoBarbs**  
Steve Wilcenski; BNNano, Inc., Cary, North Carolina, United States.

Boron nitride nanotubes have become a material of significant interest due to their unique combination of physical and chemical properties. Among the desirable properties are the high thermal stability, high thermal conductivity, electrical resistivity, very high strength and stiffness, and super hydrophobicity. This combination of properties makes boron nitride nanotubes an attractive material for use in wide-ranging markets from aerospace to automotive and defense to biomedical.

The most significant limitation to these potential applications has been the lack of supply of high purity boron nitride nanotubes in the marketplace. Recent advances in the manufacture of this material are now enabling additional research and product development. The high-volume NanoBarb process is uniquely positioned to manufacture and supply commercial volumes of high purity boron nitride nanotubes to fulfill this need.

**Rational Design of Novel Dielectric and Photocatalytic Core-Shell Nanomaterials by a Sacrificial Template Method**  
Prabodha M. Balasinghawaka1, Swati Naik2, Liang Hong3, Robert Klie2 and Gabriel Caruntu1; 1Central Michigan University, Mount Pleasant, Michigan, United States; 2Physics, University of Illinois at Chicago, Chicago, Illinois, United States.

SrTiO3 has a well-known perovskite crystalline structure and exhibits excellent dielectric, electro-optic and catalytic properties, being the leading candidate in many cutting-edge technological applications. We report here on the rational synthesis of SrTiO3/TiO2 nanodimensional heterostructures by using TiO2 colloidal nanocrystals as sacrificial templates under different reaction conditions, with the main goal of achieving control over the morphology (size, shape), internal structure and surface composition of the resulting nanoparticles. Both the synthesis of TiO2 nanocrystals and their subsequent conversion into SrTiO3 were performed using a hydrothermal method. These nanocrystals were characterized by powder X-ray diffraction (XRD), transmission electron microscopy (TEM), vibrational spectroscopy (Fourier transform infrared spectroscopy (FT-IR) and Raman spectroscopy) and optical absorption measurements. Various reaction parameters have been finely tuned in order to optimize the reaction conditions. A detailed characterization of the dielectric properties of these nanopowders was carried, revealing that dielectric permittivity has a value around 120 at room temperature with a low loss, which make these nanomaterials desirable for applications in energy storage and as dielectrics. Moreover, the photocatalytic properties of SrTiO3/TiO2 heterostructures were analyzed by using dye degradation method under ultraviolet light. An enhanced photocatalytic activity was observed, which can be ascribed to the improved charge separation between photogenerated electrons and holes in conduction and valence bands of SrTiO3 and TiO2. Thus, this synthesis strategy of nanoscale heterostructures is useful to develop functional materials with superior efficiency for implementation into functional electrical devices, as well as photocatalysts.

NM04.03.13  
**Hierarchical Porous Solvogel Monoliths—Synthesis and Application**  
Marie-Christin Röpert, Christoph Weidmann and Rainer Ostermann; Westphalian University of Applied Science, Recklinghausen, Germany.

Bimodal pore systems are of utmost importance for many high-tech applications, for example in chromatography or as carrier material for catalysts. A hierarchical structure with both micro/mesopores and macropores allows to obtain both high surface areas and good transport properties (accessibility of and low pressure drop in the porous structure). The inorganic sol-gel-chemistry offers reliable routes to synthesize materials with tunable pore sizes, most prominently via phase separation during condensation and solidification of silica precursors [1]. This concept was successfully transferred from inorganic to organic polymers, based on the radical polymerization of divinylbenzene [2]. In contrast to these studies, we extend this strategy to novel bicontinuous porous polymers, which form readily under mild conditions. Therefore, we use the cyclotrimerization of inexpensive diisocyanates to obtain materials with continuous macropores and very high adsorption capacities. The ratio of solvent, polymer and diisocyanate in the studied system can be varied over a wide range, allowing to independently control both pore size and volume. In addition, the isocyanate chemistry allows using tailored prepolymer to optimize the properties (e.g. shrinkage) or functionalizing the resulting solvogels for adjusting polarity and incorporating catalysts. Furthermore, the crosslinked polysiloxane network is thermally and mechanically stable and therefore suitable for applications involving high pressure or temperature.

We will present the considerations leading to systems of suitable solvents and polymers for controlled phase separation, focus on the parameters for synthesis and functionalization, as well as giving a first outlook on applications.

NM04.03.14  
**Effect of Surface Modification and Confinement Effect of Crystalline and Amorphous SiC for Sustainable Renewable Energy and Environmental Remediation**  
Akash Mathur1, Dipayan Pal2, Ajaib Singh1, Rinki Singh1 and Sudebha Chattopadhyay1, 2, *; 1MEMS, Indian Institute of Technology Indore, Indore, India; 2Physics, Indian Institute of Technology Indore, Indore, India; 3BSBE, Indian Institute of Technology Indore, Indore, India.

Silicon carbide (SiC) became an important material whose popularity has been constantly increasing due to its excellent mechanical, electrical, optical and chemical properties, which recommend it for cleaner, smaller, stronger and more efficient technologies for solar cell applications as well as for environmental monitoring and decontamination [1]. The occurrence of different polytypes of SiC makes it suitable for photocatalytic material for hydrogen generation and environmental remediation [2] in crystalline SiC forms and for solar cell applications as diffusion barriers, antireflection coatings in amorphous SiC form [3]. Herein, the confinement effects of the different polytypes of crystalline SiC particles and amorphous SiC thin films are being addressed. Here, we report the significant enhancement of photocatalytic activity and substantial bandgap narrowing of EG/SiC composites. Graphitization of SiC by high temperature thermal decomposition method [4] has been employed to grow epilayer graphene (EG) on silicon carbide (EG/SiC hybrid system) to modify the surface and interface structure in controlled manner. The systems have been characterized by Raman and UV–vis spectroscopies along with the XRD, SEM and HRTEM analysis. Significant enhancement of the photocatalytic activity (~1000%) and bandgap narrowing (~30%) of EG/SiC systems were observed, relative to the bare SiC, depending on the quality and quantity of the EG and heterojunction interface structures. Furthermore, we report on a dual ion beam sputtering assisted deposition (DIBSD) of confined SiC thin films (about 450 nm to 20 nm thickness range) with low surface roughness. The thin films have been characterized by Spectroscopic Ellipsometry technique along with AFM, XPS, XRD and XRR. Clear indication of systematic band gap variation was observed for the changes in surface roughness as an effect of confinement of DIBSD grown SiC films. The effect of different types of SiC (polytypes/amorphous) at their different confinement levels (thin films, nanoparticles) have been studied further to explore the potential application in photocatalysis for renewable energy and environmental remediation (e.g., waste water treatment) and for different...
optoelectronics and solar cell applications

Core-Shell Nanoparticle Synthesis—A Novel Strategy to Achieve Heterostructures at the Nanoscale using a Molten Salt Solvent

Benjamin Levitas1, Yuexing Zhu2, Katsuyoshi Kakinuma3 and Srikanth Gopalan3; 1Boston University, Boston, Massachusetts, United States; 2Fuel Cell and Nanomaterials Center, University of Yamanashi, Yamanashi, Japan.

In the last three decades, solid oxide fuel cells (SOFCs) have garnered significant interest for viable alternative energy systems owing to their high electrical efficiency and fuel flexibility. In this work, we introduce a novel synthesis of cathodes in SOFCs, wherein oxygen reduction occurs in two steps—adsorption and electronegation, and surface/bulk diffusion to incorporation sites. Transition metal oxides such as strontium-doped lanthanum manganite (LSM) and strontium-doped cobalt iron oxide (LSCF) have been used as cathode materials, however both individually lack the key characteristics to successfully complete oxygen reduction. Furthermore, the accumulation of chromium (chromium poisoning) on SOFC cathodes is known to significantly hinder the performance of the cells. Incorporating core-shell composites as the cathode material could alleviate this problem: effectively combining the functionalities of both materials and providing a nanoscale protection from Cr poisoning with a shell such as Cr-doped LSM (LSCM). Core-shell oxide composites have broad applications in fuel cells, catalysis, magnetic devices, spintronics, nanophotonics, and many more fields. However, synthesizing core-shell composites previously has proved difficult requiring multiple steps, resulting in non-uniform core-shell structures. In this work we propose utilizing a molten salt synthesis process to create core-shell composites with precise composition with relative ease. The core is synthesized using high-temperature calcination and ball milled with the precursors of the target shell material. The milled powder mixtures are added to a LiCl-KCl eutectic melt to form core-shell hetero-structures via heterogeneous nucleation. Prior results have shown the successful formation of LSM and LSCF using the molten salt synthesis, along with the formation of core-shell LSCF-LSM hetero-structures. Synthesis temperatures dropped from the conventional 1000 °C to 500 °C, with dwell times as low as 10 minutes. Furthermore, SOFC cathodes consisting of LSCM were found to have stable polarization resistances, whereas the polarization resistance in LSM cathodes steadily increased. This result provides a strong motivation to further explore LSCM as a shell for core-shell cathodes to ensure protection from chromium poisoning. In essence, this work demonstrates an inexpensive, sustainable method to synthesize core-shell cathodes that can simultaneously provide high power densities and low rates of degradation arising from Cr-poisoning.

NM04.03.17

All-Solution-Processed Transistors on Paper for Cheap Flexible Electronic Applications

Do Hoon Lee, Taewan Kim, Hyun Soo Kim, Ye Rim Lee and Byung Yang Lee; Korea University, Seoul, Korea (the Republic of).

Paper electronics is receiving great interest because it is one of the best candidates for next generation devices with many useful features such as low cost, disposability, and flexibility. In this work, we demonstrate the fabrication of zinc oxide nanowire (ZnO NW) field-effect transistors (FETs) on paper with facile, low-cost and large area manufacturing. This was achieved using the high absorption property of paper. By absorbing silver nanowire (AgNW) solution into the paper, AgNW network formed on the paper surface that acts as a gate electrode with low sheet resistance (9.5 Ω/μ) and low RMS roughness of 120±20 nm. Then, a dielectric layer was deposited by injecting poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) solution on top of the gate. This enabled precise control of the dielectric layer thickness by controlling the concentration of the solution according to pore size of the paper. As a result, a uniform thin dielectric layer of less than 10 nm was formed. The ZnO NWs were self-assembled on a dielectric layer by a simple dipping and pulling method. Afterwards, electrodes were formed via inkjet printer. The all-solution-processed flexible FETs on paper exhibit electrical performance with charge carrier mobility of 0.1 cm2 V-1 s-1, and current on/off ratio of 2×103. Furthermore, even after 100 bending cycles, only a 10% decrease in mobility was observed. By utilizing simple equipments such as a vacuum chamber and a syringe pump alone, we could produce outstanding FETs that are desirable for cheap flexible electronic applications.

NM04.03.18

Magnetic Separation and High Reusability of Chloroperoxidase Entrapped in Multi Polysaccharide Micro-Supports

Sonia García-Embíd 1, 2, Francesca Di Renzo1, Laura De Matteis 4, 2, Nicoletta Spreti3 and Jesús M. de la Fuente1, 2; 1Instituto de Ciencia de Materiales de Aragón (ICMA), CSIC/University of Zaragoza, Zaragoza, Spain; 2CIBER-BBN, Instituto de Salud Carlos III, Madrid, Spain; 3Department of Physical and Chemical Sciences, University of L’Aquila, L’Aquila, Italy; 4Instituto de Nanociencia de Aragón, University of Zaragoza, Zaragoza, Spain.

The World Commission on Environment and Development introduced the term sustainable development, indicating the present need of modern industrial processes to optimize the use of raw materials, reduce waste and avoid the use of toxic molecules. Amongst the approaches used over the years to achieve this sustainability, biocatalysts, especially enzymes, have been in the spotlight due to their great properties. Sustainability of enzymatic catalysis is maintained through the whole cycle: from their production (living organisms) to the waste treatment.1 However, their present application at industrial scale is hampered by the high costs in their production that decrease cost-effectiveness of their application. Reutilization of the enzyme is therefore the tool to obtain more cost-effective and sustainable industrial processes. Immobilization of these biocatalysts allows an easy recovery of the material and protection from the reaction conditions in the different production steps.2 Nowadays, nanotechnology offers one of the most forefront approaches for enzyme immobilization. Magnetic nanoparticles allow an easy recovery of an immobilized enzyme using a simple magnet to separate the catalyst from the reaction product. To improve colloidal stability of the support, reduce interactions between the magnetic cores and prevent interactions with the environment that can affect both support and enzyme stability, a polymer coating is an easy and cheap approach.3 Using this approach, in this work we developed a hybrid, modular micro-support based on organic and inorganic nanocomponents. The easiness of tuning the composition of the support makes this system a potentially universal support for the immobilization of very different catalytic systems.

Here we present the application of the developed micro-support for the immobilization of chloroperoxidase (CPO), an enzyme able to catalyze many reactions of large-scale interest. A multipolysaccharidic shell containing the immobilized enzyme and obtained through a combination of chitosan and alginate, biodegradable polymers from natural sources, was used to stabilize a nanoemulsion core in which magnetic nanoparticles were embedded. Microsystems obtained through different combinations of nanocomponents were characterized and tested in terms of their chemical stability under reaction conditions.

An excellent reusability of the entrapped enzyme was observed opening the way to the immobilization of different catalytic systems and to the scale-up study in view of future industrial application.4

**Synthesis and Characterization of Ferroic Materials, Introducing Perovskite and Pyrochlore Europium Titanate Nanocrystals Synthesized by Gel-Collection Nasim Farahmand**

Chemistry, The City University of New York, New York, New York, United States.

Europium Titanate is one of the most interesting materials used in various applications such as sensors, memory devices and energy storage. Its unique features are due to its rich properties, mostly in the area of magnetic properties, which is a result of its seven unpaired spins in its 4f orbital. There are several methods in synthesis Europium Titanate compounds, most of which are among solid state reactions. In this work we have synthesized Europium Titanate compounds both in Perovskite and Pyrochlore crystal structure using gel-collection method. The synthesized material was heat treated both in air and in Argon. XRD of the samples heated in different temperatures indicated interesting results. A dramatic change observed in X-ray diffraction at 750°C indicates a dramatic transfer from amorphous to crystal. While the heated samples in air proved to be pyrochlore structure with interesting electrical properties which make them good candidates as dielectric materials, the sample heated in tube furnace indicates a perovskite structure.

In conclusion we could make europium titanate both in perovskite and pyrochlore structure using the gel-collection method. PDF analysis was done and proved that our perovskite structure is likely to be cubic pm3m, while our pyrochlore structure is in good agreement with the refinement for cubic Fd3m.

 NM04.03.20

**Facile Solution Synthesis of V-VI-VII Inorganic Semiconductors and Their Potential for Applications in Electronic Devices Prashant Kompag Hendrik Faber, Kalaivanan Loganathan, Yuliar Firdaus, Emre Vengel and Thomas Anthopoulos; KAUST Solar Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.**

V-VI-VII compounds are semiconductor materials consisting of elements from group V, VI and VII of the periodic table. These materials usually consist of at least one metal, one chalcogen and one halogen. The recent discovery of Bi2S3 and Bi2S5 as efficient solar cell materials has stimulated research interest from different disciplines to explore various interesting (opto-)electronic properties and applications for V-VI-VII materials. Traditionally, V-VI-VII compounds are synthesized at high temperature following an elemental reaction/flux method using specifically designed and dedicated experimental apparatuses. Unfortunately, both the solid state as well as solution phase synthesis suffers from the formation of V-VI and V-VII phase binary products and phase pure material can only be synthesized under specific experimental conditions. Simultaneously, specific precautionary/safety conditions are required, making the synthesis of these systems only accessible to experts.

In order to further study of these materials in terms of applied, as well as fundamental research, the development of a robust synthetic methodology is therefore highly desirable. Specifically, a low temperature solution based synthesis route with easy-to-handle precursors will open up lots of research possibilities and will facilitate potentially more widespread practical uses in the future. Herein we report a low cost, energy efficient and less time-consuming solution-based synthesis of nanoparticles of various compositions in V-VI-VII materials using Bismuth-Sulfur-Iodine as the model system. In addition to separate precursors for all the required constituent elemental precursors, we have also employed a molecular precursor approach and summarized results will be presented. Synthesized nanoparticles can be dispersed well in organic/aqueous solvents and deposited in the form of homogeneous thin films. Electronic devices such as diodes, transistors and solar cells are used for a comparative study of the electronic transport properties of the synthesized materials.

 NM04.03.21

**UV-Enhanced Gas Sensors Based on SnO2: Nanoparticles Obtained via Microwave-Assisted Nonaqueous Method Luis F. da Silva1, 2, Mattia A. Lucchini2, Ariadne C. Catto1, Waldir Avansi Jr1, Sandrine Bernardin2, Caue Ribeiro de Oliveira2, Markus Niederberger2 and Khalifa Aguir1**

1Department of Physics, Federal University of São Carlos, São Carlos, Brazil; 2Department of Materials, ETH Zürich, Zürich, Switzerland; 1Institute of Physics of São Carlos, University of São Paulo, São Carlos, Brazil; 2Laboratory of Microsensors, Aix Marseille University, Marseille, France; 1Embrapa Instrumentation, São Carlos, Brazil.

Gas sensors based on semiconducting metal oxide (MOS) nanostructures have drawn the attention of researchers mainly due to their sensitivity and stability. Nowadays, these sensor devices are necessary for the detection of harmful gases arising from industrial processes, vehicle emissions, and environmental control. In last decades, several MOS have been used as sensitive layer, due to its excellent performance. Among them, tin oxide (SnO2) has been widely investigated as resistive gas sensors. Despite its remarkable properties, gas sensors based on SnO2 require thermal activation (<150°C) for an enhancement of their gas sensing performance. Recently, the use of UV-light irradiation to activate the gas sensors has been an efficient and inexpensive way for room-temperature stimulation and improvement of the gas sensing properties. In this work, we present an investigation on the influence of the experimental parameters (time and temperature) in the preparation of the SnO2 nanoparticles via microwave-assisted nonaqueous route. The SnO2 samples were evaluated as ozone gas sensors operating at room-temperature under continuous UV illumination. The structural (long-and short-range order), surface, and morphological properties were characterized by X-ray diffraction (XRD), X-ray absorption and, X-ray photoelectron spectroscopies, and high-resolution scanning transmission electron (HR-STEM) analyses. The XRD and Sn LIII-edge XANES measurements indicated an increase in crystallization degree with time and temperature treatment, where Sn4+ ions are in an octahedral coordination. Regarding the surface properties, XPS spectroscopy indicated a significant reduction of carbon species (from precursors) and oxygen vacancies on the samples surface. HR-TEM analyses showed an increase of particle size from 3 to 15 nm, as well as, the formation of necks between the particles, as function of time and temperature treatment. DC electrical measurements revealed that SnO2 nanoparticles were sensitive to sub-ppm ozone levels (80 to 1400 ppb) at room temperature under UV-light illumination, presenting a fast response, good reproducibility, and total reversibility. These findings demonstrate that this chemical method provides a fast and efficient route to manufacturing ozone gas sensor devices for practical applications.

**All Gas-Phase Synthesis and Functionalization of Silicon Nanocrystals Zhaohan Li and Uwe R. Kortshagen; Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, United States.**

Silicon nanocrystals have attracted increasing attention as light emitting materials, luminescent downshifters, and imaging sensors. Among various quantum dot materials, silicon is earth abundant, biocompatible, and has low toxicity compared with group II-VI and III-V materials. Nonthermal plasma synthesis has been successfully applied for production of quantum confined, luminescence silicon nanocrystals with narrow size distribution. However, the relatively low luminescence efficiency of silicon nanocrystals will limit their use as light emitting materials. Engineering of silicon nanocrystal surfaces is usually necessary for enhanced luminescence performances, and this is typically done by functionalization of silicon surfaces with organic ligands.

In this work, we develop an all gas-phase synthesis route that integrates nonthermal plasma synthesis, plasma-assisted functionalization and in-flight heating of nanocrystals in a single flow stream. In this approach, ligands are attached to nanoparticle surfaces in the plasma afterglow, after which the gas stream carrying nanocrystals enters a tube furnace. With the appropriate furnace temperature, the as-produced silicon nanocrystals have photoluminescence quantum yield exceeding 20%. This is a five-fold increase relative to the case when no in-flight heating is applied. We attribute the enhanced photoluminescence to a reduction of dangling bond densities and a change of surface silyl species composition associated with heating. Compared with colloidal synthesis methods, the all gas-phase approach eliminates the use of solvents, produces no by-products, and has higher process yields. With gas-phase deposition methods, silicon nanocrystals can be directly deposited as nanocrystal thin films with densities approaching the theoretical limit of random close packing. We further demonstrate that it is feasible to control the average interparticle distance in nanocrystal films by using ligands with different lengths for functionalization. This work was supported by the DOE Energy Frontier Research Center for Advanced Solar Photophysics.

New Green Chemical Method for the Preparation of the Semiconducting FeCrO3 and NiO Nanoparticles Rajesh Kumar Rajagopal and Venimadhav Adyam; IIT Kharagpur, West Bengal, India.

In the recent years, focus on the nanoparticle synthesis has shifted towards the clean and eco-friendly methods, for: simple, cheap, nontoxic, reusability and ecofriendly green chemical synthesis. Here, a novel, environmentally benign method for the FeCrO3 and NiO nanoparticles is reported by using the gelling property of biopolymer pectin. The prepared powders are calcinated at different temperatures, from Transmission electron Microscope (TEM) analysis revealed the 300°C calcinated has the particle size of ~6 nm and uniformly distribution spherical shape nanoparticles. For the 500°C particle size was ~36 nm, UV-Vis spectroscopy confirmed the narrowing of the band gap for the nanoparticle. The proposing method is highly reproducible and simple for the preparation of the nanoparticles.

Variable Kinetic-Control Effect Towards Porous Nanostructures via Solvents Selection Amrita Sarkar and Morgan Stefik; Chemistry and Biochemistry, University of South Carolina, Columbia, South Carolina, United States.

Controlled fabrications of porous nanostructured materials are pivotal for studying structure-property and performance relationships in energy storage and conversion devices. Regardless of great success, fully tunable nanostructures are remains elusive based upon block copolymer self-assembly. Fundamental studies of structure-performance relationship in energy devices require tunable materials with architecture control where one can tailor pore size and wall-thickness independently. A unique kinetic-controlled self-assembly based approach, termed as persistent micelle templating (PMT), recently reported establishing a custom-made block copolymer structure-directing agent, poly(ethyleneoxide-block-hexyl acrylate) and a solution processing guideline where the kinetic rates are regulated by adjusting cosolvent amount. It directs to formation of nanostructured materials with tunable 6-9 nm wall-thickness with ~2Å precision and constant pore diameters of 13 nm with a wide range of inorganic material addition. Also, interestingly, the nanoscale morphology remains constant throughout the addition of various amounts of inorganics. This approach launches a new era to fine-tune small architectural feature limiting micelle chain exchange. However, the excessive amount of cosolvent may cause the formation of secondary pores into the material wall. This is addressed by improving the PMT approach via adding major solvents of higher Hildebrand solubility parameters (6) and minimizing the cosolvent amount. This new approach not only avoids the formation of secondary pores, it also expands the PMT window tunability. PMT control with a range of solvents will be presented here.

NM04.03.25
Low Temperature Sintering Copper Fine Particle System Tetsu Yonezawa and Hiroki Tsukamoto; Hokkaido University, Sapporo, Japan.

We are now proposing low temperature sintering copper fine particle systems. Usually, in order to sinter metal components at very lower temperature than melting temperature, nano-sized objects are frequently used. Nanoparticles or other nano-sized objects show melting point depression, which are often used for low temperature sintering. Gold and silver nanoparticles have been proposed for low temperature sintering printed electronics materials. However, they are noble metals and these materials are very expensive. Therefore, low temperature sintering system of copper is eagerly desired. However, since copper is easily oxidized even under air, its surface is necessary to be coated with organic materials and inorganic materials to prevent oxidation, so even if stable copper nanoparticles are prepared, their sintering temperature cannot be lowered according to the passivate layer. Therefore, in order to perform low temperature sintering of submicron copper fine particles, we attempted to prepare the surface stable state of specially designed copper fine particles. Detailed discussion will be done at the site.

Controlling Morphology of Noble Metal Replica Nanostructures Using Silver Halide Templates for Sustainability and Environmental Applications Jang Ho Joo and Jae-Seung Lee; Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

Noble metal nanostructures have been extensively investigated owing to their morphology-dependent physical and chemical properties. In particular, a number of synthetic methods have been widely used to synthesize the noble metal nanostructures because the morphology of the template can easily determine the shapes and sizes of the replicated nanostructures. Therefore, controlling structural properties of templates is essential to synthesize the replica metallic nanostructures having desired physical and chemical properties. Especially, nanometer-sized silver halide templates have been conventionally replicated into gold and silver nanostructures, and demonstrated excellent photocatalytic properties under visible light irradiation. In fact, the silver halide nanomaterials hardly generate hot electrons under visible light because of their wide band gap, which is a crucial disadvantage as visible light photocatalysts. On the other hand, the gold or silver metal nanoparticles on the surface of the silver halide templates can absorb light using localized surface plasmon resonance (LSPR), which consequently results in the generation of hot electrons in the silver halide templates. In spite of the aforementioned advantages of silver halides over conventional TiO2 catalysts, limited morphologies of the silver halide templates are hurdles for many applications. In this work, we present our systematic investigation of key factors to control shapes and sizes of AgCl templates, and demonstrate their replicated noble metal nanostructures. Not only the mole ratio of silver ion and chloride ion, but also the concentration and molecular weight of polyvinylpyrrolidone (PVP) dominantly affect the shape and size of the AgCl nanostructures. To precisely figure out the components, we analyzed several metallic replica nanostructures with different shapes and sizes using energy dispersive x-ray spectrometer. In addition, the surface-enhanced Raman scattering (SERS) properties of the replicated metallic structures were observed, which was additionally supported by theoretical simulation. Importantly, the synergistic effect of gold and silver was determined to be crucial for the SERS activity. Finally, we demonstrated the shape-dependent photocatalytic properties of the noble metal replica nanostructures under visible light for the removal of Cr(VI), which would be highly important for the environmental applications.

NM04.03.27
Excellent Acetone Sensor Based on Ordered Mesoporous In-SnO2 Loaded g-CN Ritu Malik1, Vijay Kumar2 and S.P. Nehra3;1University of Kiel, Kiel, Germany; 2National Chemical Laboratory, Pune, India; 3School of Chemistry, IIT Bombay, Mumbai, India.
Compared to mesoporous In-SnO$_2$, the g-CN supported In-SnO$_2$ nanocomposite shows ~2.8 fold increase in response to acetone gas while reducing the operating temperature by 50 °C. This outstanding response is due to easily accessible 3D mesoporous structure with higher surface area and their unique planar morphology of In-SnO$_2$/g-CN. The findings reported in this study shows promising glimpse for designing a novel strategy to the development of ultrasensitive VOCs sensors working at low operating temperature.

NM04.03.28
Controlled Synthesis of Transition Metal Doped Lead Sulfide Semiconductors Emmanuel Onche and David J. Lewis; Materials, University of Manchester, Manchester, United Kingdom.

Semiconductors are important materials for a wide range of scientific and industrial applications. Continuous effort are made to improve limitations in their electronic, optical and magnetic properties. These properties are dependant on chemical composition, the type and method of synthesis. Doping – an intentional introduction of impurities (dopant) into the semiconductor (host) is often used to improve properties. The optical properties can also be tuned by introducing different impurity atoms, the concentration of these dopants determine the degree to which the band gaps are tuned. In this work, imidodithiodiphosphinates complexes of Mn(II), Zn(II) and Pb(II) were synthesised and used deposit metal sulfide materials using melt reactions. Controlled doping of Zn$^{2+}$ and Mn$^{2+}$ into host PbS was carried out between 2 to 12 percent. Peak shifts in XRD and Raman indicated successful doping. The P-XRD peaks of the Mn$^{2+}$ doped PbS shifted towards lower 2θ angles while that of the Zn$^{2+}$ doped PbS shifted towards higher 2θ angles. The cubic structure of the PbS phase was not altered even at high dopant concentration.

Liquid-Crystalline Dendrons Modified Self-Assembling FeO$_x$ Nanoparticles Takehiro Yachi, Masaki Matsubara, Atsushi Muramatsu and Kiyoshi Kanie; Institute of Multidisciplinary Research for Advanced Material, Tohoku University, Sendai, Japan; National Institute of Technology, Sendai College, Natori, Japan.

Two- and three dimensional arrangement of magnetic nanoparticles (NPs) enables us to control the magnetic properties and novel functions since the magnetic properties of the NPs are affected by the interparticle interactions. Liquid crystalline dendritic molecules are representative organic materials with self-assemblying property by the change in the temperature. In our previous studies, precise modification of liquid crystalline dendrons on the surface of the functional NPs enables us to introduce self-assembling and dynamic structure-changeable abilities into the NPs.

In the present study, we focused on FeO$_x$ NPs to introduce the dynamic functions into the NPs by the surface dense modification by the liquid crystalline dendron. The FeO$_x$ NP-cores were synthesized by the thermal decomposition method in the presence of oleic acid and oleylamine as ligands. Then, oleic acid and oleylamine on the particle surface were changed to phosphonic acids by the ligand exchange reaction, followed by the introduction of the carboxyl group onto the NPs surface. In this case, dodecylphosphonic acid (DPA) and carboxyl group-terminated 16-phosphonohexadecanoic acid (PHDA) were used as a ligand. From the TEM observations, particle mean diameter of the phosphonic acid modified FeO$_x$ NPs was assigned as 7.1 ± 0.4 nm. It is to be noted that the interparticle distance was controlled to 9.0 ± 0.8 nm and that the phosphonic acids were bound to the surface of FeO$_x$ NPs, confirmed by the absorption at 1070 cm$^{-1}$ due to Fe-O-P bond. In addition, the ligand exchange was successfully performed with high efficiency because any peaks of oleic acid were not detected.

After modification by DPA and PHDA, amiation between carboxy group of NPs and amide group-containing dendron was carried out to obtain FeO$_x$NPs with double layers structure in which the inner was phosphonic acids and the outer dendron. The amount of COOH groups on the particle surface was controlled by change in the molar ratio of DPA and PHDA in feed. At the same time, the modified density of the dendrons layer was brought to form an ordered NPs array. FT-IR profile of the dendron-modified NPs showed the absorption at 1645 cm$^{-1}$ derived from the amidation bond between carboxy group of NPs and amide group-containing dendron. In conclusion, the modification by liquid crystalline dendron have successfully enabled FeO$_x$ NPs to control to give the ordered array.

Subtractive Laser Patterning of Silver Nanoparticle Ink by Marangoni Effect Saewoong Park, Wooseop Shin, Younggeun Lee, Seonje Park, Jaemook Lim, Junyeob Yeo and Sukjoon Hong; Optical Nanoprocessing Lab, Department of Mechanical Engineering, Hanyang University, Ansan, Korea (the Republic of); Novel Applied Nano Optics Lab, Department of Physics, Kyungpook National University, Daegu, Korea (the Republic of).

Patterned metal film is an inevitable component for wide range of electronic devices, and it is fabricated by standard photolithography and vacuum deposition methods in general. These conventional fabrication methods have achieved tremendous success to date, but also possess a number of limitations such as requirement of high vacuum environment, high processing temperature and the use of toxic chemicals. As a consequence, the need for alternative method is growing continuously in the area of low cost, large area electronics in particular.

Regarding this matter, selective laser sintering (SLS) of silver (Ag) nanoparticle (NP) ink has been reported recently to create metal pattern through all-solution process in low temperature and non-vacuum environment. In the previous studies, Ag NP ink is firstly coated on the target substrate and...
selectively sintered to create continuous metal patterns at micron scale by utilizing the focused laser as a localized heater, while the other NPs are removed by a simple cleaning procedure with the solvent. The entire process can be conducted in 0.3W power and 1mm/s speed with the smallest amount of heat affected zone. Through the proposed method, two types of negative photomask – single slit and alphabetic letters – which are difficult and time-consuming to achieve with the conventional SLS process are created successfully and tested through optical means.

Unique p-n Heterostructured Water-Borne Organic Semiconductor Colloids via PC60 Micelle Surfactants—Toward Extremely Efficient Photo-Induced Particle Activity

Yu Jin Kim, Xiaobing Zuo, Richard D. Schaller and H. Christopher Fry; Argonne National Laboratory, Lemont, Illinois, United States.

In the last a few years, research using water-borne organic semiconductor nanoparticles (NPs) has intensified as an eco-friendly route to electronic materials without toxic chlorinated-solvents. The water-processable NPs are so far the most environmentally friendly outcome. In syntheses of the NPs, typically sodium dodecyl sulfate (SDS) is used as a surfactant. However, they suffer limited charge carrier behavior particularly for the charge separation owing to their confined structure, a randomly blended core of p- and n-type materials surrounded by a surfactant shell. To overcome this phenomenon, we introduced a new surfactant, PC60, which comprises an n-type semiconductor fullerene molecule grafted with a polyethylene glycol (PEG) chain. We found that the PC60 has a spherical micelle structure with double-layer formation, which allows specific shell structure in the heterojunction NPs. Consequently, unique p-n heterostructured NPs with precisely phase-separated core (p-type)-shell (n-type) morphology were obtained when combined with p-type semiconductor polymer, and they showed superior photo-induced charge separation characteristics. Furthermore, we could control the shell morphology of the NPs through one- or two-phase methodology, and the resulting water-borne NPs showed not only shell-morphology-dependent carrier quenching effect but also ultra-stable colloidal property under thermal- and long-term conditions. Our NPs, thus, can open up and provide a new paradigm in the current fields of water-based organic semiconductor colloids.

NM04.03.32
Versatile Nanomanufacturing of Ternary III-V Nanostructure Arrays via Inverse Metal-Assisted Chemical Etching

Thomas S. Wilhelm1, 2, Zihao Wang1, Cody W. Soule1, Mohadesheh A. Baboli1, 2, Jan Yar1, Stefan F. Preble1 and Parisan Mohseni1, 2; Microsystems Engineering, Rochester Institute of Technology, Rochester, New York, United States; 3NanoPower Research Laboratory, Rochester Institute of Technology, Rochester, New York, United States; 4Microelectronic Engineering, Rochester Institute of Technology, Rochester, New York, United States; 5Matrix Opto Co., Ltd., Suzhou, China.

Ternary III-V semiconductor alloys, such as InGaP and AlGaAs, play vital roles in many nanoelectronic, optoelectronic, and photovoltaic devices. However, these materials are often plagued by a variety of nanomanufacturing difficulties that stem from either detrimental or incompatable top-down etching, or expensive bottom-up growth techniques. Here, low-cost, high-throughput, and lean nanofabrication processes are demonstrated via metal-assisted chemical etching (MacEtch), with the potential to revolutionize wafer-scale III-V nanomanufacturing. Specifically, novel Au-catalyzed etching approaches are defined for fabrication of suspended InGaP nanofoils and ordered arrays of AlGaAs nanopillars. MacEtch methods show promise as robust, solution-based alternatives for fabrication of high aspect-ratio nanostructures with smooth surfaces. These methods rely on catalytic oxidation of a semiconductor directly beneath a metal catalyst layer, followed by site-specific dissolution of the selectively oxidized material. MacEtch techniques combine many of the advantages of other top-down etching approaches, such as the anisotropic nature of reactive ion etching (RIE), and the fabrication simplicity and cost-efficiency of conventional wet chemical etching. Additionally, many of the correspondingly advantageous disadvantages are not present, including surface damage from high-energy ion bombardment and use of hazardous gases associated with RIE, and the crystallographic dependences or isotropic nature of traditional wet etching. While MacEtch research has been predominantly focused on silicon processing, these techniques have been recently adapted to overcome fabrication challenges associated with III-V nanomaterials synthesis. In this work, Au-enhanced inverse-MacEtch (I-MacEtch) of heteropitaxial InGaP/GaAs systems is presented, and differential etch rates between epilayer and substrate are exploited as a viable method to produce suspended III-V nanofoils. A comparison of vertical etch rates (VER) between nominally undoped, p-type, and n-type InGaP is detailed, showing VER in the I-MacEtch regime is independent of doping type. Au-enhanced I-MacEtch of AlGaAs is also demonstrated, and the VER and lateral etch rates (LER) are shown to be tunable with Al fraction and etching temperature. Control over the VER:LER ratio allows for etch conditions to be tailored to provide ordered AlGaAs nanopillar arrays with predefined aspect ratios. The work detailed here provides efficient means to customize nanomanufacturing processes for specific needs, such as tuning MacEtch process parameters to achieve a desired ternary III-V nanoflament geometry. It is anticipated that these processes can be utilized for adaptable and versatile manufacturing of nanomaterials for LEDs, lasers, HEMTs, and multijunction solar cells applications.

NM04.03.34
Detecting Entrapped Humans with Nanostructured Gas Sensors

Nicolau J. Pineau, Andreas T. Günther and Sotiris E. Pratsinis; ETH Zurich, Zurich, Switzerland.

Earthquakes are lethal natural disasters frequently burying people alive under collapsed buildings. Tracking entrapped humans from their unique volatile chemical signature with hand-held devices would accelerate urban search and rescue (USAR) efforts. Here, a compact and orthogonal sensor array has been designed to detect the breath- and skin-emitted volatile markers acetone, ammonia, isoprene, CO2 and RH, all together serving as sign of life. It consists of three nanostructured metal-oxide sensors (Si-doped WO3, Si-doped MoO3, and Ti-doped ZnO), each specifically tailored at the nanoscale for highly sensitive and selective tracer detection along with commercial CO2 and humidity sensors. When tested on humans enclosed in plethysmography chambers to simulate entrapment, this sensor array rapidly detects tracers of human presence with low parts-per-billion (ppb) level accuracy and precision, unprecedented by portable detectors but required for USAR. These results were validated by bench-top selective reagent ionization time-of-flight mass spectrometry (SRI-TOF-MS). As a result, an inexpensive microstructured sensor array is presented that can be integrated readily into hand-held or even drone-carried detectors for first responders to rapidly screen affected terrain.

One-Step Aqueous Synthesis of Zn-Based Quantum Dots as Direct Generators of Reactive Oxygen Species

Julio A. Rivera de Jesus1, Sonia J. Bailon2, Vinoth Kumar Jayaraman3, Agileo Hernandez-Gordillo and Monserrat Bizarro1
1Instituto Investigaciones en Materiales, Mexico City, Mexico; 2Department of Chemistry and Physics, University of Puerto Rico, Ponce, Puerto Rico; 3Department of General Engineering, University of Puerto Rico, Mayaguez, Puerto Rico.

Abstract

Semiconductors quantum dot (QDs) are fluorescent nanocrystals with a ranging diameter of 2 nm - 10 nm. Due to their intrinsic optical properties, which are dependent of their size, these nanoparticles have many industrial and bio-medical applications e.g. bio-imaging, diagnostic, LED’s (light emitting diode) production, and photocatalyst of organic compounds. More recent applications are based on their potential use as photosensitizer to generate cytotoxic reactive oxygen species (ROS) when activated by light. The factors that govern the cytotoxicity associated to the generation of ROS include: particle size, shape, surface chemistry, the presence of lattice defects, degree of aggregation, among others. Based on these considerations, the present work was focused on: (i) the development of a synthesis protocol of water dispersible pure and doped ZnS-based QDs, (ii) modify their surface chemistry with biocompatible molecules and, (iii) evaluate their potential capacity to generate ROS under light irradiation. QDs were synthesized in water using a microwave reactor system under controlled temperature and reaction time in presence of 3-mercaptopropionic acid (MPA) as sulfide supplier. ZnS QDs were also doped with Mn2+ or Cu2+. As-synthesized ZnS QDs, as evidenced by XRD, were optically characterized by X-ray Diffraction (XRD), HRTEM, UV-Vis and Photo-luminescence spectroscopy techniques. UV-Vis analyzes evidenced the presence of excitonic peaks around 310 nm, 314 nm and 315 nm for ZnS, Cu-ZnS and Mn-ZnS, respectively. The band gap energy of the pure ZnS QDs was estimated at 3.70 eV that indicates a strong quantum confinement effect, as evidenced by this high value compared to the bulk (3.54 eV). In addition, the photoluminescence analyses of the QDs showed a strong emission peak (438nm for pure ZnS) that was red-shifted when Mn2+ (487nm) or Cu2+ (521nm) were used as dopant species. The incorporation of these transition metals into the ZnS lattice should have created new intermediate energetic levels between the valence and conduction bands of the ZnS particle. The effect of doping on the crystal size and the corresponding intermediate capacity of ZnS-based QDs to generate ROS, via the photo-degradation of specific organic dyes, will also be presented and discussed.

Reference

[5] Güntner, A. T.; Pineda, N. J.; Mochalski, P.; Wiesenhofer, H.; Agapiou, A.; Mayhew, C. A.; Pratsinis, S. E., Anal Chem (2018), 100% discoloration of indigo carmine occurred for Ag-Ni co-doped ZnO thin films in less than one hour, whereas the Ag-doped ZnO, Ni-doped ZnO, and undoped ZnO achieved only 30-50% of discoloration in one hour. In this work, we propose the possible degradation mechanism of indigo carmine dye with respect to dopants type and their concentration.
80 °C, 1 h reaction time, 1 wt. % of the catalyst, using methanol:oil molar ratio of 20:1. The best results were obtained with the catalysts containing 3 and 5 wt. % of sodium carbonate, which gave methyl esters (ME) yields of 90-91 %. In the same conditions, the reference STN catalyst resulted only in a 53 % of ME yield. Such a strong increase in the catalytic activity of Na2CO3-containing sodium titanate nanotubes was attributed to a synergetic effect between the impregnated sodium salt and 1D nanostructured STN material.

NM04.03.39 Sustainable and Green Manufacturing of Diagnostic Iron Oxide Nanoparticles using Natural Products Isabel Gesner1, Lisong Xiao2 and Sanjay Mathur2; 1University of Cologne, Cologne, Germany; 2University of Duisburg-Essen, Duisburg, Germany.

During the last years, an enormous variety of nanomaterials with different shapes and compositions have been developed for a broad range of applications including optics and electronics but also for their employment in health care and foods. However, many of these fabrication processes still rely on the employment of toxic and environmentally hazardous substances, offering potential risks to manufacturers and customers. Therefore, alternative synthetic procedures are focus of current research to allow for the synthesis of nanomaterials under the important aspects of biosafety and environmental compatibility.

Herein we report a green and facile one-pot synthesis for the preparation and in situ functionalization of water-dispersible and biocompatible iron oxide nanoparticles (IONPs) for their employment as contrast agents for magnetic resonance imaging (MRI). Two classes of naturally available nutrients namely ascorbic acid (vitamin C) and green tea were employed. In the first approach, easily water-dispersible crystalline IONPs were produced in a hydrothermal synthesis using ascorbic acid as reducing agent whereby the oxidation product instantly formed a protecting and stabilizing layer around the particles. As-obtained particles were not only highly biocompatible, but demonstrated enhanced r2/r1 ratios compared to the clinically approved contrast agent Sinerem.

In this context we further developed the synthesis of iron oxide nanoparticles using green tea catechins. Green tea is a promising material which additionally exhibits beneficial antioxidative, antiinflammatory and anti-inflammatory effects. Similar to vitamin C, green tea functionalized IONPs were long-term stable in water and highly biocompatible. Moreover, in vivo studies revealed accumulations of the particles in tumor tissues similar to clinically approved contrast agents. Indeed, a strong contrast enhancement was visible based on high relaxivity values, which further support their employment as novel MRI contrast agents in clinics.

NM04.03.40 Nanostructured TiO2 Support Effect on Hydrothermal Stability of Platinum-Based Catalysts Xingyu Lu1,2, Wenyi Yang1 and Puxian Gao1,2, 1Institute of Materials Science, Storrs, Connecticut, United States; 2Department of Materials Science and Engineering, University of Connecticut, Storrs, Connecticut, United States.

Platinum (Pt) based catalysts are widely used in petrochemical refinery, automotive emission control, and fuel cell applications (1). However, the catalytic activity of Pt nanoparticles (NPs) catalysts tends to decrease drastically as a result of the loss of active surface area via sintering at high temperature (2). TiO2 is an earth-abundant and chemically stable material and has been extensively studied as support for Pt-based catalysts (3). However, for the precursors of TiO2, such as layered protonated titanates (LPTs), the sintering resistance effects on noble metal NPs are not well studied. The high surface area and cation exchange capacity of LPT make it the ideal supports for catalytically active materials (4). In this work, the promotional effects of the support structures on the hydrothermal stability of the TiO2 nano-array supported Pt catalysts were studied. Two types of TiO2 nano-array supported Pt catalysts were prepared with different initial support structures, namely the anatase TiO2 and LPT nanowires. Pt NPs were loaded onto both types of supports and went through the same hydrothermal aging at 800 °C for 50h. The evolution of the Pt NPs before and after the hydrothermal aging was studied by scanning transmission electron microscope and CO oxidation was employed as a probe reaction to compare the catalytic performance of these catalysts. According to the microstructural evolution of the Pt NPs and the catalytic activity of the sample before and after hydrothermal aging, the LPT-nano-arrays based Pt catalysts showed better hydrothermal stability than the crystalline anatase nano-arrays based ones. The better hydrothermal stability of the LPT nano-array supported Pt NPs might be due to the greater interaction between the Pt NPs and the LPT surfaces formed during the dip-coating process through ion-exchange. The sintering resistance of the Pt NPs is therefore enhanced by the potentially better anchoring effect from the LPT nano-array supports.

Considering the wide application of TiO2 supported Pt catalysts, this new finding may provide a new pathway to design highly stable Pt-based catalysts for different gas phase reactions.

Keywords: Pt-based catalysts; Hydrothermal stability; Layered protonated titanates; Sintering resistance; CO oxidation.

NM04.03.41 Enhanced Performance of Inverted Indium Phosphide Quantum-Dot Light-Emitting Diodes via Thermal Annealing Jinwoon Lee and Changhee Lee; Electrical and Computer Engineering, Seoul National University, Seoul, Korea (the Democratic People’s Republic of).

Indium phosphide (InP) quantum-dots (QDs) have attracted as most promising luminescent material for developing cadmium-free QD light-emitting diodes (QLEDs). However, the performance such as efficiency, maximum luminance and operational lifetime of InP QLEDs is still far behind that of CdSe QLEDs [1, 2]. This is mainly attributed to unoptimized synthesis of InP QDs and device structure. InP QDs have relatively low electron affinity (EA), so the electron injection barrier is quite large with conventionally available electron transporting materials, thereby resulting in low electron injection [2]. In this work, we will demonstrate that thermal annealing of zinc oxide nanoparticle (ZnO NPs) electron transport layer and the QD emissive layer can lead to enhanced QLED performance. The current density of electron-only devices with ZnO NPs increases and exhibits trap-free space-charge-limited-current (SCLC) characteristics after thermal annealing. Furthermore, the photoluminescence (PL) quantum yield of the QD layer increases with thermal annealing due to increased packing density of QDs, as previously reported [3]. Optimizing annealing temperature of inverted green InP QLEDs results in increased external quantum efficiency from 2.32 % to 3.61 % and maximum brightness over 10,000 cd/m2. The half-lifetime (LT50) at an initial luminance of 1000 cd/m2 increases up to nearly 2 hours. Therefore, thermal annealing process can be effectively utilized to optimize the device performance of InP QLEDs.

Efficient Photocatalysis with Biomimetic Hedgehog Supraparticles

Luiz F. Gorup, Gleiciania d. Silveira, Naomi S. Ramesar, Douglas G. Montjoy, Suwon Tung, Emerson R. Camargo, and Nicholas A. Kotov; 1 Federal University of Sao Carlos, Sao Carlos, Brazil; 2 Chemistry, Federal University of Grande Dourados, Dourados, Brazil; 3 Chemistry, University of Michigan, Ann Arbor, Michigan, United States.

Nanostructured hedgehog supraparticles (SPs) were formed by the self-assembly of erdite nanoparticles (NaFeS2·2H2O) into a remarkable functional geometry. The nanoscale corrugation with the particles allows for enhanced dispersion stability and leads to greater effectiveness for photocatalytic degradation. The self-assembly of nanoparticles is a promising strategy to fabricate hybrid biomimetic nanostructures that can be used as an innovative alternative to obtain superior properties from conventional material. In the present study, erdite hedgehog supraparticles were successfully synthesized using a cost-effective self-assembly method and employed as a photocatalyst for degradation of organic dyes. The nanostructures were formed by altering the ionic strength of the synthesis solution, resulting in SPs (6.62 μm ± 1.4) with spikes that provided a surface area greater than 8.2 m²/g. The structural morphology and optical features of the synthesized erdite SPs were confirmed by X-ray diffraction, electron microscopy and UV-visible spectrophotometry. The pollen morphology prevents aggregation of the particles and promotes high surface area. The supraparticles exhibit excellent photocatalytic activity under illumination of H2O2 (SP+ H2O2) in a fenton reaction, resulting in degradation of methylene blue (MB) (25 μg/mL) in 5 minutes under 302 nm light. Additionally, The SP+ H2O2 are very effective in the catalytic degradation of phenol red (PhR), nitrophenol (NP), and rhodamine B (RhB) under UV light, visible light, and dark condition. Finally, the erdite SP catalyst has excellent activity and recyclability for more than 55 cycles, with the addition of H2O2 on average every 13.8 ± 2.2 cycle. The excellent photocatalytic activity is owing to the synergistic interaction between the SPs and H2O2. The SPs exhibit high adsorption capacity and low recombination of the photogenerated electrons and holes due to the shape and erdite composition. This work showed how particles with singular morphology, such as hedgehog supraparticles are highly attractive because of their enhanced properties.

NM04.03.43

Defect Engineering of Low-Dimensional Heterostructures Toward an Efficient Electrocatalysts

Sehman Ozden; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Designing novel efficient and robust catalysts with enough active sites and excellent conductivity is one of the key parameters for water splitting devices to produce hydrogen as a clean energy source. Existing Pt-based noble catalysts have some issues with their relatively high-cost and limited abundance. In this regard, the development of novel catalysts that exhibit higher catalytic activity, longer durability and lower cost can significantly facilitate the realization of clean energy. Recently, low-dimensional materials such as nanotube, graphene, MoS2, and h-BN, have gain attention for hydrogen evolution reactions (HER), oxygen reduction reactions (ORR) and oxygen evolution reactions (OER) etc. Although these nanostructures have been used for HER, ORR and OER, they need to be engineered to improve their catalytic activity for large scale industrial applications. Novel catalysts with unique properties can be fabricated by creating heterostructures of low dimensional nanomaterials with rich defect density. Here, we will discuss outstanding catalytic activity of metal-free low-dimensional carbon-based hybrid heterostructures with rich defect density as an efficient electrocatalyst. In addition, the role of increased defect density on the free-energy of hydrogen adsorption from density functional theory (DFT) calculations will be discussed.

NM04.03.44

Characteristics of Biogenic Sulfide Semiconductor Nanomaterials

Yoriko Tominoaga, Ryo Shimizu, Shachiko Maki, Makoto Maeda and Yoshiko Okamura; Hiroshima University, Higashihiroshima, Japan.

We report here the characteristics of PbS formed by bacteria. X-ray diffraction (XRD) measurements and transmission electron microscope (TEM) revealed clear diffraction peaks and lattice fringes, respectively, revealing that the bacteria synthesized polycrystalline PbS. Current-voltage (I-V) measurements showed that the electric current across the PbS increased linearly with increasing applied voltage, and the amount of the current increased with increasing the area of crystalline PbS. Bionimallization have been actively studied for more than 20 years. It can be performed to form such as magnetite, silica, calcium carbonate, hydroxyapatite, metal particles and so on under ordinary temperature and normal pressure. This can develop material synthesis techniques with low power consumption at low cost. Under this kind of circumstances, microbial synthesis for sulfide semiconductors such as CdS and PbS has been explored in some previous studies. The studies have already demonstrated the formation of nanocrystallite of these sulfide semiconductors by some yeasts. However, it has not been clarified whether they can have crystalline quality that may be applied to the semiconductor devices or not. In this study, we aim to reveal their crystalline qualities and semiconductor characteristics by focusing on PbS towards the future fabrication of the biogenic semiconductor devices. We established bacterial strains involved in PbS formations and confirmed micro structures and crystalline quality of PbS formed by the bacteria using a X-ray diffractometer and a JEOL JEM-2010 TEM equipped with an energy dispersive X-ray spectroscopy (EDS) system, operated at 200 kV. XRD spectra of the PbS samples exhibited clear diffraction peaks, and there were good agreements with experimental data and theoretical ones of polycrystalline PbS on peak diffraction angles on each crystal plane of PbS. TEM images and EDS analysis for the samples also showed that the materials consisted of Pb and S, and lattice fringes and electron diffraction patterns corresponding to crystalline PbS. I-V characteristics were measured using probe after Indium electrodes were formed on the surface of the PbS samples mounted on semi-insulated InP substrate. When the shape of PbS was formed to be spherical nanocrystallites, the amounts of the current were in the range between 0 and 17.5 pA with applied voltage was in the range between -1 and 1 V. On the other hand, the shape of crystalline PbS was changed to be thin film, the amounts of the current changed to be in the range between 0 and 18.5 μA. The former amounts of the current increased to be 0 - 25.0 pA under light irradiation. These results suggested that the biogenic PbS have bandgaps and it exhibited general fundamental characteristics of the semiconductors.

3D Cubic Ordered Mesoporous SnO2@SBA-16—A Highly Sensitive Humidity Sensor

Vijay K. Tomer, Ekta Poonia and Krishan Kumar; 1Berkeley Sensor and Actuator center, University of California, Berkeley, Berkeley, California, United States; 2Department of Chemistry, Deenbandhu Chhotu Ram University of Science and Technology, Sonipat, India.

The need for the development of highly sensitive humidity sensors for monitoring of indoor climatic conditions has always remained a challenging task. Myriads of study have been performed to formulate an ideal humidity sensor, wherein, the mesoporous materials are leading among the others in the quest for designing highly sensitive humidity sensor. Due to high surface to volume ratio, easy charge transportation, tunable geometry of pore structure and excellent capability in the role of a host matrix for a variety of dopants (metals and metal oxides), the mesoporous materials have emerged as the new hot-spot for designing humidity sensors. In the present study, we propose a simple and low-cost strategy to prepare 3D-cubic ordered mesoporous silica-nanohybrid impregnated with SnO2 nanoparticles. The relative humidity (%RH) sensing results in the 11–98%RH range reveal that the SnO2/SBA-16 nanohybrid sensor possesses fast response/recovery (4.2/3.5s), negligible hysteresis (0.8%), high sensitivity, wide range of applicability and high stability. The high resolution transmission electron microscopy (HR-TEM) confirms the porous nature of the nanohybrid. Field emission scanning electron microscopy (FE-SEM) revealed the long range network of these pores even after impregnation of SnO2 which is an essential facet for high performance %RH sensor. The N2 adsorption-desorption isotherms studies confirmed the high surface area (746m²/g) for the nanohybrid which suggests that the mesoporous nature remained intact even after impregnation of SnO2 in the SBA-16 matrix. The XRD and IR analysis further indicated that the inclusion of
SnO₂ does not disintegrate the 3D cubic channels of SBA-16. The present work not only highlights an efficient scheme for designing the high performance %RH sensors and but also advocates the promising applicability of mesoporous materials for gas sensing application.

Defect Enriched Fe Incorporated β-Ni(OH)₂ Nanosheets with Both High Total Electrode and Intrinsic Activity for Oxygen Evolution Reaction Tianyi Kou. University of California, Santa Cruz, Santa Cruz, California, United States.

Accompanied by the fast world population growth, the depletion of energy resources and environmental pollutions have become two major issues that pose serious threats to the survival of human beings. As a clean and renewable alternative, hydrogen has been given special attentions in the past decades and is believed to be a high gravimetric energy density carrier for fuel cells. Nonetheless, most of the hydrogen in earth is still generated through energy intensive industries such as steam reforming which unavoidably makes the energy resource shortage and environmental problems even worsen. In contrast, generating hydrogen in the cathode through water electrolysis is a green chemical route in which pollutant free and zero carbon emissions can be realized. Additionally, the energy sources driving water electrolysis can also be renewable, further making water electrolysis a promising strategy to produce hydrogen. However, the sluggish kinetics and high energy barriers of oxygen evolution reaction (OER) in the anode have largely restricted the overall efficiency of water electrolysis, and thus limited the hydrogen production. Different catalysts have been investigated so far to address the limitations of OER. Iridium oxides, for example, are found to exhibit a great OER activity but the high costs of iridium become the barrier of their large-scale application. Developing inexpensive catalysts is critical but to boost their activity it is still challenging, as most of the OER catalysts still require an overpotential around 250 to 300 mV to achieve the geometric current density of 10 mA/cm². In this work, we synthesized Fe incorporated β-Ni(OH)₂ nanosheets on macroporous nickel foam through a facile one-pot hydrothermal method. The as-synthesized Fe incorporated β-Ni(OH)₂ nanosheets are found to be composed of mixed crystal and amorphous structures. Along the boundary of crystal and amorphous structures are enriched defect sites. By virtue of these structural merits and electronic structure modification of Fe dopants, the as-prepared Fe incorporated β-Ni(OH)₂ nanosheets exhibit a low and competing overpotential of 219 mV at a geometric current density of 10 mA/cm², demonstrating a high total electrode activity. In addition, at the overpotential of 300 mV, a electrochemical surface area current density of 6.25 mA/cm² has also been obtained, which represents the highest value among the reported NiFe based OER catalysts at the same or higher overpotentials, indicating its high intrinsic activity.

Moving from Environmental Remediation to Energy—What We Learned about Nb₂O₅ Photocatalysts Caue Ribeiro de Oliveira. Brazilian Agricultural Res Corp, Sao Carlos, Brazil.

Literature has many examples of semiconducting materials as photocatalysts for degradation of water contaminants. Despite a large concentration in TiO₂ and TiO₂-based materials, other semiconductors have gained attention due specific aspects that promote higher photoactivity (e.g., in visible light, reduced electron-hole recombination) but few was done to understand the role of surface acidity in these process. A study-of-case is Nb₂O₅, which is a wide-band semiconductor, with similar electronic properties to TiO₂ but with very acidic surface. This feature indicates that the way that Nb₂O₅ plays its photooxidative role is different from other semiconductors, depending of the equilibrium of charges in degradation medium. We developed a method to produce this semiconductor through a peroxocomplex formation, which is further destabilized in hydrothermal conditions to promote oxide precipitation in a controllable manner. This synthesis, despite very simple, was easily controlled to produce different surface features, as well as heterostructures based on T/TT Nb₂O₅ phases. This material has showed a considerable photoactivity in UV light for degradation of different pollutants, but also a good versatility: the mixture with g-C₃N₄ (a polymeric semiconductor) in adequate pH conditions has lead to a self-organized heterostructure, with also remarkable photoactivity. However, these materials did not present only photooxidative activity: measuring their potential for photo reduction, we have observed that modifications with other semiconductors (e.g. CuO) allows this system to promote Cr(VI) reduction and, more interesting, promote the CO₂ reduction to CO in significant yields, despite the acidic surface suggest that this reaction would not be favored. Therefore, the knowledge about this material for environmental remediation is now opening other application for this material in renewable energy production, which needs be deeper investigated.

Single-Source Precursors for Controlled Gas Phase Deposition of Iridium-Based Catalytic Coatings for Water Splitting Applications Lasse Jørgensen. Michael Frank, Jennifer Leduc and Sanjay Mathur; Inorganic Chemistry, University of Cologne, Cologne, Germany.

Investigation of the interplay of metal-organic chemistry will enrich the state-of-the-art of chemical vapor deposition (CVD) and atomic layer deposition (ALD) technology and open new possibilities for the applications of new Ir-based materials. Therefore new heteroleptic Lanxæs-types compounds exhibiting high volatility and defined thermal decomposition under CVD and ALD conditions are reported to elaborate the precursor chemistry – materials synthesis – functional property chain. The new precursors unify both reactivity and sufficient stability through its heteroleptic constitution to provide a precise control over compositional purity in CVD and ALD deposits. CVD- and ALD-grown materials were tested towards their (electro)catalytic applications, particular in the oxygen evolution reactions. In this work functional characterization of deposited materials will be reported and their catalytic behavior is examined. The deposition on various substrate materials without the need of additional reactant gases underlines the potential of this heteroleptic precursor class for CVD and ALD of metallic thin films. The presented CVD data opens new possibilities in the vapor phase synthesis of materials facilitating the application of such films, for example, as electro- or photocatalyst in oxygen evolution reaction (OER) and oxygen reduction reaction (ORR).

Nanostructured Co-Precipitated Cu₇Zn₄O₁₂ Catalytic Nanoparticles for Solar Driven Thermochemical H₂O/CO₂ Valorization Rahul R. Bhosale and Gorakh Nath Takalkar; Department of Chemical Engineering, Qatar University, Doha, Qatar.

Thermochemical splitting of H₂O and CO₂ generates a mixture of CO and H₂ i.e. syngas which can be used for the production of storable and transportable...
Reverse osmosis (RO) is one of the most widely employed technologies for water desalination. A drawback of this technology is high consumption of electricity by electric motors used for high-pressure water pumping. Energy consumption can account for up to 70% of the desalination costs. Due to the high-energy intensity, the carbon footprint of the process is substantial. Most of pumps and compressors including those used in RO desalination plants are driven by electric motors or internal combustion engines. Pumping systems account for nearly 20% of the world’s electrical energy demand and range from 25-50% of the energy usage in certain industrial plant operations. To improve economics of water desalination plants we propose innovative energy efficient, inexpensive, robust water pump powered by heat. The basic principle of the pump is the same as that of regenerative type external combustion engines. Generation of heat makes pumps of this type very energy efficient. The novelty of the pump comprises a new working cycle in combination with the use of a dense working fluid which is liquid in the cold space of the pump and gas or supercritical fluid in the hot space of the pump. Carbon dioxide, water-alcohols mixtures or mixtures hydrocarbons can be used as the working fluids. This pump does not have any high precision parts and even does not require super alloys and any other expensive materials. The pump can generate very high pressures (hundreds bars) and therefore can be used instead of modern plungers pumps driven by electric motors, thus eliminating completely the consumption of electricity for pumping in RO processes. Another important feature of the pumps is that no high temperature heat sources are needed. Heat sources with temperature of 200 – 300°C is sufficient to create pressure drops typical of RO processes. Therefore, renewable energy sources such as solar radiation can be used to power the pump. Replacement of fossil fuels with renewable energy sources in desalination processes will minimize greenhouse gas emissions. In addition, a substantial improvement of the economics of the RO processes is expected due to the use of solar power. In this study, we have attempted to improve the solar energy absorption capacity of the solar unit by adding metal oxide nanoparticles. These metal oxide nanoparticles are synthesized in our laboratory using sol-gel method. Due to the improvement in the solar energy absorption capacity, the overall efficiency of the desalination process is observed to be enhanced significantly. The detailed results will be presented.
characterized by X Ray Diffraction, nitrogen adsorption–desorption isotherms, Linear Sweep Voltammetry (LSV), Chronoamperometry, Scanning Electron Microscopy, Micro Raman and FTIR spectroscopy technics. The microscopy images reveal that the FeOx nanospheres decorated with extreme efficiency on the flower structure of ZnO. A significant increase in the surface area is observed with the addition of the α-FeOx in the ZnO flowers and also significantly alters the pore volume of this material. The LSV showed a high current density of the FTO/ZnO/FeOx (0.58mA.cm-2) film being superior to the FTO/ZnO (0.16mA.cm-2) film in light condition. The analysis showed that these materials are promising photoelectrode for DSSC applications, characterizing them FeOx nanoparticles improving the ZnO photoelectrochemical properties. Simultaneously with this the method that was used to produce the nanoparticles adds to the production process of the same, a methodology that does not require the need for high technology equipment, not have a high energy demand or time to run it and does not generate waste, that is, a highly practical, economically viable and environmentally friendly method.

11:00 AM NM04.04.08

The performance of concentrating solar power (CSP) receivers is limited by thermal losses, particularly at concentrations <100 suns. Existing CSP receivers rely on spectrally selective surfaces placed within vacuum glass enclosures to minimize heat loss due to radiation and convection. However, using spectrally selective coatings and maintaining a high-quality vacuum at high temperatures (400 °C) increases cost and significantly limits longevity. We have developed a high-temperature solar-transparent thermal insulation that enables high-efficiency heat collection and obviates the need for selective coatings and vacuum in CSP receivers. We use silica aerogels, a class of highly porous (porosity >90%) materials known for their thermally super-insulating properties, which we have engineered to achieve extremely high solar transparency. The optimized aerogel nanostructure has reduced pore sizes of 2-50 nm that minimizes scattering losses at low wavelengths, increasing the solar-weighted transmittance to >95% for an 8 mm thick sample compared to <85% typically reported in literature. The low near-UV scattering, high infrared absorption, and high porosity of our aerogels maximize solar transmittance and minimizes heat loss due to conduction, convection and radiation, enabling CSP receiver efficiencies >80% even at concentrations <50 suns. In this work, we report the results of optical and high-temperature thermal characterization of the fabricated solar-transparent silica aerogel. We compare experimental results with a numerical model based on the spectral equation of radiative transfer that predicts the optical and thermal properties of silica aerogel. Finally, we model the performance of a linear CSP receiver comprising of our solar-transparent aerogel and optimize its thickness, density and pore-size to maximize receiver efficiency.

Rational Design of Nanostructured Electrodes for Capacitive Energy Storage Husam N. Alshareef, Chuan Xia, Qiu Jiang and Narendra Kurra; Materials Science and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Electrochemical supercapacitors are important energy storage devices that bridge the gap between electrostatic capacitors and batteries. A critical component of supercapacitor design is the electrode material. We have been developing electrode materials and fabrication strategies for conventional electrochemical capacitors as well as micro-supercapacitors (in-plane devices fabricated on-chip). Pseudocapacitive materials in particular hold promise of significantly higher capacitance than carbon-based materials and hence have recently become a subject of intense investigations. These materials can store charge through both surface redox reactions and fast intercalation process leading to intercalation pseudocapacitance. We will discuss strategies that we have developed to rationally design pseudocapacitive materials, including oxide and chalcogenides. Material structure, conductivity, electrochemical activity, defect concentration, and dimensionality are critical parameters to maximize both ion and electron transport within the electrode material, and hence improve capacitor performance. Selected examples from our work will be presented to show how dramatic improvements in electrode performance can be achieved through rational approaches. For micro-supercapacitors, we also show that collector material type, geometry (e.g., 3D and macroporous structures), and microfabrication techniques can be used to improve the kinetics and capacitance of devices. Recent integration of microsupercapacitors in energy harvesting and sensing devices will also discussed.

CSilk® Carbon Nanotube Sheet Based Origami Triboelectric Nanogenerators and Its Yarn Applications Jaeh Lee and Raquel Ovalle-Robles; LINTEC Nano-Science % Technology Center, LINTEC of America, Inc., Richardson, Texas, United States.

Due to an increase in demand, low-carbon and environmentally-friendly energy, as well as thin and lightweight portable electronic devices and wearables that can generate power has attracted great attention. We have here demonstrated origami triboelectric nanogenerator (origami-TENGs) using cSilk® sheets as the starting material, having a high degree of alignment, being lightweight, and having a high electric conductivity. Sandwich structure combined with cSilk® Sheets and PEDOT:PSS as a current collector were prepared via layer-by-layer coating and acid treatment. Two individual strips (cSilk® Sheets/PEDOT:PSS) were prepared and infiltrated with two different polymers having the positive and negative triboelectric affinity. The cSilk® Sheet-TENG can be fabricated from these two separate strips that are folded together to form a resilient structure that reversibly compresses in response to an applied compressive force and spontaneously returns to its uncompressed state, spring-like, when the applied compressive force is removed. The output short-circuit current (Isc) and open-circuit voltage (Voc) of this cSilk® Sheet-TENG can reach 20 μA and 1500 V, respectively. This generated electricity could directly light up 500 commercial light-emitting diodes (LEDs) connected in series without any energy storage devices. In addition, the as-fabricated cSilk® Sheet-TENGs are capable of harvesting mechanical energy from various kinds of human motions such as stretching, pressing, and bending. Furthermore, we have been developing TENGs using highly flexible, electrically conductive, and mechanically robust cYarn® fibers by providing twist-insertion to cSilk® sheets. cYarn®-TENG can be woven to make a textile and harvest energy from human motions such as rubbing, bending, and stretching. Also, cYarn®-TENG can harvest energy by hand-powered torsional actuation.

Computational Modeling of 2D Materials and Their Heterostructures for Sustainable Energy Storage—Opportunities and Challenges Kamalika Ghatak, Vidushi Sharma and Dibaker Datta; New Jersey Institute of Technology (NJIT), Newark, New Jersey, United States.
Because of the low gravimetric capacity of conventional graphite anode (theoretical value ~ 372 mAh/g), and massive structural changes and volume expansion of silicon anode (on the order of 300%); extensive research has been carried out during last few decades to develop stable and high-capacity anode materials. Moreover, large-volume expansion leads to stress built-up at the interface between the Si film and the current collector, leading to delamination at the interface. We, therefore, examined the possibility of 2D materials for application of high-capacity anode materials. By first-principle calculations based on density functional theory (DFT), we investigated the adsorption of lithium (Li), sodium (Na), and calcium (Ca) on graphene with divacancy and Stone-Wales defects. We find that with controlled defect topology, we can achieve a maximum storage capacity of approximately 1675, 1450 and 2900 mAh/g for Li-, Na-, and Ca-ion batteries respectively. However, despite enormous opportunities, we need to concern about several challenges such as adatom trapping at the defect sites, the effect of defects on adatoms diffusivity, microstructural changes, etc., mechanical degradation at defect sites, etc. In addition, our recent work shows that for the Si-based anode, we can achieve far better electrochemical stability by simply coating the current collector surface with graphene sheets. The combined DFT-MD work shows that graphene can be utilized as slippery interfaces to enhance the electrochemical stability of Si film anode in Lithium-Ion Batteries because of the less stress build-up and less stress cycling of the slippery substrate as opposed to a fixed surface. Our results indicate a new paradigm of 2D materials based energy storage. Besides graphene, several other 2D materials such as graphene allotropes, Transition Metal Dichalcogenides (TMD), etc. have tremendous potential in energy applications. Moreover, by building heterostructures (stacking of different 2D materials), it is possible to combine the advantage and eliminate the disadvantages of the individual sheet.

We need a computational genome to identify the optimal heterostructures for the energy storage. In this presentation, we will provide a detailed overview of opportunities and challenges of modeling of 2D materials and its heterostructures for the next-generation sustainable energy storage applications.

2:15 PM NM04.05.03
One-Dimensional Nanomaterials for Emerging Energy Storage  
Liqiang Mai; Wuhan University of Technology, Wuhan, China.

One-dimensional nanomaterials can offer large surface area, facile strain relaxation upon cycling and efficient electron transport pathway to achieve high electrochemical performance. Hence, nanowires have attracted increasing interest in energy related fields. We designed the single nanowire electrochemical device for in situ probing the direct relationship between electrical transport, structure, and electrochemical properties of the single nanowire electrode to understand intrinsic reason of capacity fading. The results show that during the electrochemical reaction, conductivity of the nanowire electrode decreased, which limits the cycle life of the devices. We have developed a facile and high-yield strategy for the oriented formation of CNFs from metal–organic frameworks (MOFs). The appropriate graphicitic N doping and the confined metal nanoparticles in CNFs both increase the densities of states near the Fermi level and reduce the work function, hence efficiently enhancing its oxygen reduction activity. Then, we fabricated a field-tuned hydrogen evolution reaction (HER) device with an individual MoS2 nanosheet to explore the impact of field effect on catalysis. We also identified the exciting electrochemical properties (including high electric conductivity, small volume change and self-preserving effect) and superior sodium storage performance of alkaline earth metal vanadates through preparing CaV4O9 nanowires. Our work presented here can inspire new thought in constructing novel one-dimensional structures and accelerate the development of energy storage applications.

Correlating Nanoporous–Carbon Anode Materials Properties with Li-Ion Intercalation  
Matthaus Wolak, Katharine L. Harrison, Michael Siegal, Kyle Fenton and Dorina Sava-Gullis; Sandia National Laboratories, Albuquerque, New Mexico, United States.

Graphite is the state-of-the-art anode material for Li-ion energy storage due to its low cost and high coulombic efficiency, enabling long term cycling. Alternative carbons can store more lithium than graphite (specific capacity ~ 370 mAh/g), likely due to increased interplanar spacing, defects, pores, and grain boundaries; however, they suffer from low coulombic efficiency, capacity fade with repeated cycling, and often do not allow precise control of the relevant structural properties. Nanoporous-carbon (NPC) films can grow directly onto anode current collectors without the complication of binder materials, allowing direct correlations between nanostructures and the electrochemical properties governing Li-ion intercalation. Graphite is fully dense and alternative carbons are disorganized with pores and varied interplanar spacings. NPC can bridge the gap between alternative carbon materials through exquisite control of the mass density and surface area and help provide greater mechanistic understandings.

Using pulsed-laser deposition of pyrolytic graphite at room temperature, NPC self-assembles into randomly oriented nm-sized graphene fragments only a few layers thick. NPC density is controlled via the deposition energetics from below 0.1 g/cm³ to 2.25 g/cm³ (near graphite). The density is homogeneous throughout a sample, i.e. NPC does NOT consist of dense graphicitic particles separated by voids. Such densities are due to expanded interplanar spacings between the graphene sheet fragments resulting from the deposition kinetics. NPC surface area increases with decreasing mass density, e.g. ~ 1300 m²/g for 1 g/cm³ NPC, so far only reported for foams with densities < 0.1 g/cm³.

NPC specific capacity increases above that for graphite with decreasing density, attributed to the plethora of grain boundaries, pores, and the greater interplanar spacings. NPC with densities < 1 g/cm³ have initial specific capacities 4 – 5X > graphite, higher than many alternative carbon materials. Coulombic efficiencies rise quickly after the first two cycles to a range between 98 and > 99%, indicating minimal initial SEI formation. Both specific capacities and coulombic efficiencies remain high beyond 100 cycles.

This work may lead to determining the optimal interplanar spacing between graphene sheets to maximize Li-ion accessibility while minimizing SEI formation for high cyclability, and may eventually lead to the development of appropriate bulk material fabrication processes.

We thank Lyle Brunke for assistance growing NPC films, Kyle Klavetter for discussions, and Carlos Gutierrez for programmatic guidance. This work is supported by the Laboratory Directed R&D program at Sandia National Labs, a multi-mission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. DOE National Nuclear Security Administration under contract DE-NA0003525.

Bio-Inspired Supercapacitors: Francesco Soavi1, Federico Poli1, Antonio Terella1, Jacopo Seri1, Alessandro Brilloni1, Ruben Aldrin Albis Vasquez1, Francesca De Giorgio1, Catia Arbizzani1, Maria Letizia Focarete1, Davide Fabiani1, Clara Santato1, Carlo Santoro2 and Nicholu Manyala3; 1University of Bologna, Bologna, Italy; 2University of West of England, Bristol, United Kingdom; 3University of Pretoria, Pretoria, South Africa; 4Polytechnique Montréal, Montreal, Quebec, Canada.

Water and energy underpin the economic and social development of Countries. Water is needed for each stage of energy production, and energy is crucial for the provision and treatment of water. Within the so-called Water-Energy Nexus, smart and sustainable energy harvesters and storage technologies are required for an efficient managing of water and renewable energy sources. Within this context, microbial fuel cells (MFC) and supercapacitors (SC) are playing a key role. MFCs are bio-electrochemical devices that convert the chemical energy of wastewater organic compounds directly into electrical energy. SCs can store the energy harvested by the MFC and deliver it back at desired power. Strategies that lower the environmental and economic impact of disassembly and recycling of waste devices are mandatory. The use of water-processable electrode binders and new membrane production techniques like electrospinning are viable approaches to decrease cost and environmental footprint. A study on the development of bio-inspired supercapacitors, including natural binders, electrospun separators and eumelanine-based electrodes, as well their integration with MFCs is reported and discussed.

Simulated Nanoparticle-Functionalization Interface Towards High Energy Density Dielectric Capacitors: Joshua Shipman, Brian Riggs, Binod Subedi, Jianwei Sun and Douglas Chrisey; Tulane University, New Orleans, Louisiana, United States.

Increasing the energy density of high power density dielectric capacitors using nanoparticles (NPs) has often been attempted, but interfacial breakdown has often resulted in lower storage density, cancelling the effect of a higher dielectric constant, especially at higher loadings. We present work in optimizing the interface using a priori simulations combined with experimental verification and feedback. We began by simulating a system used previously that has mitigated some of the interfacial effects using covalent bonding. We modelled the interface of nanoparticle and surface functionalization using a vacuum slab containing a barium titanate NP surface and a surface functionalization molecule. Several different possible metrics for the efficacy of the surface functionalization in mitigating the concentrated electric field at the NP interface were calculated and compared, including the binding energy of the molecule, the HOMO-LUMO gap, and the local dielectric constant. Ultimately, combining the local dielectric constant with a Monte Carlo simulation of the location of NP-functionalization dielectric traps in the material proved to be the most accurate predictor of a NP- functionalization’s effect on the breakdown of the overall composite. 6 different functionalizations were examined both in silico and in spin coated and PulseForge (high energy pulsed Xe light illumination) cured samples. The overall energy density is presented and our model’s efficacy at predicting the highest energy density of our experimentally produced films. We also discuss how our modelling technique could be applied elsewhere where interface control is paramount, such as supercapacitor electrodes, surface functionalization for organometallic perovskite solar cells, and quantum dot solar cells.

3:45 PM *NM04.05.08
2D Materials as Binders for Electrodes of Electrochemical Capacitors: Bin Xu1 and Yuriy Gogotsi1; 1Department of MSE and A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States; 2State Key Laboratory of Organic-Inorganic Composites, Beijing University of Chemical Technology, Beijing, China.

Carbon-based materials have attracted much attention as electrodes for electrochemical capacitors. However, they are usually made into free-standing films with the aid of polymeric binders which add electrochemically inactive weight. Fluorinated polymers used as binders produce toxic gases when incinerated. Here, we discuss manufacturing of freestanding supercapacitor electrodes made of highly porous carbide-derived carbon (CDC), highly accessible hierarchical porous carbon, and activated carbon fibers (ACF) using electrochemically active materials, such as reduced graphene oxide (rGO) and Ti3C2MXene2, as the binders. In these hybrid electrodes, the 2D layers hold carbon particles together, producing freestanding films. The sandwiched carbon particles prevent layer stacking and increase accessibility of the active material to the electrolyte ions, which improves electrochemical performance. As a result, electrodes with excellent capacitance, high-rate performance and good lifetime can be manufactured and operated in aqueous and organic electrolytes. These hybrid electrodes material design is greatly viable in high-power and high energy applications.

4:15 PM RAPID FIRE PRESENTATION
Ultra-Thin, Embedded High-Volumetric Density Capacitors with High Operating Frequency and Low Leakage Properties

Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.

Smart systems have continuously evolved with the integration of computing, communication, power, and sensing functions that utilize heterogeneous technologies such as digital, RF, analog, MEMS, sensors and optics in ultra-miniaturized form-factors with escalating component densities. This entails the use of multiple power converters for specific voltage and current applications. These power converters invariably utilize components such as capacitors and inductors to store and release the energy in specific intervals determined by the switch frequency. Today’s components with low volumetric density and thick form-factors are a major roadblock to miniaturization of the power modules. Moreover, such components are placed far away from the chips leading to large interconnect parasitics and lower operating frequencies. On the other hand, thin-film passive technologies are limited to low densities and would require a large area to meet the required capacitance or inductance values. Hence, novel thin-film technologies with high densities and small form-factors are required to enable miniaturization and performance at high frequencies. However, processing high surface area electrodes as thin-films with substrate-confined processes, and achieving low leakage currents and low ESR (equivalent series resistance) for high frequency stability are major challenges to accomplish these goals. Furthermore, novel packaging technologies are required to integrate these high-density passives as thin-films in substrates. This research work addresses these challenges with tantalum-based ultrathin high-density capacitors at higher operating frequencies with lower leakage properties and their integration in silicon substrates. The work focuses on the processing of high-density capacitors as thin-films based on tantalum with low leakage properties (< 0.01 µA/F) and for high-frequency applications in low power modules. The anodization kinetics and the underlying leakage current mechanisms are investigated to provide optimal process guidelines. The capacitors demonstrated high capacitance density of 0.1 µF/mm² at 1-10 MHz in form-factors of 50 µm, which corresponds to 6X higher volumetric density relative to the commercial capacitors. The aforementioned tantalum-based high-density capacitors are laminated as thin-films on silicon substrates followed by planarization, via-drilling, lithography and metallization to complete the integration process.

Reduced Graphene Oxide - Molybdenum Disulfide Aerogel Nanocomposite Electrodes for Supercapacitors

Reduced Graphene Oxide - Molybdenum Disulfide Aerogel Nanocomposite Electrodes for Supercapacitors

Alptekin Aydinli¹,², Ozgur Dogan¹, Serkan Koylan¹, Erhan Bat¹ and Husnu E. Unalan¹,², ¹Department of Metallurgical and Materials Engineering, Middle East Technical University, Ankara, Turkey; ²Energy Storage Materials and Devices Research Center (ENDAM), Middle East Technical University, Ankara, Turkey; ³Department of Chemical Engineering, Middle East Technical University, Ankara, Turkey.

Super capacitors have attracted extensive attention for their high specific power and moderate energy densities. Nanoscale structure and high surface area are the two main requirements for a supercapacitor electrode with high performance. We report on the fabrication and electrochemical characterization of hybrid aerogel nanocomposite supercapacitor electrodes composed of reduced graphene oxide and molybdenum disulfide nanosheets on nickel foams. Graphene oxide was produced using Tour Method. Reduced graphene oxide (rGO) aerogel was produced from graphene oxide dispersion via solvothermal technique followed by freeze-drying and thermal reduction. For the fabrication of hybrid electrodes, produced rGO aerogels were simply pressed onto nickel foams, which was followed by drop-casting of exfoliated molybdenum disulfide (MoS₂) nanosheets onto the rGO aerogel. Electrochemical properties such as specific capacity and capacity retention of the fabricated nanocomposite electrodes were examined through cyclic voltammetry, chronopotentiometry and electrochemical impedance spectroscopy in two electrode configuration. Results of the measurements were compared to that of control samples fabricated simply by pressing bare rGO aerogel and bare MoS₂ nanosheets directly onto nickel foils. In order to determine the effect of electrolyte type on the electrochemical properties of the hybrid nanocomposite electrodes, various environmentally friendly and neutral aqueous solutions, such as lithium sulfate (Li₂SO₄), sodium sulfate (Na₂SO₄), sodium chloride (NaCl) and potassium chloride (KCl) were investigated as the electrolytes. Fabricated hybrid supercapacitor electrodes showed encouraging results with a specific capacitance of 38.69 mF/cm² and a Coulombic efficiency of 83%. Following 1000 charge/discharge cycles, specific capacitance of the fabricated electrodes degraded to 94% of its initial capacitance value. A comprehensive analysis on the electrochemical properties of the fabricated supercapacitor will be presented.

Aqueous Phase Synthesis Method of Cu-In-S₂ Compound Solar Cell Nanoparticles by Controlling the Metal Complexes in Original Solutions

NM04.06.05

Aqueous Phase Synthesis Method of Cu-In-S₂ Compound Solar Cell Nanoparticles by Controlling the Metal Complexes in Original Solutions

Hideyuki Takahashi, Kohei Sato, Shun Yokoyama and Kazuyuki Toji; Graduate School of Environmental Studies, Tohoku University, Sendai, Japan.

CIS (CuInS₂) type solar cell is one of the most suitable photovoltaic devices with high stability and efficiency, since the bandgap of CIS is 1.5eV while ideal band gap for solar cell is 1.4eV. Moreover, it does not contain toxic materials, such as Se. In usual case, these CIS type solar cell is synthesized by gas phase method. However, since vaporizing temperature of four elements (Cu, In, Ga, Se) is extremely different, productivity under the gas phase is relatively low, which reads the large amount of waste of resources. Thus, to decreasing the cost of CIS type solar cell, synthesis method with high recovery rate should be developed. On the other hand, it is also well known that liquid phase reduction methods can be easily produced the nanomaterials with high recovery rate. However, in many cases, crystallinity of the products was relatively low, which reads the large amount of waste of resources. Thus, to decreasing the cost of CIS type solar cell, synthesis method with high recovery rate should be developed. In our presentation, detailed description of CIS₂ particles synthesis from Cu, In and Se was to be described. In this research, we aim to develop a new synthesis method for CIS₂ nanoparticles with high recovery rate and high crystallinity. We expected that CIS₂ nanoparticles with high crystallinity and high recovery rate can be synthesized using aqueous phase synthesis method. In this method, metal complex is dissolved in water and mixed with metal source (Cu, In and Se). After that, the reaction mixture is heated up to 120°C for 10 hours. In this reaction, CIS₂ nanoparticles were synthesized with high recovery rate and high crystallinity. These nanoparticles were characterized by XRD, SEM and TEM analysis.
Fossil fuels—coal, petroleum and natural gas—have provided more than 80% of total U.S. energy consumption for more than 100 years. To alleviate our dependence on fossil fuels, renewable energy sources such as solar, wind, and geothermal play an important role in the future. Among them, solar harvesting takes advantage of clean and abundant energy from sun by converting the solar energy to electrical or thermal energy. Considering the clean source and product, solar harvesting is a promising tool to utilize endless energy and reduce greenhouse gases in the environment. In a typical solar thermal conversion system, sunlight is absorbed in the form of heat at the absorber surface. To enhance the conversion, this absorber needs to strongly absorb the sunlight, while losing less heat to the environment by convection and radiation. Spectrally selective solar absorbers, having a strong solar absorptance and low infrared emittance, are now widely investigated for solar radiation capture in the form of heat. More specifically, Al2O3-based selective solar absorbers have been extensively investigated for their excellent optical properties and thermal stability. Several techniques, such as co-evaporation, reactive sputtering and solution-based methods, have been employed to fabricate Ni-Al2O3-based selective solar absorbers. The solution-chemical method is desirable due to its low cost and readiness. This method includes two steps: the generation of ordered anodic aluminum oxide pores and the impregnation of nickel. The anodic aluminum oxide with ordered pore geometry is typically fabricated by a two-step anodization in acid solution. The nickel impregnation can be performed under direct or alternating voltage. Salmi et al. carried out the impregnation in a nickel sulphate solution under alternating voltage, which resulted in a coating with a low emissivity (0.14 at 700 °C) and high solar absorptivity (> 0.9). To further improve the uniformity of nickel deposition, Nielsh et al. developed a pulsed electrodeposition (PED) method, which shows that nearly 100% of the pores were filled with nanocrystalline nickel with a very small fluctuation in growth rate.

Although the uniform deposition of nickel into porous alumina had been investigated before by using the PED method, the direct connection between porous geometry and surface optical properties has not been previously investigated. Also, by using more modern equipment (e.g. SEM, FIB) with higher resolution, details inside the materials can be characterized with higher accuracy. Understanding this connection and the detailed microstructure of Al2O3-based selective solar absorbers will lead to a better understanding and further improvement in solar conversion efficiency.

In this study, we refined the nickel deposition by using PED method and investigated the effects of various nickel deposition parameters on the optical properties of selective solar absorbers.

Microkinetic Analysis of Hydrogen Evolution Reaction on Graphene Coupled Molybdenum Carbide Heterostructure Timothy T. Yang and Wissam Saadì; Materials Science, University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Molybdenum carbides have shown high catalytic activity towards hydrogen evolution reaction (HER) by coupling with graphene supports. However, the atomistic mechanism for the enhanced activities is still lacking. Herein, we use first-principles calculations in conjunction with ab initio thermodynamics to investigate the HER on Gamma-phase MoC coupled graphene. Analyzing the reaction pathways and charge transfer events from first principles results, we develop a novel model to predict linear sweep voltammetry in electrochemical conditions based on Volmer-Butler kinetics. Particularly, this model shows that the heterostructure with graphene vacancies reaches its optimum for HER resulting in an overpotential of ~0.1 V vs. SHE for 10 mA/cm2 current density. We validate this kinetic model by demonstrating that the Volmer-Heyrovsky pathways on the heterostructure are mainly controlled by hydrogen adsorption Gibbs free energy, the descriptor which has been widely used to measure HER activities in the catalyst community.

IR-Driven Photoelectrochemical Properties and Band Structures of CdSe/ZnO Heterostructures Fabricated on the Up-Conversion Glass-Ceramics Joo-Won Lee, Joon-Soo Yoon and Yun-Mo Song; Korea University, Seoul, Korea (the Republic of).

We report the new approach for utilizing infrared (IR) light, which is differentiated from the established routes using heterostructures of up-conversion (UC) fluoride nanoparticles and semiconductor photocatalysts. We introduced the IR-driven photoelectrochemical (PEC) cells using UC glass-ceramics as substrates and this enabled the overcome of the natural instability of UC fluoride nanoparticles, the blockage of incident light, and the restricted exposure of photocatalysts to liquid electrolytes. Oxyfluoride glass-ceramics containing (Yb,Er)-doped and (Yb,Tm)-doped YF3 nanoprecipitates were verified to radiate UC green and UC ultraviolet/blue emissions, respectively under 980 nm illumination. High-density ZnO nanorod arrays were fabricated on the UC glass-ceramics substrates via the hydrothermal method and subsequently CdSe/ZnO heterostructures were realized with the chemical bath deposition method. CdSe nanoparticles with the bandgap of ~1.8 eV were activated by both the UC ultraviolet emission from Tm3+ ions and the UC visible emissions from Er3+ and Tm3+, whereas ZnO nanorods with the bandgap of ~3.2 eV absorbed the UC ultraviolet emission from Tm3+ mostly. Two distinct carrier transport mechanisms, so called sensitization and type-II cascade, turned up in the identical CdSe/ZnO photocatalysts originated from the difference in the UC emissions from Er3+ and Tm3+ ions. Eventually, the CdSe/ZnO fabricated on the UC glass-ceramics containing (Yb,Tm)-doped YF3 exhibited increased photocurrent density compared to that on the UC glass-ceramics containing (Yb,Er)-doped YF3 because of the charge separation activated by the type-II cascade transport mechanism.

Optically Transparent, Thermally Insulating Aerogels for Energy Efficient Window Applications Elise M. Strobach1, Bikram Bhatia1, Lin Zhao2, Sungwoo Yang2, Shaoing Lin1, Xuahne Zhao3 and Evelyn N. Wang1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Civil and Chemical Engineering, The University of Tennessee at Chattanooga, Chattanooga, Tennessee, United States.

The United States uses 14% of the total annual energy produced on heating, ventilation, and air conditioning in buildings. A large portion of this energy is lost through windows, a necessary but lossy portion of the building envelope. High-performance windows use exotic low conductivity gases, large frame footprints, low-emissivity coatings, and complex sealing strategies to achieve high performance, often leading to long payback periods. We propose using high-transparency silica aerogel developed in our lab to reduce energy losses via the super-insulating properties of its nanoporous structure. In this work, we have shown that by controlling density and pore/particle size, we can achieve a visible transmission of >98%, a visible haze <3.0%, and a thermal conductivity of <0.02 W/mK through a 3 mm monolithic slab in ambient conditions. This exceeds the highest clarity reported in literature for silica aerogels, allowing the material to be competitive with traditional window insulating materials at a relatively low cost ($2 per square foot). We also present an approach to optimize the high-transparency aerogel structure for optical, thermal, and mechanical performance critical to window applications. This is done using structure-property relationships developed in combination with a center-of-pane window performance model to identify the ideal achievable aerogel structure. This optimization approach creates a framework that allows the aerogel to maximize energy efficiency in windows for the varied performance needed in many different buildings and climates.

SnS2 Nanoparticles and P3HT Blends for Hybrid Solar Cells Maria E. Perez Barthaburu, Daniela Oreggioni, Loengrid Bethencourt, Mauricio Rodríguez Chialanza, Ricardo Santana, Lauro Maia and Laura Formaro; 1Departamento de Desarrollo Tecnológico, CURE - Universidad de la República, Rocha, Uruguay; 2Instituto de Física, Universidade Federal de Goiás, Goiania, Brazil.
Hybrid solar cells are among the studied technologies for the generation of electric energy from solar energy. In these solar cells, an inorganic electron acceptor of nanometer size must be developed, being a polymer is generally used as donor, while a NPs is used as the most common one. SnS$_2$ is a semiconductor with an energy band gap of 2.35 eV adequate for its use in hybrid solar cells. Many studies were performed for its application as sensor, in lithium batteries, photocatalysis, etc. In the present work, we synthesized Sn$_x$S$_y$ NPs (by the hydrothermal method. SnCl$_2$·H$_2$O and Thiouacetylmete were used as Sn and S sources. In all the syntheses citric acid was used as capping agent (CA). The ratio Sn:CA was varied to study its influence in morphology and size of NPs. For this purpose, the ratios [2:1], [1:10] and [1:15] were tested. All obtained samples were centrifuged with water and ethanol. The sample with a Sn:CA [1:10] ratio yielded the best results, with hexagonal NPs of 15-50nm and rounded NPs of 2-4nm in size, observed under Transmission Electron Microscope. This sample was selected to perform an exchange of CA. The sample was refluxed in pyridine or aniline during 6 hours (samples S-Py and S-Ani, respectively). They were washed following the same procedure described before. The success of CA exchange was studied by FTIR, confirming the presence of aniline in sample S-Ani and pyridine in sample S-Py. The stability of NPs suspension in chloroform was studied, being important for the preparation of P3HT/SnS$_2$ blends. It was proved that NPs capped with aniline were more stable than the pyridine ones, presenting a decanting coefficient of 0.02g/L.min. Blends and then layers of Sn$_x$S$_y$/P3HT were obtained with both samples, S-Ani and S-Py. Layers were deposited onto glass covered with ITO/PEDOT:PSS substrates, using the spin coating technique. The layers S-Ani and S-Py were studied by Scanning Electron Microscopy (SEM) and Energy Dispersive Spectroscopy (EDS). EDS results confirmed presence of SnS$_2$; NPs, while SEM showed that both layers have uniform distribution of NPs. Phoatoluminescence experiments were performed on S-Ani, S-Py, LS-Ani and LS-Py samples. Emission peaks of CA were observed for the samples S-Ani and S-Py; Sn$_x$S$_y$ emission is possibly included in these peaks. The layers also showed the characteristic emission peaks of P3HT. UV-Vis spectroscopy studies were carried out to the same samples and to substrates covered with P3HT only, observing two bands of P3HT. Results of layers prepared with different proportions of nanoparticles, proved that there is an electronic coupling between the polymer and the NPs. Our results show that the presence of aniline or pyridine are necessary for the suspension of Sn$_x$S$_y$, being aniline the best. Moreover, the spectroscopy results encourage us to further study the photovoltaic properties of layers for the development of hybrid polymeric-inorganic solar cells.

Gold Deposited Flexible Nickel Micro-Pillar Structured Substrate for Solar Steam Generator Soomin Son, PilHoon Jung, Jaemin Park, Dongwoo Chae, Sucehoel Ju and Heon Lee; Korea University, Seoul, Korea (the Republic of).

Solar steam generators are potential technologies that can be used in a variety of applications such as desalination and sterilization, and are emerging as promising technologies for solar energy harvesting. In recent years, various artificial structures have been developed for the purpose of improving the energy conversion rate by improving solar absorption, thermal localization, water supply and steam transportation. In this research, a solar steam generator was fabricated by depositing plasmon metal particles that can efficiently convert light into heat under sunlight, such as gold on a nickel micropillar (NiMP) structured substrate. The NiMP substrate was confirmed to have a high absorption of 98% or more in the broad spectrum of 300-2500 nm. As a result, we have fabricated the steam generator with high solar conversion efficiencies using high absorbance and light-to-heat efficient conversion under solar light illumination. This structure demonstrates the potential for future regeneration functions, portable solar energy generation and phase change applications, and solar energy based desalination.

Improving Ni-VSZ Cermet Anode Performance by Liquid Infiltration of Nickel Catalyst Particles with LSCM Yanchen Lu, Paul Gasper, Boshan Mo, Uday Pal, Srikanth Gopalan and Soumenendra Basu; Boston University, Brookline, Massachusetts, United States.

Hydrogen generation and storage are a critical part of a sustainable energy future; a key technology for the production of energy from hydrogen fuel is the solid oxide fuel cell (SOFC). Impregnation of nanoscale metallic catalysts into the anode electrode has been shown in many studies to improve SOFC performance in various ways, such as increase catalytic performance, improve sulfur tolerance, and mitigate coking. The goal of this study is to infiltrate nickel nanoparticles into both anode symmetric cells and anode supported button cells to increase electrochemical active site density and improve anode performance, and for catalytic energy conversion reactions such as water splitting. The synthesis of such compounds is commonly done in time and energy consuming batch processes. Alternatively, spray-flame synthesis (SFS) allows the formation of functional perovskite nanoparticles in a single step. Cost-efficient production requires the utilization of cheap and abundant precursors such as metal nitrates, which are more attractive than the organometallic precursors (acetates, carboxylates). However, the use of metal nitrates in SFS is often associated with the formation of particles non-homogeneous in size. Furthermore, the different melting/decomposition mechanisms and their different solubility in solvents such as ethanol cause the formation of undesired phases, e.g., La$_2$CoO$_4$, La$_2$O$_3$ and Co$_3$O$_4$, which are often obtained in parallel to the main perovskite phase. In order to improve the perovskite homogeneity in size and composition, mixtures containing the metal nitrate precursors and two different solvents, ethanol and 2-ethylhexanoic acid (2-EHA), were employed in this study. The incorporation of 2-EHA has been previously investigated and a positive effect toward narrow particle-size distributions has been observed. It is suggested that the addition of 2-EHA leads to the formation of micro-explosions in the droplets through superheating of ethanol and the formation of volatile metal carboxylates, which is investigated in this study. The LaCoO$_3$ and LaFeO$_3$ nanoparticles were synthesized from solutions of the respective nitrates in ethanol/2-EHA. To understand the effect of 2-EHA on the product properties, temperature-dependent liquid-phase ATR-FTIR studies were performed. It was found that an esterification of 2-EHA with ethanol occurred forming ethyl-2-ethylhexanoate (verified by GC/MS). We assume that the metal nitrates act as catalysts as reported for similar reactions. The nanoparticle products were characterized using XRD, XPS, TEM, SAXS, and Mößbauer spectroscopy. The measurements confirm that the incorporation of 2-EHA in the solution was effective for obtaining homogeneous, single-phase, and high-surface-area products (LaCoO$_3$: $d_p = 11$ nm, SSA $> 90$ m$^2$/g, LaFeO$_3$: $d_p = 15$ nm, SSA $> 88$ m$^2$/g). The LaFeO$_3$ and LaCoO$_3$ perovskites were evaluated for the catalytic oxidation of carbon monoxide, reaching a 50% CO conversion at temperatures lower than 206°C.

NM04.06.13

Spray-Flame Synthesis (SFS) of the Nanosized LaMO$_3$ (M = Fe, Co) Perovskites from Metal Nitrate Precursors—Influence of the Mixture of Ethanol and 2-Ethylhexanoic Acid on Materials’ Homogeneity Steven Angeli$^{1, 2}$, Mira Klinge$^3$, Hermann Nirschl$^3$, Klaus Friedel-Ortega$^4$, Yuan Wang$^1$, Hamidreza Arandiyan$^5$, Hartmut Wiggers$^{1, 2}$ and Christof Schulz$^{1, 2}$; 1IVG, Institute for Combustion and Gas Dynamics, University of Duisburg-Essen, Duisburg, Germany; 2CENIDE, Center for Nanointegration, University of Duisburg-Essen, Duisburg, Germany; 3Institute of Mechanical Process Engineering and Mechanics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 4Faculty of Chemistry, Inorganic Chemistry, University of Duisburg-Essen, Essen, Germany; 5Particles and Catalysis Research Group, University of New South Wales, Sydney, New South Wales, Australia; 6Laboratory of Advanced Catalysis for Sustainability, The University of Sydney, Sydney, New South Wales, Australia.

Perovskite nanomaterials composed of LaMO$_3$ (M = Fe, Co) are of current interest for environmental catalysis applications, e.g., oxidation of CO and CH$_4$, and for catalytic energy conversion reactions such as water splitting. The synthesis of such compounds is commonly done in time and energy consuming batch processes. Alternatively, spray-flame synthesis (SFS) allows the formation of functional perovskite nanoparticles in a single step. Cost-efficient production requires the utilization of cheap and abundant precursors such as metal nitrates, which are more attractive than the organometallic precursors (acetates, carboxylates). However, the use of metal nitrates in SFS is often associated with the formation of particles non-homogeneous in size. Furthermore, the different melting/decomposition mechanisms and their different solubility in solvents such as ethanol cause the formation of undesired phases, e.g., La$_2$CoO$_4$, La$_2$O$_3$ and Co$_3$O$_4$, which are often obtained in parallel to the main perovskite phase. In order to improve the perovskite homogeneity in size and composition, mixtures containing the metal nitrate precursors and two different solvents, ethanol and 2-ethylhexanoic acid (2-EHA), were employed in this study. The incorporation of 2-EHA has been previously investigated and a positive effect toward narrow particle-size distributions has been observed. It is suggested that the addition of 2-EHA leads to the formation of micro-explosions in the droplets through superheating of ethanol and the formation of volatile metal carboxylates, which is investigated in this study. The LaCoO$_3$ and LaFeO$_3$ nanoparticles were synthesized from solutions of the respective nitrates in ethanol/2-EHA. To understand the effect of 2-EHA on the product properties, temperature-dependent liquid-phase ATR-FTIR studies were performed. It was found that an esterification of 2-EHA with ethanol occurred forming ethyl-2-ethylhexanoate (verified by GC/MS). We assume that the metal nitrates act as catalysts as reported for similar reactions. The nanoparticle products were characterized using XRD, XPS, TEM, SAXS, and Mößbauer spectroscopy. Spray-Flame Synthesis of Ba$_{1-x}$Sr$_x$TiO$_3$ Nanoparticles for Photocatalytic Hydrogen Production

Alexander Tarasov$^{1,2}$, Marco Relohs$^2$, Frank Marlow$^2$ and Hartmut Wiggers$^{1,2}$; $^1$Institute for Combustion and Gas Dynamics – Reactive Fluids (IVG), University of Duisburg-Essen, Duisburg, Germany; $^2$Max-Planck-Institut für Kohlenforschung, Mülheim, Germany; $^3$Center for Nanointegration Duisburg-Essen, CENIDE, Duisburg, Germany.

Barium titanate (BaTiO$_3$) and strontium titanate (SrTiO$_3$) are oxide perovskites with large band gap values (~3.2 eV) suitable for hydrogen production via water splitting under UV light. These materials show high thermal and chemical stability, and the flexibility of the ABO$_3$ perovskite structure offers the possibility of substituting cations on both, A and B sites, therefore allowing to selectively adjust properties of interest such as band gap width and particle size. While nanoscale cubic SrTiO$_3$ has been shown a promising catalyst, BaTiO$_3$ is afflicted by the existence of multiple phases over a narrow temperature range. The cubic phase of BaTiO$_3$ can be stabilized by the introduction of smaller Sr-atoms, however, the influence on the catalytic activity is not known so far. Therefore, the formation of Ba$_{1-x}$Sr$_x$TiO$_3$ and its catalytic properties was investigated.

Nanosized barium strontium titanate was synthesized in the gas phase by means of spray-flame synthesis (SFS). This scalable method allows a continuous production of oxide nanoparticles and provides a good control over size, crystallinity, and phase composition. The SFS method is essentially a combustion process, whereby high temperatures of the burning spray lead to the evaporation of the dissolved metal precursors, gas-phase reactions, and subsequent particle formation. The applicability of the SFS technique to nanoparticle synthesis has been already demonstrated for many simple oxides (e.g., TiO$_2$, Al$_2$O$_3$). Once using this method to extend the SFS technique to oxide nanoparticles could enlarge the number of catalytically interesting materials.

As-produced (AP) and heat-treated powders (HT) were tested in UV light water splitting reaction with methanol and compared with commercially available BaTiO$_3$ powder. On average, the Sr-containing AP powders show 15% higher hydrogen production rate than the commercial sample. Surprisingly, HT samples show similar activity despite having less surface area as suggested by BET measurements. We attribute this to an initial decomposition of the adsorbents, which no longer hinder the catalytic reaction.

NM04.06.15

High-Efficiency, High-Temperature Cu and Mn Oxides Nanoparticle-Pigmented Anti-Oxidation Solar Selective Coatings via Spray-Coating Method

Can Xu, Eldred Lee, Xiaoxin Wang and Jifeng Liu; Dartmouth College, Hanover, New Hampshire, United States.

As an important component of concentrating solar power (CSP) systems, solar selective absorber coatings can help enhance the absorbance in the solar spectrum regime and reduce the emittance loss in the infrared (IR) range [1]. However, many of the current coating products are not capable of maintaining the solar selectivity as well as satisfying the thermal efficiency requirement (~90%) when undergoing high operating temperature [2]. Herein, we report Cu and Mn oxides nanoparticle(NP)-pigmented silicone solar selective coatings on Inconel substrates via a simple hot spray-coating method. The coatings can withstand a high temperature of 750 degrees C for future generations of CSP systems [3], and hence improve the thermal efficiency according to Carnot's Theorem. Based on theoretical modeling [4] and verified by experiments, these NP-pigmented coatings can tolerate a relatively large variation in the pigment NP concentration, diameter, as well as coating thickness, thereby enabling facile spray coating method without the need of stringent thickness control. By adequately selecting silicone precursors with low emissivity and high enough viscosity, the pigment NPs can be well dispersed in the solution for spray coating with excellent stability against precipitation of NPs. To further explore the impact of relevant factors, we varied parameters including type of silicone precursors, organic solvents, compositions and concentrations of NPs, and the thickness of the coatings. Our preliminary optimization effort has already achieved a high solar absorbance of 96.7%, a thermal emittance of 59.1%, and a record-high overall optical-to-thermal energy conversion efficiency of 93.0% for 1000x solar concentration ratio at 750 degrees C, exceeding that of the state-of-the-art Pyromark 2500 black paint (90%) at the same temperature [4]. These coatings also block the IR emittance losses of the thermal oxide layers on the Inconel substrates found in previous research [5]. Furthermore, they have already passed 100 h endurance testing at 750 degrees C in air without deterioration in efficiency or mechanical integrity, promising for long-term thermal stability at high temperatures. The high efficiency, high-temperature thermal stability, and simple and facile fabrication process make these Cu and Mn oxide NP-pigmented solar selective coatings especially promising for scaling up in CSP industry.

NM04.06.16

Cellulose Based Nanomaterials Synthesis for Sustainable Energy Conversion

Anand Kumar$^1$, Isna Ashraf$^4$ and Anchul Ashok$^1$; $^1$Department of Chemical Engineering, Qatar University, Doha, Qatar; $^2$Department of Mechanical and Industrial Engineering, Qatar University, Doha, Qatar.

Fuel cells (FCs) have long been considered as an alternative to fossil fuel energy for a sustainable growth and the protection of the ecosystem from harmful emissions. Direct methanol fuel cells (DMFCs) among various types of FCs, have been intensively studied because of their low-operating temperature, high-energy conversion efficiency, and environmental-friendly nature for micro-power energy strategy. However, Pt is the only commercially available anodic materials, that is reasonably active and stable, as it has shown low CO-poisoning in alkaline media. Alternative materials with low costs are still being sought as suitable catalysts to enable commercialization and widespread application of DMFCs. Here we explore a more sustainable approach that is based on the application of cellulosic materials for large-scale synthesis of transition metals and their alloys with noble metals for various catalytic applications, in particular, fuel cells. In this technique, an aqueous solution of metal nitrate and a reducing agent is impregnated on a thin cellulose paper. The paper is dried and locally ignited at one end to start combustion reaction that is self-sustained under optimum loading of reactive solution, continuously producing nanoparticles. The thin film helps in generating a quenching effect and limits nanoparticles sintering in post-combustion stages. This paper
describes the synthesis of Cu, Ni and Co based nanomaterials that are found to be active for sustainable hydrogen production from bioethanol, methanol that can be generated from bio-wastes. A detailed mechanistic study of nanoparticle evolution during synthesis process was conducted along with the reaction pathway analysis for hydrogen production from bioethanol. In-situ FTIR (DRIFTS) studies on the metal surfaces reveal the differences in their catalytic performance and help in explaining the observed product distribution.

NM04.06.17 Sustainable CO2 Conversion Over Visible-Light-Responsive Perovskites via Artificial Photosynthesis Eduardo Morais1, Kristy Stanley1, James Sullivan1 and Ravindranathan Thampi2; 1School of Chemistry, University College Dublin, Dublin, Ireland; 2School of Chemical and Bioprocess Engineering, University College Dublin, Dublin, Ireland.

The bulk of energy generation on Earth derives from combustion of fossil fuels. This has undesired consequences including the depletion of fossil fuel resources (which are also the principal feedstock of the chemical industry) and the generation of CO2 (a greenhouse gas which has recognised the generation of which has implications for climate change implications). This reliance on fossil fuels is unsustainable and therefore it is imperative to find alternative cleaner energy sources.

This work aims to harness the energy available in solar radiation using photo responsive catalysts to carry out the reduction of CO2 into CO and/or CH4 using H2O as a co-reactant (i.e. the artificial photosynthesis reaction). The materials studied are a range of semiconductor Bi2WO6 quasi-perovskites Bi1-xCoxWO3. These were prepared via facile solvothermal methods at low temperatures and the use effects of surfactants, template agents and microwave radiation within the preparation mixture and surface modifications with amine groups on reactivity was investigated. Also, surface modifications with terminal amine moieties and doping were carried out on the parent materials with the aim of enhancing the photocatalytic activity. All the plain and modified catalysts were characterised using a range of techniques and applied in a batch reactor in the artificial photosynthesis reaction.

CO2 + H2O + hv → CH4 + CO + O2

The characterization techniques included XRD, UV Visible spectroscopy, TEM, BET, and XPS. X-ray diffraction showed both crystalline and amorphous Bi2WO6 depending on the synthetic route adopted. SEM and TEM studies revealed that nanoparticle morphologies also depended on the synthesis. The materials had relatively large BET surface areas and TPD experiments confirmed the adsorption / desorption of CO2 and H2O on (and from) the catalyst surface.

The catalysts were tested in the CO2 + H2O reaction under simulated solar radiation, evolving CO and CH4 as products. CO2 conversion and CO/CH4 product ratios were dependent on aspects such as surface area and functionalization and light absorption properties (which in turn were dependent on the morphology of the particles).

NM04.06.19 Photovoltaic and Photocatalytic Properties of Bismuth Oxyiodide-Graphene Nanocomposites Candy C. Mercado, Levannie A. Mabuti and Ian Kenneth Manding; Department of Mining, Metallurgical, and Materials Engineering, University of the Philippines Diliman - ANSYD Lab, Quezon City, Philippines.

Solar energy is considered to be the most viable solution for the future energy crisis and water pollution. In this study, we evaluate the photovoltaic and photocatalytic properties of chemical vapor deposited bismuth oxyiodide (BiOI) and bismuth oxyiodide-graphene (BiOI-GR) nanocomposite thin films.

They were characterized using XRD, SEM, UV-Vis spectrophotometer, and EIS. The BiOI thin film has an average thickness of 574 nm and a bandgap of 2.12 eV. The BiOI and BiOI-GR thin films exhibited nanoflake morphology. It was found that addition of graphene increases absorbance by causing vertical growth of nanoflakes, imparting anti-reflectance and light trapping and also suppresses recombinations due to its electron accepting nature. The photocatalytic activity of the thin films were evaluated by examining methylene blue (MB) degradation under visible light irradiation. BiOI-GR degraded 56-62% of MB in two hours while BiOI degraded 44.16%. Afterwards, FTO | BiOI | Graphite | Al and FTO | BiOI-GR | Graphite | Al solar cells devices were fabricated with photocurrent density values of 0.20 μA/cm² and 0.27 μA/cm², respectively. The improved properties of BiOI-GR are attributed to the anti-reflecting and light trapping properties of vertical BiOI-GR nanoflakes and the enhanced carrier separation due to graphene.

NM04.06.20 Oxide Anchored, Carbidie Supported Pt Nanoparticles for Oxygen Reduction Reaction Zishuai Zhang1, Amin Sadeghi1, Nicolas Brodusch1, Raynald Gauvin1, Jeff Gostick2, Siyu Ye1, Geraldine Merle1 and Jake Barral1; 1McGill University, Montreal, Quebec, Canada; 2University of Waterloo, Waterloo, Ontario, Canada; 3Ballard Power System Inc., Burnaby, British Columbia, Canada.

Transition metal carbides have attracted increasing attention recently as low-cost electrocatalyst supports for the oxygen reduction reaction (ORR) due to some conductivity and relative stability. Furthermore, transition metal carbides can promote electron transfer between the catalysts and supports. To further improve the carbide conductivity and stability, especially at higher potentials (T<1.5V), we developed a process for the formation of a cobalt oxide protective shell on Pt decorated TiC. The oxide was removed selectively at the location of the Pt thereby creating a protective layer for the carbide only. It had the unexpected advantage of pHsically anchoring the Pt to the carbide. We examined ORR activity and stability of these composite particles by chronoamperometry analysis in oxygen-saturated solution. The process method consists in depositing platinum before the cobalt layer, and 5 wt% hydrogen peroxide was used to burst the cobalt shell to expose platinum nanoparticles.

Electron microscopy confirmed that the platinum nanoparticles were in contact with both the carbide core and cobalt shell. These coated carbide nanomaterials had greatly improved stabilities as supports compared with pristine carbides (chronoamperometry curve showed no activity loss at 0.6 V vs
Nanoscale complex metal oxides have transformed how technology is used worldwide. The most widespread examples are the electroactive components of Li-ion batteries found in portable electronic devices. As the number of portable devices is projected to increase, so too will the inadvertent release of complex metal oxide nanomaterials into the environment. This is a pressing problem because the environmental and biological impact of complex metal oxide nanomaterials is most times unknown, since they are subject to transform rapidly with changes in pH and concentration. This brings us to a looming problem that needs to be solved on a global scale. There is a fundamental knowledge gap in developing sustainable nanotechnology because there is not yet a systematic method to predict how the properties of a complex metal oxide will change with changes in chemical environment. We have developed an analysis, based on Hess’s Law, which combines DFT-computed total energies and experimentally adjustable reaction conditions to compute the surface dissolution of complex metal oxides. We focus on the materials found in a Li-ion battery cathode, namely LiCoO2 and compositionally tuned variants with general chemical formula Li(NiMnxCoy)O2. We find that adjusting surface terminations, compositions and pH will change the dissolution properties of this family of materials, and yields insights into the nanoscale transformations that may take place under a given set of conditions. Not only can these results be used to improve environmental fate and toxicity models, but we are able to use the results of our analysis to create a set of rational design rules to govern the creation of the next-generation of Li-ion battery cathodes that will be benign by design.

**Internal Polarization Modulation in Nanostructured Bi2MoO6 for Photocatalytic Performance Enhancement Under Visible Light Illumination**

Yan Chen¹, Weiye Yang¹, Shuang Gao², Linghang Zhu¹, Caixia Sun¹ and Qi Li²; ¹Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China; ²Graduate School at Shenzhen, Tsinghua University, Shenzhen, China; ³Beihang University, Beijing, China; ⁴Qingdao Binhai University, Qingdao, China.

Recently, the introduction of a built-in electric field inside polar photocatalysts was proved effective for the improvement of their photocatalytic performances because the internal electric filed could provide the driving force for electrons and holes to move in opposite directions for their enhanced transport. Most research in polar photocatalysts is now focused on exploring polar semiconductors as novel photocatalysts, including GaN, ZnO, BaTiO₃, NaNO₂, Sr₂(Ta,Nb)₂O₇, Cu₂(OH)PO₄, BiOCl, BiOF, BiOIO₃, Na₃VO₂B₆O₁₁, and Bi₇Fe₃Ti₃O₂₁, while fewer efforts had been made on the modulation of its current efficiency, maximum luminance and FWHM from 3,300 nit to 31,700 nit, and FWHM from 41 nm to 37 nm. Refining the device structure by inserting hole suppressing interlayer further suppresses hole injection from HTL to QDs. We believe that our result is a step forward to make highly efficient InP QLEDs.
Strong Covalent Bonding Modulated Graphene Oxide/Epoxy Interfacial Enhancement and Advanced Corrosion Resistance

Recent interests in graphene-based polymer nanocomposites for structural applications have been driven by the expectation of enhancing the mechanical properties of composites. Although there has been a rapid growth of interest in graphene-based polymer nanocomposites, the mechanics of reinforcement in such materials has only recently become understood [1,2].

The modern structures employed in aerospace and automotive applications are becoming lighter and thinner, but still require high levels of aerodynamic and vibration stability, leading to the stiffness becoming a dominant design driver. Since graphene has high levels of stiffness and strength its use as a reinforcement in polymer composites shows huge potential of further enhancing the mechanical properties of composites. Although there has been a rapid growth of interest in graphene-based polymer nanocomposites for structural applications, the mechanics of reinforcement in such materials has only recently become understood [1,2].

It is shown that the addition of approximately 2% by weight of graphene to the matrix of a unidirectionally-reinforced carbon fiber epoxy composite can lead to a significant enhancement in mechanical properties. In particular, it is found that the axial stiffness of the composites can be increased by the order of 10 GPa accompanied by an increase in axial strength of 200 MPa. X-ray computed tomographic imaging and polarized Raman spectroscopy have demonstrated that the graphene is predominantly aligned parallel to the axes of the carbon fibers. Moreover stress-induced Raman band shifts showed that the self-aligned graphene is subjected to high levels of stress during axial deformation of the composite. The graphene is found to have an effective growth of interest in graphene-based polymer nanocomposites for structural applications, the mechanics of reinforcement in such materials has only recently become understood [1,2].

Chemically functionalized graphene oxide (MAGO) was achieved by building covalent bonds between graphene oxide (GO) and a small molecule containing benzene structure and multi-amino groups. FT-IR, XRD, X-ray photo electron spectroscopy and TEM-EDX results certified that the molecule was successfully grafted onto GO nanosheets. Subsequently, functionalized GO was incorporated into waterborne epoxy (EP) coating through ball-milling method. This molecular design can significantly improve the dispersion of MAGO in EP matrix, as well as the compatibility and interaction between MAGO and EP. Compared with GO/EP, the water absorption of MAGO/EP decreased from 4.38% to 2.59%, the adhesion strength of MAGO/EP increased from 4.72 MPa to 6.32 MPa after immersion of 40 days in 3.5% NaCl solution. Incorporation of 1 wt% of MAGO into EP matrix prominently improved the long-term corrosion resistance. The impedance modulus of GO/EP coating decreased by four orders after 40 day immersion, while that of MAGO/EP coating only decreased by one order. The impedance modulus was still $1.47 \times 10^8 \Omega \cdot cm^2$, and two-time constant wasn’t detected for MAGO/EP coating. This research developed a facile approach to prepare green anticorrosion coating with enhanced durability for metal protection. MAGO can also be utilized as nanofillers for other waterborne polymer matrixes to fabricate green anticorrosion coatings of high performance.

Real-Time Observation of Single CNT Fiber Subjected to Transverse Ballistic Impact

Axial Reinforcement of Unidirectional Composites by Self-Aligned Graphene

Our way of producing master alloy and dispersing them are thus key for the comprehensive superiority of the properties over other methods of making Al+CNT nanocomposites. This cold welding and rapid surface burying process were revealed by in situ transmission electron microscopy (TEM) experiments under similar vacuum conditions. Our way of producing master alloy and dispersing them are thus key for the comprehensive superiority of the properties over other methods of making Al+CNT nanocomposites.
Young’s modulus in the composite of around 825 GPa, approaching its theoretical value of 1050 GPa. This behavior has been modelled using the rule of mixtures and shear-lag analysis and it is demonstrated that highly-aligned graphene in a constrained environment between high-modulus fibers can give significantly better mechanical reinforcement than graphene in conventional polymer-based nanocomposites. It has been demonstrated the enhancement is due to three effects: (a) the alignment of graphene around the fiber by a ‘filtering’ effect; (b) confinement of graphene between the fiber gaps and (c) the matrix being stiffened by the carbon fibers. It shows the considerable potential of using graphene to enhance the mechanical properties of conventional carbon fiber composites even in the high-stiffness fiber direction.

Strong, Tough Graphene Sheets by a Low Temperature Sequential Bridging Process Sijie Wan1, Qunfeng Cheng2 and Ray H. Baughman1; 1The University of Texas at Dallas, Richardson, Texas, United States; 2School of Chemistry, Beihang University, Beijing, China.

We here show that infiltrated bridging agents can convert inexpensively fabricated graphene platelet sheets into high performance materials, thereby avoiding the need for a polymer matrix. Two types of bridging agents were investigated for interconnecting graphene sheets, which attach to sheets by either π-π bonding or covalent bonding. When applied alone, the π-π bonding agent is most effective. However, successive application of the optimized ratio of π-π bonding and covalent bonding agents provides graphene sheets with the highest strength, toughness, fatigue resistance, electrical conductivity, electromagnetic interference shielding efficiency, and resistance to ultrasonic dissolution. Raman spectroscopy measurements of stress transfer to graphene platelets allow us to decipher the mechanisms of property improvement. In addition, the degree of orientation of graphene platelets increases with increasing effectiveness of the bonding agents, and the interlayer spacing increases. When compared with other materials that are strong in all directions within a sheet, the realized tensile strength (945 MPa) of the resin-free graphene platelet sheets was higher than for carbon nanotube or graphene platelet composites, and comparable to that of commercially available carbon fiber composites. The toughness of these composites, containing the combination of π-π bonding and covalent bonding, was much higher than for these other materials having high strengths for all in-plane directions, thereby opening the path to materials design of layered nanocomposites using multiple types of quantitatively engineered chemical bonds between nanoscale building blocks. Y. Li, J. Mu, A. Aliev, S. Fang, N. A. Kotov, and L. Jiang also collaborated on this work.

Preparation and Nanostructure Analysis of Graphitic Carbon Infused Copper Alloys Beihai Ma1, Uthamalingam Balachandran1, Steve Dorris1, Tae Lee1, Jie Wang1, Jianguo Wen1, Yuzi Liu1, Jonathan Poplawsky2 and Adam J. Rondinone3; 1Argonne National Laboratory, Lemont, Illinois, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

We prepared graphitic carbon nanostructure infused copper alloys by electron-beam melting. This new class of materials, known as copper covetics, exhibit enhanced electrical and thermal conductivities. We observed up to 30% enhancement in electrical conductivity in covetic copper thin films deposited by electron-beam evaporation. Our results revealed remarkable promise for applications as interconnects in the next generation integrated circuits and memory devices. Understanding the nature of interaction between the carbon nanostructures and their host metal is critical to elucidate the origins for superior properties. We utilized atom probe tomography (APT), helium ion microscopy (HIM), high-resolution transmission electron microscopy (HRTEM) and scanning transmission electron microscopy (STEM) in the study of carbon nanostructures in copper covetics and thin films. APT revealed 3D distribution of carbon-rich nanoclusters; HIM provided unique opportunity to visualize carbon nanostructures in metal matrix due to its superior contrast and resolution; HRTEM and STEM elemental mapping verified the existence of carbon nanoparticles and networks in the copper metal hosts. Details of experimental results will be presented in this talk.

This work was supported by the U.S. Department of Energy (DOE), Energy Efficiency and Renewable Energy, Advanced Manufacturing Office, under Contract DE-AC02-06CH11357. HRTEM and STEM were performed at the Center for Nanoscale Materials at Argonne, a DOE Office of Science User Facility. APT and HIM experiments were conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

Water-Processable Cellulose-Based Resist for Green Nanofabrication Camilla Dore1, Johann Osmond2 and Antonio Agustín Mih1; 1ICMAB-CSIC, Bellaterra, Barcelona, Spain; 2ICFO–The Institute of Photonic Sciences, Barcelona, Spain.

Cellulose is the most abundant polymer on Earth and for centuries has had a wide technological impact in areas such as textile, packaging or knowledge storage. Cellulose is biodegradable, biocompatible and possesses excellent mechanical characteristics that have raised the interest of many engineering fields. In our manuscript, we introduce an exciting new path for cellulose derivatives. We report a new lithographic process employing hydroxypropyl cellulose (HPC), a biocompatible and biodegradable cellulose derivative, and water as only chemicals. We use hydroxypropyl cellulose as a nanoimprinting and electron beam lithography resist and demonstrate its potential by fabricating photonic crystals and 2D metal nanoparticle arrays with up to 100 nm resolution over 1 cm² areas. Beyond its biocompatibility and abundance, we combine this cellulose with traditional resists non-soluble in water (PMMA), leading to advanced fabrication possibilities. We fabricated alternating stacks of HPC and PMMA in which each material is selectively removed with the proper solvent. Furthermore, when combined with nanoimprinting, sub-micrometric air cavities are left inside the PMMA, enabling a straightforward nanofabrication strategy for novel optofluiddic devices.

11:30 AM RAPID FIRE PRESENTATION
Cellulose nanofibers (CNFs) are high aspect ratio nanofibers (dia. ~10 nm) that have high specific stiffness and strength, and are also optically transparent and biodegradable. These properties make them attractive building blocks for bulk structural materials. However, to date, the overall dimensions of bulk materials comprised of CNFs are significantly limited by the development of residual stresses generated during the drying process. CNF solutions gel at low volume fractions (~1%), thus a significant amount of water must be removed during drying. Here, we overcome these issues by producing CNF films and structures by additive manufacturing (i.e., 3D printing) of a shear thinning aqueous CNF suspension under controlled drying conditions. The multistep layer-by-layer manufacturing process allows for control of drying and management of residual stresses. The fabricated materials have Young’s moduli and fracture strengths greater than 10 GPa and 70 MPa, respectively. Mechanical characterization is supported by additional characterization via atomic force, optical, and electron microscopy. This study demonstrates the ability to additively manufacture stiff, strong, and uniform materials comprised of sustainable cellulose nanofibro materials.

From Sol Gel Electrospun Composite Nanofibers to Ultralight and Flexible Aerogels
Tahira Pizzada and Saad A. Khan; Chemical & Biomolecular Engineering, North Carolina State University, Raleigh, North Carolina, United States.

We present a facile and sustainable solid templating approach to fabricate highly porous and superhydrophobic aerogels of composite nanofibers of cellulose diacetate and silica which are produced through sol gel electrospinning. Scanning electron microscopy, contact angle measurement and attenuated total reflection-Fourier transform infrared spectrometry are used to understand the structural features of the resultant aerogels while thermogravimetric analysis and differential scanning calorimetry demonstrate their thermal stability as compared to cellulose diacetate. These aerogels exhibit a self-supportive three-dimensional network abundant in large secondary pores surrounded by primary pores resulting in a highly porous structure. Thermal crosslinking of the aerogels has further stabilized their structure and flexibility without compromising on the porosity. Ease of processing, thermal stability, high porosity and superoleophilic nature of these aerogels make them promising candidate for applications like thermal insulation and oil and water separation.

A High Concentration Approach to Magic-Sized Cluster Scale-Up

Magic-sized clusters (MSCs) are renowned for their identical size and precise composition, existing at an intermediate length scale between small molecule and conventional nanocrystal. Nanocrystal systems have been extensively studied and modeled to understand the synthesis, yet this knowledge does not directly translate upon scale-up and current production yields are miniscule. Furthermore, despite efforts, nanocrystals still possess a disparity in size, shape, and composition (although small) that in essence is a distribution of products. Hence, MSCs provide a quintessential framework to understand colloidal synthesis and assembly across length scales. Traditionally, the origin of the MSC stability was thought to derive from the “closed-shell” arrangement of atoms; this inhibits the continuous growth that is typically seen with nanocrystals. However, in semiconductor MSCs, we report that the MSC stability is strongly coupled to an organic-inorganic mesophase: a fibrous self-assembly of inorganic clusters passivated with organic ligands that form during high concentration (1000 mM) synthesis. This mesophase behaves as a large suspended network (~100 nm grains) that stabilizes and promotes a well-defined reaction pathway for the formation of high-purity MSC. Conversely, diluting precursor concentration (<500 mM) impedes mesophase formation and thus inhibits MSC formation. To identify the hexagonal mesophase where these MSCs persist, we utilized in-situ small and wide angle x-ray scattering, which also revealed that the rate of mesophase formation is proportional to the MSC nucleation rate. The MSCs still preserve their fibrous mesophase assembly after separation and purification. Akin to protein systems, these fibrous assemblies (secondary structure) of MSCs (primary structure) align into bundles (tertiary structure) that form banded (quaternary) structures under uniaxial shearing and drying. Polarization spectroscopy revealed that not only are the individual clusters strongly anisotropic with polarized emission, but also their assembly into highly ordered banded structures at the millimeter length scale yield polarized absorption. This high degree of polarization across magnitudes of self-assembled length scale enables investigation into novel optical properties, which previously has only been accomplished in metatomaterials. The high concentration synthesis of magic-sized clusters not only produces larger quantities of single-sized nanomaterials, but also deepens the understanding of nanosynthetic pathways and enables novel property development.

Lightweight Organosilica Foams Prepared from a Surface-Active Aminosilane and Cellulose Nanofibers
Korneliya S. Gordeyeva, Hugo Voisin, Niklas Hedlin, Lennart Bergström and Nathalie Lavonne; North Carolina State University, Raleigh, North Carolina, United States.

Organosilica foams are commonly obtained by elaborate multistep processes involving hydrolysis and condensation of organosilanes followed by solvent exchange and e.g. supercritical CO2 drying. Here, we report a novel, simple and energy-efficient approach for the preparation of hybrid organosilica foams from aqueous mixtures of a surface-active aminosilane (AS) and TEMPO-oxidized cellulose nanofibers (TCNF) that introduces air bubbles in the TCNF/AS dispersion by mechanical blending followed by ambient pressure drying to obtain the solid foam. The dry foams displayed low densities (25-50 kg/m3) and high porosities (96-99 %) with monodisperse macropore sizes of 150-300 µm. NMR showed that the hydrolysis and condensation of the surface-active AS was triggered by the increase of the temperature and solvent evaporation during the drying step. The influence of the pH and AS concentration on the foaming behavior and foam stability will be presented and correlated to the rheological properties and the interactions between the AS and TCNF. We will demonstrate that by variation of pH and AS concentration foams with defined density, homogeneity and porosity can be prepared.

Nanocomposite Sensing Skins for Human and Structural Monitoring
Kenneth J. Loh; Department of Structural Engineering, University of California, San Diego, La Jolla, California, United States.
Both physical structures and human assets are susceptible to deterioration and damage that can degrade their performance, especially in challenging operational conditions. For example, the safety of aerospace, civil, and marine structures are jeopardized by damage due to excessive loading, corrosion, and impact. On the other hand, monitoring the health and physiological performance of the warfighter is necessary for ensuring their combat readiness. Therefore, the objective of this research is to develop a sensing platform that can be used for both structural health monitoring and human performance assessment. The approach is to design flexible and scalable coatings that are designed whose electrical properties are selectively sensitive to a certain type of external stimulus and can be deposited onto various structural surfaces. Here, these sensors are designed from a materials perspective stemming from a “bottom-up” design methodology. Nanomaterials and conductive polymers are judiciously chosen, and then assembled, to realized nanocomposite thin films that are sensitive to parameters such as strain or pH. First, this work begins with a discussion of how carbon nanotubes (CNT) and graphene nanosheets (GNS) could be used during spray-coating, micro-plotting, and screen-printing to form thin film strain sensors. Second, tensile-compressive tests were performed to validate their sensing behavior. Third, a percolation-based model was implemented to explain the nano/micro-scale mechanisms that enable their bulk film behavior, and the model was employed for determining fabrication parameters that enhanced sensing performance. However, even after optimization, a fundamental limitation was that they remained as discrete sensors, where one could only obtain information about the physical or human structure at the location where the sensor was instrumented. Thus, by coupling the films with an electrical impedance tomography (EIT) measurement strategy and algorithm, reconstruction of the two-dimensional resistivity or conductivity distribution of these materials was possible. These “sensing skins” could then be implemented to sense and localize damage features over large spatial domains. Distributed strain, impact, crack, and pH sensing was successfully validated.

Impact of Graphene Oxide Disparsity on Its Applications Harish V. Kumar, Thomas Francinc and Douglas Adamson; Polymer Program- Institute of Materials, University of Connecticut, Storrs, Connecticut, United States.

Graphene oxide (GO) is used in various applications due to its unique surface properties. One of the important features of GO is that it stabilizes oil-in-water emulsions by staying at the interface of the two phases. We harness this property of GO to act as a surfactant in order to characterize, fractionate, and use the system for various applications. Different batches of GO are composed of graphene sheets with different degrees of oxidation. We divide graphene oxide sample into differently oxidized fractions using emulsion based fractionation method. In this emulsion based method, more oxidized GO sheets suspend in a water phase, while the less oxidized material stabilizes the emulsion phase. This method provides the ability to control different properties of GO. These GO fractions are characterized by different techniques including XRD, UV/vis, elemental analysis, and Raman spectroscopy.

Further, we explore the property changes of polymer/graphite oxide (GO) nanocomposites as the degree of GO oxidation is changed. We have found that emulsifying a sample of GO separates the sheets into fractions of differing degrees of oxidation and we have demonstrated that this variation in degree of oxidation of GO plays a role in the improvement of tensile properties of GO based polymer nanocomposites. The interaction of GO sheets with the polymer matrix plays an important role in the mechanical properties of the nanocomposites. In addition, the mechanical properties are also dependent on the hydrophilic or hydrophobic nature of the polymers. We further investigate polymer nanocomposites made from oil-in-water emulsion systems stabilized by GO. The nature of the emulsion is controllable by replacing a part of GO with graphene sheets as well as by altering the type of GO used. This approach provides a route to control the shape and conductivity of these polymer nanocomposites.

In addition, we describe further merits of the fractionation method, as well as explain the impact controlling the extent of oxidation has on various other GO based applications.

NM04.09.02
Ultrasonic Deacetylation—A Rapid Method to Covert Cellulose Acetate into Cellulose Nanofibers Muzamil Khatri, Ick Soo Kim and Zeeshan Khatri; Shinshu University, Ueda City, Japan.

Electrospun nanofibers are getting more attraction because of their prominent applications such as light weight, permeability, breathability, filtration, biomedical, apparel and functional applications. Cellulose nanofibers because of high absrobency and high surface area is also considered one the efficient material for potential applications. Getting electrospun cellulose nanofibers is highly time consuming, conventionally deacetylation process takes upto 30 hours to convert cellulose acetate into cellulose. We attempted to use ultrasonication to enhance efficiency of deacetylation process. We successfully deacetylated cellulose acetate by using ultrasonic method which only took 1 hour instead of 30 hours. SEM showed smooth morphology before and after ultrasonic deacetylation. XRD showed increased crystallinity after deacetylation because cellulose substrate has more crystalline region. Wicking behaviour was also enhanced after deacetylation which is another evidence to justify conversion. FTIR showed chemically converted cellulose after deacetylation process.

NM04.09.03
Surface-Modified Cellulose Nanofibers for the Effective Reinforcing Materials of Poly(e-caprolactone) Composites Hiroki Ichimura, Naruki Kurokawa and Atsushi Hotta; Keio University, Yokohama-shi, Japan.

Poly(e-caprolactone) (PCL) is one of the leading biocompatible and biodegradable polymers, having the great potential for an alternative material of polyolefins such as polyethylene and polypropylene. However, the mechanical property of PCL is relatively poor as compared with that of polyolefins, which has limited the active applications of PCL for an industrial material. In this study, to enhance the mechanical property of PCL, cellulose nanofibers (C-NF), compounding agents of several composites due to their high mechanical property, were investigated for the reinforcement material of PCL. The C-NF were fabricated via the electrospinning of cellulose acetate (CA) before the saponification of CA. The spinning solution was prepared by dissolving CA in the mixed solvent of acetone/dimethylacetamide (6/4 wt/wt) and the concentration of CA was set at 20 wt%. The electrospun CA nanofibers were saponified in a 0.05 M NaOH/ethanol solution to finally obtain C-NF. For the enhancement of the mechanical property of the PCL composite, the compatibility of C-NF and PCL was studied. The surface modification of C-NF was performed by the ring-opening polynamidation to graft PCL onto C-NF.
The RC-NF were compounded into poly(vinyl alcohol) (PVA) by the film-casting method to fabricate RC-NF/PVA composites. The mechanical properties such as modulus. However, it was found that the direct annealing of RC-NF resulted in no effect in increasing the crystallinity of the RC-NF. It was considered that annealing at higher temperature was necessary for improving the crystallinity of the RC-NF. By considering the Helpin-Tsai equation, it was found that the Young's modulus of the RC-NF increased from 11.2 to 28.0 GPa. The correlation between the crystallinity of the RC-NF and the annealing time at 50°C was observed and it reached ~3.0 GPa, when CA-NF were annealed at 75°C for over 4 h or annealed at 100°C for over 0.5 h. The Young's modulus of PVA with non-annealed RC-NF was ~2.1 GPa, and the modulus of PVA with annealed RC-NF increased from 37 to 41% up to the annealing time of 12 h, which became constant after 12 h. The CA-NF were annealed at 50°C, the crystallinity of the resulting RC-NF increased by 17% compared to that of PCL, while, compounded with CA-NF-g-PCL, it reached 25%. The fracture surfaces of the composites were analyzed by SEM. Through the image analyses, it was confirmed that the interfacial adhesion between PCL and CA-NF was successfully improved by the surface modification. The results demonstrated that the effective surface modification of CA-NF fabricated via electrospinning was realized by the CA-NF-g-PCL/PCL composites.

NM04.09.04
Enhancement of the Mechanical Property of poly(ε-caprolactone) Composites with Surface-Modified Cellulose Nanofibers Hiroki Ichimura, Naruki Kurokawa and Atsushi Hotta; Keio University, Yokohama-shi, Japan.

The use of natural products as reinforcement materials of composites has recently been actively studied. Among the reinforcement materials, cellulose is attracting considerable interest because of its high mechanical property and high biocompatibility. In fact, the enhancement of the mechanical properties of the composites by reinforcing cellulose nanofibers (CNF) has already been reported. In this study, CNF fabricated via the electrospinning of cellulose acetate (CA) before the saponification of CA, were compounded into poly(ε-caprolactone) (PCL) to improve the mechanical properties. In the electrospinning method, the spinning solution with CA in the mixed solvent of acetone/dimethylacetamide (6:4 v/v) was concentrated at 20 wt% was prepared. The CA-NF were then introduced to a syringe with stainless needle. Then a high voltage of 12 kV was applied between the syringe needle and a ground collector to fabricate CA nanofibers. The obtained CA nanofibers were dried under vacuum at 50°C for 24 h and saponified in 0.05 M NaOH/ethanol solution for 24 h to convert CA nanofibers into CA-NF. In addition to the fabrication of CNF, the surface modification of the CNF was also performed to improve the compatibility with the PCL for the enhancement of mechanical properties of the composites. In order to graft PCL onto the CNF to make CNF-g-PCL, the ring-opening polymerization was carried out as follows: CNF, tin(II) 2-ethylhexanoate (a commonly used catalyst for the polymerization of lactones), ε-caprolactone, and super-dehydrated toluene were added to a flask in a glove box under argon atmosphere. The flask was then set into an oil bath and the polymerization was allowed to proceed in the flask at 130°C for 1 hour to obtain CNF-g-PCL. The Fourier transform infrared (FTIR) spectroscopy was used to determine the structures of the CNF and the CNF-g-PCL. The FTIR results indicated that the polymerization was successfully conducted. The compression molding method was employed to fabricate CNF/PCL or CNF-g-PCL/PCL composite films. CNF or CNF-g-PCL was inserted between two compression-molded PCL sheets, which was thermally compressed at the pressure of 8 MPa at 80°C. Tensile testing was performed to examine the mechanical property of the CNF/PCL and the CNF-g-PCL/PCL. At the fiber concentration of 15 wt%, the Young's modulus of PCL compounded with CNF-NF-g-PCL increased by 17% compared to that of the composite with neat CNF. The fracture surfaces of the composites were analyzed by the scanning electron microscopy (SEM). The image analyses confirmed that the interfacial adhesion between the PCL and the CNF was substantially improved by the surface modification.

NM04.09.05
Mechanical Properties of Poly(vinyl alcohol) Composites with Electrospun Cellulose Nanofibers Annealed at Different Temperatures Shunya Inukai, Naruki Kurokawa and Atsushi Hotta; Keio University, Yokohama, Japan.

We synthesized highly crystallized regenerated cellulose nanofibers (RC-NF) through the annealing and the subsequent saponification of cellulose-acetate nanofibers (CA-NF) that were used as reinforcement materials for poly(vinyl alcohol) (PVA). We especially focused on the studies of the effects of the annealing temperature on the mechanical property of RC-NF/PVA composites. To enhance the mechanical properties of the RC-NF/PVA composites, annealing was first carried out for the RC-NF to raise the crystallinity. However, it was found that the direct annealing of the RC-NF did not affect the crystallinity. It was considered that the hydrogen bonding of the hydroxyl groups (-OH) in the RC-NF could be too strong to maintain the molecular movement of the cellulose required for the increase in the crystallinity. In this study, we investigated highly crystallized RC-NF through the annealing and the subsequent saponification of CA-NF. Cellulose-acetate (CA), a derivative of cellulose, possesses a smaller amount of hydrogen bonding as compared with cellulose, thus maintaining a sufficient molecular movement to obtain higher crystallinity. Therefore, highly crystallized RC-NF could be obtained via the saponification of the annealed CA-NF. CA-NF were fabricated by electrospinning, subsequently annealed at 50, 75, and 100°C for 0-12 h above the glass transition temperature of the CA. The annealed CA-NF were then saponified to obtain highly crystallized RC-NF. The crystallinity of the RC-NF was measured by the X-ray diffraction (XRD). The RC-NF were compounded into poly(vinyl alcohol) (PVA) by the film-casting method to fabricate RC-NF/PVA composites. The mechanical properties of the RC-NF/PVA were investigated by tensile testing. It was found that the CA-NF annealed at 50°C, the crystallinity of the resulting RC-NF increased from 37 to 41% up to the annealing time of 12 h, which became constant after 12 h. The CA-NF annealed at 75°C for over 4 h and at 100°C for over 0.5 h produced highly crystalline RC-NF reaching 41% in crystallinity at the maximum. The Young's modulus of PVA with non-annealed RC-NF was ~2.1 GPa, which increased as the annealed RC-NF annealing time increased. The Young's modulus eventually reached ~3.0 GPa at the maximum, becoming constant after 12 h of the annealing time at 50°C. It also reached ~3.0 GPa, when CA-NF were annealed at 73°C for over 4 h or annealed at 100°C for over 0.5 h. By considering the Helfin-Tsai equation, it was found that the Young's modulus of the RC-NF increased from 11.2 to 28.0 GPa. The correlation coefficients between the crystallinity and the Young's modulus of the RC-NF fabricated from the CA-NF annealed at 50, 75, and 100°C, were 0.970, 0.945, and 0.991, respectively. It was concluded that the maximum crystallinity and Young's modulus could be gained at shorter annealing time when annealed at higher temperature.

NM04.09.06
Annealing and Saponification of Electrospun Cellulose Nanofibers for a Reinforcement Material of Poly(vinyl alcohol) Composites Shunya Inukai, Naruki Kurokawa and Atsushi Hotta; Keio University, Yokohama, Japan.

Compounding relatively strong fibers into polymer materials has been one of the effective ways to enhance the mechanical properties of the polymers. It is well known that the higher aspect ratio of nanofibers in polymer composites could result in the increase in the specific surface area of the nanofibers, thus eventually improving the adhesion between the polymer matrix and the fibers. Electrospinning is also known as an effective way to make polymer nanofibers with high aspect ratios. Among the electrospun cellulose nanofibers, regenerated cellulose nanofibers (RC-NF) fabricated by the saponification of electrospun cellulose-acetate nanofibers (CA-NF), are attracting considerable interest as reinforcement materials. In fact, improvement of the mechanical property of RC-NF is the key to generate polymer composites with excellent mechanical property. For this purpose, an annealing process is an effective way to raise the crystallinity of the targeted polymers, hence improving the mechanical property, leading to the fabrication of fibers with higher tensile modulus. However, it was found that the direct annealing of RC-NF resulted in no effect in increasing the crystallinity of the RC-NF. It was considered that...
the hydrogen bonding of the hydroxyl groups (-OH) in the RC-NF was too strong, inhibiting the enough molecular movement of the cellulose required for the improvement of the crystallinity.

In this study, we, therefore, synthesized highly crystallized RC-NF through the annealing and the saponification processes of CA-NF. Cellulose-acetate (CA), a derivative of cellulose, possesses a smaller amount of hydrogen bonding as compared with cellulose, thus carrying sufficient molecular-movement characteristics to obtain higher crystallinity. In more detail, the CA-NF were first annealed, and acetyl groups (-OCOCH3) of the annealed CA-NF were then replaced with hydroxyl groups (-OH) to obtain highly crystallized RC-NF. The annealing time was changed, while the annealing temperature was kept constant at 50°C, which was above the glass transition temperature of CA.

The CA-NF were fabricated by electrospinning, which were then annealed and saponified to obtain highly crystallized RC-NF. The crystallinity of RC-NF was measured by the X-ray diffraction (XRD). By increasing the annealing time of CA-NF from 0 to 12 h at 50°C, the crystallinity of RC-NF increased from 37 to 41%, which became constant after 12 h. It indicated that highly crystallized RC-NF were successfully obtained by the annealing and the saponification of CA-NF. Finally, the RC-NF were compounded into poly(vinyl alcohol) (PVA) by the film-casting method to fabricate RC-NF/PVA composites. The mechanical properties of the RC-NF/PVA were investigated by tensile testing. The Young’s modulus of the RC-NF/PVA increased from 2.1 to 3.0 GPa by raising the annealing time from 0 to 12 h, after which it became constant, whereas that of pure PVA was 1.5 GPa.

NM04.09.07 Highly Stable Photoconductive Cellulose Paper—A Bright Future for Flexible Paper Electronics Naveen ul Hassan Alić, Samim Sardar, Xavier Crispin and Magnus Jonsson; Laboratory of Organic Electronics, ITN, Linköping University, Norrköping, Sweden.

These days cellulose paper is ubiquitous in our daily life. For thousands of years, cellulose paper has been a major medium for displaying and transmitting information in many parts of the world. Its chemical and mechanical stability under atmospheric conditions and ability to absorb ink readily remain unmatched by other materials used in large abundance. Cellulose, the major component of paper, can be obtained from plants and represents one of the most abundant organic materials on earth. Cellulose by itself is usually limited in functionalities. Recently, research on organic/inorganic cellulose composites has increased dramatically due to the potential applications in electronics, biosensors, and energy storage devices [1-4].

The integration of functional micro and nanostructures into the paper, such as zinc oxide tetrapods or nanoparticle powders, has opened up many opportunities for applications in advanced energy harvesting systems and electronic devices [5-6]. In this respect, one of the major challenges is to avoid leakage of the micro- and nanoparticles from the paper over time. This is a serious problem that is limiting their applications into the practical devices. In this work, we present a novel, environmentally friendly and fully scalable approach enabling the production of highly stable paper functionalized with zinc oxide nanotetrapods or nanoparticle powders, has opened up many opportunities for applications in advanced energy harvesting systems and electronic devices [5-6]. In this respect, one of the major challenges is to avoid leakage of the micro- and nanoparticles from the paper over time. This is a serious problem that is limiting their applications into the practical devices. The device shows a strong and repeatable 65 µA photocurrent signal under simulated sunlight. This is more than 100 and 10,000 times better than the photocurrent of our control samples fabricated using zinc oxide tetrapods and nanoparticles, respectively. In addition to the superior photoconductive properties, our paper is smooth and mechanically strong, allowing its applications in a range of flexible energy and electronics devices.

NM04.09.08 Effect of Surface Nanocrystallization on the Mechanical Properties of AISI 304 Stainless Steel Wire Temitope O. Olugbade and Jian Lu; City University of Hong Kong, Hong Kong, Hong Kong.

The effect of surface mechanical attrition treatment (SMAT) on the mechanical properties of 304 stainless steel (SS) wire was investigated using different ball materials and wire diameter. The surface characterization after SMAT was observed by scanning electron microscope (SEM) and X-ray diffraction (XRD). The mechanical properties were studied through yield stress, ultimate tensile stress, and fracture elongation. At different treatment time, the SMAT operation using the same amount of Tungsten Carbide (WC) and 304 SS balls significantly enhanced the strength of the material as well reduced the fatigue damage and other material-related failures such as crack. The tensile test, with a tensile speed of 1.5 mm/min at room temperature, indicated a marked increase in strength after SMAT. Compared to the untreated sample, the 304 SS wire subjected to SMAT experienced a great improvement in yield stress, ultimate tensile stress, and reduction in fatigue fracture. The type of ball used, and the wire diameter also has a significant effect on the mechanical properties. The surface characterization by SEM and XRD revealed an improvement in the yield and ultimate tensile stress of the SMATed samples using WC balls and 1.5 mm wire. The nanostructured material will find applications in biomedical and nanomanufacturing sectors.

NM04.09.09 Flame Retardant and Antiwetting Cellulose-Based Composite Aerogels as Sustainable Engineering Materials for Sound Adsorption Application Xianjing Gong; Materials Science and Engineering, City University of Hong Kong, Hong Kong, SAR, Hong Kong.

Cellulose nanofiber (CNF) is an attractive bio-material and has advantageous properties such as light weight, excellent mechanical property, high aspect ratio, good thermal stability, as well as relatively low cost. In this study, we demonstrate a sustainable composite aerogel with sound adsorption, flame retardant and antiwetting abilities, the structure of which is composed of modified CNF and aluminium hydroxide (Al(OH)3). Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD) were used to confirm the modification of CNF and the formation of Al(OH)3. Then scanning electron microscopy (SEM), sound-adsorption test, thermogravimetric analysis (TGA) and contact angle test were conducted. These results imply promising applications for practical engineering materials.

NM04.09.10 Strong, Flexible and Transparent Films of Lignocellulose Produced by Tailoring the Electrostatic Interactions Yingxin Liu; Department of Materials and Environmental Chemistry, Stockholm University, Stockholm, Sweden.

The assembly of nature-based nanomaterials into complex architectures is both a design principle of biological composites, e.g., nacre with outstanding properties and a promising route for developing functional macroscopic materials. Our study aims to investigate the colloidal assembly behavior of nanocellulose in aqueous dispersions. Moreover, composite films of nanocellulose and nanoclay/lignin with diverse functionalities are fabricated by tailoring the electrostatic interactions of these building blocks.

Initially, optically transparent films of synthetic aminoclay (50 wt%) and cellulose nanofibril (CNF) were fabricated, of which tensile strength and strain to failure (205 MPa and 7.5%) were significantly higher than previously reported nacre-mimicking nanocellulose-based materials, e.g., montmorillonite-CNFM04.09.11
films, due to the formation of ionic bonding between the cationic clay and anionic CNF. On the other hand, anionic lignin nanoparticles were tested to enhance the colloidal stability and dispersity of carboxylated CNF in dispersions, and showed an effective strengthening and stiffening effect on the matrix of CNF. The mechanical properties of lignin-CNF films were superior to previously reported polymer/nanoparticle-CNF composites, such as polyvinyl alcohol-CNF films and even reduced graphene oxide-CNF films. The low cost of nanocellulose in combination with the excellent mechanical performance and functionalities of above composite films sheds light on potential applications such as substrates for optoelectronics.

**Mechanical and Microstructural Characterisation of Graphene Oxide Reinforced Aluminium Matrix Nanocomposites**

Fei Li1, Ian A. Kinloch1, Robert Young1, Shaojun Yan2, Qihu Hong2, Xiang Chen3, Xiaoyan Zhang2 and Shenglong Dai4; 1Advanced Nanomaterials Group, National Graphene Institute and School of Materials, The University of Manchester, Manchester, United Kingdom; 2Beijing Institute of Aeronautical Materials, Beijing, China.

Due to its low density and high Young’s modulus, graphene is able to make Aluminium (Al) matrix composites lighter and stronger. These materials are in demand for structural materials in airplanes, automobiles and other transportation applications. These structural materials can contribute to low carbon emissions, sustainable development and the overall economy. Al matrix nanocomposites reinforced with graphene related materials, have been developed well in the last decade. We have investigated the relationship between the mechanical properties and microstructure for Graphene Oxide (GO) reinforced Al matrix nanocomposites.

A powder metallurgy (PM) method was employed to produce GO reinforced Al matrix composites. We fabricated Al matrix composites with 0.3, 0.5, 1.0 wt. % loadings of GO, and pure Al as well for comparison. By using large area Raman mapping and SEM respectively, we found the GO flakes to be dispersed well and located at the grain boundaries of the Al matrix in the composite. In addition, GO was aligned well in the direction of extrusion, indicated by Raman orientation investigations. Interestingly, the GO can even hinder grain growth of the Al matrix. Grain refinement was observed in the composite, caused by the barrier effect of GO. Quantitative information of the grain orientation and grain size was obtained from the analysis of EBSD (Electron Backscatter Diffraction) results. Aluminium carbides were not detected by either X-Ray Diffraction (XRD) or Raman spectroscopy, and thus chemical reaction at the interface did not take place. Nanoindentation experiments were conducted to determine the mechanical properties of the pure Al and reinforced Al matrix composites as well. For macro mechanical properties, Young’s modulus and hardness of the Al matrix composite were improved by adding 0.3, 0.5 and 1.0 wt. % GO in comparison with pure Al. GO has the ability to improve the mechanical properties of Al matrix composite when it is dispersed uniformly in the composite. However, the composite with a loading of 0.5 wt. % GO, rather than with 1.0 wt. %, was found to have the most strengthening effect. We observed some agglomeration in the composite reinforced with 1.0 wt. % GO from SEM images, which induced more defects, more pores, less interfacial area, and a lower effective modulus. We believe these factors may explain why its Young’s modulus was not as high as expected. In addition, SEM (Scanning Electron Microscopy) was used to observe the microstructure around the indented areas. Indeed, the mechanical properties of the composites are closely linked to the microstructure. After indentation, we can see that the GO flakes between grain boundaries hinder the movement of the dislocations. Al matrix grains experienced their plastic deformation by slipping or twinning when the dislocations cannot move further due to obstruction by the GO. These microstructural changes resulted in better mechanical performance of the composites.

**A Novel Process to Fabricate Nano Carbon Reinforced Copper Matrix Composites Utilizing Self-Assembly of Bioinspired Polydopamine**

Yao Zhao, Filippo Di Carlo, Bosen Qian, Haoqi Li, Zhuohe Zhang and Fei Ren; Mechanical Engineering, Temple University, Philadelphia, Pennsylvania, United States.

Introduction of nanocarbons, such as graphene and carbon nanotubes, to metal matrices may enhance the electrical and thermal transport and mechanical properties of the composite materials. In this study, copper (Cu)-polydopamine (PDA) composite was fabricated by coating Cu powders with the bioinspired PDA polymer, which was then converted to graphite-like structure during the subsequent sintering. Structural characterization using SEM, TEM, and Raman spectroscopy demonstrated the formation of the graphite-like structure in the composite. Compared to the pure Cu sample, the Cu-PDA composite showed increased electrical conductivity, higher microindentation hardness, and enhanced wear resistance. These findings suggest inclusion of nanocarbon phase converted from PDA can simultaneously improve the electrical and mechanical properties of sintered Cu materials. Effect of coating time (carbon content) on the microstructure and properties of the composites will also be discussed.

**NM04.09.13**

**Mechanical Properties of Polydopamine Thin Films**

Haoqi Li, Qian Dong, Quiting Zhang, Yao Zhao, Zhuohe Zhang, Huijun Liu, Jie Yin and Fei Ren; Temple University, Philadelphia, Pennsylvania, United States.

Polydopamine (PDA) is a recently discovered bioinspired polymer. Coating and freestanding films of PDA can be fabricated via the self-assembly process of dopamine molecules in mild conditions. Many interesting properties of PDA have been reported. One potential application of PDA thin film is in soft and flexible devices, where the mechanical property of the film and adhesion to substrate are critical. By adding dopamine hydrochloride into alkaline solution, freestanding PDA films were synthesized at the air/solution interface, which was then transferred onto capillary tubes. The vibrational response of PDA freestanding film was investigated using acoustic impulse method, from which the elastic modulus was determined. Meanwhile, by studying the surface buckling behavior of PDA coating on PDMS substrate, the adhesion between the two materials was obtained. Furthermore, wear resistance of PDA films was evaluated using nanoscratch test. Effects of film thickness and metal ion doping were also investigated.

**Effect of Encapsulation of Citric Acid with Zeolite Nanoparticles on Its Heat Resistance in Polymer Composite**

Hye Mi Choi1, Young Min Lim1, Dong Soo Shin2, Gun Young Kwak1 and Tae Hwan Oh3; 1Yeungnam University, Gyeongsan, Korea (the Republic of); 2Clavis, Gyeongsan, Korea (the Republic of); 3Dyteec, Daegu, Korea (the Republic of).

Citric acid having low heat resistance was encapsulated by zeolite nanoparticles and zeolite/citric acid capsules were coated by titanium oxide (TiO2) to enhance the heat stability of the citric acid during melt processing of polymer/citric acid composite. The conditions to maximize adsorption of the citric acid were investigated for citric acid concentration, adsorption temperature and time. Reaction conditions for TiO2 coating onto zeolite were also investigated for enhancing the heat resistance of the citric acid during melt processing of polymer/citric acid composite. The presence of the citric acid after its adsorption into zeolite was measured by electrical conductivity change with concentration. By coating TiO2 on zeolite, the heat resistance of the citric acid increased and hence after melt extrusion, we could observe the survival of the citric acid after melt extrusion.

**Synthesis of Eco-Friendly Nano-Structured Biosurfactants from Vegetable Oil Sources and Characterization of Their Interfacial Properties for**
Cosmetic Applications: JongChoo Lim, DaNan Yea and SeonHui Jo; Dongguk University, Seoul, Korea (the Republic of).

The enormous market demand for surfactants is currently met by numerous synthetic, mainly petroleum-based, chemical surfactants. These compounds are usually toxic, non-biodegradable and environmentally hazardous. Tightening environmental regulations and increasing awareness for the need to protect the ecosystem have effectively resulted in an increasing interest in biosurfactants as possible alternatives to chemical surfactants. They have advantages over their chemical counterparts in specificity, relative ease of preparation, mildness, and effectiveness even at extreme temperature or pH. Biosurfactants also have the merit of diversity, environment friendly nature such as nontoxicity and excellent biodegradability, possibility of large-scale production, selectivity, performance under extreme conditions, and potential applications in environmental protection. Due to their unique functional properties, biosurfactants have been used in various industries including agriculture, fertilizers, petroleum, petrochemicals, cosmetics, pharmaceuticals, personal care products, food processing, beverages, textile manufacturing, metal treatment and processing, pulp and paper processing, paint industries and many others. They can be used as emulsifiers as well as demulsifiers, wetting agents, foaming agents, spreading agents, environmental cleanup of pollutants, functional food ingredients and detergents. In this study, 3 types of zwitterionic phospholipid biosurfactants were prepared using 3 different raw materials such as rapeseed oil, coconut oil, and cottonseed oil respectively and the structure of the resulting products was elucidated by FT-IR, 1H NMR, and 13C NMR spectroscopies. Biodegradability, acute oral toxicity (LD₅₀), acute dermal irritation and acute eye irritation tests revealed that the newly synthesized biosurfactants possess excellent mildness and superior environmental compatibility as well as superior interfacial properties, indicating the potential applicability in cosmetic product formulations. The patch test has been performed with 0.1 mL of 0.5 wt% surfactant solution and the result has shown that the newly prepared biosurfactants indicated no allergic inflammation on a skin during 48 hrs. The prescription test in shampoo formulation prepared with the newly synthesized biosurfactants indicated excellent sensory feeling and foam ability compared with conventional hydrocarbon and silicon surfactants. In particular, CDP(S) surfactant can be considered as a strong candidate for the potential applicability in cosmetic product formulations since the newly synthesized CDP(S) surfactant is highly surface active, mild, nontoxic, non-irritating and readily biodegradable.

Mechanical Properties of Rubber Composite Reinforced by Cellulose Nanofiber: Tomoyuki Sakai; The Yokohama Rubber Company Ltd, Kanagawa, Japan.

Yokohama Rubber Company Ltd. has been researching on sustainable materials for rubber as an environmentally friendly company. We prepared NR and SBR reinforced with TEMPO oxidized cellulose nanofibers (TOCN), which were modified from wood pulp, instead of traditional carbon black derived from petroleum. The Wood-derived TOCN can contribute to an effective use of forests and to a recycling-based society. They have average 3 nm in diameter and high aspect ratio. The wear resistance and viscosity of the rubber-TOCN composites were investigated for the application of automotive tires. Their tensile stress was larger than that of the same amount of carbon black reinforcement. We will discuss how to improve their mechanical property by examining the rubber on the interface of cellulose nanofibers.

This research was supported by grants from the Project of the NARO Bio-oriented Technology Research Advancement Institution (R&D matching funds on the field for Knowledge Integration and innovation)

NM04.09.17
Manganese Incorporation on Structural, Optical and Photocatalytic Properties of ZnO Nanofibers: Ilyas Savkilyildiz1, 2, Elif Baylam2 and Ozlem A. Yildirim1, 1: 1Selcuk University, Konya, Turkey; 2Konya Technical University, Konya, Turkey.

There is currently intense interest in the elimination of the organic dye compounds in the water via photocatalytic reactions. Zinc oxide (ZnO) nanofibers are known to act as a promising photocatalyst for its high catalytic activity, low cost, and environmental friendliness. Visible-light photocatalytic properties of ZnO nanofibers can be improved with metal doping. To improve photocatalytic activity of ZnO nanofibers, manganese-doping (ZnO:Mn) is appreciable because manganese behaves highly reactive catalyst in the photocatalytic reactions. Furthermore, synthesis of ZnO:Mn nanofibers with well-controlled size and morphology have been also attracted great attention to enhance photocatalytic efficiency. In this study, we aimed to improve visible-light photocatalytic activity of Mn doped ZnO nanofibers via electrospinning technique to eliminate interparticle interactions. The effects of doping level and aspect ratio of nanofibers, on the band structure of ZnO and finally photocatalytic properties of ZnO:Mn nanofibers were investigated through XRD, XPS, HRTEM, FESEM and UV-Vis spectroscopy. The results showed superior photocatalytic activity for 1.5 at.% Mn doped ZnO nanofibers and the complete decomposition of Methylene Blue has been achieved after 120 minutes UV illumination.

NM04.09.18
Polymerization of Valerolactone Derived from Biomass for Eco-Friendly Powder Coating: Lim Hanwhyu1, 1: 1Yonsei University, Seoul, Korea (the Republic of); 2Green Chemistry and Materials Group, Korea Institute of Industrial Technology, Cheonan, Korea (the Republic of).

Valerolactone is a biomass material that can be obtained through catalysis from mevalonic acid obtained by fermentation of glucose. It is used as an environmentally friendly application material and it also can be applied as powder coating material without organic solvent. In order to use valerolactone as a coating material, it is necessary to polymerize by ring opening transesterification polymerization (ROTEP) reaction, and it have to be optimized according to the type, amount of catalyst and reactant conditions. As a result, ROTEP polymer was successfully synthesized using valerolactone using 0.75 wt% TBD catalyst. The result is 30,000 g/mol, Mw and PDI = 1.2 confirmed by GPC. Furthermore, we also discussed the application of additional functional groups to enhance the biomass ratio. After replacing the terminal of the polymerized polymer with hydroxyl groups, molecular weight could increase with bio-based content. The synthesized compounds were applied to coating material as the powder form.

NM04.09.19
Flammability and Structural Characterization of LDPE/EVA Blend Composites Containing Keratin Fibers and DNA as a Flame Retardant: Saul Sanchez, Eduardo Ramirez, Jorge Albitre, Yuresis Nuñez and Rogelio Ramirez; CIQA, Saltillo, Mexico.

The combination of keratin fibers obtained from feathers, with deoxyribose nucleic acid (DNA) applied as a coating with a segregated structure on filler dispersion and flame retardant properties of low-density polyethylene-ethylene vinyl acetate (LDPE/EVA) blends was investigated. A maleic anhydride modified polyethylene (PEGMA) was used as compatibilizer. The thermal stability and flame retardant properties were evaluated by Limiting Oxygen Index (LOI), Cone calorimeter determinations and Flammability test (Underwriters Laboratory - UL-94). The structural characterization was carried out by
FTIR and scanning electron microscopy in transmission mode (STEM). The mechanical properties were also evaluated. The effect of coating procedure, directly affecting segregated structure deposition, on DNA dispersion and flame-retardant behavior was discussed. The results indicated that the DNA deposition method of segregated structure promoted the best flame retardant behavior and that the incorporation of keratin fibers enhanced the mechanical performance of the nanocomposites. It was demonstrated that DNA induced a char foam layer that was able to quite efficiently protect the blend polymer matrix against heat, reducing the combustion kinetics. The thermal stability of PE/EVA blends increased to a higher extent when using these filler combinations.

Materials Engineering—Controllable Defect Nanomaterials for Electrical and Biological Application
Li Wei Huang1, Chun-Yen Lai2, Lin M. Ling1, Ping-Hung Ye1 and Wen-Wei Wu2; 1Tamkang University, New Taipei City, Taiwan; 2National Chiao Tung University, Hsinchu City, Taiwan.

For materials engineering, the various electrical properties of Poly-SnO$_2$ nanofiber can be obtained by controlling fabrication processes. By well controlling fabrication processes, there are several specific materials can be found, such as defect-free, defect-rich and defect-controlled SnO$_2$ nanofiber. In this research work, defect-free sample has strong reaction with UV light. But if the defect amount was increased by changing formation process, the defect-rich poly crystal nanofibers can be obtained to make an ultra-sensitive nano-sensor. Because the nano-sensor has huge defect that will give the device to has ultra-high sensitivity; the current of the nano-sensor can be easily varied by light and surrounding gas. This property can make our nano-sensor as room temperature gas (50 ppb NO) detector. This nanomaterial also can control the defect amount to fit the biological antibacterial purpose by well controlled the fabrication process. In a well-controlled defect amount, the nanomaterial can provide Hydroxyl by specific light in moisture solution to prevent bacterial infections. In our work, the E-coli can be effectively reduced by our nanomaterials substrate due to the Hydroxyl.

Nanotoxicology and Environmental Impact of Carbon Nanomaterials—A Focus on Double-Walled Carbon Nanotubes

Carbon nanotubes (CNTs) are often the emblematic figure of nanoparticles in general, promoted by many for their exceptional physico-chemical properties which have led to applications in almost all fields, and criticized by the others for their potential toxicity toward human health and the environment. After a general introduction to the toxicity of nanoparticles, we will focus on the case of CNTs and in particular of double-walled CNTs (DWCNTs) [1] which represent a unique category at the interface between single-wall CNTs and multi-walled CNTs. The interaction of DWCNTs with the immune system [2, 3] will be described, showing that if these CNTs activate this defence mechanism, there are also potential ways to moderate this through appropriate surface functionalisation. Some examples of interaction of DWCNTs with cancer cells [4] or bacteria [5] will also be given as illustrations of potential biomedical applications.

Finally, we will summarise our recent work on the question of the choice of the most appropriate metric in order to allow the comparison of the results obtained for different kinds of nanocarbons (different carbon nanotubes, few-layer graphene, nanodiamonds) as well as a sample of carbon black, in the case of their environmental impact [6]. Experimental results obtained using an amphibian larvae model (xenopus), very relevant for the aquatic compartment and especially the water column, clearly show that only the specific surface area allows the plot of all the data on the same "master curve", even making possible to become predictive and to propose a "Surface effective concentration" SEC$_{50}$. These results have also been recently extended to the comparison of nanocarbons dispersed in water by either covalent (oxidation) or non-covalent (addition of a surfactant) functionalisation, confirming that the specific surface area is still the relevant parameter.

Sustainability should be an objective of every future technology. Especially nanotechnology has shown that worries and concerns of consumers may hamper the development of nanomaterials. In the face of the conflict between immediate marketing of innovative products containing engineered nanoparticles (ENP) and the precautionary principle regarding the potential environmental and human risks we established a multidisciplinary consortium of 10 academic, industrial and regulatory partners, which worked on manifold questions within project. For a sustainable production of goods containing ENPs it is crucial to have no adverse effects on the environment. Therefore, the project focused on the study of the long-term characteristics of ENPs under various environmental conditions. Silicon dioxide nanoparticles (SiO\textsubscript{2} -NP) and cerium dioxide nanoparticles (CeO\textsubscript{2} -NP) were selected because of their prevalence and commercial relevance. Utilization oriented aspects were studied on SiO\textsubscript{2} -NP spiked lubricants as an exemplary application. On the other hand innovative functionalized variations of SiO\textsubscript{2} -NP and CeO\textsubscript{2} -NP (e.g. doped) are produced by lab- and pilot scale gas phase reactors. For these materials an enormous marketing potential is expected due to their presumed low toxicity and multiple application possibilities.

On the other hand we detected, tracked and modeled the life cycles of the ENPs in the lab and the near-natural environment to enlarge the knowledge of ENPs ecotoxicological potentials and to fill methodological gaps concerning their environmental exposures. The environmental fate and pathways of the ENPs were studied using numerous methods on different levels: characterization of the ENPs, environmental exposure and fate modeling. The effects of ENPs on organisms representing different trophic levels and environmental compartments were addressed for the identification of early warning indicators required for the long-term risk assessment of ENPs. The bilateral approach of DENANA addresses the interests of all stakeholders (producer, user and consumer). The identification of early warning indicators of the long-term risk potential supports the progress in the statutory approval of new ENPs; the generation of data on the environmental exposure provides a basis for regulatory measures and, finally, materials risk quantification. We present methods (e.g. Europium doping) to tune particle morphology, which allows to trace, track and identify particles in biological systems. Furthermore, the exposure of nanoparticle into soils and the effect of plant growth are shown. Results of end of life cycle assessment using new models of nano particle distribution scenarios are displayed. The project ended with the collective evaluation of obtained results required for the identification of design criteria of sustainable ENPs. Finally, the selected test materials did not reveal any ecotoxicological potentials to organisms.

Cellulose is the most abundant natural polymer, is readily available, biodegradable, and inexpensive. Recently, interest is growing around nano-scale cellulose due to the sustainability of these materials, the novel properties, and the overall low environmental impact. The rapid expansion of nanocellulose uses in various applications makes the study of the toxicological properties of these materials of great importance to public health regulators. However, most of the current toxicological studies are highly conflicting, inconclusive, and contradictory. The major reason for these discrepancies is the lack of methods to and to characterize nanocellulose in various forms. In order to address these issues, industry-relevant synthesis platforms were developed to produce nanocellulose with controlled properties that can be used as reference materials in toxicological studies. In this work we report the synthesis and characterization of CNF and CNS reference ENMs and outline some of the most important challenges in our efforts. Among the greatest challenges is to characterize the CNF length and thus to obtain the complete morphology of CNF. We developed a new method that utilizes Scanning Electron Microscopy (SEM) to resolve these issues. Furthermore, another issue is the characterization in liquid in particular when DLS is not suitable. In our work we have developed a method to image the cellulose aggregates in various biological media.

Challenges in Characterizing Nanocellulose for Toxicological Studies Zhenyuan Zhang\textsuperscript{1}, Georgios Pyrgiotakis\textsuperscript{1}, Dimitrios Bitounis\textsuperscript{1}, Ana Stavanovic\textsuperscript{1}, Wing Luu\textsuperscript{2}, Douglas Bousfield\textsuperscript{2} and Philip Demokritou\textsuperscript{2}; 1Center for Nanotechnology and Nanotoxicology, Harvard University, Boston, Massachusetts, United States; 2Department of Chemical and Biological Engineering, University of Maine, Orono, Maine, United States.

Nanostructures (including gold nanoparticles, AuNPs, and nanorods, AuNRs) using real and mimetic membrane models. The interaction of the nanomaterials with the lipidic membrane models was studied using Langmuir monolayers, revealing that incorporation of AuNRs into the mimetic cell membrane was more pronounced compared to nanoparticles (AuNPs), as revealed by the adsorption kinetics and surface pressure measurements. We also evaluated the toxic effects of graphene-oxide (GO) on aquatic organisms, in vivo, after exposure to sub-lethal concentrations. Flow cytometric analysis showed that sub-lethal GO exposure led to an increase in the number of gill cells that were in early apoptotic and necrotic stages in zebrafish. The toxic mechanism of GO to zebrafish was attributed to an increase in the oxidative stress level, as observed by the enzymatic biomarkers that showed significant increases in the activity of superoxide dismutase (SOD) catalase (CAT) and lipid peroxidation after sub-lethal exposure. We showed that both gold and carbon-based nanostructures may be harmful to human cells and aquatic species. In the latter, such effects could be permanent, threatening the aquatic food chain balance. Our results may help in the determination of environmentally safe concentrations of nanomaterials for regulatory purposes.
target gas or gases mixture discrimination. Multiple gases (H₂, NO₃, benzene and water vapor) and gases mixtures (H₂ and ethanol, H₂ and acetone, H₂ and methanol) have been tested, and benefiting from the excellent repeatability of the sensor array, the developed classification algorithm, bagging decision tree, could reach a very satisfied classification performance (more than 95%) for both single gas and gases mixtures. Such a robust smart E-nose system can address the imperative needs for distributed environmental monitoring in smart homes, smart buildings and smart cities in the form of a portable or wearable device.

Highly Selective Formaldehyde Detection with Microporous Zeolite Membranes for Environmental Monitoring
Andreas T. Güntner, Sebastian Abegg, Jan van den Broek, Karsten Wegner and Sotiris E. Pratsinis; ETH Zurich, Zurich, Switzerland.

A major challenge in environmental sensing is the detection of trace-level pollutants (e.g. carcinogenic formaldehyde) in complex gas mixtures. Devices based on chemo-resistive gas sensors would offer sufficient sensitivity and low detection limit down to ppb, but lack selectivity. Here, we combine nanomanufactured ensors with highly selective zeolite membranes pre-separating gas mixtures. Zeolites - broadly applied in catalysis and gas separation - effectively separate molecules based on kinetic diameter, sorption and diffusion characteristics. Therefore, zeolite membranes are suitable filters for gas sensors removing undesired species from indoor air. As proof-of-concept, a zelite MFU-Al₂O₃ membrane is placed upstream a highly sensitive but weakly selective Pd-doped SnO₂ sensor. Their combination exhibits exceptional selectivity (>100) for formaldehyde down to 30 ppb at 90% relative humidity, outperforming state-of-the-art detectors by more than an order of magnitude. This novel concept is readily extendable to other tracers, as manifold combinations of widely tunable microporous membranes and gas sensor types can be realized in the modular sensing device. This could enable a new class of highly sensitive and selective environmental monitors.

Environmental Transformation and Biological Impact of LiCoO₂ and LiNixMnyCo(1-x-y) (NMC) Lithium-Ion Battery Cathode
Silica Based Hybrid Colloidosomes and Pickering Emulsions and Their Implantation For Single Cell Microencapsulation
Xiaowei Xu1, 2, Liping Zhu1 and Shuguang Yang1, 2; 1Center for Advanced Low-dimension Materials, Donghua University, Shanghai, China; 2State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, College of Materials Science and Engineering, Donghua University, Shanghai, China.

The mixture of dye/salt generated from digital ink-jet printing industry is not only a crucial source of pollution but also a huge waste of materials. Recently, polymer complex membranes (PCMs), as a nano-filtration membrane, have drawn a considerable attention in treatment of the dye/salt mixture in order to recycle dye due to its inherent ionic cross-linking structures and high hydrophilic property. The preparation of polymer complex membrane usually requires the protonation and de-protonation of certain functional groups to make the solution homogeneous and processable in a large scale. In this work, in order to avoid the adjustment in the amount of ionic groups after complexation, a new solution preparation method is developed to maintain the viscosity and homogeneity of solution, and thus to skip the common and necessary precipitation process existed in most of the membrane preparation methods. Partially hydrolyzed poly (2-ethyl-2-oxazoline) (PEO-E) which is consisted of poly (2-ethyl-2-oxazoline) and polyethyleneimine (PEI, as cation polyelectrolyte, and poly(acrylic acid) (PAA), as anion polyelectrolyte, are selected to prepare PCMs by solution-casting first, then followed by an interfacial polymerization process. The structural characteristics and surface properties are then systematically investigated. The number of hydrogen-bonding sites can be easily manipulated with solution pH, which provides an opportunity to efficiently clean the membrane and make it reusable under extremely conditions. A high water permeability and good antifouling ability are expected due to the hydrophilicity of membrane provided by the excess amount of carboxyl groups. Though the dye barrier ability is currently lower than the commercialized nano-filtration membrane systems, the overall performance of the as prepared PCMs, including facile fabrication process, high selectivity for the dye/salt mixture, high permeability and good antifouling ability, find them a promising future in separation of dye/salt mixture.

11:00 AM NM04.10.08
PEOs-EI/PAA Complex Nano-Filtration Membrane for Dye/Salt Separation
Xiaowei Xu1, 2, Liping Zhu1 and Shuguang Yang1, 2; 1Center for Advanced Low-dimension Materials, Donghua University, Shanghai, China; 2State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, College of Materials Science and Engineering, Donghua University, Shanghai, China.

This research presents an in-situ functionalization of silica nanoparticles in oil-in-water (o/w) biphaseic system with two equimolar organosilanes of antagonistic polarity. Homogeneous and stable Pickering emulsions have been obtained, where droplet size can be tuned according to the silica particle concentration and the o/w ratio used. The micro and nano-structure was analysed by optical and fluorescence microscopy and cryo-SEM. The introduction of carbon nanotubes (CNT) to the silica based Pickering emulsion enabled us to prepare electrically conductive CNT/silica nanohybrid colloidosomes with controlled porosity. CNTs and silica nanoparticles both are located in the interface, as evidenced by confocal laser scanning microscopy and cryo-SEM. After drying, hierarchical porous structures have been generated spanning the micro, nano, and macropore range. The emulsions have shown high stability against coalescence and sedimentation. Additionally, a highly tunable bio compatible Pickering emulsion system enabled us to develop a new approach for
successful single cell encapsulation of fungal spores of *Metarhizium anisopliae*, which is implemented in efficient biopesticide formulation for arthropod pest control in agricultural applications. This successful single cell encapsulation system led to a significantly higher distribution of conidia cells on the leaves. The Pickering emulsion based formulation exhibited significantly higher pest control against *Spodoptera littoralis* larvae, thus making it a promising cost effective, innovative approach to tackling the pest control challenge.

**Advancing Nanocellulose Technologies for Water Purification**

Benjamin S. Hsiao; Stony Brook University, Stony Brook, New York, United States.

The fabrication of nanocellulose can be accomplished by chemical and mechanical treatments of any natural biomass, including agricultural waste, weeds and shrubs, where some sources can provide "effortless extractability" with very low energy consumption. Nanofibrous scaffolds have very unique properties including interconnected pores, a very large surface-to-volume ratio and a high capacity for surface modifications, making them ideal candidates for fabrication of high throughput separation membranes (e.g. microfiltration and ultrafiltration) and/or highly efficient sorptive media. Directed water channels in the barrier layer of reverse osmosis and nanofiltration membranes can also be formed through the formation of interface between the nanofibers and barrier layer polymer matrix, while the gap thickness can be regulated by physical interactions or chemical bonding. In the present context, advances in fundamental studies on cellulose microfibrils, the building blocks from the cell wall of any plant, and their interactions with metal ions by means of synchrotron x-ray and neutron techniques have provided us with new insight into the design and fabrication of highly permeable nanofibrous membranes, having a hierarchically tiered structure, that can enable higher flux, higher retention and lower energy consumption water purification. Nanocellulose may serve as a revolutionary platform technology for the design and fabrication of low cost, sustainable and highly efficient filtration and sorptive media.

**Design and Development of Process for Wastewater Treatment Using Sustainable Adsorbents**

Nathan Grishkevich1; Nishil Mohammed1, Richard Berry2 and Michael K. Tan1; 1Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada; 2Celluforce, Montreal, Ontario, Canada.

This study describes the design and development of a continuous process for use in textile effluent remediation. The system utilizes an adsorbent prepared from eco-friendly materials derived from renewable sources, cellulose nanocrystals (CNCs) and sodium alginate (ALG). The ability of the adsorbent to remove a model cationic dye, methylene blue (MB), was studied in detail.

Equilibrium batch adsorption experiments provided information on the equilibrium uptake of MB dye from water as well as the adsorption kinetics. In addition, the impact of ionic strength, pH, and temperature on the equilibrium uptake were examined. Continuous experiments were conducted in a fixed bed vessel to study the impact of flow rate, initial MB concentration and packing height on the capability of the process to remove MB. A self-sustained system that could produce this adsorbent in-situ was also developed.

From the batch experiments we determined a theoretical maximum adsorption capacity for MB by the adsorbent to be 431.6 mg/g, and additional experiments demonstrated that the adsorbent could undergo repeated adsorption–desorption cycles, achieving ~97 % dye removal efficiency after 5 cycles. From lab scale continuous experiments we determined the influence of flow rate, initial MB concentration and packing height on breakthrough curve and shape of the breakthrough curve, allowing for the scale-up of the system for field tests. Continuous tests also validated theoretical predictions of maximum adsorption capacity obtained from batch adsorption experiments, achieving an MB loading of 391.7 mg/g.

Following this, a pilot scale fixed bed was developed to treat wastewater generated at a batik textile mill in Yogyakarta, Indonesia. However, the influence of other contaminants in the wastewater impacted the adsorption of MB onto the adsorbent, resulting in a lower projected performance. Following this, the influence on divalent salts during the start up of the fixed bed process on the adsorption of MB dye and the swelling of the adsorbent was studied. The CNC–ALG hydrogel beads were determined to be effective adsorbents for the removal of organic dyes from wastewaters in both batch and continuous processes, and their development for use in industrial water treatment systems is progressing well.

**Tension Gradient Self-Assembly to Facilely Fabricate Polytetrafluoroethylene Nanofibrous Coating for Oil-Water Separation**

Dong Feng, Jiadao Wang and Ding Wong; Tsinghua University, Beijing, China.

Oil-water mixtures, which result from food processing, metal finishing, petrochemical and so on, have become the most common contaminant all over the world. Thus, oil-water separation is an important challenge in the field of scientific research and environment protection. Traditional methods for the oil-water separation, including air flotation, ultrasonic separation and biological treatment, have difficulty in practical applications due to the limitations of low separation efficiency and the generation of secondary pollutants. Recently, the superhydrophobic and superoleophilic materials for selectively adsorbing or filtrating oil from oil-water mixtures have flourished with advantages of high separation efficiency and wide applicability. Numerous preparation methods are developed, such as electrochemical deposition, electrosprinning and vapor phase deposition. However, they are complex, high-cost, or inapplicable for large-area fabrication.

Here, we present a facile method to create durable superhydrophobic and superoleophilic coating on the porous metal fiber sintered felt (PMFSF) via tension gradient self-assembly. Firstly, PMFSF was immersed into ethanol and then pulled out vertically. A thin film of ethanol formed on the surface of PMFSF. Secondly, PMFSF was vertically placed into polytetrafluoroethylene (PTFE) solution (6 wt%) at a speed of 1 cm/s. The tension gradient appeared as a result of the dissolution of ethanol into water, and induced the Marangoni convection and the relative motion between the solution and the PTFE nanoparticles. The particles moved towards the surface of PMFSF and a PTFE nanoparticle coating formed. Thirdly, the sample was heated to 380 °C for 40 min, followed by cooling down in air. During the sintering process, the PTFE particles melted and rearranged to form nanofibers. As a result, the PTFE nanofibers not only offered low surface energy, but also provided nanoscale roughness, which was beneficial for the oil-water separation. After a series of
tests, the PMFSF coated with nanofibers could separate a series of oil–water mixtures with an efficiency over 98%. The separation efficiency was still stable after the sample was reused for 30 times. Moreover, the sample worked well under extreme environmental conditions of strong acidic or alkaline solution, high temperature and ultraviolet irradiation. In summary, we have demonstrated a simple, low-cost and rapid method to fabricate larger-area PTFE nanofibrous coating on PMFSF for oil-water separation based on tension gradient self-assembly. The coated PMFSF has the advantages of high-efficiency, durability and good environmental adaptability, which is suitable for industrial application.

Nanofluidic Channels and Electrokineti Energy Generation on Two-Dimensional Boron Nitride Membrane Si (Alex) Qin, Zhiyu Wang, Dan Liu, Weitwei Lei and Joselito Razal; Deakin University, Geelong, Victoria, Australia.

Recent research show that two-dimensional (2D) membrane can provide unprecedented large number of nanofluidic ion channels through economic and easy fabrication processes. However, constructing a 2D membrane suitable for harsh environment such as highly acidic or alkaline solutions is still a challenge. Boron nitride (BN) membranes constructed from highly stable, acidic and alkaline resistant functionalised BN nanosheets are promising alternatives for organic or GO membrane. Herein we show BN membranes which allow ions to pass through intra-layer spaces. Measurement across the BN membrane showed a surface-charge-governed ionic conductivity in a variety of salt solutions (KCl, NaCl and CaCl₂) at low salt concentrations (<10⁻⁴ M). Moreover, due to outstanding chemical and thermal stability of BN nanosheets, the ionic channels remain fully functional in harsh conditions and at elevated temperatures. The BN membrane can operate in highly acidic and basic environments, and does show degradation after immersing in solutions with extreme pH (pH close to 0 or 14) for one week. More interestingly, pressure gradient results in a current response across the membrane. Current in the range of 8–13 nA can be generated on a 5 mm² membrane with a pressure gradient of 5 kPa in 0.1 M NaCl solution. The electrokineti electric generation can be scale up by connecting multiple devices. Those excellent properties make the BN membranes suitable alternative to organic or GO membranes and attractive for applications in nanofluidic devices and membrane separation.

3:15 PM NM04.11.05

Ultrahigh Performance of Novel Energy-Efficient Capacitive Deionization Electrodes Based on 3D Nanotubular Composites Nageh K. Allam; American University in Cairo, New Cairo, Egypt.

Capacitive deionization (CDI) is being progressed as an auspicious ions removal technique from brackish and seawater. Herein, we introduce a novel one-step facile chemical approach to fabricate tubular architecutured composite electrodes made of both Titania and Multi-walled carbon nanotubes (TNTs/MWCNTs). The composites have been exploited, for the first time, as the electrode materials for capacitive deionization. The composite electrodes were fully characterized via Field Emission Scanning Electron Microscopy (FESEM), Raman spectroscopy, X-Ray Diffraction (XRD), X-ray Photoelectron Spectroscopy (XPS) techniques, and Nitrogen Sorption. The electrochemical response was investigated by using Cyclic Voltammtry (CV), Galvanostatic Charge and Discharge (GCD), and Potentio-Electrochemical Impedence Spectroscopy (PEIS) measurements. The fabricated composite electrodes containing 5 wt% TiO₂ nanotubes showed a remarkable specific capacitance, conductivity, reversibility, and durability compared to pristine MWCNTs and other MWCNTs-based composite electrodes reported in the literature. The desalination capability of the composite electrode was investigated using batch mode operation. The electrosorption capacity of the composite electrode containing 5 wt% TiO₂ nanotubes (13.2 mg/g) is approximately two folds of magnitude larger than that of pristine MWCNTs (7.7 mg/g), indicating an improved desalination efficiency. Therefore, the fabricated TNTs/MWCNTs composite electrode is a promising candidate for CDI technology.

3:30 PM NM04.11.06

Using Nickel Sulfide Nanoparticles Incorporated PMMA-Zirconia Membranes as Efficient Adsorbent for Ultra Deep Desulfurization of Thiophenes Adnan Miahial1, Tuba Choudhury1, Tajmal Hussain1 and Sadia Zafar Bajwa2; 1Institute of Chemistry, University of the Punjab, Lahore, Pakistan; 2National Institute of Biotechnology and Genetic Engineering, Faisalabad, Pakistan.

Ultra deep desulfurization of liquid fuels such as gasoline/diesel has attracted considerable attention of modern clean fuel research due to strict environmental regulations. Apart from that, SO₂ produced during combustion, poison the catalytic converter and exhaust emission system. Comparing to conventional catalytic and hydrodesulfurization techniques, adsorptive method for removal of sulfur bearing compounds e.g. thiophene derivatives is a promising approach which does not require hydrogen, or high temperature and pressure. In this study, we used nickel sulfide nanoparticles as a potential affinity material for adsorptive extraction of thiophene derivatives i.e. thiophene, benzothiophene and dibenzothiophene from n-hexane. The functionality and surface morphology of synthesized material was examined by Fourier transformation infrared (FTIR) and atomic force microscopy (AFM) images, respectively. The quantitative data regarding adsorptive removal of thiophene derivatives was determined by monitoring the absorbance values of their standard solutions before and after treating with synthesized material under ambient conditions. It was noticed that nickel sulfide nanoparticles exhibited excellent rebinding response for removal of dibenzothiophene down to 0.5ppm which is useful concerning ultra deep desulfurization. The prepared nickel sulfide nanoparticles were incorporated in poly(methylmethacrylate-zirconia) matrix for adsorptive desulfurization of tedious thiophenes from liquid fuels without using hydrogen gas or any other catalyst.

3:45 PM NM04.11.07

Chemically Functionalized Laminar MoS₂ Membranes for Nanofiltration Mark A. Bissett, Wisiit Hirunpinyopas, Eric Prestat and Robert A. Dryfe; University of Manchester, Manchester, United Kingdom.

Environmental pressures, along with the discovery of two-dimensional (2D) materials such as graphene, have combined to provide renewed interest in the development of membrane technologies. Laminar membranes of two-dimensional materials are excellent candidates for applications in water filtration due to the formation of nanoapillaries that can exhibit a size and charge sieving effect, while allowing high water flux. Laminar membranes of 2D materials have been demonstrated previously in the case of graphene oxide, however these membranes suffer from swelling when exposed to liquid water, leading to low ionic rejection and reducing their applicability for desalination applications.

In this work, we demonstrate that thin (~5 μm) laminar membranes of exfoliated molybdenum disulfide (MoS₂) can be modified by a simple chemical functionalization step and can efficiently reject (~99%) of the ions commonly found in sea water (e.g. Na⁺, K⁺, Ca²⁺, and Mg²⁺), while maintaining water fluxes significantly higher (~5 times) than those reported for graphene oxide membranes. These chemically functionalized MoS₂ membranes exhibit long-term stability with no swelling, and consequent decrease in ion rejection, when immersed in water for periods exceeding 6 months. Similar stability is observed when exposed to organic solvents, indicating that they are ideal for a variety of technologically important filtration applications.

We also performed ion transport measurements through the chemically functionalised MoS₂ membranes as a function of applied electric potential to
differenct between the effects of size and charge. Hydrated and non-hydrated cation permeability was measured for various mono-, bi-, and trivalent ions, demonstrating that higher charge density has a greater effect on the permeability of the inorganic cation than on the organic cation of comparable radii. The method presented here, based on non-toxic organic-functionalized MoS2 laminar membranes, demonstrates impressive potential for application in water purification technologies such as desalination, ion exchange, electrodialysis, reverse osmosis, and electrodeionization (EDI).

Coffee Waste as Biocleaning Agent for Polluted Water Reservoirs
Pedro Perdigon-Lagunes1, Sofia Aguillera-Barraza2, Alejandro Isaza-Orozco2, Pablo A. Cano-Martinez3, Lorena Arreguin-Lozano3, Humberto Pro White3, Daniel David Nehmad4, Diego Delgado Fajardo4 and Raul Herrera-Becerra1; 1Universidad Nacional Autonoma de Mexico, Mexico City, Mexico; 2Instituto Tecnológico y de Estudios Superiores de Monterrey, Ciudad de Mexico, Mexico.

Fresh water reserves are being depleted quickly in the last century and the rest of them are being contaminated. Different types of pollutants are released in the environment from various industries, specially, heavy metals in water reservoirs are a harsh task to solve. This is because these types of materials bound strongly to water molecules; hence, it is necessary to use different methods such as electro-Fenton reactions, advanced oxidation processes and nanotechnology to remove them [1]. An interesting approach is to use living microorganisms or fungi as bioremediating agents, because in the native these organisms work as caretakers of water and soil. However, in this case the contaminants surpass their resilience to toxic waste. In our case, we decided to solve this problem using nanotechnology approach [2], utilizing a common waste as our main reduction agent: Coffee waste. Despite the fact it is used as a compostable waste, we used it as a biocleaning agent instead. Coffee extracts have demonstrated their capability to bioreduce metals into nanostructures [3]; therefore, we obtained a bioactive extract from used coffee capable of quickly reducing metallic ions into nanoparticles. Then, we tested our extract to collect heavy metals from polluted water. In this experiment, metal-oxide nanoparticles of different composition were precipitated at the bottom of the test tube. Then those nanoparticles were analyzed to determine their composition. This technique is a promising one, because it is simple to escalate, it uses small nanoparticles as their main reagents, and small nanoparticles can be recovered to be used in technological applications.

NM04.12.02
Synthesis of Nanoporous Adsorbents Showing High CO Selectivity to CO2 and High CO2 Selectivity to CH4, Based on Systematic Study on Effect of Physico-Chemical Properties of Nanoporous Materials to Adsorption of Each Component
Kanghee Cho, Jong-nam Kim, Sang Sup Han, Jong-ho Park, Hee Tae Beum, Jongkee Park and Sun Hyung Kim; Korea Institute of Energy Research, Daejeon, Korea (the Republic of).

We synthesized two types of nanoporous adsorbents: one for CO-selective separation from CO2/CH4 mixture, and the other for CO2-selective separation from CO2/CH4 mixture. For the synthesis of the CO-selective adsorbent, we impregnated CuCl species which shows strong interaction with CO on suitable alumina-type nanoporous supporting material. The driving force of CO-selective adsorption is strong interaction between the CuCl species and CO molecules. For the synthesis of the CO2-selective adsorbent, we modified zeolite to tune finely the size of micropore aperture of the zeolite to certain size between the molecular sizes of CO2 (0.33 nm) and CH4 (0.39 nm). The driving force of the CO2-selective adsorption is the size-selective effect (molecular sieving effect) of the micropores in the zeolite. For both cases of the adsorbent syntheses, it is highly important to choose suitable nanoporous supporting material and to modify the nanoporous supporting material, in order to enhance adsorption capacity and selectivity of target component. For this purpose, it is necessary to understand the effect of the physico-chemical properties of the nanoporous materials to the adsorption of each adsorbate. In the case of the CO-selective adsorbent, nanoporous supporting material is desired to disperse well the CuCl species to increase CO adsorption capacity, and it is simultaneously desired to show weak interaction with CO2 to enhance CO selectivity. Zeolite 13X which has been normally used for the preparation of CO-selective adsorbent shows high CO2 adsorption capacity owing to electro-static interaction with CO2 and zeolite microporosity, even though it shows high surface area which is good for high dispersion of CuCl. We used mesoporous alumina as a supporting material for the CuCl, and the mesoporous alumina has weaker electrostatic interaction than zeolite and no microporosity. We confirmed that our new CO-selective adsorbent 35 cm3 g−1 of CO2 adsorption at 293 K under 100 kPa of each gas. In the case of the CO2-selective adsorbent, the adsorbent is desired to show nanopore size between the sizes of CO2 and CH4 to have size-selective effect. When the size of micropore aperture of the zeolite is reduced to desired range, CH4 molecules cannot enter the micropore aperture. However, the adsorption speed of CO2 becomes inevitably too low to use fully the size-selective effect of the zeolite in CO2 separation. In order to resolve such a problem of slow adsorption, we generated additional mesopores in the zeolite crystals by using organosilane surfactant as a mesopore generating agent. The adsorption of CO2 into the micropores is still slow in the case of the mesoporous zeolite, but the mesopore generation increases the number of micropores exposed to external surface. The mesoporous zeolite shows high CO2/CH4 selectivity, and is shows much higher CO2 adsorption rate than solely microporous zeolite counterpart.

NM04.12.03
Dielectric Mirrors for Vapor Sensing and the Study of Time-Resolved Response
Shuai Gao, Karen Forberich and C. Brabec; University of Erlangen-Nuremberg, Erlangen, Germany.
Organic solvent and water vapor detections play an important role in industrial and life areas. Predictable and selective sensing shows a large number of applications. Dielectric mirrors (DMs), also known as Bragg stacks or one-dimensional photonic crystals, have certain reflection bands, and the position of the reflection band can be controlled by changing the thicknesses or the refractive index of the stacked layers. Polymers or organic-inorganic materials are popular in vapor sensitive dielectric mirrors, and the variation of refractive index or thickness is easily controlled because polymers show the property of swelling. The tunable reflection bands enable the mirrors to work as vapor sensors. In most research, polymers are deposited as the active layer and oxide nanoparticles are deposited as the other porous layer to improve the permeability and increase the refractive index contrast in the bilayer structure. However, due to the specific properties of the polymers, they can only respond to either water or organic solvents.

In this work, dielectric mirrors based on bilayers are fabricated for the purpose of vapor sensing, which are made of polystyrene-block-poly (ethylene-ran-butylene)-block-polystyrene (SEBS) and polyvinyl alcohol (PVA)-zirconium dioxide (ZrO2) nanocomposites. The specific reflection bands of dielectric mirrors depend on the refractive indices and thicknesses of the alternating layers. When dielectric mirrors are exposed to solvent vapor, layers swell which causes a shift of the reflection band. Since SEBS and PVA respond to organic solvents and water, respectively, these mirrors can be used as sensors for a large variety of different solvents. Hydrophilic ZrO2 nanoparticles are introduced to increase the porosity of the PVA layers, and the ratio of ZrO2 nanoparticles was optimized to achieve the optimum effect. The time-resolved response is studied to understand the swelling processes. Time-resolved measurements show that the mirrors with nanoparticles have a significantly faster response compared with those without nanoparticles. Due to the different Flory-Huggins interaction parameters between materials and solvents, the dependence of the responses on the relative humidity and on the type of solvents is studied, which provides an approach to make responses predictable and selective. The swelling of the mirrors is reversible upon thermal annealing so that the response of the vapor sensors shows good reproducibility. The combination of good properties such as selectivity, predictability, and reversibility with the simple fabrication procedure is promising in the development and application of the dielectric mirrors as vapor sensors.

**TiO2 Encapsulated AIOOH Dual Nanostructures with Robust Anti-Oil Fouling**

Sun Mi Yoon1,2; Hyebin Lee1, Young Cheol Park1, Sahn Nahm3 and Myoung-Woon Moon3, 1Materials and Life Science Research Division, Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Department of Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

More researches are under progress for developing an oil-water separation or recovery method as oil spillage accidents continuously occurs. Technology for removing oil spilled in the sea or the river includes adjusting surface energy like hydrophilicity and hydrophobicity as well as the structures in nano- or microstructures or their hybridization. Among functional materials, the hydrophilic/underwater oleophobic materials have advantages in the various applications such as self-cleaning, oil transportation or oil-water separation. However, the hydrophilic or superhydrophilic surfaces are still required for the long-term durability in mechanical and chemical stability.

In this work, we present a durable superhydrophilic and underwater superoleophobic mesh filter with dual nanostructures of nanoflake and nanoparticle clusters. The aluminum (Al) mesh surfaces show the long-term superhydrophilicity/underwater superoleophobicity induced by hydrothermal treatment in containers having Al mesh and TiO2 nanofluid. As Al is immersed in boiling TiO2 nanofluid, the Al surface reacts hydroxyl ion decomposed water to form flake-like AIOOH nanostructure encapsulating TiO2 nanoparticles inside. Al ions are diffused out from the Al2O3 matrix, leaving Al depletion zone, then the Al ions in TiO2 nanofluid can be precipitated on the surfaces of Al depletion zone and TiO2 nanoparticles. Pristine Al mesh filter without TiO2 nanoparticles showed mild hydrophilic but not lasted for longer duration, while the mesh filter with dual nanostructures has long-term stability in superhydrophilicity more than 10 weeks due to dual scale roughness in nanoscale as well as TiO2 effect. The hybrid nanostructures have very low wetting angle of near 0° degree in air and superoleophobic underwater long-lasting anti-oil property. We applied this surface to oil collecting filter by separating oil/water, which are required for the spontaneous oil detachment at the water surface for cyclic oil-water collection-separation-release process with the crude oil over 5,000 times.

**NM04.12.05**

**Cost-Effective Fabrication of Metal Oxide Nanoparticles (WO3, ZnO) Based Gas Sensor for Selective Detection of NO2 and CO Environmentally Hazards Gases**

Sapana Ranwa, Vikas Sharma, Habeebur Rahman and Bodh R. Mehta; Department of Physics, Indian Institute of Technology Delhi, New Delhi, India.

In today’s era, real-time monitoring of toxic pollutant gases is vital for domestic sector as well as automotive sector to uphold human health and safety. The selective detection of most common and hazardous gases CO and NO2 at low operating temperature is one of the critical challenges in the area of environmentally sensitive sensors. Metal oxide nanoparticles (ZnO, WO3) based gas sensor provides an opportunity to fabricate cost-effective environmental gas sensor with low concentration gas detection possibility even at moderate operating temperature. In this study, a WO3 nanoparticles based sensor able to give ~36.3% sensor response towards 10 ppm NO2 gas even at 50 °C operating temperatures. This sensor shows highly selective sensor response towards 10 ppm NO2 gas in comparison to other air pollutant gases (10 ppm CO ~ 2% and 10 ppm NO ~ 3%) at a low operating temperature (50 °C). Furthermore, doping of Ga (1% to 5%) into ZnO based sensor could provide the possibility to solve the selectivity problem for NO2 gas concentration among other common environmental pollutants (CO, NOx). 2.5% Ga doped ZnO based sensor able to depicts 10 fold increased sensor response with high selectivity towards 10 ppm NO2 gas at 150 °C operating temperature in comparison to pristine ZnO based sensor for other hazards gases (CO, NO). ZnO nanoparticles and Ag loaded ZnO Nanoparticles based chemical sensor performance have been further studied for selective detection of 10 ppm CO gas concentration at operating temperature ranging from 50 °C to 150 °C. Functionalization of ZnO sensor with surface decoration of Ag nanoparticles (5-20 nm) has been achieved by a continuous gas phase deposition method. Gas sensing response of Ag loaded ZnO sensor shows significantly enhanced sensor response ~40% in comparison to ZnO sensor response ~9% for 10 ppm CO gas concentration at 150 °C operating temperature. This improved sensor response towards reducing gas (CO) for Ag loaded ZnO sensor could be explained by electronics as well as chemical gas sensing mechanism. Ag loaded ZnO sensor also has been able to depict selective sensor response towards 10 ppm CO gas with ~40 % sensor response in comparison to other air pollutants (10 ppm NO with ~10% and 10 ppm NO2 with ~20%) at 150 °C operating temperature. This current approach enables us to fabricate cost-effective and low operative temperature (50 °C) gas sensor with high selectivity for the detection of CO and NO2 gases. These studies also motivate us to record both NO2 and Ag loaded ZnO based sensor response at the same time which gives selective detection of NO2 and CO gases without changing sensor from the chamber.

**Photocatalytic activity of Ce doped SnO2 nanoparticles for the degradation of organic toxic pollutants**

Akanksha Gupta1, Sunjeet K. Yadav2, Prateek Saini2, Ayesha Seth1 and Vinod Kumar2; 1Chemistry, Sri Venkateswara College, Delhi, India; 2Chemistry, KIIT Mal College, Delhi, India.

Water pollution by different harmful compounds is becoming an increasing global concern. Most industrial dyes, pesticides are toxic, carcinogenic, and mutagenic, and have low biodegradability. Moreover, dye-containing effluents are highly colored, so discarding these effluents into natural water bodies affects the balance of aquatic ecosystems because they can prevent the penetration of sunlight into the water, which results in a reduction in dissolved oxygen content. Therefore, the removal of dyes and pesticides prior to the discharge of wastewater from industries is of great importance. The inadequate treatment and inappropriate disposal of these toxic carcinogenic organic compounds pose a considerable threat to the environment [1].

Water pollution by different harmful compounds is becoming an increasing global concern. Most industrial dyes, pesticides are toxic, carcinogenic, and mutagenic, and have low biodegradability. Moreover, dye-containing effluents are highly colored, so discarding these effluents into natural water bodies affects the balance of aquatic ecosystems because they can prevent the penetration of sunlight into the water, which results in a reduction in dissolved oxygen content. Therefore, the removal of dyes and pesticides prior to the discharge of wastewater from industries is of great importance. The inadequate treatment and inappropriate disposal of these toxic carcinogenic organic compounds pose a considerable threat to the environment [1].
Several binary oxides such as TiO₂, ZnO, SnO₂ etc. have been recognized as preferable materials for photocatalytic activities due to their high photosensitivity, low cost, and chemical stability and hence, they have been investigated for the degradation of these pollutants in waste water [2]. Little information is available in the literature regarding the SnO₂-RE (RE=rare earth) system [3].

Tin dioxide (SnO₂) is a n-type semiconductor that has a wide range of potential applications in gas sensors, catalysts, batteries, transistors, and transparent electrodes. The structure, band gap, and chemical stability of SnO₂ are similar to those of titanium dioxide (TiO₂), which is a widely used photocatalyst. Moreover, SnO₂ has no adverse health effects and is poorly absorbed by the human body when injected or inhaled. Thus, SnO₂ is potentially an ideal photocatalyst and possess large surface area. Semiconductor photocatalytic processes are based on the generation of electron-hole pairs by means of band gap radiation. SnO₂ has also been used as a component of composite photocatalysts such as SnO₂/TiO₂, SnO₂/ZnO, and SnO₂/ZnO/TiO₂ [4]. Doping of rare earth ion in metal oxide introduce defects lowering the effective optical gap and hence leading to a better photocatalytic. Ce doped SnO₂ is a promising material and several scientists have reported its gas sensing properties for various harmful gases but to the best of our knowledge its photocatalytic activity has not been explored much.

Herein, we present the synthesis and structural characterization of varying concentration of Ce-doped SnO₂ nanoparticles. Detailed characterization have not been explored much. Material and several scientists have reported its gas sensing properties for various harmful gases but to the best of our knowledge its photocatalytic activity has not been explored much.

In this study, we report the synthesis and electrochemical characterization of varying concentration of Ce-doped SnO₂ nanoparticles. Detailed characterization are attempted based on the PXRD measurements, FTIR, Raman, UV-visible spectroscopy etc. We have successfully degrade the organic dyes and pesticides under UV irradiation, which might be helpful for the wastewater treatment in future.

High Performance Single Magnéli Phase Reactive Electrochemical Nanoporous Membrane for Waste Water Treatment Sasmita Nayak and Brian P. Chaplin; University of Illinois at Chicago, Chicago, Illinois, United States. Reactive electrochemical membrane (REM) based on Magnéli phase titanium oxides (T₄O₇₋₃n, n = 4 to 10), are attractive, because of their high conductivities, chemical stability, and low cost with unique functionality to produce OH via water oxidation. Most of the present Magnéli phases based REM are limited to formation of high-quality, the most conductive and single magnéli phase, i.e., TlO₂. This study reports the synthesis and electro-oxidation capabilities of Magnéli Tl₄O₇ REM using probe molecules and organic compounds through both direct oxidation (oxalic acid) and interaction with OH (terephthalic acid). High membrane fluxes of (1736 L/M².hr) resulted in a convection-enhanced rate constant for Fe(CN)₆₄⁻ oxidation of 8.13 × 10⁴ m²/s⁰ and that for Fe(CN)₆₃⁻ reduction of 10.84 × 10⁴ m²/s⁰ that approaches the kinetic limit. Batch experiments were also performed for electrochemical destruction of N-nitrosodimethylamine (NDMA) in flow-through electrode for single-pass sequential reduction–oxidation.

Highly Efficient Adsorption of Heavy Metal Ion from Wastewater Using Hollow Carbon Coated with Fe₃O₄ Hybrid Composites Byeong Seok Lim, Bongkyun Kang and Woo Seok Yang; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

The presence of hazardous heavy metals in water is an important issue in environmental pollution management with crucial effects on human health. Heavy metal can cause several serious health problems and skin cancer. Iron oxide based materials are very effective in the removal of heavy metal. However, Fe₃O₄ nanoparticles are actually prone to aggregate by spontaneous magnetization that decreases specific surface area. Additionally, heavy metal adsorbed Fe₃O₄ nanoparticles are difficult to separate in water owing to their low magnetic properties and nanosize. In this work, we synthesized the hollow carbon coated with Fe₃O₄ hybrid composites via SiO₂@dopamine core shell. The hollow carbon coated with Fe₃O₄ hybrid composites did not aggregate well compared to other Fe₃O₄ materials because the hollow carbon structure had a three dimension (3-D) sphere shape and high outer surface area with inner surface. Consequently, the hollow carbon coated with Fe₃O₄ hybrid composites exhibited more heavy metal adsorption capacity compared to pure Fe₃O₄ and other materials with Fe₃O₄.

NM04.12.09
An Intelligent Dual Mode Reversible Filtration Device for Separation of Immiscible Oil/Water Mixtures and Emulsions Parul Raturi and Jitendra P. Singh; Physics, Indian Institute of Technology Delhi, Delhi, India.

For the treatment of oily wastewater strategies used for oil/water separation, including immiscible light/heavy oil water mixture, both oil in water and water in oil emulsions are of great demand. Recently, materials with specific wettability properties have become interesting due to their importance in the field of oil/water separation. Herein, we report intelligent mesh for dual mode reversible separation of immiscible heavy/light oil water mixture and both oil- in-water as well as water-in-oil emulsions. ZnO nanowires coated stainless steel meshes with pore size of 50 μm and 10 μm were fabricated successfully. The wettability of mesh can be reversibly switched between “oil-blocking” and “water-blocking” modes by alternative exposure and removal of low surface energy material. The “oil-blocking” mode was suited for the efficient separation of light oil/water mixture and oil-in-water emulsion, while “water-blocking” mode was found to be suitable for the separation of heavy oil/water mixture and water-in-oil emulsion. This work provides a simple, cost effective, eco-friendly and time saving approach applicable for separation of both form of oil/water mixture, free as well as surfactant stabilized emulsions, irrespective of the types of oil involved. The separation efficiency of the mesh was found to be more than 99% for free as well as emulsified mixtures. Even after cyclic usage in both modes alternatively, the separation efficiency of the mesh remained relatively unchanged, showing anti fouling property and excellent recyclability of the mesh.

NM04.12.10
Recyclable and Multifunctional 3D Hybrid Networks for Adsorption, Detection and Decomposition of Environmental Pollutants Yajieong Lee, Seungki Lee, Chang Min Jin, Hye Sil Kim and Inhee Choi; Department of Life Science, University of Seoul, Seoul, Korea (the Republic of).

Monitoring and removal of environmental pollutants have been regarded as important tasks nowadays due to global and public health issues. For this purpose, efficient materials that can adsorb, detect, and decompose such pollutants have been consistently sought after. Even for such an essential necessity, there are only a limited number of reports on suitable platforms or materials that can allow combining multiple roles of adsorption, detection, and decomposition of VOCs. Herein, we present a simple, inexpensive and eco-friendly fabrication method of recyclable and multifunctional three-dimensional (3D) network with functional nanoparticles (hybrid network). Water-soluble crystals (e.g., sugar and salt) and photocatalytic nanoparticles (e.g., TiO₂ nanoparticles) are utilized to construct porous templates where liquid polydimethylsiloxane (PDMS) mixture (base and curing agent) is filled. For more sensitive detection of pollutants, metal precursors (e.g., HAuCl₄ and AgNO₃) can be added into the liquid PDMS mixture to form the plasmonic nanoparticles such as Au and Ag nanoparticles in the porous PDMS network. After curing the PDMS, porous network structures with the self-integrated nanoparticle are finally obtained by dissolving the templates by water. To demonstrate the performance of the hybrid network, we quantitatively and qualitatively detect the pollutants such as organic dyes and volatile organic compounds (VOCs) via molecular-specific and label-free Raman scattering.
Furthermore, we show the recyclability by achieving photocatalytic decomposition of the adsorbed pollutants by using the TiO$_2$ hybrid networks. We believe that the developed hybrid 3D networks could be widely utilized in managing organic pollutants in aquatic and atmospheric environments.

**Enhanced Aqueous Copper(II) Ion Adsorption Efficiency of Polyaniline Nanofibers via Phytic Acid Doping**

Hyeyeong Jin Kim and Young Joon Hong; Department of Nanotechnology and Advanced Materials Engineering, Sejong University, Seoul, Korea (the Republic of).

Scavenging discarded metal in aquatic environment has been of note in both polluted water purification and mineral mining, which have been usually processed using various methods. Among the diverse methods, adsorption/metal-organic complexation by ion exchange has gained a great deal of interest for low processing cost, energy saving, and greener chemical technology. Because of the ability of the technique to reuse the adsorbent and the discarded metal, as of late, many types of meso-porous and nanostructured have been developed for high efficiency collection of aqueous metal ions, due to the high surface-to-volume (s/v) ratio. In particular, nanostructure adsorbents are thought to be ideal for high-efficiency metal adsorption, but high density surface ionic functional groups are further needed to strongly attract aqueous metal. Especially, polymer has a structural advantage of being viable to modify surface chemical properties via doping chemical functional groups to backbone, enabling it to substantially raise the aqueous metal adsorption efficiency. Also, many polymers are deformable such that they can be structurally designed to form desirable shapes in demand. In addition, considering the significance of reuse of adsorbed metals.

Here, we report on radical polymerization synthesis of phytic acid-doped polyaniline nanofibers (Ph-PAni NFs) and enhanced adsorption of aqueous Cu$^{2+}$ after the doping. To pose a higher negative charge, the dopant of phytic acidic molecules with phosphoric acid functional groups was employed. The Cu$^{2+}$ adsorption efficiency of Ph-PAni NFs was markedly increased after the doping, presumably due to high ionic attraction feature of phosphoric acid group in phytic acid. The adsorption efficiency of Ph-PAni NFs is discussed in terms of Langmuir and Freundlich adsorption models. We further investigated the pH-dependent adsorption efficiency of Ph-PAni NFs and found much higher Cu$^{2+}$ adsorption capability under high pH conditions owing to spontaneous deprotonation by the basic solution. Furthermore, Ph-PAni NFs showed stable, high Cu$^{2+}$ adsorption efficiency, irrespective of Co$^{3+}$ concentration in the bi-metallic Cu and Co aqueous solution. Surface modification and/or doping to enhance the adsorption efficiency of Cu(II) introduced in this study will provide a great venue for expanding the use of many other polymeric nanostructures for reclamation in metal mining as well as the conventional environmental applications such as water purification.

**Smart Metal Mesh to Simultaneously Harvest Atmospheric Fog and Remove Pollutants**

Ritwick Ghosh$^{1,2,3}$, Rakesh P. Sahaj$^{4}$, Igor Zhiltominrsky$^{1}$, Ranjan Ganguly$^{2}$ and Ishwar K. Puri$^{4}$; $^{1}$Materials Science and Engineering, McMaster University, Hamilton, Ontario, Canada; $^{2}$Power Engineering, Jadavpur University, Kolkata, India; $^{3}$Mechanical Maintenance, NTPC Ltd., Farakka, India; $^{4}$Mechanical Engineering, McMaster University, Hamilton, Ontario, Canada.

Water harvesting from fog-laden atmospheric and industrial wind streams is finding increasing application. Since fog often contains SO$_x$, NO$_x$, and VOCs, use of the harvested water is limited by its quality. We describe an integrated approach that simultaneously harvests fog and removes pollutants from the collected water. A stainless steel (SS) mesh is coated with TiO$_2$/ZnO nanoparticles through electrophoretic anodic deposition. These two types of nanoparticles used to coat the meshes are correlated with this mesh efficacy. This technology can potentially be used to improve the local air quality by arresting smog in large complexes, such as hospitals, schools and public arenas.

**Gas-Phase Interrogation Module For Lower-Power Chemical Collection (GIMLI)**

Myeongseob Kim, Michael J. Bowers, Don Ahmasi Harris and Pierre-Alain Auroux; FAST Labs, BAE Systems, Columbia, Maryland, United States.

In this presentation, we provide partial results of IARPA supported MAEGLIN (Molecular Analyzer for Efficient Gas-Phase Low-Power Interrogation) program. The MAEGLIN program intends to develop an ultra low power chemical analysis system for remote site detection and identification of explosives, chemical weapons, industrial toxics and pollutants, narcotics, and nuclear materials in the presence of significant background and interferents. The system should be traceable to a package fitting within 0.5 L and 2.5 kg. The power threshold is < 7.5 J per analysis run with a goal of < 1.5 J per analysis run. The autonomy of the systems shall be at least 730 cycle sampling performance (one sample per day for two-year use). To accomplish this task, BAE SYSTEMS utilized its open cell proprietary foam as a low pressure drop broad-based adsorbent medium which enables sampling at high rates (liters per minute or lpm) utilizing a computer fan or blower. Upon collection the analytes are thermally desorbed from the foamed sorbent material and delivered directly to a GC column without use of a cryo-focusing system. Currently our system is able to collect over 50 targets (among 100 background compounds and with 5 true unknowns) with a compound mass range of 30-350 amu. With energy per sample 1.248J, system volume 0.82 L, and reusability is >730 times.

**Ultra-Durable Superhydrophobic/Superoleophilic Mesh Prepared by Spray-Coating for Oil/Water Separation**

Chuang Cheng, Ding Weng, Aways Mahmood and Jiaoda Wang; Tsinghua University, Beijing, China.

Nowadays, the efficient separation of oil/water mixtures has become an urgent challenge all over the world. Superhydrophobic/superoleophilic materials have been widely employed to separate oil/water mixtures due to its high efficiency, high flux and high selectivity. However, the poor mechanical durability of superhydrophobic materials has always been a common drawback, which limits their applications in real industry. Here, we propose a facile method to fabricate superhydrophobic mesh by spraying commercial adhesives and PTFE nanoparticles. The adhesives were used to bond the PTFE nanoparticles to the substrates and enhance its durability. The PTFE nanoparticles were used as building blocks to decrease the surface energy of substrates and promote hydrophobicity. The coated mesh exhibited superhydrophobic/superoleophilic properties with water contact angle of above 155$^\circ$ and oil contact angle of 0$^\circ$. Moreover, the as-prepared mesh can be applied to separate not only immiscible oil/water mixtures, but also water-in-oil emulsion with high separation efficiency. The coated mesh also exhibited good hydrophobicity and possessed high separation efficiency for various oil/water mixtures even after over 600 abrasion cycles, showing ultra-durable property. Furthermore, this method could be flexibly applied to almost any soft and solid substrate such as fabric, sponge, glass and so on, which could have significant application in industries.
NM04.12.15
Toxicity Evaluation of Boron- and Phosphorous- Doped Silicon Nanocrystals Towards *Shewanella oneidensis* MR-1
Bo Zhu1, Sadhana Mishra2, Natalie V. Hudson-Smith1, Uwe R. Kortshagen2 and Christy L. Haynes1; Chemistry, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; 3Mechanical Engineering, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

Silicon nanocrystals, also known as silicon quantum dots, are regarded as green alternatives to traditional quantum dots composed of heavy metal elements. While the semiconductor properties of these materials can be tuned by doping with p-type dopants (*i.e.*, boron and phosphorous), little is known about the potential environmental impacts of these doped nanocrystals. This work demonstrates that introduction of dopants, especially phosphorus, causes the doped silicon nanocrystals to produce reactive oxygen species, resulting in significant toxicity to a model microorganism, *Shewanella oneidensis* MR-1. In addition, the interaction between bacteria cells and silicon nanocrystals was investigated using hyperspectral dark field microscopy and TEM. Interestingly, likely due to Lewis acid-base interactions, the boron-doped silicon nanocrystals tend to attach to the bacterial cell surface while this phenomenon was not observed for undoped or phosphorous-doped silicon nanocrystals. This mechanistic understanding of nanocrystal-bacteria interactions yields critical insight for future design of sustainable nanomaterials.

NM04.12.16
Surface Modification of Polymer Filters by Etching and a PDA Coating for Oil-Water Separation
Pei Zhao, Ning Qin, Carolyn Ren and John Wen; Department of Mechanical and Mechatronics Engineering, University of Waterloo, Waterloo, Ontario, Canada.

Oil-water separation has been a global challenge due to extensive oily wastewater from industry and oil leakage. The polymer filters possessing underwater oleophobicity have been used for oil-water separation, which selectively allow water to flow through while resist oil. Those filters have been achieved either by the surface etching or by using novel coatings, as the wettability depends on the nature of the surface materials as well as the topography. Here, we developed a two-step strategy to modify polymer meshes and nonwoven fabrics for oil-water separation, where an underwater oleophobic PDA bio coating was applied onto a pre-etched polymer surface that had a large roughness. This strategy combines the required wettability of the coating and the large roughness that could further enhance the wettability.

Such modified polymer filters possessed superoleophobicity (>150°) in water and were capable of separating various oil-water mixtures with a high efficiency (>98.5%). These filters also showed increased intrusion pressure than the only coated or only plasma treated filters. The rugged surface created by the etching reinforced the coating stability and prevented the coating from peeling off of the substrate. Then the two-step modified filters were more durable than the only coated ones. Different from other durability investigations, in our work, for each cycle of use the filter was intruded (contaminated) by oil in order to measure its intrusion pressure. After 6 cycles of uses, the nonwoven filter was no longer underwater oleophobic due to severe oil contamination, and thus came to a failure in oil-water separation. After 19 repeated uses, the mesh filter was still capable of separating a certain amount of oil-water mixture but presented a decreased intrusion pressure due to slight oil fouling. Filters with different structures had different oil fouling levels during repeated uses that affected their durability for oil-water separation. The nonwoven with complex layers of pores was less durable than the mesh with a simple one layer porous structure, due to the much heavy oil fouling of the nonwoven. A way to efficiently clean the viscous oil residual in the filters could benefit the durability. The recoverability of the filter from oil fouling should be considered for practical applications. The two-step method of surface modification for polymer filters and the durability investigations give a new insight for filter design.

NM04.12.17
Electroimpedance Sensor for Detection of Cd with a Low-Cost Solution-Processed Sensing Layer
Priya Vinayak, Henam Sylvia Devi, Soumen Saha, Madhusudan Singh and Bhaskar Mitra; Indian Institute of Technology Delhi, New Delhi, India.

Cadmium is a trace metal in the Earth’s environment that presents with significant toxicological and carcinogenic effects in multiple organs in humans. The Centers for Disease Control (CDC) prescribe a maximum daily Cd exposure limit of 9 mg/m3. In this work, we have used chemical bath deposition to deposit CdS on gold for sensing Cd ions in test solutions. A Cr/Au layer (15nm/40nm) was deposited on glass under vacuum (4.2 x 10−6 Torr) using thermal evaporation. Subsequently, this substrate was immersed in an aqueous solution consisting of triethanolamine, cadmium acetate and thiourea (sulfur excess) at a pH of 12 using ammonium hydroxide, for over one hour at 50°C under constant stirring. Thin film X-ray diffraction (XRD) revealed CdS (111) deposition, while the absorption of resulting film was consistent with published data. The composition of the film was verified using energy dispersive X-ray spectroscopy (EDX) to reveal a Cd:S ratio of approximately 1:1. Electroimpedance measurements were carried out using a Biologic SP-150 potentiostat using an AC bias of 50 mV peak to peak on a DC ramp, with a Pt counter electrode and Ag/AgCl reference. Spiked Cd(NO3)2·4H2O solutions with concentrations 1M to 10−4M were used to characterize the operation of the sensor. The sensor showed linearity below 10−6M, with a detection limit of 2 x 10−5 M.

NM04.12.18
Functionalized Single Walled Carbon Nanotubes as Novel Nanoresin for Fast, Safe and Sustainable Water Purification
Abhinav Sahu and Jordan C Poler; Chemistry, University of North Carolina at Charlotte, Charlotte, North Carolina, United States.

Ground water & surface water quality in rural & urban areas are affected by natural & anthropogenic contamination. These water resources are being contaminated by pervasive Low Molecular Weight Organic Compounds (LMWOCs) which are not effectively removed by the current wastewater technologies. The US Environmental Protection Agency (USEPA) is focused on the removal of many classes of LMWOCs from drinking water & wastewater including; disinfection byproducts (DBP) precursors, pharmaceuticals, personal care products, heavy metals & perfluoroalkylated substances. In order to address removal of these pervasive compounds, an anion exchange resin polymer (AEP) functionalized Single Walled Carbon Nanotubes (SWCNTs) in the form of nanoresin has been developed. The large surface area of SWCNTs increases the availability of active ion exchange sites of the AEP. These nanoresins have higher & faster adsorption capacity compared to other current commercialized materials like magnetic ion exchange resins, DOWEX, etc.

This nanoresin was synthesized by modified activator regenerated electron transfer atom transfer radical polymerization technique in aqueous media. The hydrodynamic diameter of the purified AEP & nanoresin was 1.660 ± 0.10 nm & 194.9 ± 11.3 nm, respectively. The ratio between D & G bands, measured using Raman Spectroscopy, increased by 100% compared to pristine carbon nanotubes which is indication of covalent functionalization of the AEP. The proton nuclear magnetic resonance of the growing AEP showed 99.8% conversion from monomer to polymer in 69.30 hours. The scanning electron microscopy of nanoresin films fabricated on mixed ester cellulose (MCE) membrane for performance testing showed a smooth morphology of mesh of SWCNTs with conformal polymer coating. The step height of the fabricated film determined under atomic force microscopy was 142.31 nm. The measured membrane resistance of the thickest nanoresin film was determined to be $R_m = 2.1 \times 10^{12} \text{ m}^{-1}$ which is smaller than typical ultrafiltration membranes with $R_m = 2 \times 10^{10} \text{ m}^{-1}$.
We demonstrate the removal of several types of pharmaceuticals (viz., tetracycline hydrochloride and carbencimillin sodium), pesticides (viz., bentazon, terbutryn, Dithiopyram, DBCP, benomyl, chlorpyrifos, and clomazone) and PFAS (viz., perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS)), from water via adsorption capacity measurements. The percentage removal of PFOA and PFOS, for a starting concentration between 2-4 mg/L of contaminant, was 92.67% and 95.8%, respectively. The regeneration studies performed upto 20 cycles, showed a slope of -0.23 ± 0.18% per cycle which demonstrates that the nanorein could be regenerated. The green synthesis of nanorein, the ability to remove different classes of pervasive contaminants & the regeneration capacity corroborate an effective & sustainable solution to water purification & enhancement of water quality.

NM04.12.19 Microbial Platinum/Carbon Based Anode for Wastewater Treatment Andres F. Gonzalez, Myreisa Morales-Cruz and Carlos R. Cabrera; University of Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico.

The recycling of human urine has become a main area in wastewater treatment due to the increased demand of water. Urine is composed of 95% of water and 2% of urea and the rest are organic and inorganic salts. Urea is a toxic molecule that may cause renal failure and gastrointestinal bleeding. It is difficult to remove urea by common methods since it is a small uncharged molecule. In this work we develop a microbial carbon brush anode for the removal of urea. The bacterium uses urea and generates ammonia as a byproduct, subsequently oxidized by platinum at the carbon fiber surface. To improve the efficiency of the system we prepared carbon brush electrode as the anode material since it has been used to provide high surface areas for bacterial growth and high power densities in microbial fuel cells and modified with platinum for better catalytic properties. We synthesized platinum nanoparticles in our laboratory and attached it to the carbon fiber brush surface by impregnation. We tested unsupported and supported with Vulcan platinum nanoparticles synthetized in our laboratory and commercial platinum black and platinum nanoparticles in order to compare the catalytic activity for ammonia oxidation. The Pt-based catalysts were characterized by cyclic voltammetry and SEM to compare their capability and adhesion to the carbon fibers. We obtained better ammonium oxidation currents using the synthetized Pt nanoparticles than by using commercial platinum. Also we did a series of modification experiments with the bacteria in the anode surface to find the best modification conditions among temperature, voltage and time. These results were characterized by SEM imaging to compare the amount of carbon fiber surface covered by the bacteria. In our results the modifications of the carbon with bacteria were best when we didn’t use any voltage at 37°C.

NM04.12.20 A Scalable Approach for Manufacturing Nanoporous Silicon Membranes for Unconventional Separations Rahul Ramakrishnan, Brendan D. Smith and Jeffrey C. Grossman; Department of Materials Science and Engineering, Massachusetts Institute of Technology (MIT), Cambridge, Massachusetts, United States.

Thermal separations are extremely energy-intensive processes integral to many industries worldwide, and are responsible for 12% of all energy use in the United States. By switching from thermal to membrane separations, over 70 TWh could be conserved. Traditional polymer membranes, which are commonly used for filtration, possess high chemical sensitivity as well as an inability to withstand temperatures above 40 °C. Ceramics are a second class of membrane materials which offer chemical and thermal resilience. Their high cost, however, deters their popular use. Nanoporous silicon (NPSi) membranes have recently been shown to provide excellent performance and enhanced chemical and thermal stability, but have only been produced on the millimeter scale.

Here, we present a scalable method for the production of NPSi membranes via a modified metal-assisted chemical etching (MACE) process that allows for catalyst-dependent control over pore morphology. Through a simple three-step process involving selective chemical thinning of standard silicon, sputter-deposition of metal catalysts, and MACE of ultrathin aspect ratio nanotubes, a novel membrane is produced using common commercial materials and processes.

The core advancement of metal catalyst sputter-deposition allows for greatly improved avoidance of nanoscale catalyst aggregation and sintering on the surface prior to MACE, translating to well-dispersed individual nanotubes which cannot exceed aspect ratios of 1000:1. SEM and TEM images reveal pore diameters of less than 5 nm and surface porosities greater than 5%. In terms of membrane performance, we also demonstrate that the NPSi produced via our method is suitable for water filtration, achieving 92% rejections of 2 nm gold nanoparticles while exhibiting minimal permeability loss with respect to pure water as measured by UV-Vis spectroscopy and flow rates. These results suggest that NPSi membranes produced via this process can remove bacteria, viruses, emulsified oils, and even heavy metals from water in one step. We demonstrate that even after harsh chemical and thermal treatment via immersion in nitric acid (pH < 0) and high temperature environments (over 200 °C), NPSi membranes created via our method remain able to conduct filtrations with the same rejections and permeabilities. Our simple and innovative approach can also be modified for health care applications such as hemodialysis, as well as numerous other applications in the food and beverage and biopharmaceutical spaces, among others.

NM04.12.21 High Performance Capacitive Deionization via Manganese Oxide-Coated, Vertically Aligned Carbon Nanotubes Wenbo Shi1, Xuechen Zhou1, Jinyang Li1, Eric R. Meshot1, André Taylor1, Shu Hu1, Jaehong Kim1, Menachem Elimelech1 and Desiree Plata2; 1Department of Chemical and Environmental Engineering, Yale University, New Haven, Connecticut, United States; 2School of Materials Science and Engineering, Southwest Jiaotong University, Chengdu, China; 3Physical and Life Sciences Directorate, Lawrence Livermore National Laboratory, Livermore, California, United States; 4Department of Chemical and Biomolecular Engineering, New York University, Brooklyn, New York, United States.

The growing population and corresponding rise in clean water scarcity create appeal for transformative and sustainable desalination technology development and innovations. The capacitive deionization (CDI) desalination, where salt is removed by an electrochemical method, has emerged to tackle the limitations of poor energy efficiency, complex infrastructure, and high cost of other well-developed desalination technologies. Discovering electrode materials with exceptional capacitance, an indicator of the ability of a material to hold charge, is critical for CDI device development. Manganese oxides (MnOx) have shown promise, but exhibit a trade-off of lower active MnOx loading, coming at a cost of lower conductivity. To address this challenge and achieve high salt adsorption, we designed and fabricated carbon nanotube (CNT)-MnOx core-shell vertically aligned array electrodes using atomic layer deposition (ALD) to coat thin films of MnOx onto vertically aligned CNTs (VACNTs). The hierarchical, anisotropic, 3D macroporous structure of VACNT-MnOx and the unique tunable coating hallmark of ALD enabled the co-optimization of the hybrid material’s specific capacitance in dimensions of mass and geometric area, with an exhibited optimized mass-specific and geometric area-specific capacitance at 215 ± 7 Fg and 1.1 ± 0.1 Fcm², respectively. This co-optimized, outstanding capacitance not only positions them as candidate materials for traditional usage as energy storage devices, but also exhibits promise with a remarkable salt adsorption capacity (29 ± 1 mg NaCl/g material; two-fold higher than pristine VACNTs) to enable water desalination via CDI.

NM04.12.22
Highly Efficient Oil/Water Separation by Superhydrophobic/Superoleophilic Sponges Based Oil Skimmer

In recent years, nanotechnology has been proven to offer promising biomedical applications for in vivo diagnostics and drug delivery, stressing the importance of thoroughly investigating the biocompatibility of potentially translatable nanoparticles (NPs). Herein, we report the cellular responses of uncoated chitosan NPs (CS NPs) and hyaluronic acid-coated chitosan NPs (HA-CS NPs) when introduced into Chinese hamster ovary cells (CHO-K1) in a dose-dependent manner (2.5, 0.25, 0.025, 0.0025, and 0.00025 mg mL−1) at two time points (24 and 48 h). MTS assay, cell proliferation, showed a decrease in the viability of cells when treated with high doses of CS NPs (0.25 and 2.5 mg mL−1). When exposed to high doses of CS NPs, the lactate dehydrogenase (LDH) enzyme started to leak out of the cells and the cellular levels of mitochondrial potentials were significantly reduced accompanied by a high production of intracellular reactive oxygen species (ROS). Our study provides molecular evidence of the biocompatibility offered by HA-CS NPs, through ROS scavenging capabilities rescuing cells from the oxidative stress, showing no observed cellular stress and thereby revealing the promising effect of cationic hyaluronic acid to significantly reduce the cytotoxicity of CS NPs. Our findings are important to accelerate the translation and utilization of HA-CS NPs in drug delivery, demonstrating the pronounced effect of surface modifications on modulating the biological behaviors.

NM04.12.23

Formation of Metal Nanoparticles Directly from Bulk Sources Using Ultrasound and Application to E-Waste Upcycling

We present a method for creating nanoparticles directly from bulk metal sources using ultrasound, therefore bypassing high energy and potentially toxic intermediates and increasing atom efficiency. Nanoparticle formation occurs in water, in the presence of a bilayer forming surfactant system. Implosive collapse of cavitation bubbles occurs asymmetrically near the bulk metal surface, which generates powerful microjets leading to material ejection. This liberated material is captured by the surfactant bilayer and stabilized in the form of nanoparticles. The method is first characterized in detail using gold, but is also demonstrated on other metals and alloys, and is generally applicable. We show that nanoparticles can be produced from a number of different bulk metal form factors, as long as there is a sufficiently large planar surface to induce asymmetric bubble collapse. We then extend the method to an environmentally important problem, the reclamation of gold from an electronic waste stream.

Highly Efficient Oil/Water Separation by Superhydrophobic/Superoleophilic Sponges Based Oil Skimmer

Functional materials inspired from lotus leaves possess outstanding water repellency and oil affinity simultaneously, which refers to superhydrophobicity and superoleophilicity, respectively. By utilizing the contrary extreme wettability to water and oil, such bio-inspired functional materials can be used for oil/water separation. In recent years, oil/water separation has received extensive attention owing to the growing oil pollution problem caused by oil spills, domestic sewage and industrial effluents. Therefore, the fabrication of functional materials for oil/water separation has been a research hotspot. However, most of the methods to fabricate the extreme wettability materials involve the use of toxic chemical reagents and complex processes. Herein, a simple and efficient immersion method is presented to prepare superhydrophobic/superoleophilic sponges for sustained separation of oil/water mixtures. The sponge with super-wettability is fabricated by dipping common polyurethane sponge in cupric stearate solution. The introduced micro/nanostructures and long-chain alkyl group of cupric stearate enable the sponge to be superhydrophobic and superoleophilic in air. Water droplets can be supported as spheres with contact angles above 158° and can easily roll off from the surface, while oils can spread completely on the sponges. The prepared sponge can maintain its superhydrophobicity after being fixed under water for more than 4 hours, showing good durability and stability. By employing the as-prepared superhydrophobic/superoleophilic sponges, a large-scale oil skimmer is designed to collect oil spills with a wide range of kinematic viscosities (0.42–74.4 cSt at 40 °C). Results show that the floating oils can be successfully separated from the mixtures with separation efficiencies above 90% for different oils. Additionally, no water is observed in the separated oils, demonstrating high purity of the collected oils. This facile, environmentally friendly and efficient method could offer a new perspective on practically solving pollution caused by oily industrial/domestic wastewater and oil spills.

NM04.12.25

Aldehyde Gas Detection Based on Cellulose Colorimetric Films

Aldehyde gas detection based on cellulose colorimetric films is of great importance for monitoring environmental gases. We demonstrate that cellulose-based colorimetric films can be utilized for the detection of aldehyde gases from food deterioration, especially the rancidity of fat. The film is fabricated by cellulose and nanocellulose fibers on a reflectant metal surface such as Au or Ag. By simple dip and pulling method, cellulose-based films with diverse colors from dark blue to yellow are formed. The color range can be controlled by changing the layer thickness from 46 nm to 165 nm with the pulling speed (from 1 mm/min to 10 mm/min) and drying conditions (from 58 to 60% relative humidity) during the self-assembly of cellulose fibers. Afterwards, the films are functionalized with amine groups to make them sensitive to aldehyde gases. When the film is exposed to the target gas, this functionalization intensifies structural color change and makes it possible to detect aldehyde gas down to several ppm. We demonstrate that sensing data analysis with a phone camera and discriminant analysis algorithms can tell apart the different gases to which the sensor is exposed. We expect that our results will be utilized in providing a low-cost and low-power systems for the monitoring of environmental gases.
covered CdTe/CdS QDs are facilely decorated with the low cost sulfur tolerant [Mo3S13]2− nanoclusters to exhibit enhanced visible-light photocatalytic H2 generation than the CdTe QDs catalyzed with classical cocatalysts of Pt. In all, the combination of sulfur tolerant [Mo3S13]2− nanoclusters and CdTe/CdS core/shell structure significantly enhance the activity and stability of CdTe QDs for visible-light photocatalytic hydrogen evolution.

Detection of Environmental Imidacloprid Using a Molecularly Imprinted Polymer Sensor Alyson G. Michael and Joseph J. BelBruno; Dartmouth College, Hanover, New Hampshire, United States.

A sensor for the environmental detection of the neonicotinoid pesticide imidacloprid has been designed by leveraging the selectivity of molecular imprinting and the sensitivity of conductive polyaniline nanowires. Imidacloprid is a widely used pesticide that has been linked to declines in bee populations. Imidacloprid from solution hydrogen bonds with imprinted PMMA-co-PMAA, and de-dopes the surrounding polyaniline nanowires, thereby increasing the resistivity of the system. The success of the system is justified by LCMS, FTIR spectroscopy, and resistance measurements. The sensor permits straightforward monitoring of the presence of imidacloprid in the environment and the assessment of sustainable bee keeping practices.

SESSION PM01.01: Shape Morphing and Origami/Kirigami Materials I
Session Chairs: Katia Bertoldi and Lorenzo Valdevit
Monday Morning, November 26, 2018
Hynes, Level 1, Room 102

8:00 AM *PM01.01.01
Shape Morphing Metamaterials Damiano Pasini; McGill University, Montreal, Quebec, Canada.

Thermal expansion can be challenging to control in applications that require thermal stability, yet it can be exploited to generate shape transformations that are highly predictable. In this talk, I will first present compliant building blocks that can deform under temperature, and then illustrate how their sequence can be encoded to attain macroscopic reconfigurations that are reversible. Investigated through theory and computations, the metamaterial behaviour is tested through proof-of-concept prototypes that show promise for deployable satellites, morphing components, and actuation devices.

8:30 AM PM01.01.02
Mechanical Instability Tuning in Architected Magnetoelastomers Vincent Chen1, 2, Artemii Goshkoderia3, Matthew Robinson1, 2, Carson Willey1, 2, Stephan Rudykh4, Abigail Juhi1 and Phil Buskohl1; 1Air Force Research Laboratory, WpaFB, Ohio, United States; 2UES, Inc., Dayton, Ohio, United States; 3Technion–Israel Institute of Technology, Haifa, Israel; 4University of Wisconsin–Madison, Madison, Wisconsin, United States.

Magnetoelastomers (MAEs) are an important class of soft, strain tolerant materials that generate a stiffness increase in response to a magnetic field. Stiffness tuning under magnetic field is advantageous due to the fast, reversible and non-contact control of the material properties, which is relevant for applications such as soft actuators, adaptive vibration dampers and acoustic filters. Architected MAE composites, such as laminates and periodic MAE inclusions in a non-active matrix, have been predicted to possess novel mechanical instabilities, due to the spatial distribution of stiffness mismatch and the ability to tune the mismatch with magnetic field. To demonstrate these concepts experimentally, we fabricated MAE composites using a commercial silicone as the non-responsive soft matrix and a silicone loaded with carbonyl iron particles for the stiff, magnetoactive regions. The silicone matrix underwent several modifications to increase the stiffness ratio between the soft encapsulating matrix and the stiff MAE regions, including tuning of the crosslinker to polymer ratio, incorporation of hydride-terminated silicone to promote a linear network, and addition of silicone oil to further reduce crosslinking. Laminates and 2D periodic MAE architectures were constructed through a series of drop casting and molding steps using 3D printed molds. A custom compression test jig was developed to systematically load the laminate specimen in the presence of a magnetic field. The study provides feedback on the sensitivity of the buckling strain to experimental specimen sizing/edge effects and provides broader insight on the practical integration of MAE instabilities into functional devices.

8:45 AM PM01.01.03
Field Responsive Architected Materials Julie A. Mancini1, 2, Mark Messner3, William L. Smith1, Logan Bekker1, Bryan Moran1, A. M. Golobic1, Andrew Pascale1, Eric B. Duoss1, Kenneth J. Loh2, 4 and Christopher M. Spadaccini1; 1LLNL, Livermore, California, United States; 2Mechanical Engineering,
We present a method of creating field responsive architected materials by combining additive manufacturing with magnetorheological (MR) fluid. MR fluid, a fluid that commonly consists of oil and magnetic particles, goes through a change in its rheological properties under a magnetic field. This rheological change observed in the MR fluid is on the order or milliseconds and is highly reversible. We demonstrate these field responsive architected materials by infilling tubular cuboctahedron unit cells and lattices with MR fluid. The result is a dynamically tunable structure that can rapidly and reversibly change its effective stiffness through the simple application of a magnetic field without changing its overall form. We will also discuss a predictive model that we have created to aid in future design of these field responsive architected materials. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. Supported by LDRD Strategic Initiative 14-SI-004. LLNL-ABS-753060.

**3D Uniaxial Chiral Metamaterials with Ultra-long Characteristic Length Scale**

Patrick Ziemke* and Peter Gumbsch1, 2; 1Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Fraunhofer Institute for Mechanics of Materials, Freiburg, Germany.

Ordinary linear elastic materials do not exhibit a chiral mechanical response. This means that they do not convert a stretch or a compression into a twisting deformation mode. Recent research into the fabrication and design of metamaterials has made this degree of freedom accessible. By stacking 3D laser printed unit cells in each spatial direction, Frenzel et al.[1] created samples of a chiral mechanical metamaterial and successfully mapped its behavior onto a micropolar continuum[2]. Micropolar continuum theory predicts that the magnitude of the twist decreases inversely proportional to the ratio of the sample size to the size of one unit cell. To maintain the global chiral response for larger samples, the scaling behavior must be manipulated to minimize the decay of the twist.

This can be approached by either increasing the intrinsic chiral response of the material or by decreasing the coupling strength for the chiral component of the distortion. We attempt the latter and approach it with three-dimensional lattices based on a geometrically simple uniaxial chiral unit cell. Such simple structures can be modeled with reduced-order finite element formulations (cf. [3]) yielding an efficient numerical technique which allows the execution of extensive parameter studies with large three-dimensional samples.

We combine chiral unit cells with non-chiral coupling elements to form different lattices. Chiral and non-chiral elements can then be arranged just like in binary crystals forming CsCl or NaCl structures and the like. By testing different structures and tuning the properties of the different unit cells, we have designed lattice structures exhibiting an ultra-long decay-length compared to previously presented chiral mechanical metamaterials. In fact, some of our structures show an increasing chiral response at small numbers of unit cells and do not show a significant decay in the chiral response up to an edge length of 20 unit cells.

**9:15 AM PM01.01.05**

**Deployable Multi-State Structures via Pre-Strained, Multistable Elements**

Jochen Mueller1, 2, Jennifer Lewis1, 2 and Katia Bertoldi1, 2; 1John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 2Wyss Institute for Biologically Inspired Engineering, Harvard University, Cambridge, Massachusetts, United States.

Inspired by the shape memory of crumpled sheets and prior art on multistable structures, we present a new type of architectural metamaterial that can be fabricated flat and buckle out-of-plane to form complex shapes with defined load bearing capacity. The material is composed of discrete elements, of which the sides are exposed to different levels of pre-strain, locally induced during fabrication. Through experiment and simulation, we show that the elements buckle out of plane into different, stable states when exposed to small, orthogonal loads. The resulting, global shape can be pre-programmed via local pre-stress levels or changed by the fly via the activation sequence. By adding additional hierarchy levels, large displacements are achieved. All deformations are elastic and, hence, reversible. This reprogrammable and versatile material is expected to find application in a range of small and large-scale structures, such as deployable space frames and robotic manipulators.

**10:00 AM PM01.01.06**

**Morphing Sheets into Freeform Objects, at the Micro- and Macro-Scales**

Chiara Daraio; California Institute of Technology, Pasadena, California, United States.

Morphing two-dimensional sheets into three-dimensional objects is a classical problem in mechanics, mathematics and art. Today, the ability to manufacture two-dimensional materials with an almost arbitrary microstructure, architecture and pre-stress distribution opens the door to new approaches for bending sheets into complex forms. In this talk, I will review recent progress in the design of micro- and macro-scale, nonuniform sheets that can bend into freeform objects. Engineering the distribution of residual stresses, stiffness gradients and/or cut patterns, we control the buckling of sheets at both local and global scales. The designed distribution of responsive materials within the sheets provides a time dependent control of the developing shapes. I will discuss examples of sheets that change shape in response to environmental stimuli or the application of point loads. Programming 2D sheets into rigid, 3D geometries expands the potential of existing manufacturing tools for efficient and versatile production of 3D objects.

**10:30 AM PM01.01.07**

**Atomic Origami—A Technology Platform for Nanoscale Machines, Sensors and Robots**

Itai Cohen; Cornell University, Ithaca, New York, United States.

What would we be able to do if we could build cell-scale machines that sense, interact, and control their micro environment?
In Richard Feynman’s classic talk “There’s Plenty of Room at the Bottom” he foretold of the coming revolution in the miniaturization of electronics components. This vision is largely being achieved and pushed to its ultimate limit as Moore’s Law comes to an end. In this same lecture, Feynman also pointed to the possibilities that would be opened by the miniaturization of machines. This vision, while far from being realized, is equally tantalizing. For example, even achieving miniaturization to micron length scales would open the door to machines that can interface with biological organisms through biochemical interactions, as well as machines that self-organize into superstructures with mechanical, optical, and wetting properties that can be altered in real time. If these machines can be interfaced with electronics, then at the 10s of micron scale alone, semiconductor devices are small enough that we could put the computational power of the spaceship Voyager onto a machine that could be injected into the body. Such robots could have on board detectors, power sources, and processors that enable them to make decisions based on their local environment allowing them to be completely untethered from the outside world.

In this talk I will describe the work our collaboration is doing to develop a new platform for the construction of micron sized origami machines that change shape in fractions of a second in response to environmental stimuli. The enabling technologies behind our machines are graphene-glass and graphene-platinum bimorphs. These ultra-thin bimorphs bend to micron radii of curvature in response to small strain differentials. By patterning thick rigid panels on top of bimorphs, we localize bending to the unpatterned regions to produce folds. Using panels and bimorphs, we can scale down existing origami patterns to produce a wide range of machines. These machines can sense their environments, respond, and perform useful functions on time and length scales comparable to microscale biological organisms. With the incorporation of electronic, photonic, and chemical payloads, these basic elements will become a powerful platform for robotics at the micron scale. As such, I will close by offering a few forward looking proposals to use these machines as basic programmable elements for the assembly of multifunctional materials and surfaces with tunable mechanical, optical, hydrophobic properties.

11:00 AM PM01.01.08
Reconfigurable Rotationally Symmetric Kirigami Structures and Their Applications
Erin Evke, Dilara Meli, Tristan Blanzy and Max Shelnit; Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Kirigami design principles increasingly are being used to engineer auxetic materials and structures to achieve 2D to 3D transformations and precisely tune their physical properties. Here, we design, fabricate, and characterize rotationally symmetric kirigami (RSK) structures with complex elasticity, allowing for deformations of planar sheets to approximate curved surfaces and reversibly undergo large deflections. A combination of theory, finite element modeling, and experiments are used to depict the relationship between the cut pattern and the structure’s cross-plane deformation. We classify the RSK structures based on the order of rotational symmetry, defined by the number of sides and cuts along the perimeter. While in the planar, relaxed state, RSK structures exhibit inversion symmetry; this is broken upon cross-plane deformation, a property that may be of interest in controlling wave propagation. The deformed state can be interpreted as a superposition of deformed sub-units, in which the total deflection is a summation of the individual rings’ displacements. The rings can further be partitioned into beams that correspond to the cut geometry, which strongly influences the mechanical properties. We find the effective spring constant decreases with radial cut density but increases with azimuthal cut density, resulting in a theoretical 200-fold reduction in stiffness over the noncut membrane. To demonstrate the electrical characteristics and feasibility of RSK structures for flexible electronic applications, we fabricate conductive nets that maintain electrical properties even under large strains, well beyond 100,000% of the original profile. We also show the reconfigurability of the structures using thermally activated shape memory polymers and analyze their fatigue mechanism.

11:15 AM PM01.01.09
Inflatable Origami-Inspired Structures
David Melancon1, Chuck Hobern1, 2, Jason Ku3, Erik Demaine4 and Katia Bertoldi1, 3; 1John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 2Graduate School of Design, Harvard University, Cambridge, Massachusetts, United States; 3Wyss Institute, Boston, Massachusetts, United States; 4Computer Science and Artificial Intelligence Laboratory, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Origami has long been used as a source of inspiration to design creative and esthetic constructions, from the iconic paper swan to facades of multi-story buildings. More recently, the rules of folding have been applied to fabricate architectured materials with functional properties such as compactness, self-foldability, and multi-stability. These properties highlight the potential of origami to become a new design paradigm for rapidly deployable structures. Whereas multiple origami-inspired deployable surfaces have been reported in the literature, there is a lack of research on enclosed deployable geometries. In this work, we introduce a novel type of inflatable origami-inspired structure comprised of a polyhedron with triangular faces and elastic hinges. From simple geometry principles, this star-shaped structure possesses two compatible configurations – flat-folded and deployed – giving rise to a bi-stable behavior. Based on experiments of prototypes and simulations of an energy-based model, we characterize the mechanics of the deployment and explore the design space of this origami-inspired structure. The insights gained from the study of this simple geometry enable understanding the enabling of the folding principles of a novel class of enclosed origami-inspired structures that can be deployed to different stable configurations through inflation.

11:30 AM PM01.01.10
Kirigami Inspired-Metamaterials—From Morphable Structures to Soft Robots
Katia Bertoldi; Harvard University, Cambridge, Massachusetts, United States.

In recent years kirigami has become an emergent tool to design programmable and reconfigurable mechanical metamaterials. Kirigami-inspired metamaterials allow the practitioner to exploit cuts in addition to folds to achieve large deformations and create 3D objects from a flat sheet. Therefore, kirigami principles have been exploited to design highly stretchable devices and morphable structures.

In this talk I will show that precreased folds are not necessary to form complex 3D patterns in kirigami, as mechanical instabilities in flat sheets with an embedded array of cuts can result in out-of-plane deformation. Furthermore, by largely stretching the buckled perforated sheets, plastic strains develop in the ligaments. This gives rise to the formation of kirigami sheets comprising periodic distribution of cuts and permanent folds. As such, the proposed buckling-induced pop-up strategy points to a simple route for manufacturing complex morphable structures out of flat perforated sheets. Finally, I will also show that kirigami principles enable the design of morphable and transformable skins that facilitate the design of soft robots capable of locomotion.

11:45 AM PM01.01.11
Kirigami Inspired Self-Folding
Aref M. Abdullah1 and K. Jimmy Hsia2; 1Mechanical Science and Engineering, University of Illinois at Urbana–Champaign, Urbana, Illinois, United States; 2Mechanical Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Realization of complex programmable metamaterials where the structural characteristics and functionalities could be tuned beyond their original, as fabricated design remains as one of the challenging problems within the research field of architectured materials. To that end, Kirigami - the art of cutting and folding flat sheets of paper, provides scalable routes to generate intricate three-dimensional shapes from thin, planar (two-dimensional) sheets of materials. Researchers have utilized mechanical force actuated Kirigami structures in functional disciplines as diverse as energy harvesting, actuation, optics, stretchable electronics, and soft robotics. Achieving shape reconfiguration of freestanding, Kirigami-cut sheets in a stimuli-responsive, autonomous manner would not only enable new functionalities but also contribute to self-assembled...
This work aims to understand the self-folding behavior of Kirigami-cut bilayers where one layer isotropically expands with respect to the other in response to an external stimulus. We investigate two distinct types of cut geometries namely squares with radial cuts and rectangles with side cuts through a combination of nonlinear finite element modeling and experiments with soft polymeric systems. The Kirigami cuts decompose the pristine squares and rectangles into interconnected beams (length >> width) and plates (length ~ width) of varying aspect ratios. Our finite element calculations reveal that it is possible to tune both the bending direction and curvature values of each individual geometric units within the Kirigami-cut structures and thus transform the bilayers into complex three-dimensional architectures with spatially varying bi-directional curvatures in an on-demand manner. To experimentally demonstrate the potential of our approach, we design planar bilayered samples with side cuts and swell them in organic solvents to generate letters from the English alphabet to make up "UIUC" (University of Illinois at Urbana-Champaign) and "MRS" (Materials Research Society). We also design bilayers with radial cuts, and as they transform shapes with varying mismatch strains (solvent concentrations), we show that it is possible to use them as freestanding tunable optical systems where the transmission and reflection windows for incident light could be controlled through the deformation behavior of individual geometric units between the cuts. We also use a combination of the cuts to realize polyhedral shapes (such as tetrahedron and cube) through the self-folding of planar bilayers. The design principles proposed in this work would be applicable to a variety of material systems across length scales and contribute toward the development of smart programmable metamaterials.

SESSION PM01.02: Shape Morphing and Origami/Kirigami Materials II
Session Chairs: Damiano Pasini and Martin Wegener
Monday Afternoon, November 26, 2018
Hynes, Level 1, Room 102

1:30 PM *PM01.02.01
Sequential Mechanical Metamaterials Martin Van Hecke; Leiden University, Leiden, Netherlands.

Ordered sequences of motions govern the morphological transitions of a wide variety of natural and man-made systems, while the ability to interpret time-ordered signals underlies future smart materials that can be reprogrammed and process information. Here we introduce two novel classes of mechanical metamaterials, that can (1) exhibit sequential output and (2) are sensitive to sequential input. To obtain metamaterials that translate a global uniform compression into a precise multistep pathway of reconstructions, we combine strongly nonlinear mechanical elements with a multimodal hierarchical structure, and demonstrate multi-step reconstructions of digitally manufactured metamaterials. To obtain metamaterials that are sensitive to a sequence of mechanical inputs, we introduce the notion of non-commuting metamaterials, and show their capability for storing and processing information. Our work establishes generic principles for infusing metamaterials with sequential input and output.

2:00 PM PM01.02.02
In Situ Tunable Stiffness Using Multistable Kirigami Metamaterials Yi Yang1, Marcelo Dias2 and Douglas Holmes3; 1Boston University, Boston, Massachusetts, United States; 2Aarhus University, Aarhus, Denmark.

Materials with in situ tunable stiffness are needed for engineering programmable materials, shape-shifting structures, artificial muscles, and soft robotic actuators. While most examples of materials with in situ tunable stiffness focus on stimulus-responsive material properties, recent investigations on reconﬁgurable mechanical metamaterials opened another door to attain tunable material properties by systematically programming the microstructure of a constituent material. The mechanical properties of these architected materials depend on the topology of the substructure regardless of the constituent materials used. By introducing morphological structures into the unit cell, reprogrammable and reconﬁgurable metamaterials can be attained. Among various types of mechanical metamaterial, kirigami and origami metamaterials attracted tremendous attention due to its robust and straightforward ability to transform 2D sheets into 3D structures. Compared with its sister, origami metamaterials which have been extensively studied, understanding the mechanical behavior of kirigami metamaterials is limited. In this study, through a combination of experiments, simulation, and theoretical analysis, we demonstrate how a multistable microstructure inspired by kirigami provides a new design approach. By changing the spacing between the adjacent slits in the conventional linear parallel cutting patterns, we obtain multistable kirigami lattice structures composed of repeating unit cells whose structure is endowed with a bistable snap-through mechanism. Each stable state of the mechanical metamaterial exhibits a corresponding stiffness. By switching unit cells between the two stable states, we can tune the stiffness of this kirigami metamaterial in situ by a factor of five. Since this multistable kirigami approach is material independent, it could be integrated with stimulus-responsive materials, 3D printing technique, or combined with origami structures to be applied in multifunctional materials, deployable space structures, soft robotics, and biomedicine.

2:15 PM PM01.02.03
Observation of Mechanical Activity in a 3D Chiral Metamaterial Tobias Freznel1, Muamer Kadic1,2 and Martin Wegener3,4; 1Institute of Applied Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Institute of Nanotechnology, Karlsruhe Institute of Technology, Karlsruhe, Germany; 3FEMTO-ST, Université de Bourgogne Franche-Comté, Besançon, France.

In a medium exhibiting optical activity, an incident transverse linear polarization of a light wave rotates because the eigenpolarizations of the chiral medium are not linear but rather circular, with a lifted degeneracy between left- and right-handed circular modes. Therefore, a linear incident polarization must be decomposed into the two circular eigenpolarizations, which propagate with different phase velocities. The resulting phase difference accumulated during propagation leads to a periodic rotation of the linear polarization axis versus the propagation coordinate. A rotation by 90 degrees corresponds to mode conversion.

Regarding elasticity, a different kind of mode conversion has recently been observed in two-dimensional (2D) centrosymmetric metamaterials [1]. There, the conversion between in-plane longitudinal (compression) and in-plane transverse (shear) modes did not require chirality. Chirality is crucial in quasi 2D monolayers of non-centrosymmetric tungsten diselenide crystals, for which the presence of chiral phonons [2] was deduced via selection rules of optical transitions.

In this contribution, we report the first experimental observation of mechanical activity, the elastic counterpart of optical activity, in 3D chiral polymer microlattices [3]. We have previously investigated related 3D chiral micropolar metamaterial samples made by 3D laser nano imprinting in the static regime [4]. Our present experimental approach in the dynamic regime is based on cross correlations of microscopy images taken under phase-delayed synchronized stroboscopic illumination with a light-emitting diode and sinusoidal excitation of the sample with a piezoelectric actuator. This approach is distinct from the established mapping of out-of-plane surface excitations by interferometric laser detection and laser excitation (see, e.g., [5]).

For an incident linearly polarized transverse elastic wave, we demonstrate the polarization rotation by 90 degrees at 225 kHz frequency over as few as 10
unit cells in the axial direction, with 3-by-3 unit cells in the cross section. The experimental results are in good agreement with numerical finite-element calculations for finite beams as well as with band structure calculations for fictitious infinitely extended beams. These experiments pave the road for molding the polarization and the propagation direction of elastic waves in three dimensions by micropolar mechanical metamaterials.

Architected Nanocomposites as Model Materials for Armor Systems
Anna Guell Izard, Jens Bauer and Lorenzo Valdevit; Mechanical and Aerospace Engineering, University of California, Irvine, Irvine, California, United States.

Armor systems must be carefully designed to mitigate two threats: blast and penetration. A successful armor dissipates the kinetic energy of the blast via plastic deformation while being able to resist the penetration of a projectile. These functional requirements require a material with high toughness and hardness, two properties that are generally mutually exclusive in monolithic materials. Current armor solutions consist of multi-layer systems encompassing one or more metallic or polymeric phases for energy absorption and a ceramic phase for penetration resistance. Here we propose a novel strategy based on the optimal design of functionally graded micro/nano-architected ceramic/polymer or ceramic/metal composites. The optimal intertwining of the two phases at the nanoscale has the potential to vastly outperform current solutions, while reducing weight. In this talk, we will present the performance of ceramic/metal and ceramic/polymer architected nanocomposites based on ordered lattice topologies and spinalod architectures.

4:15 PM PM01.03.03
Mechanical Behaviour of Architected Auxetic Hybrid Lattice Structures
Frédéric Albertini1, Justin Dirrenberger1, André Molotoiak2 and Cyrille Solligoub1; 1PIMM, CNRS, Paris, France; 2Material Science and Engineering, Monash University, Clayton, Victoria, Australia.

Architected Materials are an emerging class of advanced materials that bring new possibilities in terms of functional properties, filling gaps in Ashby’s material performance maps. The term architected materials describes any heterogeneous material that exhibits improved specific properties due to a thoughtful and predetermined morphology and/or topology design. This usually induces characteristic length-scales comparable to the size of the final component being produced, i.e. the millimetre scale in the case of lattice structures. Different strategies have been studied in the literature for mitigating the surface defects of additively manufactured metallic lattices: chemical etching, electro-erosion, mechanical polishing. A new proposition is presented in this work: polymer coating or embedding of metal struts, by analogy to the soft-hard turtle-like strategy for mitigating crack propagation. Besides processing of such architected lattice structures, the present work brings experimental and numerical results concerning the mechanical behaviour in compression for negative Poisson’s ratio lattices, also known as auxetics. As a matter of fact, one engineering challenge is to predict the effective mechanical properties of architected materials; computational homogenization using finite element analysis is a powerful tool to do so when considering quasi-static behaviour; difficulties arise when analysing the effective damping behaviour. A straightforward solution is to rely on full-field finite element dynamic simulation, accounting for the intrinsic viscoelastic damping of the constitutive material, as well as the structural damping due to the geometrical definition of the lattice structure considered in the present work. Homogenized behaviour of architected materials can thus be used in large structural computations, hence enabling the dissemination of such materials in the industry. Comparison is made between the metal and hybrid lattice structures.

4:30 PM PM01.03.04
Architected Viscoelastic Impact Attenuators for Sports Padding Applications
Eric C. Clough1, 2, Zak Eckel1, Alvin Escobar1, Jacob Hundleby1 and Tobias Schaedler1; 1HRL Laboratories, Malibu, California, United States; 2Materials, University of California Santa Barbara, Santa Barbara, California, United States.

Mitigating injury as a result of an impact between multiple players or between a player and the ground presents a significant challenge to the sports protective equipment designer. These designs must consider multiple injury criteria (e.g. concentrated loads, peak acceleration, peak torque) for multiple successive impacts, while balancing human factors such as comfort and player mobility. For padding components, maximal volumetric energy absorption is key to achieving impact attenuation performance without sacrificing player mobility. Typical padding materials include urethane and vinyl nitrile closed-cell foams which attenuate impacts through the collapse of internal pores when compressed. The stochastic internal geometry of foams limits optimal design of foam pads to essentially two design variables: composition and apparent density. Conversely, lattices provide the designer with a host of architectural degrees of freedom enabling the optimal design of lattice pads that can significantly outperform foams through tuning of buckling and post-buckling response. The open-celled architecture of lattices additionally affords improvements in airflow for comfort or enhanced energy absorption. In this talk, we will present our recent work on the design, fabrication, and optimization of lattice padding materials fabricated via HRL’s rapid and scalable self-propagating photopolymer waveguide process. We demonstrate that by optimal design of the architecture, in conjunction with tuning the viscoelastic properties of the parent solid, lattice pads with impact attenuation performance exceeding 1.3X that of state-of-the-art foam padding can be achieved.

4:45 PM PM01.03.05
Plate Mechanical Metamaterials and Their Applications
Igor Bargatin; Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Wynnewood, Pennsylvania, United States.

Recently, we introduced the concept of plate mechanical metamaterials—cellular plates with carefully controlled periodic geometry and unique mechanical properties—as well as its initial realization in the form of freestanding corrugated plates made out of an ultrathin film. We used atomic layer deposition (ALD) and microfabrication techniques to make robust plates out of a single continuous ALD layer with cm-scale lateral dimensions and thicknesses between 25 and 100 nm, creating the thinnest freestanding plates that can be picked up by hand. More recently, we also fabricated and characterized plate metamaterials made from multiple layers of nanoscale thickness, whose geometry and properties are reminiscent of honeycomb sandwich plates or corrugated paper cardboard. The two layers are offset from each other but at the same time are connected using vertical-wall webbing, which prevents shear of the two layers with respect to one another. As a result, these “nanocardboard” plates orders-of-magnitude higher bending stiffness than the single-layer structures we reported earlier, while still possessing extremely low weight (as low as 0.5 g/m²) and mechanical robustness. The increase in the bending stiffness is expected, and its mechanism is similar to that used in conventional honeycomb sandwich plates, which offer the best possible combination of high bending stiffness and low mass. However, in contrast to sandwich composite plates, our nanoscale two-layer mechanical metamaterials can sustain extremely large deformations without fracture, fully recovering their original shape and not displaying any signs of internal damage.

Like the nanotuss-based mechanical metamaterials reported by other groups, plate mechanical metamaterials are extremely lightweight and resilient due to their nanoscale thickness and microscopic cellular structure. However, in contrast to the cube-shaped metamaterials that typically form a lattice easily penetrated by the ambient air, our plates form continuous flat plates. Ultralow weight, mechanical robustness, thermal insulation, as well as chemical and thermal stability of alumina make plate metamaterials attractive for numerous applications, including structural elements in flying microbots and interstellar light sails, high-temperature thermal insulation in energy converters, photophoretic levitation, as well as ultrathin MEMS/NEMS sensors and resonators. I will briefly discuss our experimental progress on all these applications, including demonstration of extremely robust thermal insulators that can sustain a temperature difference of ~1000 C across a micron-scale gap, macroscopic plates that levitate when illuminated by light, and hollow AFM cantilevers that offer greatly enhanced sensitivity and data acquisition rates.

**Materials by Design—Three-Dimensional (3D) Nano-Architected Meta-Materials** Julia R. Greer, Andrey Vyatskikh, Carlos M. Portela, Xiaoxing Xia and Arturo J. Mateos; California Institute of Technology, Pasadena, California, United States.

Creation of extremely strong and simultaneously ultra lightweight materials can be achieved by incorporating architecture into material design. We fabricate three-dimensional (3D) nano-architectures, i.e. nanolattices, whose constituents vary in size from several nanometers to microns or even centimeters. These nanolattices can exhibit superior thermal, photonic, electrochemical, and mechanical properties at extremely low mass densities (lighter than aerogels), which renders them ideal for many scientific pursuits and technological applications. The dominant properties of such meta-materials, where individual constituent size at each relevant scale (atoms to nanometers to microns) is comparable to the characteristic microstructural length scale of the constituent solid, are largely unknown because of their multi-scale nature. To harness the beneficial properties of 3D nano-architected meta-materials, it is critical to assess properties at each relevant scale while capturing the overall structural complexity.

We describe the fabrication and synthesis using Additive Manufacturing (AM) techniques, as well as the mechanical, biochemical, electrochemical, and thermal properties of nanolattices made of different materials with varying microstructural detail. Attention is focused on uncovering the synergy between the internal atomic-level microstructure and the nano-sized external dimensionality, where competing material- and structure-induced size effects drive overall response and govern these properties. Specific discussion topics include the nanofabrication and characterization of (often hierarchical) three-dimensional nano-architected meta-materials and their applications in chemical and biological devices, ultra lightweight energy storage systems, damage-tolerant fabrics, and photonic crystals.

8:30 AM PM01.04.02 
**Nanocrystalline Aluminum Truss Cores for Lightweight Sandwich Structures** Tobias Schaedler¹, Lisa Chan², Eric C. Clough³, Morgan A. Stilke³, Lawrence J. Masur² and Jacob Hundle³; ¹HRL Laboratories, LLC, Malibu, California, United States; ²Xtalic Corporation, Marlborough, Massachusetts, United States.

Substitution of conventional honeycomb composite sandwich structures with lighter alternatives has the potential to reduce the mass of future vehicles. Here we demonstrate nanocrystalline aluminum - manganese truss cores that achieve 2 - 4 times higher strength than aluminum alloy 5056 honeycombs of the same density. The scalable fabrication approach starts with additive manufacturing of polymer templates, followed by electrodeposition of nanocrystalline Al-Mn alloy, removal of the polymer, and facesheet integration. This facilitates curved and net-shaped sandwich structures, as well as coating of the facesheets, which eliminates the need for extra adhesive. The nanocrystalline Al-Mn alloy thin -film material exhibits high strength and ductility and can be converted into a three-dimensional hollow truss structure with this approach. Ultra-lightweight sandwich structures are of interest for a range of applications in aerospace, such as fairings, wings, and flaps, as well as for the automotive and sports industries.

8:45 AM PM01.04.03 
**Additive Manufacturing and Design of Multi-Functional 3D Architected Metamaterials** Xiaoyu Zheng; Virginia Tech, Blacksburg, Virginia, United States.

Rapid progress in additive manufacturing methods has led to the creation of a new class of ultralight, stiff and strong 3D architected metamaterials comprised of a network of hierarchical, stretch-dominated, micro-scale unit cells. The performance of these micro-architected metamaterials, spanning across multiple length scales, will ultimately be limited by their tolerance to damage and defects, yet an investigation of their fracture toughness has remained elusive. Here, we provide the first experimental observations of different crack initiation modes activated by model -loading of notched low density, hierarchical metamaterials. We find that, through hierarchical micro-architected features, the low density, stretch-dominated metamaterials can achieve simultaneously higher fracture toughness and strength: properties that are usually mutually exclusive. Numerical and scaling relationships are also reported that accurately capture the measured fracture toughness and strength values. These are then used to develop design maps for the optimal hierarchical architectures as functions of the density of the metamaterial and failure strain of the parent material.

9:00 AM PM01.04.04 
**Subtractive Post-Processing to Create Delicate Nano-Scale Structures** Andrew Gross and Katia Bertoldi; Harvard University, Cambridge, Massachusetts, United States.

Two photon polymerization (TPP) has become a popular technique for testing new devices and designer materials at the nano and micro scales. This technique provides much of the flexibility of a desktop 3D printer with access to physics that are uniquely scale dependent. Like every additive manufacturing technique, TPP is limited to a minimum achievable size for the voxel that can be rastered to create a structure. The constraint on reducing the size of the voxel is a practical limit arising from both the spatial photon density distribution within the diffraction limited focal volume of the laser illumination and the contrast curve of the photoreisit that describes the degree to which it polymerizes in response to exposure at a certain dose. Here, we present an approach for achieving smaller feature sizes that is accessible to researchers without specialized equipment. This approach leverages the high resolution of a piezo stage to precisely raster the voxel into shapes that upon isotropic etching allow access to a smaller length scale. Free-standing fully three-dimensional structures with feature sizes under 100 nm are demonstrated. Additionally, this technique allows for the fabrication of structures which are otherwise too delicate to make. This is achieved both by simply etching a structure of interest to impart more slender features, and also by including secondary support material to create complex structures that cannot be fabricated by any other method at this length scale.

9:15 AM PM01.04.05 
**Carbon-Based Nanolattice Materials** Jens Bauer, Anna Guell, Cameron Crook and Lorenzo Valdevit; University of California, Irvine, Irvine, California, United States.

From a traditional perspective, there is little room for further expansion of the accessible material property space by classical material fabrication methods.
Single one- and two-dimensional nanoscale objects, such as nanowires and thin films, are known to exhibit exceptional physical properties. Yet, their properties are intrinsically coupled to their small size and, therefore, can hardly be accessed in actual materials of practical volume. If nanowires and thin films are simply scaled up, many of their exceptional properties, which relate to surface to volume effects, drop dramatically; similarly, if nanoscale objects are clustered in a composite material, interfaces dominate the overall behavior, again substantially reducing performance. Nanolattice materials, regular three-dimensional networks constructed from nanowires or thin films, can potentially resolve this dilemma. Nanolattice materials can be thought of as metamaterials which can scale up beneficial size effects by topological design of their architecture.

In our work, we have fabricated carbon-based nano-architected lattice materials by direct laser writing (DLW) and pyrolysis. The combination of DLW and pyrolysis facilitates complex three-dimensional carbon-based ceramic structures of uniquely high resolution, with feature dimensions below 100 nm. This enables to take advantage of pronounced size-dependent effects on material strength. We systematically investigate the effects of processing parameters, dimensional scale, topology and topology-dependent strain during pyrolysis on the mechanical and functional properties of nanolattices. Here, we offer an overview of manufacturing routes, with emphasis on the key processing parameters. The interplay of size-dependent effects with different topological and material design approaches is emphasized.

Designing and Manufacturing Cellular Mechanical Metamaterials
Carolin Körner1,2 and Maximilian Wormser2; 1Chair of Materials Science and Engineering for Metals, FAU Erlangen-Nuremberg, Fürth, Germany; 2Joint Institute of Advanced Materials and Processes (ZMP), FAU Erlangen-Nuremberg, Fürth, Germany.

The geometrical structure of a material can drastically change its mechanical behavior. Mechanical metamaterials are architected structures with extreme properties that surpass the capabilities of conventional bulk material. Periodic cellular structures lend themselves to be used as metamaterials because of their high variability. In the past, manufacturing methods limited the possibility to create intricate three-dimensional cellular structures. This changed with the advent of additive manufacturing technologies. Nowadays, cellular structures can be printed as polymers, ceramics or metals. Finding new shapes for cellular materials can be difficult. We developed a new method to find interesting unit cell designs by using eigenmode analysis on a basic unit cell. The eigenmode shapes of the basic cell then serve as new unit cell for further simulations. Cellular materials can have an excellent ratio of stiffness to weight, making them highly suitable for lightweight construction. By adding additional metamaterial functions to these structures, we get a so-called intelligent or smart material. An example for such a feature is auxetic behavior, i.e. a negative Poisson ratio. Therefore, if the structure is compressed, it will also compress laterally to the applied force and reduce its volume as opposed to regular materials that expand laterally.

Other metamaterial effects influence the way structures interact with mechanical waves. Given the right geometry, a structure can be unable to resonate in a certain frequency band. This effect is called phononic band gap and it can be used for wave guiding and filtering. Selective Electron Beam Melting (SEBM) is a powder-based additive manufacturing technology that enables us to produce complicated structures on a millimeter scale with very few limitations. We used this technology to create auxetic structures as well as phononic band gap structures using the above mentioned eigenmode analysis method and tested their properties. A new measurement method for mechanical wave transmission in lattice materials was developed. Piezoelectric transducers were used to create and measure the incoming and outgoing signal. The experimental results were compared to numerical simulations and were found to be in agreement with each other. By further improving the design based on gradient based optimization the phononic band gap of a macro-level unit cell could be pushed into the audible range below 20 kHz.

10:30 AM PM01.04.07
Single Atom Scale Fabrication by Scanning Transmission Electron Microscopy
Ondrej Dyck1,2, Sergei V. Kalinin1,2 and Stephen Jesse1,2; 1Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Institute for Functional Imaging of Materials, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Fabrication of atomic scale structures remains the ultimate goal of nanotechnology. The reigning paradigms are scanning probe microscopy (SPM) and synthesis. SPM assembly dates to seminal experiments by Don Eigler, who demonstrated single atom manipulation. However, stability and throughput remain issues. The molecular machines approach harnesses the power synthetic chemistry to build individual functional blocks, yet strategies for structural assembly remain uncertain.

In this presentation, I discuss research activity towards a third paradigm — the use of the atomically focused beam of a scanning transmission electron microscope (STEM) to control and direct matter on atomic scales. Traditionally, STEM’s are perceived only as imaging tools and beam induced modifications as undesirable beam damage. Our team and several groups worldwide have demonstrated that beam induced modifications can be more precise. We have demonstrated ordering of oxygen vacancies, single defect formation in 2D materials, and beam induced migration of single interstitials in diamond like lattices. What is remarkable is that these changes often involve one atom or small group of atoms and can be monitored real-time with atomic resolution. This fulfills two out of three requirements for atomic fabrication. I will introduce several examples of beam-induced fabrication on the atomic level, and demonstrate how beam control, rapid image analytics, better insight through modelling, and image- and ptychography based feedback allows for controlling matter on atomic level.

This research is supported by and performed at the Center for Nanophase Materials Sciences, sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division, BES DOE.

10:45 AM PM01.04.08
Facile Electrochemical Fabrication Route for Multicomponent and Multifunctional Inverse Opaline Films for Highly Sensitive VOC Detection
Pei-Song Hung1, Ju-Szu Chou1, Shih-Cheng Chou2, Guang-Ren Wang1, Chuan-Jyun Wang2, Yu-Ting Cheng2, Pochun Chen1, Tsung-Eong Hsieh1, Kuei Tsong Tang3 and Pei Wu1; 1National Chiao Tung University, Hsinchu, Taiwan; 2National Taiwan University of Technology, Taipei City, Taiwan; 3National Tsing Hua University, Hsinchu City, Taiwan.

Non-invasive diagnosis for early detection of diseases have drawn considerable attention during past few decades. Earlier, several biomarkers have been identified in exhaled breath specimens using GC-MS technique. However, the GC-MS analysis is a tedious process requiring high-end instruments, spacious facility, and well-trained personnel. With rapid development of artificial intelligent e-nose system, there is a promising potential serving as a portable alternative to the aforementioned analytical technique. With ultra-high specific surface area and activities, numerous nanomaterials have been explored for sensing applications. However, a dilemma often exists as researchers trying to increase the amount of materials used for enhanced sensitivity and meanwhile maintaining accessible surface area. Unlike 2D thin film sensors, 3D nanostructured sensing materials provide a larger surface-to-volume ratio with enhanced mass transfer due to their open cell configuration. Several architectures have been proposed and designed for these purposes. Among them, inverse opal (IO) is considered as a promising candidate as it possesses ordered and monodispersed porous scaffolds with numerous interconnected channels for superior permeability.
Ideally ordered nanohole array of TiO₂ has attracted attention due to its wide applicability based on the periodicity of the nanoholes, high refractive index and semiconductor properties of TiO₂. Various types of optical devices based on an ideally ordered nanohole array of TiO₂ have been proposed, such as photonic crystal, photocatalyst, solar cells and so on. Until now, several kinds of fabrication process of nanohole array structure of TiO₂ have been proposed. By applying semiconductor microfabrication process using electron beam lithography and focused ion beam etching apparatuses, an ideally ordered nanohole array could be obtained. However, this process is time consuming. By anodization process, porous TiO₂ could be obtained in large sample area. However, it is difficult to obtain ideally ordered nanohole array structure because the nanoholes in anodic porous TiO₂ usually form multi domain structure. In this presentation, fabrication process of anodic porous TiO₂ having ideally ordered nanohole array and its application to photonic crystal will be presented [1–4]. Prior to the anodization of Ti, concaves were fabricated onto the surface of Ti through a texturing process. In subsequent anodization, each concaves acted as a starting point of the formation of nanoholes, resulting in the formation of an anodic porous TiO₂ having ideally ordered nanohole array. Photonic crystal properties of the anodic porous TiO₂ were evaluated by measuring reflection spectra. In this study, we have demonstrated that photonic crystal properties were significantly enhanced by the photonic crystal fabrication process using anodization, and that these results could be applied to various optical devices.

Self-assembly of particles into long-range, three-dimensional, ordered superstructures is crucial for the design of a variety of materials, including plasmonic sensing materials, energy or gas storage systems, catalysts and photonic crystals. This kind of structures have been demonstrated mostly with spheres that, owing to their entropically favoured fcc packing, form the densest structures possible.[1] Polyhedra have been tested but so far only with metals and oxides.[2]

Here, we have combined experimental and simulation data to show that truncated rhombic dodecahedral particles of the metalorganic framework (MOF) ZIF-8 can self-assemble into millimetre-sized superstructures with an underlying three dimensional rhombohedral lattice with photonic crystal properties.[3]

These superstructures feature a photonic bandgap that can be tuned by controlling the size of the ZIF-8 particles and is also responsive to the adsorption of guest substances in the micropores of the ZIF-8 particles. Superstructures with different lattices can also be assembled by tuning the truncation of ZIF-8 particles, or by using octahedral UiO-66 MOF particles instead. These well-ordered, submicrometre-sized superstructures might ultimately facilitate the design of three-dimensional photonic materials for applications in sensing.

Robust Architected Materials—Deformation and Failure of Microlattices Under Cyclic Loading Ruth Schweiger: Karlsruhe Institute of Technology, Karlsruhe, Germany.

Cellular materials with designed nanoarchitectures have redefined the limits of the accessible material-property space throughout different disciplines.

Having characteristic features in the micro to nanometer regime, such architected materials exhibit exceptional mechanical properties at low density, including ultrahigh strength, damage tolerance, and stiffness. However, the design of lightweight structures that are both strong and damage tolerant is still a challenge and requires a better understanding of cyclic deformation and failure of the strength-optimized structures. Not only the absorbed energy during one loading cycle is important, but also the ability of the lattices to recover, maintain the strength, and be able to absorb energy during additional cycles. The highest resolution in manufacturing is currently achieved by 3D direct laser writing, which enables the fabrication of highly customized polymeric microlattices. We then apply additional processing steps, such as additional heat treatments and ceramic or metal coatings, to further improve or tailor the effective mechanical properties. While a ceramic coating in general results in enhanced strength, the failure mechanisms depend on the coating thickness. Brittle fracture of the struts rather than buckling is observed, when comparing the effect of 10 nm and 100 nm thick alumina coatings. However, in addition to high strength our solid-beam microlattices exhibit significant energy dissipation during cyclic loading experiments. Overall, the energy dissipation is a function of progressively failing ligaments, while upon multiple loading cycles to the same strain stable cyclic behavior is approached. In situ experiments showed that post-yield softening was induced by plastic buckling and crushing of individual ligaments. The contributions of the different deformation and failure mechanisms to the specific dissipated energy were quantified through progressive cyclic loading of the microlattices.

Architected Interfaces with Enhanced Fracture Toughness Kevin T. Turner1, Simon Heide-Jørgensen2, Sumukh Pande1 and Michal K. Budziszek1; 1University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2Aarhus University, Aarhus, Denmark.

Additive manufacturing has opened new opportunities for engineering the mechanical properties of materials via geometry. While there have been significant efforts in the architected materials field to exploit geometry to realize materials with unique properties such as high specific stiffness and the ability to recover from large deformations, the engineering of fracture properties and crack growth resistance via geometry is less studied. Here, we use a combination of experiments and computational modeling to investigate the role of geometric structuring on the toughness of interfaces containing arrays of pillars. Specifically, we establish quantitative relationships between toughness and geometry and to demonstrate how compliance introduced by structuring can reduce the strain energy release rate at crack tip, resulting in higher effective toughness. Toughness of architected interfaces made via laser patterning as well as additive manufacturing were measured using double cantilever beam experiments. Measurements on a relatively brittle acrylic (PMMA) and higher toughness ABS structured specimens were performed. The experimental results are in agreement with model predictions. A key and significant finding of this work is that less material can lead to higher toughness when the geometry of the interface is designed based on an understanding of the mechanics of the interface. The experiments, mechanics modeling, and an overall design strategy for using geometry to enhance interface toughness will be presented.

2:15 PM PM01.05.03
Control of Interfacial Crack Behavior via Architected Cellular Materials in 3D Printed Structures Chengyang Mo and Jordan R. Raney; Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Natural materials, with their remarkable fracture toughness and low density, have long been a source of inspiration to engineers. In recent years, researchers have made great strides in cataloging the specific mechanisms by which these properties are attained. These mechanisms arise from the very complex microstructures that are observed in natural materials, including mechanisms that arise due to internal geometric parameters (e.g., structural hierarchy, interface density, interface angle, etc.) and due to material parameters (e.g., interfacial adhesion between two distinct material types). It is often difficult to isolate the respective contributions, particularly in an experimental context, where it is difficult to precisely and uniformly control the interfacial properties between two materials along an internal interface. As one example, the Conch Shell has three different levels of hierarchy to prevent shell
fracturing under puncture loading allowing dissipation of a large amount of energy by crack divergence, with characteristic hard calcium carbonate sheets separated by soft protein layers where initial cracks form during loading. The goal of this research is to separate the effects of geometry from that of the material interface, and thereby determine how toughness can be maximized purely through a structure’s internal geometry. To do this, we fabricate structures (from a single material) that contain internal lattices, which act as weak interfaces due to their decreased relative density. Rather than relying on a material interface, internal cellular structures act as crack arresting regions with variable effectiveness based on such properties as relative density and lattice shape. We experimentally characterize fracture behavior, measuring properties such as fracture toughness, energy dissipated, and crack path in 3D printed single edge notched bend samples (SENB). We study geometric parameters including defect region orientation, lattice density, and lattice shape for crack diversion to occur and maximize energy dissipation. The effect of lattice parameters to critical defect region orientation is studied analytically and compared with experiments. Numerical simulation is also implemented to better predict the critical angle taking account of differences in fracture toughness of cellular materials under different modes.

2:30 PM PM01.05.04

Selective Laser Melting of Ti6Al4V Lattice Structures with Hollow Struts—Processability, Mechanical Behaviour and In Vitro Response

Ezgi Onal1, Wencheng Liu2, Bernard Chen3, Jessica E. Frith1, Xinhua Wu1 and Andrey Molotnikov1; 1Department of Materials Science and Engineering, Monash University, Melbourne, Victoria, Australia; 2Department of Mechanical and Aerospace Engineering, Monash University, Melbourne, Victoria, Australia; 3Monash Centre for Additive Manufacturing, Monash University, Melbourne, Victoria, Australia.

Advances in additive manufacturing are enabling fabrication of multitude of complex cellular structures for numerous applications in aerospace and biomechanical fields. Among periodic lattice structures hollow lattice structures are gaining popularity due to their improved mechanical properties, such as higher flexural and inelastic buckling strength [1] and higher compressive strength due to greater resistance to plastic buckling when compared to the solid lattice structures [2]. Furthermore, additional channels provided by hollow struts provide ample space for tissue ingrowth and cell colonization. The latter aspect is of a particular interest since our recent study demonstrated [3], that pore size and distribution significantly affect the cell migration in the lattice scaffolds.

In this work, we explore the potential use of hollow lattices for bone implant scaffolds. We have designed and fabricated Ti6Al4V hollow body centered cubic (BCC) lattice structures with different hollow thicknesses and unit cell pore sizes using selective laser melting process. We also included additional hollow z-struts at the nodes and centres of each BCC unit cell to study the effect of vertical channels. The mechanical properties and failure behaviour of the obtained scaffolds are investigated using compression testing. Furthermore, in-vitro studies with pre-osteoblast cells are conducted to study cell migration and colonization behaviour in channels and hollow struts. This study explores the use of novel lattice structure designs for orthopaedic implants and contributes to understanding of mechanical and biological response of hollow architectural materials.

Collective Magnetic Behavior and Domain Formation in Magnetite Nanoparticle Assemblies

Nils Neugebauer1,2, Alexander Fabian1,2, Matthias T. Elm1,2, Michael Czernecki1,2, Christian Heilig1,2 and Peter J. Klar1,2; 1Institute of Experimental Physics I, Justus-Liebig-Universität Gießen, Gießen, Germany; 2Center for Materials Research, Justus-Liebig-Universitat Gießen, Gießen, Germany; 3Institute of Theoretical Physics, Justus-Liebig-Universität Gießen, Gießen, Germany; 4Institute of Physical Chemistry, Justus-Liebig-Universität Gießen, Gießen, Germany.

Ferromagnetic nanostructures, such as arrays of magnetic nanodots, are of high interest for applications on the field of high density storage media, non-volatile logic or spintronic devices, as the magnetic properties of the arrays can be tuned by their shape and their arrangement. An alternative approach to patterning magnetic thin films is the fabrication of arrangements of ferromagnetic nanoparticles. Such low dimensional assemblies show collective magnetic behavior due to dipolar coupling between the nanoparticles, which offers an additional degree of freedom in manipulating the magnetic interactions inside the magnetic elements. However, in order to tune the magnetic interactions of the assemblies a detailed understanding of the magnetic coupling phenomena is necessary.

Here we present the investigation of the magnetic properties of magnetite nanoparticle assemblies using angle-dependent ferromagnetic resonance measurements [1]. Nanoparticle assemblies of different shape were prepared using the meniscus force deposition method. For this, electron beam lithography was used to prepare PMMA openings. In a horizontal dip-coating process the nanoparticles with an average diameter of 20 nm are arranged in these openings by self-assembly. To investigate the influence of the shape on the magnetic interactions between the particles, rectangular assemblies with different aspect ratio varying from 1:1 to 1:1000 were prepared. The angle-dependence of the resonance was described using the Smit-Suhl formalism. For assemblies with aspect ratios below 1:10 the demagnetization factors obtained are in good agreement with the values expected from the aspect ratio revealing a single magnetic domain behavior due to dipolar coupling. For larger aspect ratios the ratio of the demagnetization factors is much smaller than the expectation indicating the formation of a magnetic domain structure inside the assemblies. This assumption is further supported by magnetic simulations of the magnetic structure and probably arises due to inhomogeneities in the filling of the openings. Furthermore, magnetic coupling between the arrangements was investigated by varying the distance between circular shaped arrangements. Due to their shape, isolated arrangements reveal an isotropic behavior of the angle-dependence of the resonance field in in-plane geometry. However, below a critical distance between the arrangements occurs which is manifested by an angular dependence of the resonance field.

Nano to Macro Architected Materials and Structures—Processing Challenges and Opportunities

Haydn N. Wadley; University of Virginia, Charlottesville, Virginia, United States.

The development of light metals and ceramics with internal topologies that offer novel combinations of properties has been greatly accelerated by the recent development of additive methods for their fabrication. These enable the fabrication of complex shaped structures containing internal features with length scales that range from a few tens of nanometers to the centimeter scale. However, each of the processing methods suffer from various deficiencies such as a limited materials palate, difficult to control internal surface roughness, the presence of residual stresses and distortions of structure, and properties of the solid material that are sometimes inferior to those of conventionally processed counterparts. As a result, innovative applications of traditional fabrication-processing methods can still compete with additive approaches in many areas. Here three approaches for making microarchitected materials are described and the challenges confronting their further development discussed. At the centimeter scale, we describe the use of electron beam melting approaches for making Ti-6Al-4V octet lattice structures and show how surface roughness of the trusses impact mechanical performance, especially as the
Octet nanolattices to be 2.1-7.2 MPa g\(^{-1}\) cm\(^3\), which is comparable to that of metal lattices with 0.1-1.0 mm beam diameters fabricated using alternative methods, with shape diversity at the micro-scale. Then, bubbles are strategically assembled into meso-scale 3D structures. Subsequently, these structures are used to demonstrate a new class of carbon-based, ultralight, strong, and superelastic closed-cellular network structures. In contrast to conventional top-down approaches such as three-dimensional (3D) printing, the building units are prepared by a multi-scale design approach starting from the controlled alignment of Barium Titanate Platelets for Textured 3D Piezoelectric Architectures Using Direct Writing. Direct writing textured piezoelectric ceramics can allow for increased flexibility of 3D designs for a variety of applications through greater geometric possibilities, as well as novel orientations of crystallographic alignment. Generally, direct writing of ceramics and ceramic composites involves the extrusion and deposition of a ceramic containing paste which is then gelled to maintain its shape. Some studies on the alignment of platelets using a circular nozzle have explored the densification of textured ceramic as a function of position in the filament cross-section and length of the deposition nozzle. This work will highlight the fabrication of textured Pb(In\(_{1/2}\)Nb\(_{1/2}\)O\(_3\))-Pb(Mg\(_{1/3}\)Nb\(_{2/3}\)O\(_3\))-PbTiO\(_3\) ceramic designs with crystallographic orientations that are difficult to fabricate with traditional forming techniques. The effect of shear field shape and duration and ceramic paste rheology on the alignment of barium titanate templates and the fidelity of the printed geometries will be explored. Increasing the magnitude of the shear field in the nozzle during direct writing and controlling the rheology of the paste via pH control of the aqueous phase allows for the fabrication of dense, textured Pb(In\(_{1/2}\)Nb\(_{1/2}\)O\(_3\))-Pb(Mg\(_{1/3}\)Nb\(_{2/3}\)O\(_3\))-PbTiO\(_3\) ceramics with varied geometries and alignment directions.

Alignment of Barium Titanate Platelets for Textured 3D Piezoelectric Architectures Using Direct Writing

We used additive manufacturing methodologies to fabricate impact resistant composites. Similar to natural materials, such as mantis shrimp dactyl club, these lightweight synthetic analogues display superior structural properties and functionalities – such as fracture toughness and impact resistance. The present study is based on the hypothesis that synthetic impact resistant materials with extraordinary fracture toughness can be obtained and tuned by the 3D hierarchical micro-architected molecular structures – often enabled with nanoscale sub-structures – and that such 3D structures and mechanical properties could be enabled by additive manufacturing approach, especially with an integrated electrosprinning technique that combine multi-length scale fabrication capabilities. Further, more specifically, this study investigated the fracture toughness and impact resistance properties of the 3D helicoidal architecture inspired by the mantis shrimp dactyl club and elucidate the associated deformation mechanisms. Having layers of multiscale fibers with rotated alignments in each layer, the 3D helicoidal architecture could potentially lead to very efficient (high rate) as well as highly tunable damage dissipation mechanism. We further explore the effect of 3D hierarchy micro-architected structures and the possible size effects of the substructures on the fracture toughness and impact resistance properties of the resulting composite materials as well as the associated damage mechanisms. In this study, we fabricated structures by controlling the orientation of the polymer fibers within the composites. This is enabled by recent advances in additive manufacturing technologies. We plan to use electrosprinning further as well as a novel integrated approach involving melt near-field electrosprinning (NFES) technique and another deposition method called the fused deposition modelling (FDM). The 3D architecture would enable the composites to absorb mechanical energy before they fracture. Ultimately this high performance, impact-resistant composite technology will have other widespread technologically important applications, such as in aerospace, space, military/defense to automotive and biomedical/prosthetics. We also aim to enable design of such advanced composite materials through creation of new manufacturing technologies for micrometer and nanoscale materials and for their assembly and integration at larger scale.

Complete Space Filling Cellular Network of Graphene Bubbles for Ultralight, Strong and Superaesthetic Materials
Seon Ju Yeo1, Min Jun Oh2, Hyun Min Jun3, Minhwon Lee1, Jung Gun Bae1, Yeseul Kim2, Kyung Jin Park2, Seungwoo Lee2, Daeyeon Lee4, Byung Mook Woon2, Won Bo Lee1, S. Joon Kwon1 and Pil J. Yoo2; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Sungkyunkwan University, Suwon, Korea (the Republic of); 3Seoul National University, Seoul, Korea (the Republic of); 4University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Advanced materials with low density and high strength will have transformative impacts in construction, aerospace and automobile industries. These materials can be realized with assembling well-designed modular building units into interconnected structures. This study uses a hierarchical design strategy to demonstrate a new class of carbon-based, ultralight, strong, and superaesthetic closed-cellular network structures. In contrast to conventional top-down approaches such as three-dimensional (3D) printing, the building units are prepared by a multi-scale design approach starting from the controlled synthesis of functionalized graphene oxide nanosheets at the molecular- and nano-scale, leading to the microfluidic fabrication of solid-shelled bubbles with shape diversity at the micro-scale. Then, bubbles are strategically assembled into meso-scale 3D structures. Subsequently, these structures are transformed into self-interconnected and structurally-reinforced closed-cellular network structures through post-treatment, leading to the generation of a 3D graphene lattices with rhombic dodecahedral honeycomb structure at the centimeter-scale. The 3D graphene suprastructure simultaneously exhibits the Young’s modulus above 300 kPa while retaining a light density of 7.7 mg/cm\(^3\) and sustaining the elasticity against up to 87% of the compressive strain benefited from efficient stress dissipation through the complete space-filling closed-cellular network. The fabricated 3D graphene closed-cellular structure opens a new pathway for designing lightweight, strong, and superaesthetic materials.
Recent advances in Additive Manufacturing (AM) enable the fabrication of complex 3D lattice structures at many scales and with many materials. Through computational design optimization methods for AM lattice structures, it is possible to control the distribution of materials and structure within objects with a high degree of precision. This has the potential to dramatically improve structural performance and even enable new functionalities that can not be realized with conventional manufacturing. However, this is highly challenging for designers due to the vast design space of new possible shapes, materials and structures and often unknown AM fabrication constraints.

To address these challenges, a Design for Additive Manufacturing (DiAM) framework is developed that starts with AM material and process characterization from which quantitative models are created. These models are then used within design optimization methods for discrete lattice structures considering design variables of material, member size, shape and topology. Two methods are focused on including a Generalized Optimality Criteria (OC) method for multi-material optimization and optimization for anisotropy considering displacement, local yield stress and Euler buckling constraints. A Sequential Linear Programming (SLP) method is also discussed for the efficient optimization of member size and shape of truss lattice structures considering local yield stress and Euler buckling constraints. While the methods are process and material independent, results are shown for the characterized materials of the multi-material polyjet printing process. The results highlight the necessity of including AM fabrication constraints and tested material properties in the optimization process and the tight coupling needed among material understanding, the AM process and optimization methods to achieve optimized results.
The Representative Cellular Element (RCE) Method – Model, Implementation and Validation with Additive Manufacturing

Dhrub Bhat, Arizona State University, Mesa, Arizona, United States.

Material modeling approaches for cellular materials broadly fall into three different categories, depending on the level of discretization at which the property of interest is modeled. In order of the scale at which material behavior is represented, these models can operate at either the level of the material point (bulk property models), the connecting member (member models) or finally, at the level of the cell (homogenization models). Bulk property models are often not representative of the microstructure and surface effects at the scale of the members that constitute cellular structures in Additive Manufacturing. Member models are challenging to characterize due to the small sizes of the structures involved and the specimen geometries do not always accurately capture behavior of the cellular material. Homogenization models, while efficient to implement computationally, are shape and size dependent and are unlikely to represent irregular and stochastic cell shapes and distributions accurately.

In this work, being presented for the first time, we propose a Representative Cellular Element (RCE) method for modeling cellular materials. Our approach follows from the concept of the Representative Volume Element (RVE) developed for heterogeneous materials. The RCE method essentially involves the identification of a structural element that represents the cellular material for the property of interest. For the model to be both valid and accurate, we show that it must represent the cellular material in three critical ways: geometry, processing history and the physics of its deformation and failure. We assess the performance of the RCE model against prismatic cellular structures (honeycombs) in a wide range of conditions: different shapes (regular, graded and stochastic), Additive Manufacturing processes and materials (ABS with Fused Deposition Modeling, Inconel 718 with Laser Powder Bed Fusion, and Ti6Al4V with Electron Beam Melting) and strain rates (ranging from 10⁰ to 10⁶ s⁻¹). The model is also evaluated against a multi-material hexagonal honeycomb made with a nylon composite and Kevlar continuous fiber. In each case, we examine the model's predictability of the nonlinear stress-strain response in the elastic and plastic regimes. Three different design strategies for the RCE are compared under these conditions to identify the ones that yield the best results. Challenges in implementation and limitations of the RCE approach are also discussed.

Multi-scale Geometric Design Principles Applied to 3D Printed Architected Materials

Seyed Mohammad Sajadi1, Peter S. Owoor1, Cristiano F. Woelbing2, Varlei Rodrigues2, Robert Vajta1, Jun Lou1, Douglas S. Galvao2, Chandra S. Tiwary2 and P. M. Ajayan2; 1Materials Science and NanoEngineering, Rice University, Houston, Texas, United States; 2Applied Physics Department, State University of Campinas, Campinas, Brazil.

The emergence of 3D printing has enabled scientists to innovate complex geometrical designs in materials which were unattainable using conventional synthesis methods. The topological material design is becoming a common occurrence aided by 3D printing. Here we use inverse methods (function-to-structure) to design multifunctional materials. This work reports 3D porous structures with negative Gaussian curvatures, which forms a rigid foam-like architecture (including the network topology, truss geometry and base materials). Enabled by advances in additive manufacturing, large arrays of periodic, hierarchical or functionally graded truss unit cells have been assembled at the micro- to nanoscales, producing new ultra-lightweight cellular solids. With enhanced experimental capabilities comes the need for new theoretical and computational tools to describe and predict the performance of truss networks containing millions and more of individual struts and junctions, where classical approaches such as direct numerical calculations incur prohibitive computational expenses. We show that such truss networks can be described efficiently by advanced constitutive models and numerical tools that replace the discrete truss network by an equivalent continuum. Our formulation captures nonlinear and inelastic material behavior as well as finite deformations. We discuss the theoretical and numerical techniques (involving nonlocal homogenization based on both translational and rotational degrees of freedom), and we present representative examples of truss lattices undergoing not only homogenous deformation but also instabilities such as buckling and shear banding. Finally, we combine the methodology with topology optimization to predict optimal cellular networks with spatially varying truss architecture. Unlike classical multi-scale optimization, this approach results in compatible non-uniform truss architectures that can readily be fabricated by methods of additive manufacturing and offer opportunities for lightweight metamaterials with optimized mechanical properties.

Fracture Toughness of Truss and Shell-Based Architected Materials

Meng-Ting Hsieh and Lorenzo Valdevit; University of California, Irvine, Irvine, California, United States.

The fracture toughness of brittle 2D lattices, such as triangular and kagome lattices, has long been investigated using elastic K-field approaches. However, much less is known about the fracture toughness of 3D cellular materials, particularly those built from ductile components. Here, we numerically investigate the linear elastic and elasto-plastic fracture toughness of octet lattices and spindal shell-based architected materials. We address the issues of mesh dependence where stress singularity arises by incorporating a characteristic element size. To extract R-curves for cellular materials, local damage is modeled using the Johnson-Cook criterion and fracture toughness is obtained by the J-integral compliance with SENB (single-edge notched bend) specimens. We compare the performance of truss and shell-based architected materials in terms of scaling laws and R-curve behavior, and extract design principles. Numerical results are verified by fracture toughness experiments.
On the Correlation Between Topology and Elastic Properties of Imperfect Truss-Lattice Materials Panos Pantidis1, Andrew Gross2, Katia Bertoldi1 and Simos Gerasimidis1; 1Civil Engineering Department, University of Massachusetts, Amherst, Amherst, Massachusetts, United States; 2Harvard University, Boston, Massachusetts, United States.

The pursuit of new materials with properties superior to the current state of the art, has led many investigators to examine the behavior of materials with a truss-lattice microstructure which accommodates member sizes in the range of micro- and nanometers. Aided by the immense progress of 3D additive manufacturing techniques, such as self-assembly (bottom-up techniques), material scientists have been enabled to fabricate novel materials with complex architectures which can attain unique, unprecedented and tunable properties. However, defects of various forms and concentrations are unavoidable in any fabrication process, and it is anticipated that the application of self-assembly techniques to larger three-dimensional volumes will increase the concentration of defects. Of particular interest for the self-assembly of truss-lattice materials is the influence of struts that are missing from the network, in various defect forms such as missing blocks (clusters) or randomly missing members. In this study, the dependence of the elastic properties on the concentration and distribution of missing struts is investigated for several three-dimensional lattice-truss materials of varying coordination number. This work constitutes a systematic experimental and numerical approach to examine and identify the mechanical elastic regime of defected architected metamaterials. The experimental part of this project is conducted with a two-photon lithography approach, an advanced additive manufacturing technique capable of printing struts with sub-micron cross-sectional dimensions, while the numerical part utilizes finite element simulations accounting for the randomness of the damage spatial distribution through exhaustive Monte Carlo simulations. Focusing on a variety of elastic mechanical properties (Young’s, bulk and shear modulus), their evolution is monitored as the total defect percentage increases in magnitude, providing a comprehensive picture of the defected architected metamaterials elastic property space. Finally, this work thoroughly explores the connection between defected truss-lattices and well-established homogenization techniques for composite mediums, elaborating on the applicability of the latter methods to accurately describe the response of defected lattice-based materials.

11:15 AM OPEN DISCUSSION

Analysis of a Three-Dimensional Spider Web Architecture Isabelle Su1, Zhao Qin1, Tomás Saraceno2 and Markus Buehler1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Studio Tomás Saraceno, Berlin, Germany.

Spiders are abundant in most ecosystems in nature, making up more than 47,000 species. This ecological success is due to the web architectures and the exceptional mechanical properties of spider silk. Silk’s combination of strength, elasticity, toughness, and robustness originates from its hierarchical structure and has been a template for high-performance material design. In particular, spiders have optimized and adapted their web architecture to survive in their environment.

The most studied and familiar spider web is the 2D orb web which is composed of radial and spiral threads. However, 3D webs, such as sheet, funnel, or cob webs, are more common in nature. In contrast to 2D webs, where the spider is vulnerable to attacks, 3D webs surround the spider and offer a defensive advantage by warning the spider of intruders, blocking its predators and entangling prey.

Here, we investigate the architecture and mechanical properties of a Cyrtophora citricola 3D web. For the first time, we build a model of the 3D spider web generated through automatic laser scanning. The web is scanned by taking a high resolution picture of slices of the web illuminated by a sliding sheet laser. Using image processing algorithms, we construct a 3D fiber network. We study the response of a realistic web structure to mechanical loads using a coarse-grained bead-spring models based on the network model created through scanning and image processing. Using this new method to trace the fiber network, we can study the connection between material and performance of numerous 3D spider webs. Understanding the roles of structure and material in the functionality and evolutionary fitness of spider webs could lead to innovative 3D spider web-inspired structures such as high performance light-weight long-span structures or fiber reinforced composite materials.

Harnessing Design Principles from Glass Sponges for Structurally Robust Lattices Matheus C. Fernandes1, James Weaver2; 1Harvard University, Cambridge, Massachusetts, United States; 2Wyss Institute, Cambridge, Massachusetts, United States.

Glass sponges are predominately deep sea sponges that live in ocean depths of 100-2000m. Beyond their fracture propagation inhibiting material composition, these sponges are perceived to exhibit large structural rigidity and strength against buckling. Since these sponges are primarily made of ‘brittle silica’, buckling strength may be a crucial property in making them resistant to impact and environmentally applied stresses. Structurally, they exhibit a base square-grid architecture and regular ordering of vertical and horizontal struts that form the skeletal system. Furthermore, their base structure is overlaid with double diagonal reinforcement struts, which create a checkerboard-like pattern of open-closed cell structure. This diagonal reinforcement design is conjectured to give the sponge greater buckling resistance and strength to localized damage then it would experience having a single diagonal reinforcement strut (while allocating the same amount of mass to the diagonal reinforcement.) Analogous to the sponge, many engineering structures, such as buildings and bridges, exhibit diagonal reinforcement struts as a stability mechanism. Based on this similarity, we explore the following research question: Can we generate design principles for diagonal reinforcements of square beam lattices that are optimally designed to avoid global structural buckling? Here, we present a numerical analysis of the structure deformation under various loading conditions as well as survey different arrangements within similar design space of the sponge. Furthermore, we present experimental evidence that supports our numerical analysis. Through the various design iterations we look for the critical buckling strain and the elastic load caring capacity. Finally, we compare the results from the sponge design to what is typically used in engineering of structures such as buildings and bridges.

Advancing Acoustic Application with Architectured Metamaterials Nicholas Fang; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Today, sound is an indispensable component in numerous industrial and consumer products, such as musical instruments, cars, building technology, medical diagnostics, and many others. Acoustic characteristics are among their most important properties, greatly influencing their function and our society.
at large. Recent development of acoustic metamaterials opens a door to an unprecedented large design space for acoustic properties such as negative bulk modulus, negative density, and refractive index. These novel concept expands pave the way for the design of a new class of acoustic materials and devices with great promise for diverse applications, such as broadband noise insulation, sub-wavelength imaging and acoustic cloak from sonar detection.

In this invited talk, I will present our development of advanced design and micro/nanofabrication techniques, to enable exploration architecture of meta structures for acoustic waves. These structures show promise on focusing and rertoing ultrasound through broadband metamaterials. As example, our study on the sound absorption of thin composite aerogel foams using a bimodal porous structure predicts a possible route to perfect thin film absorber by increasing the amount of epoxy resin. In a second case, stimuli responsive acoustic metamaterials are demonstrated to be able to extend the 2D phase space to 3D through rapidly and repeatedly switching signs of constitutive parameters with remote magnetic fields. Lastly I will report our study on a prototype hydraulic hydrogel transducers with excellent optical and sonic transparency.

2:00 PM PM01.07.02
Design of a Resonant Laser Beam Scanner Based on a Topologically Protected Twist Edge State Julian Köpfler1, 2, Tobias Frenzel2, Muamer Kadic1, 2, 3, Jörg Schmalian1, 5 and Martin Wegener2, 1; 1Institute of Nanotechnology, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Institute of Applied Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 3FEMTO-ST, Université de Bourgogne Franche-Comté, Besançon, France; 4Institute for Theoretical Condensed Matter Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany; 5Institute for Solid-State Physics, Karlsruhe Institute of Technology, Karlsruhe, Germany.

The concept of band gaps in periodic mechanical systems allows, for example, the design of waveguides and cavities. However, the corresponding modes are often fairly sensitive with respect to perturbations. Therefore, the more recent idea of topologically protected boundary modes has provided a new twist. Aiming at applications as one-way waveguide architectures, recent work [1,2] designed and realized mechanical structures exhibiting topological two-dimensional (2D) band gaps. 1D topological band gaps exhibiting longitudinal and bending interface modes were achieved using a beam composed of a 1D periodic arrangement of elastic unit cells [3].

In this paper, we present an application of topological mechanical band gaps that specifically takes advantage of chirality. We design a 1D chain of two different alternating 3D elastic chiral unit cells [4]. The individual unit cells have been inspired by our previous work [5]. The chain’s topological band gap, a result of the alternation of unit cells combined with their chirality, guarantees a protected edge state at one end of the beam, corresponding to a resonant localized twist mode. This mode can be excited by an axial motion at the other end of the beam, via evanescent modes in the gap. The topological robustness of the edge state allows us to add a micro-mirror, turning the arrangement into a resonant laser beam scanner with scalable operation frequency and adjustable quality factor.

Our work starts from calculations based on a simplified 1D mass-spring model, which we solve analytically. The system resembles two Su-Schrieffer-Heeger (SSH) models [6], one for the longitudinal displacement and one for the twist, which are chirally coupled via additional springs. We justify this model by the fact that the longitudinal (or pressure) and the twist mode on the one hand, and the two transverse (or shear) modes on the other hand, live in orthogonal subspaces according to micropolar continuum theory for chiral media. Within this model, the topological protection is due to a combination of time-reversal and a mirror symmetry, generalizing the classification of mechanical metamaterials [2]. The results of the model are verified by numerical finite-element calculations for the complete 3D microstructures. These microstructures should be amenable to laser nanoprinting.

Dynamically Tunable Topological States in Soft Elastic Metamaterials Shuaifeng Li and Jianfeng Zang; Huazhong University of Science & Technology, Wuhan, China.

Topology describes the properties of space under continuous deformation in mathematics. The concept has been used to explain band structures in condensed matter physics, resulting in the theoretical prediction and experimental observation of topological insulator in electronic system, and recently also in photonic and phononic systems. Topological elastic metamaterials offer insight into classic motion law and open up opportunities in quantum and classic information processing. Theoretical modeling and numerical simulation of elastic topological states have been reported, whereas the experimental observation remains relatively unexplored. Here we present an experimental observation and numerical simulation of tunable topological states in soft elastic metamaterials. The on-demand reversible switch in topological phase has been achieved by changing filling ratio, tension, and/or compression of the elasstic metamaterials. By combining two elastic meta-materials with distinct topological invariants, we further demonstrate the formation and dynamic tunability of topological interface states by mechanical deformation, and the manipulation of elastic wave propagation. Moreover, we provide a topological phase diagram of elastic metamaterials under deformation. Our approach to dynamically control interface states in soft materials paves the way to various phononic systems involving thermal management and soft robotics requiring better use of energy.

Non-Reciprocal Wave Phenomena via Mechanical Modulation of Discrete and Continuous Elastic Lattice Systems Samuel P. Waller2, Benjamin M. Goldsberry1, 2 and Michael R. Haberman1, 2; 1Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United States; 2Applied Research Laboratories, The University of Texas at Austin, Austin, Texas, United States.

Non-reciprocal acoustic and elastic wave propagation is of significant interest due to its potential to enable direction-dependent devices that augment mechanical wave sensing and transmitting capabilities. They also open up the possibility for the construction of novel materials or structures for isolation from vibration and impacts. However, non-reciprocity can only occur under very specific circumstances, many of which are very difficult to achieve in practice. This work considers mechanical modulation as a potential means to obtain non-reciprocal elastic wave propagation in architected materials. The specific case studied is the application of a slowly-varying, large amplitude, mechanical pump wave whose motion is orthogonal to the direction of wave propagation. This pump wave acts as a spatio-temporal modulation of the mechanical structure, resulting in time and space varying effective material properties and non-reciprocal elastic wave phenomena. The mechanical system of interest is modeled using both discrete and continuous mechanical
Acoustic metasurfaces that can manipulate and control sound waves at two-dimensional subwavelength scales open new avenues to unusual applications, such as sound barrier, super-resolution imaging, and particle manipulation. However, the long-standing goals of pushing frontier metamaterials research into real practice are still severely constrained by cumbersome configuration and rigid structure of the existing metamaterials. Here we fabricate an ultrathin metasurface (10-300 μm in thickness, up to 1/650, λ the wavelength) that is capable of imparting sound wave with a non-trivial phase shift with high transmittance (>80%) in the range of 5 kHz and 30 kHz by electrospinning method. Besides, we incorporate the traditional paper-cutting art to carve the ultrathin metasurface into hollow-out patterns, resulting in a variety of remarkable functions, including acoustic vortex, focusing, and super-resolution. Our hollow-out patterning approach innovates the traditional one-step metadevice fabrication process into two separated steps: (1) fabrication of ultrathin metasurfaces; (2) hollow-out patterning of metasurfaces. Our strategy opens an avenue to mass production of acoustic metadevices, shedding light on the applications of the metamaterials in architectural acoustics.

Moreover, benefited from the flexibility of our hollow-out patterning metasurfaces, we propose the unprecedented non-planar acoustic metasurface. Actually, most objects and occasions refer to non-planar surface in nature. Non-planar metasurface is sorely in need to match these application scenarios but there has been hardly thought or design about non-planar acoustic metasurface so far. We demonstrate a high-efficiency focusing on nearly arbitrary non-planar surface and design an "umbrella structure" to implement focusing with dynamic tunable focal length.

Two-Step Manufacturing of Ultrathin Acoustic Metasurfaces and Non-Planar Acoustic Metasurfaces

James Blondeau1, Vitalyi Gusev1, Katia Bertoldi2 and Vincent Tournat1; 1LAUM, CNRS, Le Mans Université, Le Mans, France; 2John A Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

Assessing nondestructively the elastic properties of micro-scale architected materials is of key importance in several applications. Here we propose a method based on the laser generation and detection of ultrasound to extract the vibrational mode frequencies of 3D-printed micro-truss samples. Experimental results show that the first bending and compressional modes of the truss systems can be monitored in the MHz frequency range. The corresponding frequencies are then compared to finite element simulations results, which allow to assess the effective elastic parameters, Young's modulus and shear modulus, of the micro-scale trusses. Capabilities and limitations of this laser ultrasonic characterization method will be discussed in the context of micro-scale architected materials, and some prospects in wave control problems at the micro-scale will be proposed.

Additively Manufacturable Micro-Mechanical Logic Gates

Yuanming Song1, Robert Panas2, Samira Chizari2, Lucas Shaw2, Julie Jackson1, Jonathan Hopkins1 and Andrew Pascall1; 1Lawrence Livermore National Lab, Livermore, California, United States; 2Department of Mechanical and Aerospace Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Early examples of computers were almost exclusively based on mechanical devices. Although electronic computers became dominant in the past 60 years, recent advancements in 3D micro-additive manufacturing technology provide new fabrication techniques for complex microstructures which have rekindled research interest in mechanical computations[1-3]. The authors propose a new digital mechanical computation approach based on additively-manufacturable micro-mechanical logic gates. The proposed mechanical logic gates (i.e., NOT, AND, OR, NAND, and NOR gates) utilize multi-stable micro-structures that buckle to perform digital computations based purely on mechanical forces and displacements with no electronic components. Unprecedented properties have been achieved simultaneously including functional completeness, continuous operation, scalability, and near-zero energy consumption. A key benefit of the proposed approach is that such systems can be additively fabricated as embedded parts of microarchitected metamaterials[4] that are capable of interacting mechanically with their surrounding environment while processing and storing digital data internally without requiring electric power.

Additive Manufacturing of Lightweight Mirrors

Nikola Dudukovic, Logan Bekker, Wen Chen, Jesus Partida, Bryan Moran, Eric B. Duoss, Christopher M. Spadaccini, William Steele, Tayyab Suratwala and Rebecca Dylla-Spears; Lawrence Livermore National Laboratory, Livermore, California, United States.

Additive manufacturing offers new routes to lightweight optics inaccessible by conventional methods by providing a broader range of reconciled functionality, form factor, and cost. Predictive lattice design combined with the ability to 3D print complex structures allows for the creation of low-density metamaterials with high global and local stiffness and tunable response to static and dynamic loading. This capacity provides a path to fabrication of lightweight optical supports with tuned geometries and mechanical properties. Our approach involves the simulation and optimization of lightweight stretch-dominated lattices for anticipated stresses due to polishing and mounting loads via adaptive mesh refinement. The designed lattices are 3D-printed using large area projection microstereolithography (LAPuSL), coated with a metallic plating to improve mechanical properties, and bonded to a thin (1.25 mm) fused silica substrate. We demonstrate that this lightweight assembly can be polished to a desired flatness using full aperture polishing under a load, and subsequently treated with a reflective coating. This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 within the LDRD program. LLNL-ABS-738806.
SESSION PM01.08: Additive Manufacturing

title: 3D Printed Transparent Glass with Gradient Properties
authors: Timothy Ye1, Do Nguyen1, Joel Destino2, Nikola Dudukovic1, Michael Johnson1, Koroush Sanas1, Lana Wong1, Paul Ehrmann1 and Rebecca Dylla-Spear1; Lawrence Livermore National Laboratory, Livermore, California, United States; Creighton University, Omaha, Nebraska, United States.

We present an approach to fabricating glass with a gradient refractive index profile by combining additive manufacturing and conventional ceramic processing techniques. Silica and silica-titania nanoparticles are synthesized and formulated into a slurry, which is tuned rheologically to enable extrusion through a nozzle via direct ink writing. During printing, two feedstocks of different compositions are fed at variable flow rates and mixed inline, allowing for controlled compositional profiles in the printed part. After printing, an optimized heat treatment is performed to ensure the removal of organic material and the formation of fully dense, transparent glass. We demonstrate 3d-printed gradient index lenses, and we show that our 3d-printed glasses have comparable properties to commercial glasses. This approach is promising for the development of optics with new functionality that cannot be accessed through conventional methods.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 within the LDRD program 16-SI-003. LLNL-ABS-937900.

8:30 AM PM01.08.02

title: Design and Electrohydrodynamic Jet Printing of Layered Periodic Photopolymers
authors: Brian Iezzi1, Zahra Afkhami2, David Hoelzle3, Kira Barton2 and Max Stien2; Materials Science and Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; Mechanical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; Mechanical and Aerospace Engineering, The Ohio State University, Columbus, Ohio, United States.

Periodic layered mirrors and filters are used for wavelength selection in spectroscopy and imaging. These mirrors have long relied on inorganic materials that have the refractive index contrast necessary to obtain desired electromagnetic wave interference patterns but require cumbersome and expensive manufacturing processes. Photopolymers have been formulated with refractive indices ranging from 1.3 to 1.7, and are, in principle, compatible with versatile, low-cost additive manufacturing processes. We use commercially available high (n=1.70) and low (n=1.38) refractive index photopolymers to create periodic layered mirrors and filters. We design mirrors having fewer than 15 alternating index layers with reflectance exceeding 60% in the visible range and complementary Fabry-Perot filters using a polymer resonant cavity with narrow transmission peaks of 15 nm FWHM with fewer than 30 layers. Experimental validation of these constructs is done using electrohydrodynamic jet (e-jet) printing; achieving individual layer thicknesses between 50-150 nm and well-defined filter “pixels” below 100 square micrometers. The reflectance/transmission characteristics of the printed mirror/filter “pixels” are measured using custom microspectrophotometry. Initial transmission results of five-layer samples are shown to be within 5-30% of prediction in the 500 to 700 nm wavelength range. Various printing parameters, such as utilizing continuous versus pulse printing and their effect on layer interfaces are discussed, along with how this information is used in the multi-physics design of monolithically-integrated organic imaging devices with predictable external quantum efficiency characteristics.

The authors would also like to acknowledge Aaditya Hambarde, Parag Deotare, and Steven Morris for their contributions to the work.

8:45 AM PM01.08.03

title: Fabricating Nanostructured Ceramics via Block-Copolymer Soft Templates
authors: Lisa M. Rueschhoff1, Luke Baldwin1, Robert Wheeler1,2, Hilmar Koerner1, Matthew Dalton1, John D. Berrian1, Michael Cinibulk1 and Matthew Dickerson1; Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States; UES, Inc., Dayton, Ohio, United States.

Ceramics and ceramic composites architected at the nanoscale can exhibit extraordinary mechanical properties, including elastic deformation and high toughness, but are difficult to fabricate using scalable production methods. The ability to control bottom-up templates for preceramic polymers (PCPs) allows for the production of polymer-derived ceramic components with desired nanostucture and mechanical properties. The combination of block copolymers (BCPs) and PCPs allows for the templating of the PCPs as a result of the self-assembly of the BCPs. Subsequent pyrolysis of the material converts the PCP into a structural ceramic material while removing the self-assembled BCP fugitive template. Using this method we have created novel silicon carbide based ceramic structures with nanoscale features and porosity. Insight into the relationship between polymer chemistry and structure in thin films of a novel and relatively inexpensive BCP/PCP system, as well as in-situ mechanical characterization of porous ceramic micropillars, will be presented.

title: Improved Strength and Functionality in Polymer Lattice Additive Manufacturing
authors: Joshua DeOtte1, 2, James Oakdale1 and Eric B. Duoss1; Lawrence Livermore National Lab, Livermore, California, United States; University of California, Davis, California, United States.

Polymer lattices produced with stereolithography additive manufacturing often have mechanical performance lower than expected from bulk properties. During fabrication, oxygen inhibits polymerization at pattern edges, which is oftentimes exploited to reduce adhesion to the print window. For small structures, this region of reduced polymerization could include entire features, dramatically reducing stiffness. Typically, a UV post-cure step is used to finish polymerization at the surface, but improvement in stiffness is minimal. Raman spectroscopy was used to measure the conversion ratio along the radius of a 500um diameter, additively manufactured cylinder, which showed that conversion ratio begins decreasing 100um from the surface. UV post-cure was insufficient to complete polymerization over the full region, so simultaneous thermal analysis was used to probe the temperature required to initiate acrylate polymerization as well as the temperature for thermal degradation. After thermal post-processing, the average conversion ratio increased, improving stiffness in an additively manufactured lattice by an order of magnitude.
This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

3D Printed Ultrastrong and Ultratough Metallic Architectures Wen Chen1, Cheng Zhu2, Thomas Voisin2, S. K. McCall2, Andrew Pascale2, Joshua Kunz2, Eric B. Duoss2 and Christopher M. Spadaccini2; 1Mechanical and Industrial Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Lawrence Livermore National Laboratory, Livermore, California, United States.

Ultrafine grain metals are a class of advanced structural materials with superior mechanical properties due to the inherent refined microstructure. Processing of ultrafine grained metals is however very challenging and often lacks versatility and scalability. Here, we introduce a novel approach that allows fabricating a variety of ultrafine grained metal 3D architectures by combining direct ink writing based additive manufacturing with nanocrystallization of a metallic glass precursor. The developed 3D ultrafine grained metal architectures demonstrate unprecedented mechanical performance such as high strength and energy absorption compared with other metallic architectures. More generally, our finding offers a new routine to achieve high performance complex metallic architectures with high precision, scalability, and versatility.

Prepared by LLNL under Contract DE-AC52-07NA27344.

9:30 AM PM01.08.07
Print Path Optimization and Computation of Machine Motions for Direct Ink Writing on Non-Planar Substrates Eric B. Duoss, Adam Jaycox, Christopher M. Spadaccini, Seth Watts, Todd Weisgraber and Thomas Wilson; Lawrence Livermore National Laboratory, Livermore, California, United States.

Recent work in direct ink writing (DIW) of elastomers on planar substrates has shown that different lattice morphologies display interesting characteristics, including tunable compressive and shear response. A natural question is whether we can achieve the same characteristics when printing on non-planar substrates. This presents two challenges: first, the curvature of such substrates induces distortion on planar designs, preventing a direct translation of these lattices; and second, determining the machine motions necessary to print lattices on non-planar substrates via DIW is non-trivial. We discuss our approach, which uses optimization techniques to address both challenges. Specifically, we pose the mapping of lattices to non-planar substrates as a minimization of areal distortion subject to constraints on angular distortion, and we determine the machine motions by solving an inverse problem using a forward kinematics model of a six-axis DIW machine to determine the translations and rotations necessary to print the lattices of interest.

Designing Elastomeric 3D Printed Architectures with a Mechanical Reduced Order Model Todd Weisgraber, Ward Small, Jeremy Lenhardt, Christopher M. Spadaccini, Robert Maxwell, Eric B. Duoss and Thomas Wilson; Lawrence Livermore National Laboratory, Livermore, California, United States.

Direct ink writing of silicone elastomers enables printing with precise control of porosity and mechanical properties of ordered cellular solids, suitable for shock absorption and stress mitigation applications. With the ability to manipulate structure and feedstock stiffness, the design space becomes challenging to parse to obtain an architecture with a desired mechanical response. Here we derive an analytical design approach for structure and feedstock. Results from finite element simulations and quasi-static mechanical tests of two different parallel strand architectures were analyzed to understand the structure-property relationships under uniaxial compression. Combining effective stiffness-density scaling with least squares optimization of the stress responses yielded general response curves parameterized by resin modulus and strand spacing. An analytical expression of these curves serves as a reduced order model, which, when optimized, provides a rapid design capability for filament-based 3D printed structures. To demonstrate the capability, we present computed optimal architecture designs that satisfy prescribed loading conditions and porosity constraints along with validating mechanical characterization data.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. LLNL-ABS-752767.

Redox-Based EHD-Printing—Chemically Architected Metals with Submicron Chemical Resolution Alain S. Reiser, Marcus Lindén and Ralph Spolenak; ETH Zurich, Zurich, Switzerland.

The concept of architected materials, i.e., the design of properties through architecture, is of widespread interest, e.g., for the fabrication of optical and mechanical metamaterials, advanced microelectromechanical systems or biological scaffolds. Two-photon lithography (TPL) of polymeric materials is currently the major enabling technology for additively manufactured (AM) small-scale architected materials, i.e., architectures with a smallest feature size <1 μm. TPLs combination of submicron feature size and high fabrication speed is unmatched by any competing AM technology, and post-print coating- or pyrolysis-techniques extend the accessible materials range towards metals and ceramics. Nonetheless, multi-material capabilities of TPL are currently very limited, especially for inorganic materials, and property design mostly relies on design through cellular geometries – an approach that invariably renders porous materials, with absolute properties that are typically inferior to dense designs. Microscale multi-material AM has great potential to advance the synthesis of complex 3D chemical architectures with properties or functionalities that go beyond those of cellular designs. Yet, while multi-polymer approaches are relatively advanced, similar techniques for inorganic materials face serious limitations: because almost all methods are variations of ink-based, multi-nozzle strategies, the resulting as-deposited materials-quality is typically low, the chemical voxel-size, i.e., smallest feature of a fixed chemical composition, is large, and alignment can be demanding.

Here, we introduce redox-based EHD-printing. This ink-free, electrochemical technique can overcome the before-mentioned limitations of multi-material microscale AM for the case of metals: it offers multi-metal printing from a single print-head with a chemical voxel-size of 250 nm, switching of the printed chemistry at a frequency of 10 Hz, and smallest geometrical feature size <100 nm. We show that the underlying electrochemical principle enables as-deposited materials quality that compares well with that of PVD-deposited metals, e.g., a flow-strength of 1 – 1.5 GPa for Cu, or a resistivity of 8 x bulk Cu. At the same time, redox-based EHD-printing offers a deposition speed of several μm s⁻¹, which is more than an order of magnitude faster than that of other electrochemical microscale AM methods. We demonstrate the synthesis of bi-metallic Cu-Ag 3D geometries with complex, embedded chemical
3D Direct Laser Writing of Efficient X-Ray Lens Nano-Architectures

Kahraman Keskinbora, Umut T. Sanli, Hakan Ceylan, Julija Bykova, Markus Weigand, Metin Sitti and Gisela Schütz; Max Planck Institute for Intelligent Systems, Stuttgart, Germany.

Focusing optics used in X-ray microscopy often have very demanding geometries from a fabrication point of view due to extremely small features, sub-mm scale apertures, extremely tight tolerances and high aspect ratios [1]. Such X-ray optics range from Fresnel zone plates (FZP) to three-dimensional kinoforms and several types of stacked lenses [2]. Generally, top-down subtractive methods are used for fabricating diffractive X-ray optics such as binary FZPs. Fully 3D optics, on the other hand, can be fabricated only in approximated forms by resorting to subtractive methods [2] including optical lithography, direct-write ion beam lithography or e-beam lithography followed by etching and electroplating. While these methods produce binary X-ray FZPs with the highest resolution today, they fail when high aspect ratios are required for focusing harder X-rays or optics with overhang structures such as tilted, wedged or curved lenses are desired towards high-efficiency focusing at high resolutions.

Two-photon polymerization (2PP) emerged as a versatile route for manufacturing three-dimensional complex geometrical structures on the nano-scale. 2PP is an expanding field of research with a long list of technological applications in micro-robotics [3], photonics [4,5], metamaterials [6,7], and MEMS/NEMS [8] to name a few.

Here, we employed direct-write 3D femtosecond laser lithography to fabricating a highly efficient type of X-ray optic called kinoform lens, with parabolic surface profiles [9]. Then, we thoroughly characterized the focusing/imaging performances of the lenses by mounting them in a scanning transmission X-ray microscope (STXM) located in the synchrotron radiation facility BESSY II. The demonstrated an efficiency of up to 20 % efficiency, a remarkable value for soft X-ray energies. Using the fabricated lenses, we resolved 240 nm and 30 nm features via direct scanning and ptychographic imaging, respectively.

Finally, we discuss the potential application of 2PP for printing other types of X-ray optics with integrated wavefront shaping elements and nano-focusing lenses.

Additive Biofabrication of Elastic 3,4D Constructs for Human Repair and Enhanced Future Ways of Living

Raymond Oliver and Chawisa Deesomboon; Northumbria University, Newcastle upon Tyne, United Kingdom.

Humans are innovative beings that have successfully created new materials that are so durable and so efficient in so many different ways. One material in particular has been embedded into our daily lives is synthetic polymer in the form of plastic. Collectively, we can agree that we can't fully live without it, but we can probably agree on the huge negative impact that it generates through single use application. For example, it is logical to use a material for a single, brief use, but on throwing it away, it doesn't biodegrade for many hundreds of years. We therefore report on a Design:STEM approach to explore new material forms derived from natural abundant sources such as polysaccharides, responsive materials in the form of hydrogels and cellular materials such as bio-based aerogels or foams. The first area of research activity we report is based on options to facilitate a shift away from synthetic polymers to natural ones and at the same time, create additional and useful functionality. The second part of this investigation we report on is the use of additive manufacture with insights into the ease and constraints associated with 3,4D microfabrication which provide soft, elastic, bioreilient and bioeompatible characteristics for both human repair and 'smart' consumer products.

The work was carried out using an Envisiontec bioplotter or extruder to create material constructs that has allowed a comparison between different natural biomaterials under a measured range of rheological, thermal and mechanical properties associated with polysaccharide, hydrogel and organic aerogel examples. The initial experimental programme using the bio-plotter generated a range of elastic and responsive 3D constructs using PU and Acrylic elastomers which required no post work differentiating the bioplotter from other traditional 3D printers. Initial studies concentrated on creating optimal thermal, curing, mechanical and rheological conditions for the formation of reproducible 3D elastic structures. This was followed by the development of bio-elastomeric sample materials and the current state of play has been the introduction of hydrogel components into the bioplotter formulations to yield a 4D bioelastic construct. The techniques employed to achieve this included working with Rhino software and digital fabrication methods to transfer designs from laser scanned 3D images to a 3D computer controlled robotic plotting head to generate the desired complex structures. The subsequent constructs and their behaviour was filmed and recorded to create digital records of both the fabrication kinetics and the form of the various 3,4D elastic constructs. The results to date indicate that it may be possible to generate natural alternatives to synthetic polymers which have applications ranging from human repair i.e. the replacement of prosthetics with potential bio-resorbable tissue engineered constructs and industrially relevant structures for automotive and aerospace applications.

Controlling Architecture Through Active Mixing Processing

A. M. Golobic1, 2, Jason Ortega1, Jeremy Lenhardt1, Eric B. Duoss1 and Thomas Wilson1; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2University of California, Davis, California, United States.

The mixing process of multimaterial systems can impart microstructure that can affect the overall material performance. This is especially true when mixing materials with vastly different densities, rheological behavior, and mechanical properties. The use of an active mixing printhead in 3D printing processes requires an understanding of how the processing dictates the microstructure, which in turn influences the material properties. The architectures formed during mixing were investigated with an active mixing printhead and siloxane inks with different rheology and mechanical behavior. The mixing was varied by controlling the rotating impeller speed and the resulting structure was studied with spectroscopic methods. The mechanical behavior was tested and correlated to microstructure. The experimental findings were compared with simulations of the mixing process and mechanical response.
Additively Manufactured Metallic Cellular Materials—Energy Absorbing Characteristics

Morphology and Composition of Magnesium Calcium Phosphates Prepared in a Multiple Emulsion

The Effect of Adhesion Strength Between Steel and Polymer on the Formability of Their Composites

11:30 AM PM01.08.13
Additively Manufactured Metallic Cellular Materials—Energy Absorbing Characteristics

Metallic cellular materials such as lattices and honeycombs are of interest for blast and impact protection, due to their ability to dissipate energy efficiently during dynamic crushing. High-performance energy absorbing materials find applications in a wide range of industry sectors: e.g., aerospace, rail, automotive crashworthiness and structural blast protection.

Additive manufacturing (AM) processes enable new cell wall material-geometry combinations for the design of high performance cellular materials for impact energy absorption. This is of interest, for example, in the space industry, where high performance but light-weight materials that can protect structures from impact are sought.

To date, optimisation of AM cellular materials for high-strain rate loading scenarios remains relatively under-developed. Design of AM materials requires an understanding of the relationship between the AM process parameters and the properties of the resulting material across different scales: from the microstructure, to the geometric feature rendition, to the overall dynamic performance. Challenges include: (i) understanding process-property interactions for high strain rate behaviour; (ii) developing methodologies to navigate the wide design space enabled by AM processes, and hence optimise high strain rate properties; and (iii) modelling challenges spanning a range of length scales. These gaps in understanding hinder the exploitation of AM to deliver solutions for the most demanding impact protection problems.

First, focusing on the selective laser melting of a well-established alloy (316L), the influence of the laser heating strategy was investigated, specifically, the influence on defects, properties, microstructure and energy absorption. The laser power and the exposure time were varied, while maintaining a fixed total heat input. Also considered was the effect of five cellular material geometries: square honeycomb (SHC), lattice-wall square honeycomb, octet lattices (two variants), and origami.

It was found that a 125W laser power produces material with fewer porosity defects, which resulted in a higher yield strength and higher ductility. For the five geometries tested, the 125W power gives the cellular material with the greatest strength and energy absorbing capacity. However, the relative performance of the different geometries is insensitive to the laser power - SHC performs best in all cases. If we increase the strain rate, the same performance ranking holds between cellular geometries and laser powers. In all cases, a dynamic elevation in strength is observed.

11:45 AM PM01.08.14
Laser Power Optimization Using Feed Forward Control on the Overhang Geometry for 316L Stainless Steel

Arbitrarily complex architectures in metal additive manufacturing can be improved by using physics modeling and analysis to optimize the laser power throughout the scan path. Predicting the transient evolution of the thermal field to prevent overheating is critical for printing parts that meet quality criteria. This study investigates control of the laser power during selective laser melting (SLM) of 316L stainless steel to build an overhang geometry. Diablo, a parallel finite element code that models the heat transfer is used with a control algorithm to optimize the laser power across the overhang. This study investigates strategies to use predicted physical quantities for feed forward control of the laser power. Parts printed using the feed forward control strategy are analyzed and simulation results are used towards the development of a geometry based model. Prepared by LLNL under Contract DE-AC52-07NA27344.

The Effect of Adhesion Strength Between Steel and Polymer on the Formability of Their Composites

Due to global pressure to enhance energy efficiency, automotive industries have endeavoured to develop new lightweight structural materials. Steel/polymer/steel hybrid composites have been researched for this purpose because the weight of steel structure can be reduced maintaining its performance, e.g., the hybrid composites with a volume fraction of polymer of 30% theoretically shows that the flexural rigidity is maintained at 97%, but the weight is reduced to 75%, compared with the same volume of steel. In addition, these hybrid composites have showed improved damping and soundproof properties compared to pure steel structure. In order to apply those hybrid composites to industrial fields, their formability must be investigated in order to prevent the deterioration of mechanical properties of the hybrid composites during the forming process in various shapes. Therefore, experimental studies have been conducted to evaluate the formability of hybrid composites have recently been conducted. However, there are few studies to predict the formability of the hybrid composites because the physical properties of core polymer and interfacial characteristics cannot be considered properly in simplified model. In this study, first formability tests were carried out for evaluating the forming limit diagram of the hybrid composites. After that, the formability test of the hybrid composites was simulated considering the viscoelastic properties of the core polymer and the interfacial properties. Finally, the effect of the interfacial adhesion on the formability of the hybrid composites was investigated, from which an optimal condition was explored for the interfacial adhesion strengths that can ensure the formability of the hybrid composites for specific applications.
Inorganic hollow microspheres can be prepared by interfacial reaction (IR) in a W/O/W multiple emulsion. For controlling their morphology, it is worthwhile to know the transfer mechanism of the reactant ions from the outer aqueous (W_o) phase through the oil (O) phase to the inner aqueous (W_i) phase. In this study, calcium phosphate microspheres containing Mg were prepared by IR, and the effects of the solution concentration on the morphology and composition were investigated. Solution reaction (SR) was also carried out for discussing the transfer mechanism in IR.

2. Experimental

-Solutions- K_2HPO_4 solution was used as W_i phase. Solutions of CaCl_2 and MgCl_2 at a Mg molar ratio X=Mg/(Ca+Mg) of 0.05–0.6 were used as W_o phase, containing Tween20. O phase was a Span80-cyclohexane solution.

-Interfacial reaction- W_i phase at C_o=0.3 mol/kg was poured into O phase and agitated to form a W/O emulsion. This was mixed with W_o phase at C_o=0.5 mol/kg to form a W/O/W multiple emulsion. The stirring was kept at 323 K for 18 h to prepare microspheres.

-Solution reaction- At 323 K, 100 cm³ of W_i phase at C_o=0.05–0.5 mol/kg was added dropwise for 1 h into 300 cm³ of W_o phase at C_o=0.03–0.3 mol/kg, and the stirring was kept for 18 h.

-Characterization- The crystalline phase was identified by XRD. The morphology was examined by TEM. The Ca and Mg concentrations were measured by ICP-AES after dissolving in nitric acid. The relative deviation was defined as RD=(x_s–x_i)/x_i, where x_s and x_i are the Mg ratios prepared by IR and SR, respectively.

3. Results and discussion

The crystalline phase of the product prepared by IR was predominantly Mg-TCP. A hollow morphology was observed, in which primary nanosheets assemble at the interface between W_o and O phases. As X was increased, primary round shaped particles were increased. x_s was as significantly low as one-tenth or less of X. On the other hand, x_s by SR was almost the same as X, whereas the predominant phase was also Mg-TCP. This result means that Mg at a given concentration can be taken in the product when reactant ions are mixed at a given concentration. Less x_s may be due to a lower concentration of the reactants at a reaction site. Therefore, it is thought that the mixing state of both the aqueous phases in IR should be inferred if the combination of C_i and C_o by which x_s becomes equal to x_i by IR could be found.

SR was carried out at a fixed C_i. The resulting x_s was similar to X. Under any condition, RD was much greater than unity. It was not consistent with the results by IR. Next, SR was carried out at a fixed C_i. Lower C_i resulted in less x_s. Regardless of X, RD at C_i=0.03 mol/kg was almost zero, which means consistent with IR. This result suggests that a low concentration of phosphate ions are mixed at a reaction site with a given concentration of Ca and Mg ions.

In the presentation, we will propose a transferring mechanism by assuming some carrier for ions.

Challenges for the Additive Manufacturing of Shape Memory Ceramics Virag S. Raut¹, Tom Glen², Hang Yu³ and Steven T. Boles¹; ¹Electrical Engineering, Hong Kong Polytechnic University, Kowloon, Hong Kong; ²University of Edinburgh, Edinburgh, United Kingdom; ³Materials Science and Engineering, Virginia Tech, Blacksburg, Virginia, United States.

The multiplicity of phases (cubic, tetragonal, monoclinic, etc.) in zirconia-based systems has produced many opportunities for new applications and research directions. Interestingly, zirconia doped with ceria in certain compositions gives rise to a shape memory effect (SME) and superelasticity when exposed to applied stress and/or temperature. In this work, we have investigated SME behaviour in 12% ceria-doped zirconia (Ca_{12}Zr_{10}O_{37}, CZ). CZ undergoes a martensitic transformation upon application of an applied stress which is marked by a phase change between tetragonal (T) and monoclinic (M) phases. The monoclinic content (MC) generated from the applied stress can subsequently undergo a thermally induced reverse phase transformation from M to T. The findings from our experiment suggest that the shape and morphology of CZ powder influences the MC generated during stress-induced transformation.

A higher MC in pellets is produced after stress-induced transformation despite of a reduced MC i.e. fewer nucleation sites after annealing the CZ powder. The behaviour is split into two regimes: for lower temperature treatments, the morphology give rise to stress concentrations and contribute to a higher growth in MC; for higher temperature treatments, sintering and grain growth seemingly dominate the morphology and applied stress has a limited ability to increase MC. These results suggest conventional processing steps for bulk ceramics may be challenging. To avoid deleterious thermal treatments, a slurry based additive manufacturing approach is employed to produce porous ceramic structures. Infiltrating porous CZ with polymer materials using architectured topologies and new design methods may lead to optimization of SME properties for meta-materials research and applications.

PM01.09.05

Precise Synthesis for Designed Polymer Gel Networks from the Star Polymers and Its Properties  Kwon Dowoo, Yuto Jochi, Yukikazu Takeoka, Takahirou Seki, Kotoro Satoh and Masami Kamigaito; Nagoya University, Nagoya, Japan.

Polymer gels have been continuously studied by researchers, because they exhibit useful functions for various applications. Also from an academic point of view, polymer networks of polymer gels have attractive properties both theoretically and experimentally. Generally, polymer networks can be easily prepared by free radical polymerization using monomers, initiators, and crosslinking agents. However, because the reaction process is extremely complicated in the reaction solution for preparing polymer gels, the resultant conventional gels have inhomogeneous and entangled polymer networks. While the structures of the polymer networks are closely related to the properties, the network structures including homogeneity, monomer sequence, and crosslinking points have been difficult to control by the methods so far. To design optimal network structures for applications, it is necessary to clarify the relationship between the structures of the polymer gels and those physical properties in an appropriate manner.

In this research, we introduced precise strategy to control the network structures and investigated thermal and mechanical properties of the network designed gels. Two types of preparative methods for synthesizing star-shaped polymers are sequentially employed. Firstly, star-shaped polymers are synthesized using ‘Core-first method’ by living radical polymerization utilizing tetra-functional initiator. The Atom transfer radical polymerization (ATRP) system of N-isopropylacrylamide(NIPA) was selected, because highly controllable polymerization system was essential to the detailed control of the networks. By the ‘Core-first method’, tetra-branched polymers with narrow polydispersity index (<1.1) were successfully synthesized. Secondly, according to ‘Linking methods’, the resultant star-shaped polymers are converted to the polymer networks by adding linking agents in one-pot. After adding the crosslinking agents when the monomer conversion reached over 95%, the polymer gels were obtained in 5 minutes. The combination of these methods facilitates to control the homogeneity and the sequence of monomers on the polymer networks.

Considering the experiment data, we have expected that the polymer gels have repetitive structure units composed of two types of sparse or dense star-shaped polymers, which are originated by the tetra-branched polymers and the crosslinking agents. Comparing with polymer networks prepared by free radical polymerization, there might be no inhomogeneity except for a few dangling chains derive from unreacted polymer chains. The physical properties of the polymer gels were investigated on the conventional gels and the network designed gels. On the poster presentation, we would like to discuss about the detail of the synthesis data of the novel structure gels and the consideration about the structure-properties relationship.

Droplet-based microfluidics is an established technique for fabricating microemulsions, microparticles and vesicles with tailored physicochemical properties for a broad range of applications in biology, chemistry, and material science. The state-of-the-art technique for fabricating flow cells to prepare microprobes is a combination of photo-lithography and soft lithography based on poly(dimethylsiloxane) (PDMS), where a PDMS replica of microchannels is bonded to a glass slide, followed by post-processing steps, such as surface modification. While this multistep process yields microfluidic devices with feature sizes of a few micrometers in a parallelized fashion, each processing step is prone to experimental errors, which can make it challenging to reliably obtain high yields of functional microflow cells. Additive manufacturing based on micro-soft-lithography (μSL) is a promising alternative approach for fabricating microfluidic flow cells. This one-step three-dimensional (3D) printing technology is characterized by its high resolution and short process time. Utilizing a digital light processor, the 3D computer-aided design of a microflow cell is built up in a layer-by-layer fashion by exposing a liquid resin bath with stacks of xy-illumination patterns. Several parameters are optimized to make functional microflow cells, including the layer thickness, exposure time and energy, and the tilting up and down speed after each exposure. The high resolution and comparable to conventional PDMS-based fabrication methods and ultimately replace them, we have evaluated three key printing parameters in μSL: resin viscosity, alignment of the flow cell with respect to the printing direction, and the voxel compensation adjustment in the xy-plane. The same 3D-printed flow cell can be employed for forming both oil-in-water (o/w) and water-in-oil (w/o) emulsions, with respective diameters of approximately 100 µm and 50 µm. The emulsions then serve as templates for preparing hydrophobic or hydrophilic polymer microparticles with frequencies of up to 2.8 kHz in a single 3D-printed microflow cell without requiring additional steps for controlling microchannel wettability. In contrast to conventional multistep microfluidic device fabrication by photo- or soft-lithography, we report the preparation of non-planar microfluidic flow cells in a single processing step that can be used for fabricating both hydrophobic and hydrophilic microparticles without requiring surface modification.

Bio-Inspired, Metal Based, Layer-by-Layer Structured Composites with Exceptionally High Toughness Yunya Zhang and Xiaodong Li; University of Virginia, Charlottesville, Virginia, United States.

Nature’s wisdom resides in constructing delicate architectures from limited constituents and achieving superior performances by the constructed structures. As exhibited in nacre, hard CaCO3 platelets are cemented by soft biopolymers, forming laminated architecture. The hard CaCO3 platelets act as main load bearers while the soft biopolymer layers dissipating energy and redirecting cracks. Such hard-soft-hard design enables a joint enhancement of strength and toughness, which are considered mutually exclusive in engineering materials. Therefore, nature inspires us that the dilemma between strength and toughness can be overcome by rational design of microm-scale architectures. In order to mimic nacre’s structures, graphene, a single layer of carbon atoms with extremely high strength, was used to composite with metals. In one study, graphene oxide sheets were incorporated with Al flakes. After freeze drying, sintering, and rolling, nacre’s three identifying features (laminated structure, nanosuperstructures, and mineral bridges) were effectively emulated in the composite. Graphene oxide released oxygen-containing gases during high temperature annealing and the gases reacted with Al, forming Al2O3/graphene/AlOx sandwiched layers at interfaces. The confluence of multiple strengthening and toughening mechanisms resulted in a joint improvement in hardness (210%), strength (223%), stiffness (78%), and toughness (30%). In another study, Ni powders were coated with graphene layers via shear mix and freeze dry. Carbon reacted with Ni at high temperature, forming rectangular NiC2 second phase particles. The brick-and-mortar structure coupled with dissolved carbon atoms led to 97% improvement of strength with a minor reduction of ductility.

PM01.09.08
Fabrication of Electroactive ZnO Nanomesh via Vapor-Phase Materials Infiltration in Self-Assembled Pyridine-Based Diblock Copolymer Thin Films Ashwathn Subramanian1, Kim Kisslinger1, Daniel Yi2, Robert B. Grubbs3, Gregory Doerk4 and Chang-Yong Nam5; 1Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 2Department of Materials Science and Chemical Engineering, Stony Brook University, Stony Brook, New York, United States; 3Department of Chemistry, Stony Brook University, Stony Brook, New York, United States.

Thin film nanoarchitectures can offer enhanced materials properties, such as large specific surface areas that amplify the structures’ interaction with environments, making the nanostructures useful for various sensing applications. Infiltration synthesis, a new-type of organic-inorganic material hybridization technique derived from atomic layer deposition, relies on the vapor-phase inorganic precursor infiltration into polymeric matrix. When applied to self-assembled templates of diblock copolymer (BCP) thin films and combined with the subsequent removal of polymer matrix, the technique enables a reliable large-scale inorganic material nanoengineering. Although the infiltration synthesis of alumina (Al2O3) nanostructures using self-assembled poly(2-vinylpyridine)-block-poly(methylmethacrylate) (PS-b-PMMA) BCP thin films has been well documented, the generation of more useful semiconductor nanostructures, such as those made of zinc oxide (ZnO), has been relatively scarce, unless the pre-infiltration (i.e., priming) of Al2O3 is applied, due to the weaker interaction of Zn precursor with polymers in general. Here, we demonstrate the successful infiltration synthesis of pristine ZnO nanostructures without resorting to the Al2O3 priming, by taking advantage of more chemically reactive self-assembled polystyrene-block-poly(2-vinylpyridine) PS-b-P2VP BCP thin films as well as the newly developed, micro-dose infiltration synthesis protocol. By exploiting the self-registrering phenomenon between successively coated self-assembled BCP thin films, we generate the electroactive, stacked ZnO nanomesh thin film architecture with the controlled number of stacked layers. The electrical characterization under dark and illuminated conditions reveals an enhancing electrical conductance with increasing number of nanomesh stack layers. The results not only illustrate the first demonstration of electrical functionality based on the ZnO nanoarchitecture generated by the infiltration synthesis in self-assembled BCP thin films but also present a new, large-area scalable, metal oxide thin film nanoarchitecture fabrication method utilizing industry-compatible polymer solution coating and atomic layer deposition. The fabricated ZnO nanomesh architecture also promises potential applications as an efficient active sensing medium for chemical and optical detectors.

Investigating the Conformality of Shell Structures on GLAD Growth Rod Core Structures by Monte Carlo Simulation Mesut Yunkur1, Serkan Demirel1 and Fatma Merve Yurtsever2; 1University of Arkansas, Little Rock, Arkansas, United States; 2College of Computer and Information Sciences, Regis University, Denver, Colorado, United States.

Shell-core nanorod array geometry can offer enhanced durability for polymer electrolyte membrane (PEM) fuel cell electrodes, and increased surface-volume ratio for high efficiency for batteries, solar cells, sensors if a structured shell is conformally coated around the nanorod support base. The quality of volume ratio for high efficiency for batteries, solar cells, sensors if a structured shell is conformally coated around the nanorod support base. The quality of shell coating around nanorod is as crucial as the quality of the nanowires in device applications. In this study, we performed an experimental investigation of different physical vapor deposition (PVD) techniques to discover the most efficient deposition technique for a conformal shell coating around nanorods. To assess the PVD conditions to produce conformal shell coatings, Monte Carlo simulation method (MC) can provide useful guidance as well as helping investigate fundamental growth dynamics during shell-core nanorod array fabrication. Monte Carlo simulations were conducted to determine a simple and scalable fabrication technique for conformal and uniform shell coatings. We conducted Monte Carlo simulation (MC) and investigated the conformality of PVD shell layers on nanorods of the same length to predict the different materials. Our results show that high pressure with normal angle deposition can generate better conformal shell coating inside all others. The results suggest that an atomic flux with an angular distribution which can be easily maintained by sputtering at high working gas pressure can form conformal and uniform coatings. Our results indicate that...
conventional PVD techniques, which offer low cost and large scale thin film fabrication, can be utilized for highly conformal and uniform shell coating formation in shell-core nanostructures. In our previous works, the pre-patterned template was used to run the shell coating simulations. In this paper, we investigated the shell conformality on in situ grown GLAD rod structures by Monte Carlo simulation. This work will give the reader an understanding of how significant the geometry and the design of the rod structured arrays play a role in core-shell PVD coating device applications.

PM01.09.10
Study on Array Transmittance Improvement of Thin-Film Transistors Chengzhi Luo; Wuhan University, Wuhan, China.

Transparent electronics, such as thin film transistors, is one of the most advanced topics for a wide range of device applications. The key components are wide bandgap semiconductors, not only as passive component but also as active component, similar to what is observed in conventional semiconductors like silicon. Transparent electronics has gained special attention during the last few years and is today established as one of the most promising technologies for leading the next generation of flat panel display due to its excellent electronic performance. In order to achieve the high performance, TFTs need to possess high light efficiency. Transmittance improvement is the main method to improve light efficiency of TFT array substrate.

In this paper, multilayer thin films of low temperature poly-Si array transmission area is made to study the effect of thin films and structure on transmittance. The results show that the transmittance of TFTs is greatly affected by different refractive index surface after inter layer dielectrics finished. We also find that that the effect of planarization layer thickness on transmittance is not obvious. Transmittance is decreased with the increasing of ITO thickness. By decreasing the film numbers, changing the film component, the inter surface with great difference of refractive index was reduced and transmittance can be improved by 7% approximately.

PM01.09.11
Autonomous Printing of Functional Contact-Stylus Circuits Annika Muehlbradt and Gregory Whiting; University of Colorado Boulder, Boulder, Colorado, United States.

Printing enables the fabrication of flexible, lightweight, and low-cost electronic devices with potential application in batteries [2], displays [1, 7], sensors [3, 6], and actuators [4]. Printing processes offer high-throughput production capabilities, but well-known printing methods, like inkjet and gravure printing, require different ink parameters (e.g. viscosity), substrate parameters (e.g. paper), and environmental parameters (e.g. humidity), and support variable throughput, uniformity, accuracy, and resolution [5]. These requirements make it difficult to fabricate functional printed electronics quickly and at scale. Printing methods to create devices “on-the-fly” in ambient conditions are needed to fully exploit the potential of printed electronics.

We introduce a novel, automated printing process for scalable manufacturing of flexible, multi-material electronics. The printing process comprises two phases: (1) an analysis of the circuit sketch, ink, and substrate, and (2) fabrication of the circuit. The circuit sketch is processed using a nearest-neighbor classifier with a geometric template matcher to extract key features. The ink and substrate parameters are inferred from a test print in which we measure electrical properties. Using these parameters as guidelines, our printing algorithm fabricates the circuit by iteratively printing circuit components and validating their electrical properties, making adjustments “on-the-fly” to achieve a functional circuit. This autonomous printing technique is universal and can be extended to a number of different inks, multi-material prints, and printing devices and offers a flexible fabrication process for printed electronics.

PM01.09.12
Optimization of 3D Printed Low-Density Foams for Inertial Confinement Fusion Matthew Worthington, James Oakdale, Monika Biener, Daniel Malone, Chantel Aracne-Ruddle, Jean-Baptiste Forien, Salmaan Baxamusa, Jianchao Ye, William L. Smith, Todd Weisgraber, Michael Stadermann and Juergen Biener; Lawrence Livermore National Lab, Livermore, California, United States.

A complex and diverse set of materials and material processing techniques enable a wide range of high energy density (HED) physics endeavors at Lawrence Livermore National Laboratory. One such experimental platform seeks to achieve inertial confinement fusion through symmetrical implosion of a capsule containing deuterium-tritium atoms. Here, a series of laser beams are focused into the inside cavity of a cylindrical gold hohlraum creating an x-ray drive field. One issue with this method is that there is significant hohlraum “wall movement” (i.e. generation of partially ionized plasma) that interferes with the path of the lasers leading to asymmetric capsule implosion. A low density foam liner on the interior of the hohlraum has been proposed as means to retard the motion of this plasma plume. Our approach to this problem of liner fabrication is to first 3-D print a polymeric lattice-based template using direct laser writing via 2-photon polymerization (DLW-TPP), followed thereafter by atomic layer deposition (ALD) to apply a high-Z coating of tantalum oxide (Ta2O5) and finally polymer template removal to arrive at a low-density hollowed-out tubular lattice composed of the desired material. This work will focus on the 3D-printing aspect of this project and will discuss our efforts to create a customizable, uniform polymer template that will fit snugly inside the gold hohlraum. 3D-printing, or additive manufacturing foam liners offers several advantages in addition to rapid design prototyping, including the ability to make complex density gradients or architectures that would otherwise be difficult/impossible to machine. DLW-TPP enables the ability to print sub-micron features, which is important for achieving density uniformity (i.e. >10 um sized pores). The density of the polymer template is 0.1 g/cc and after ALD/etching the desired Ta2O5 foam with a density of 0.02 g/cc is achieved (solid fraction < 1/400). When printing these templates, we have to account for shrinkage while drying with shrinkage during the ALD process. It is important to make sure these values are accounted for, as the foam must fit perfectly inside the hohlraum. During insertion stress on the liner is tracked using a modified nano-indenter. This data and its relevance to the liner diameter vs. hohlraum diameter vs. fidelity during template etching will be presented.

The work was performed under the auspices of the US Department of Energy by LNL under contract No. DE-AC52-07NA27344. The project was supported by the Laboratory Directed Research and Development (LDRD) programs of LNL (18-ERD-064).

PM01.09.13
The Size Effect for Low-Temperature Synthesis of Graphene on Porous Silicon Kurbangali B. Tynyshtykbayev1 and Zinetula Z. Insepov2,3,; 1School of Nuclear Engineering, Purdue University, West Lafayette, Indiana, United States; 2Condensed Matter Physics, National Research Nuclear University MEPhI, Moscow, Russian Federation; 3Nazarbayev University, Astana, Kazakhstan.

It has been shown that reducing the size of nanocrystallites on the surface of porous silicon (PS) fabricated via electrochemical etching leads to a significant increase of the surface energy of PS and to a decrease of the melting point of the nanocomposite. This effect was used for low-temperature synthesis of a graphene-like carbon by carbonization of the porous silicon surface using a CVD method, at temperatures as low as 350 – 500 °C [1]. This...
work demonstrates that synthesis of graphene-like carbon nanocomposites in form of spatially-oriented graphene modified with small additives of carbon nanotubes CNT and SiC inclusions occurs on the surface of graphene nanocrystallites on PS surface at 1050°C. We also demonstrated that the surface of a single c-Si crystal is not carbonized at 1050°C. A low-temperature synthesis of graphene-like carbon nanocomposites in form of graphene oxides and CNT with inclusions of various carbon allotropic forms occurs at 350 ± 500°C. The temperature of the low-temperature synthesis of graphene and graphene-like structures is related to the growth of surface energy of nc-PS nanocrystallites formed during pore formation in electrochemical etching. It has also been shown that the carbonized surface of PS-C=C preserves a high chemical stability.

PM01.09.14 Liquid Crystal-Templated Synthesis of Porous Polymeric Membranes with Predetermined Pore Alignment Asli Karausta and Emre Bukusoglu; Chemical Engineering Department, Middle East Technical University, Ankara, Turkey.

Liquid crystal (LC) is a phase of material which is intermediate to a crystalline solid and an isotropic liquid such that the molecules flow but retain a degree of long-range orientational ordering. LCs, due to their long range orientational ordering and fluidic properties, can be used in templated synthesis of polymeric materials. In the past studies of oil-in-water emulsion based polymeric microparticle synthesis, it was showed that control over the particle shape, organization of polymer chains and incorporation of porosity can be achieved when LCs were used as the oil phase[1]. In this study, we indicated that polymer films templated from liquid crystals provide basic design principles for the synthesis of films with predetermined pore alignment. For the synthesis of the material, we photopolymerized the mixture of reactive (4-[3-acryloyloxypropoxy]benzoic acid 2-methyl-1,4-phenylene ester (RM257)) and nonreactive (4-cyan-4'-pentylbiphenyl (5CB)) mesogens confined in film geometries with thickness of 20-200 μm, and then extracted the unreacted mesogens with solvent to yield polymeric films of area in the order of 10 cm2. The crucial point of this study was that, when we constrained the polymer films to an area either through a mechanical or a configurational constraint, open pores were incorporated into the films. The average diameter of the pores was found to be in the range 10-40 nm, and can be tuned by varying the reactive monomer concentration. In fact, the average direction of the pores was found to be determined by the nematic director which can further be controlled by the functionality of the contacting surfaces. Having control over the sizes and directions of the pores has enabled the material to be involved in many application areas. We found that the range of the pore sizes and the alignment behavior of the pores can potentially be used for the ultrafiltration purposes as one of these applications. We also demonstrated a successful separation of protein molecules and solid nanoparticles from aqueous media using polymeric films templated from liquid crystalline media, the mass transfer performance of which was also dependent on the alignment direction of the pores with respect to the surfaces. For the synthesized polymeric materials, we used characterization methods such as thermal, optical, mechanical properties, nitrogen adsorption porosimetry and electron microscopy. Overall, the outcomes of this study provide basic tools for the synthesis of porous polymeric films with predetermined pore directions that can potentially be suitable for separation purposes, drug delivery, catalysts, etc.

PM01.09.16 Additive Manufacturing of Hierarchical Three-Dimensional Micro-Architected Graphene Aerogels Xiaoyu Zheng; Virginia Tech, Blacksburg, Virginia, United States.

Graphene foams, despite having one of the stiffest base materials ever measured, suffer incredible degradation in mechanical properties with decreasing density, so much so that polymer foams can outperform graphene foams at low-densities, despite the polymer base material being significantly less stiff than a graphene sheet. Until now there were few predictable means with which experimental approaches to alter this paradigm had been developed. A light-based 3D printing process to rapidly create three-dimensional graphene lattices of essentially any desired structure with graphene strut microstructure having pore sizes on the order of 60 nm. This flexible technique enables printing 3D micro-architected graphenes with complex, high-resolution form factors unparalleled by previous graphene 3D printing techniques. We utilize this ability to demonstrate improved mechanical properties when scaling to lower densities due to control of its three-dimensional hierarchical micro-architecture. These 3DGs are ultra-light, possess large surface area, and maintain good electrical conductivity, while greatly expanding the micro-architectural design space that 3DGs can realize.

PM01.09.17 One Pot Synthesis of a Gel with a Homogeneous Network Structure by Combining Two Methods of Synthesizing Star Polymers Yusuke Baba, Kwon Dowoo, Yuto Jochi, Yukikazu Takeoka, Takahiro Seki, Kotaro Satoh and Masami Kamigaito; Graduate School of Engineering, Nagoya University, Nagoya, Japan.

A polymer having a three-dimensional network structure and absorbing a solvent is called a gel. A gel is expected to be applied to many functional materials because of their simple adjustment method and various functionalities. Generally, when a gel is synthesized by free radical polymerization, the gel has an inhomogeneous network structure. The inhomogeneity of the network structure of the gel influences the properties of the gel. However, the relationship between the homogeneity of the network structure and the properties of the gel has not been investigated in detail. This is because there are few methods for synthesizing a gel with a homogeneous network structure. In order to investigate the relationship, our research group succeeded in synthesizing a PNIPA (poly(N-isopropylacrylamide)) gel with a homogeneous network structure by combining two methods of synthesizing star polymers. One method is a core-first method in which star polymers are synthesized by living polymerization using multifunctional initiators. Another method is a linking method in which star polymers are synthesized by adding divinyl compounds to linear living polymers and crosslinking the polymer terminations. In our study, a star polymer is synthesized from a 4-branched initiator by living radical polymerization (core first method), and then the polymer chain ends are crosslinked by adding divinyl compounds (linking method). Thereby, a gel with a homogeneous network structure can be obtained. We believe that research on how inhomogeneity affects the properties of a gel will proceed on this gel. In this study, in order to investigate the correlation between the network structure and various physical properties in a solvent-free elastomer, a monomer in which the polymer becomes liquid at room temperature was used. So we prompt to synthesize a P(2-(2-methoxyethoxy) ethyl methacrylate) gel which can take an elastomer state with a homogeneous network structure and measure the mechanical properties. First, we prepared 4 branched star-shaped P(2-(2-methoxyethoxy) ethyl methacrylate) gel using 4 branch initiator, CuCl for catalyst, and bipy for ligand in anisole. As a result, we obtained 4 branch P(2-(2-methoxyethoxy) ethyl methacrylate) gel which can take an elastomer state with a homogeneous network structure and measure the mechanical properties. Finally, by combining these star polymer synthesis methods, a homogeneous polymer network consisting of MEO2MA was successfully synthesized.
The high hardness or yield strength of an alloy is known to benefit from the presence of small-scale precipitation, whose hardening effect is extensively applied in various engineering materials. Stability of the precipitates is of critical importance in maintaining the high performance of a material under mechanical loading. The long period stacking ordered (LPSO) structures play an important role in tuning the mechanical properties of a magnesium alloy. Here, we report (10-12) deformation twin inducing decomposes into lamellar LPSO structures and their re-precipitation in an Mg0.5Zn0.5Y (at. %) alloy. Using atomic resolution scanning transmission electron microscopy (STEM), we directly illustrate that the misfit dislocations at the interface between the lamellar LPSO structure and the (10-12) deformation twin are corresponding to the decomposition and re-precipitation of LPSO structure, owing to dislocation effects on redistribution of Zn/Y atoms. This finding demonstrates that deformation twinning could destabilize complex precipitates. An occurrence of decomposition and re-precipitation, leading to a variant spatial distribution of the precipitates under plastic loading, may significantly affect the precipitation strengthening. Regarding the compression deformation twin, we uncovered the interaction between (10-13) twin and stacking faults (SFs) occurrence of decomposition and re-precipitation, leading to a variant spatial distribution of the precipitates under plastic loading, may significantly affect the precipitation strengthening. The high hardness or yield strength of an alloy is known to benefit from the presence of small-scale precipitation, whose hardening effect is extensively applied in various engineering materials. Stability of the precipitates is of critical importance in maintaining the high performance of a material under mechanical loading. The long period stacking ordered (LPSO) structures play an important role in tuning the mechanical properties of a magnesium alloy.
introduces a new energy loss mechanism at low strains of only 1-5%. This loss mechanism, known as the Payne Effect, is one of the mechanical hallmarks of filled rubbers and is a major contributor to rolling friction in tires.

We create a model filled rubber which exhibits the rheological hallmarks of traditional filled rubbers, but can be optically imaged. Optical transparency is achieved by matching the refractive index of our filler, fumed silica, and our polymer, PDMS. Visualizing the deformation of the filler subnetwork requires a contrast mechanism with sufficient spatial resolution to resolve the filler microstructure. Fluorescent silica nanoparticles, whose physical size is comparable to the smallest length scales in the filler subnetwork, provide the desired optical contrast. With this system we can directly observe microstructural changes of filler particle aggregates during *in situ* shear deformation. We complement these observations with bulk rheological tests to gain new insight into the microscopic deformations underlying the Payne effect. By controlling filler loading and crosslink density, we can tune the microstructure of our composite to better understand the relation between its structure and mechanical properties.

**Jellium Phase-Field Crystal Model—The Thermodynamic Influence of Electronic Contributions**

Salvador Valtierra1, Nan Wang1, Nana Ofori-Opoku1, 2, Nikola Provatas1 and Kirk H. Bevan1; 1McGill University, Montreal, Quebec, Canada; 2Canadian Nuclear Laboratories, Chalk River, Ontario, Canada.

In an effort to systematically engineer the performance of multiphase materials we have developed a new electronic-ionic based coupled phase-field crystal (PFC) methodology.1,2 Our results are underpinned by a deep analysis of the free energy functional formulation which leads to the addition of an electronic free energy term in PFC.3,4 This functional is normally constructed based on an atomic number density in classical density functional theory (CDFT).5,6 Through a series of approximations from CDFT and a mean-field approach, PFC permits the modeling of multiple phases and observe microstructural features in materials. In this work, a jellium system is employed as framework to formulate a free energy which allows the visualization of the electron energetics that modify the stability of liquid and crystalline phases modeled in PFC. We present a profound discussion of the physical implications behind the construction of the free energy functional and architected microstructural consequences. This formulation would extend the model to study the influence of electronic features and external forces acting on the microstructure in order to tailor the multi-functional properties of materials. The aim of this study is to provide a new perspective on PFC, that will permit the inverse design of new phenomena in materials science modeling.

**Optical Properties of an Exciton in a AlN/GaN/AIN Spherical Core/Shell Quantum Dot Under Pressure**

Mustafa Sadoglu1, Noreddine Aghoutane2, Mohamed El-Yadri1, Amsaa El Haouari1, Elmustapha Feddi1, F. Dujardin1, Chuong V. Nguyen4, Nguyen N. Hieu1, Huynh V. Phu1 and Gen Long1; 1Saint John's University, Jamaica, New York, United States; 2Group of Optoelectronic of Semiconductors and Nanomaterials, ENSET, Mohammed V, Rabat, Morocco; 3LCP-A2MC, Institut de Chimie, Physique et Matériaux, Université de Lorraine, Metz, France; 4Institute of Research and Development, Duy Tan University, Da Nang, Viet Nam; 5Division of Theoretical Physics, Dong Thap University, Dong Thap, Viet Nam.

This work is based on our recent theoretical investigation of the effects of the hydrostatic pressure and core/shell sizes on the optical properties associated with the transition from the ground state into the first excited state (1s-1p), of the exciton in a spherical core/shell quantum dot (SCSQD). Our calculations are performed in the framework of the effective mass approximation and the energies are obtained by using a Ritz variational method. We have computed the linear, third-order nonlinear and total absorption coefficients (AC) and refractive indices (RI) as a function of photon energy for different sizes of SCSQD under the influence of the hydrostatic pressure. Our results show that the optical absorption is strongly dependent on the incident optical intensity and sensitively influenced by the confinement and pressure effects. We have found that, by increasing pressure, the AC and RI curves move toward the higher energies (blue shift). Our calculation also shows that the AC and RI are affected by the core/shell quantum dot sizes.

**PM01.09.24**

**Direct Ink Writing of Polymide Composites with Density/Dielectric Tunability**

H. Clive Liu1, 2, James O. Hardin1, 2 and John D. Berrigan3; 1UES Inc., Beavercreek, Ohio, United States; 2Air Force Research Laboratory (AFRL), WPAFB, Ohio, United States.

Polymide has been an important engineering material with excellent oxidative- and thermal-stability, mechanical performance, and dielectric properties that can be employed in harsh environments. However, architectural design and exploration of novel polymide composites are still hindered by the limited manufacturing and property-tailoring strategies. Currently, hierarchical construction of polymide can be achieved through imidizing the additive-manufactured precursor polyamic acid or photo-curing a chemically modified polyimide. Yet these 3D process-ability are reported at the respective expense of significant shrinkage (≥ 40%) accompanied by the imidization reaction or a pronounced decrease (100 – 200 °C) in degradation temperature compared to other polymide analogues.

In this study, we present 3D polymide architectures through direct writing of fully-imidized polymide ink without photo-crosslinking or post-print thermal/chemical imidization. The printed structures are programmed with intrinsic micro-porosity through a simple formulation strategy that acts to suppress density, dielectric permittivity, and dissipation. Moreover, the development of composite ink formulations allow tailoring of functionality (e.g., electrical/thermal conductivity, high-$k$ dielectric) into the structures. These micro-porous and composite polymide materials enable the investigation of cellular and graded architectures to manipulate mechanical response, structural mechanics, and electromagnetic wave steering efficiency for future 3D printed antenna applications.

**PM01.09.25**

**3D Direct-Nozzle Printing of Ceramic Magnetic Core for Transformers with Viscoelastic NiZn-Ferrite Paste**

Taekyu An and Jihoon Kim; Kongju National University, Cheonan, Korea (the Republic of).

3D printing technology recently attracts a significant amount of attention due to its potential to easily fabricate complex designs of diverse products. This
technical convenience leads to the step where 3D printing technology is considered an innovative and simple way of manufacturing ceramic-based electronic components. In this study, 3D direct-nozzle printing was introduced to fabricate various shapes of the NiZn-ferrite soft magnetic core for transformers. The NiZn-ferrite paste for 3D direct-nozzle printing was formulated by incorporating various functional additives to impart viscoelastic property. This viscoelastic property of the paste plays a critical role in printing and maintaining the 3D shape of the transformer core. The correlation of viscoelastic property with 3D printability will be addressed in depth in this presentation. The 3D-printed magnetic cores of different designs were sintered at an elevated temperature. The volume shrinkage and magnetic functionality were investigated after sintering. Finally, we printed EFD type transformer cores and compare their performance against commercial transformers with the same type. Our successful demonstration implies the importance of viscoelasticity in 3D printing ink and the potential of 3D printing as a manufacturing process for ceramic-based electronic components.

PM01.09.26
Application of Box Benhken Experimental Design in the Fabrication of Anodized Aluminium Oxide Templates from Low Purity Substrates and Its Escalation to Extended Areas
Line M. Castro and Carlos Ostos; Facultad de Ciencias Exactas y Naturales, Universidad de Antioquia, Medellin, Colombia.

In the last years, the scientific community has developed multiple variations of the aluminium anodization process, with the goal to prepare nanostructures to be adapted for new technologies. The controllable microstructural parameters, self-organized pore-arrangement, parallel nanochannels, narrow pore-size distribution, and high pore density, open a wide range of possibilities for nanomaterial synthesis and the opportunity to module the properties of the periodic nanostructures. Therefore, an optimization of the experimental conditions is mandatory to achieve the desired dimensions and best arrangements of pore features; hence providing the best performance of derived nanostructures [1].

In this work, the influence of the most important operating parameters, such as potential (30V-60V), temperature (10°C-20°C), and concentration of electrolyte (0.3M-0.6M), on the structural features of alumina was investigated by means of Box-Benken experimental design (BBD). A low purity aluminium foil, 99.06%, was selected to accomplish the experiments because of its low cost and high suitability when addressing real applications. The aluminium foils were first machined with an area of 1 cm² and degreased using a mixture solution of acetone/ethanol; afterwards, the foils were processed using oxalic acid solutions with concentrations from 0.3 M to 0.6 M, temperature range from 10°C to 20°C, and potential from 30V to 60V, these parameters were used as input factors for the BBD design. The obtained models granted us the possibility to understand the individual and interaction effects of the three operational parameters on the steady state current and pore features, such as regularity ratio (R₃₅), pore diameter (Dₚ), eccentricity (Ecc), aspect ratio (AR), pore density (ρₚ), interpore distance (Dₓ), and porosity percentage (%P). Potential and temperature were found to significantly affect most of the assessed geometrical pore features of the Box-Benben design. The regularity ratio was optimized with a value of 2.0134 under the next conditions: 46V-10°C-0.6M.

The optimized set of conditions were used for the scaling up of the process in 78 cm² aluminium foils. We have found that anodization under these conditions can produce porous alumina templates with a highly ordered cell configuration, even from inexpensive aluminium substrates and without the necessity of advanced equipment, an important fact that widen its applications at industrial scale. The fabrication of the extended AAO surfaces is important to proceed with the large-scale assembly of one-dimensional structures, which must be considered to boost the development of new technologies.

PM01.09.27
Monolayer-to-Thin-Film Transition in Supramolecular Assemblies on Graphene—The Role of Topological Protection
Alexander J. Marsden, Zachary Laker, Oreste De Luca, Ada Dell’Aia, Luis M. Perdigão, Giovanni Costantini and Neil Wilson; 1Materials, University of Manchester, Manchester, United Kingdom; 3Chemistry, University of Warwick, Coventry, United Kingdom; 4Physics, University of Warwick, Coventry, United Kingdom.

Supramolecular assembly is a promising route for the bottom-up synthesis of nanomaterials. The resulting structure is guided by the non-covalent forces between molecules, and those between a substrate and the molecules. The interactions with the substrate can template up through the film: successive layers of molecules are influenced by earlier ordering, and the resulting structure can be different from its expected bulk form. These structured nanomaterials show promise for applications in electronics and optoelectronics. Here we study the supramolecular assembly of benzene-1,4-dicarboxylic acid (terephthalic acid, TPA), and benzene-1,3,5-tricarboxylic acid (trimesic acid, TMA) on graphene. The thin film structure is investigated using low-dose, aberration-corrected transmission electron microscopy (TEM) as the film thickness increases, and is compared to the monolayer structure found using scanning tunneling microscopy (STM).

At the monolayer, both molecules display a structure dictated by hydrogen bonding between molecules: TMA forms a hexagonal chicken-wire structure, and TPA, a brickwork pattern. The orientations of these 2D monolayers are influenced by the graphene substrate through van der Waals epitaxy, although this is stronger in the case of TMA. Above a monolayer, TMA and TPA behave differently. The chicken-wire structure of TMA templates up through increasing film thickness, until after a certain critical thickness when the film becomes polycrystalline with random in-plane orientations. On the other hand, after a monolayer, TPA forms fibre-like islands, with the in-plane lattice parameters gradually changing with increasing thickness to those consistent with the bulk structure. These differences are thought to be anachronisms in the differences between the 2D and bulk structures for the two molecules. TPA can transition from its 2D structure to its bulk form through tilting and compacting of the lattice. However, TMA’s 3D structure consists of interleaving planes, which cannot be smoothly transitioned to as the film thickness increases. This idea of topological protection could be used to help design supramolecular assemblies in the future.

PM01.09.28
Bioinspired Design of Cement-Polymer Composites
Jessica Rosewitz, Habibehe Choshali and Nimra Rahbar; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Recent advances in the design of structural composites often mimic natural microstructures. Specifically, the structure of abalone nacre with its high stiffness, tensile strength, and toughness is a source of inspiration from the process of evolution. The inspiration from nacre can lead to design of a new class of architected structural materials with superb mechanical properties. This work presents a combined experimental and computational study on a set...
of bioinspired architected composites created using a cement mortar cast with brick-and-mortar and auxetic polymer phases. The impact of this unit-cell architecture on polymer phase on the flexural and compressive strengths, resilience, and toughness is thoroughly studied as a function of microstructural geometry. All mechanical properties of the architected composite specimens are found to be greater than those of control samples due to prevention of localized deformation and failure, resulting in higher strength. The microstructurally designed composites showed more layer shear sliding during fracture, whereas the control samples showed more diagonal shear failure. After initial cracking, the microstructurally designed composites gradually deformed plastically due to interlocking elements and achieved high stresses and strains before failure. Results also show that microstructurally designed composites with the architected polymer phase outperform control samples with equal volume fraction of a randomly oriented polymer fiber phase. Extensive computational studies of the proposed unit cells are also performed and the results suggest that the orientation of cells during loading is critical to achieve maximum performance of a cementitious composite. The implications of these results are immense for future development of high performing construction materials.

PM01.09.29
Fabrication of Photo-Activating Acryl-polyurethane Through Short Curing Time
Hyo Jinn Jung, PilHo Huh, Kyung Soek Kang, Jihong Bae, Chanhyuk Lee, WonBin Lim and Byeongoo Kim; Pusan National University, Busan, Korea (the Republic of).

Thermoplastic photo-activating PU was successfully synthesized by the additional reaction of methylene diphenyl disocyanate (MDI), poly(tetramethylene ether) glycol, and tri-acrylate derivatives as a crosslinking point. The crosslinked PU-acrylate elastomers were fabricated by the exposure to 200–400μm UV radiation. DMF was used as a solvent for the synthesis, but THF with low UV cut off was used to crosslinked the PU-acrylate in order to reduce crosslinking time. The structures and properties of the resulting acryl-PUFs were evaluated by fourier transform infrared spectroscopy (FT-IR), gel permeation chromatography (GPC), ultra violet spectroscopy (UV-Vis), differential scanning calorimetry (DSC), and universal testing machine (UTM). The increase of acrylate concentration in acryl-PUFs elastomers led to higher tensile strength and hardness due to the increased crosslinking density and the enhanced interchain hydrogen bonding. The application as a 3D printing material was verified according to the shortened crosslinking time.

PM01.09.30
The Effects of Dynamic Transformation on the Formation of Pt-Ni Nano-Octahedra
Yiliang Luan1, Can Li2, Bo Zhao3, Amar Kumbhar3, Jun Zhang4, and Jiye Fang1; SUNY Binghamton, Binghamton, New York, United States; 2Texas Tech University, Lubbock, Texas, United States; 3University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States; 4China University of Petroleum, East China, Qingdao, China.

Colloidal synthesis has been widely used in the development of nanomaterials including metals, alloys, and semiconductors, as it can produce uniform, size-controlled and shape-controlled nanoarchitectures. It is usually desired for shape-controlled products to expose exclusive facets, correlating a collective property such as reaction activity or selectivity with the specific surface crystal face. Compared with other conventional approaches such as the hydrothermal method, the solution-based synthesis has more variable factors that govern the formation of the nanocrystal products, due to the kinetic and thermodynamic effects in the nucleation and crystal growth processes, such as a competition between the deposition and diffusion of “free atoms” on a nanocrystal. These factors greatly impact the morphology evolution of the products with some in-depth mechanistic insights to uncover. In our synthetic system, a non-polar organic solvent is usually chosen as the reaction medium to facilitate a formation of shape-controlled nanocrystals at an elevated temperature through the hydrophobic interaction between the solvent and the hydrocarbon chains in the selected capping ligands. Thus, the mass and heat transfer that is closely associated with the progress of the nanocrystal evolution could be greatly influenced by some intrinsic properties of the solvent such as the viscosity and by some tunable conditions. In the latter, stirring rate and the ramp rate of heating are identified as two of the significant factors that could alter the balance between the deposition and diffusion of “free atoms” on a nanocrystal. Nevertheless, there are limited reports of studying these factors. Herein, we present our progress of such a study using a synthesis of Pt-Ni octahedral nanocrystals in the presence of W(CO)6 as an example. A slow stirring rate (~200 rpm) and high ramp rate for heating (8 °C/min) resulted in pod-like Pt-Ni nano-products, whereas their counterpart conditions (~400 rpm and 5 °C/min) generated uniform Pt-Ni nano-octahedra when other experimental parameters remained the same. Based on our observation, a plausible mechanism is proposed. One hand, the slow stirring rate and high ramp rate of heating can promote the atom deposition on a nanocrystal, leading to pod-like products due to an accumulation of the ad-atoms on the same planes of a seed. On the other hand, the relatively high stirring rate and slow ramp rate of heating can preserve sufficient time to allow the deposited atoms to re-distribute to those thermodynamically stable sites. In other words, the dominative diffusion, in this case, is the driving force of the nano-octahedron formation.

PM01.09.31
Cement Mortar Reinforced with Polypropylene Mesh
Charles Nikou1, Konstantin Kornev1, Jeffery R. Owens2 and Igor Luzinov1; 1Materials Science and Engineering, Clemson University, Clemson, South Carolina, United States; 2AFCEC CXAE, Air Force Civil Engineer Center, Panama City, Florida, United States.

Concrete is one of the world’s most widely used building materials for many reasons including: relatively low cost, moldability, and high compressive strength. This high compressive strength is perfect for most construction applications where the building is subjected to constant and well known static forces. However, due to concrete’s brittle nature, crack formation and ultimately failure will occur when it is exposed to dynamic or tensile loading; concrete is often subjected to such conditions in highway and military applications. Polymeric fibers, namely Polypropylene (PP), are often added to the concrete mix in order to provide toughness and impact resistance, improving the survivability of concrete under such loading conditions. In this work we consider PP mesh in lieu of fibers as impact modifier for cement based structures. In brief, we have studied the effect of the mesh addition to cement mortar on physical properties, including impact resistance. It is suggested that mesh reinforcement can offer better improvements to toughness due to its connectivity and, therefore, ability to serve as macro scale reinforcement. Samples were prepared using a cement mortar mixture of constant composition (large aggregates were excluded due to the cm-scale sample size) and reinforcement with ~ 2% by volume of varying sized PP meshes. The samples were subjected to compression, tensile splitting, and impact testing in order to quantify their mechanical properties. The effect of mesh geometry and distribution on sample properties were investigated. Additionally, the properties of mesh reinforced samples were compared to those of fiber reinforced and non-reinforced samples. In the future, hybrid geometry reinforcements will be investigated alongside with mechanical modeling of the composite systems.

Polymer Templating for Metallic Foam Fabrication with Wide-Ranging Compositional Control
Chang-Eun Kim1, Raheleh M. Rahimi1, Ioannis Mastorakos2, and David F. Haley1; 1Purdue University, West Lafayette, Indiana, United States; 2Clarkson University, Potsdam, New York, United States.

Metallic foam structures can be fabricated using a wide range of techniques; at the nanoscale de-alloying forms nm-sized ligament/pore foams in noble metals, while gas foaming at the meso-scale enables bulk material formation in engineering alloys. Capturing both length scales, mm-level porosity to sub-mm porosity, is challenging, and compositions accessible by these particular techniques are often mutually exclusive. This presentation addresses a new model of metal foam creating, using electrospun polymer fibers containing soluble metal acetate. Using a combination of oxidation and thermal reduction on electrospun fibers allows for multiple length scales of structural feature control, with meso-scale pores dominated by the fiber diameter and spacing, and

Additive Manufacture of Hierarchically Porous Materials with High Resolution Siwei Liang1, Cheng Zhu2, Christopher M. Spadaccini1, Eric B. Duoss1, Theodore Baumann1 and Yat Li2; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2University of California, Santa Cruz, California, United States.

A ink system for additive manufacturing hierarchically porous materials with high resolution (ligament size < 100 μm) has been prepared by sol-gel approach. In this ink system, a resol polymer precursor was first synthesized and then mixed with other components including pluronic block-copolymer, other precursors, solvents and catalyst. The resulting clear and powder-free ink was direct-ink written into different structures and gelled at elevated temperature. The printing parts were further calcinated or carbonized to afford 3D hierarchically porous materials. The 3D products were characterized by SEM, SAXS, BET, TEM, Instron, FTIR/Raman spectroscopy and dielectric spectroscopy. They demonstrated potential application in energy storage and catalyst field.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Parameterized Lattice with High Stiffness Through Engineered Functional Gradients Joshua DeOtte1,2, Nigel Morris1, Adrian Butscher1, Erin Bradner1 and Eric B. Duoss1; 1Lawrence Livermore National Lab, Livermore, California, United States; 2University of California, Davis, California, United States; 3Autodesk, San Rafael, California, United States.

Topology optimization enables automated constraint-based design of structures. If a parametric lattice unit cell is used to construct the structure, a subsequent optimization pass can be run to redistribute mass within the generated topology and improve performance. A two-phase optimization scheme was used to generate a structure with a material gradient for supporting a cantilevered load. An isotropic unit cell with an effective modulus linearly dependent on relative density was used to populate an optimized cantilever structure. The second optimization pass then adjusted the beam diameters of each unit cell to improve stiffness. The resulting lattice structure was fabricated using a custom projection stereolithography system and mechanically tested. Four structures were used: 1) solid beam cantilever, 2) uniform lattice cantilever, 3) shape-optimized uniform lattice cantilever, and 4) shape- and material-optimized cantilever. Structures were cleaned and thermally post-processed to achieve high conversion. Mechanical testing showed that the flexural stiffness increased between the solid beam and the uniform lattice with additional gains for both shape-optimized and the shape- and material-optimized cantilevers.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Polypropylene and PETG 3D Printed Hybrid Structures Erik L. Antonio, Pu Zhu and Igor Luzinov; Clemson University, Clemson, South Carolina, United States.

With the rise of 3-D polymer based printing, especially with the potential of the mass industrial utilization of the technology, there is a need for a better understanding for fabrication of hybrid structures utilizing the materials commonly used. To this end, using fused deposition modeling (FDM) 3D printing technique we fabricated Polypropylene (PP) and Polyethylene Terephthalate Glycol-modified (PETG) hybrid samples and analyzed their properties. The properties are directly related to the printing temperature, viscosity, and percentage within the print of the two components. Our studies confirmed that the hybrid samples have lower mechanical characteristics than the samples printed from either pure material. We associate the decrease in properties with adhesive issues at PP/PETG interface. To improve these properties, PP fiber was mixed with small amount of PETG to create diffusive bonding at the hybrid samples have lower mechanical characteristics than the samples printed from either pure material. We associate the decrease in properties with adhesive issues at PP/PETG interface. To improve these properties, PP fiber was mixed with small amount of PETG to create diffusive bonding at the interface. Our approach is expected to be transferable to similar 3D printed polymer hybrid/composite systems that also face poor mechanical properties.

PM01.09.37
Additive Manufacturing of New Structures for Heat Exchange Philip DePond1, Du Nguyen1, Pratana Roy1, Victor Beck1, Omer Dogan1, Dan Tortorelli1, Eric B. Duoss1, Manyalibo Matthews1 and Joshua Stolaroff2; 1Lawrence Livermore National Laboratory, Livermore, California, United States; 2National Energy Testing Laboratory, Albany, Oregon, United States.

Recent advances in manufacturing are enabling a new range of material properties and product performance. Additive manufacturing of metals and alloys, specifically laser powder bed fusion (LPBF), allows for the production of large, robust and highly complex structures. Here we describe the development and testing of a heat exchanger for sCO2 power cycles with radically improved material efficiency and higher temperature tolerance than current technology. Triply Periodic Minimal Surfaces (TPMS) are chosen as candidate structures as previous work shows an expected order of magnitude improvement in heat transfer performance over tubes and flat plates. The project combines additive manufacturing of nickel superalloys with new, efficient hierarchical geometries, which are common in nature to achieve high interfacial area with low pressure drop, and are now achievable in synthetic with advanced manufacturing techniques. Focusing on the Schwarz-O geometry, flow characteristics and temperature fields were modeled to compare heat transfer coefficients. Thermal stress modeling was performed to couple heat transfer with solid mechanics. The process development of 5 candidate nickel super alloys is described, along with ambient and high temperature mechanical testing results. Bench scale measurements of mass transfer, pressure drop and device robustness are performed for comparison and to aid design of a viable process.

PM01.09.38
A Hydrogel-Elastomer Hybrid Fabricated via 3D Printing Xinrui Niu and Yuexing Zhan; City University of Hong Kong, Kowloon, Hong Kong.
Mechanical integrity of hydrogel-elastomer hybrids is limited by the fracture toughness of hydrogel which disables the usage of many useful but fragile common hydrogels. This work fabricated a new hydrogel-elastomer hybrid with the help of 3D printing technique. The two materials are physical engaged into each other. Peeling test demonstrated that the new hybrid had superior mechanical integrity over the conventional hydrogel-elastomer anchored by chemicals. This method enables the mechanical integrity of hydrogel-elastomer hybrid to go beyond the fracture toughness of hydrogel.

**3D Printing of Bicontinuous Hierarchical Porous Carbons and Metal Oxides**

Cheng Zhu¹, Siwei Liang¹, Bin Yao², Marcus A. Worsley¹, Yat Li², Eric B. Duoss¹ and Christopher M. Spadaccini¹; ¹Lawrence Livermore National Lab, Livermore, California, United States; ²University of California, Santa Cruz, California, United States.

Hierarchically porous materials are becoming promising candidates for biomedical, catalytic, and energy storage applications for their unique combination of low density, exceptional mechanical properties, large surface area, and excellent electrical conductivity. Recent research has focused in the topological design of cellular materials in order to satisfy multiple design objectives. Unfortunately, these design advances have not been met with similar advances in cellular material manufacturing as existing techniques constrain a designer to a predetermined part mesostructure, material type, and macrostructure. In an effort to address these limitations, we utilized 3D printing techniques to create designed architectures with bicontinuous hierarchically pores from 10nm to 1000 microns. 3D printing is one of emerging additive manufacturing techniques, which has been successfully commercialized for both prototyping and distributed manufacturing with industrial applications in architectures, automobile, aerospace, engineering, food, and biomedical areas. The key point is to develop a printable phase separable inks from precursor polymers. With this approach, we aim to demonstrate multi-scale (e.g., from the nano- to macro-length scales) assembly of arbitrarily complex, hierarchical 3D structures composed of carbons or metal oxides.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

**Structure and Energetic Characterization of Reactive Material Structures Formed by Kinetic Spray**

Jungsu Park and Sang-Hyun Jung; Agency for Defense Development, Daejeon, Korea (the Republic of).

Reactive Material Structures (RMSs) are a new group of materials designed to have simultaneously the features of structural materials and energetic materials [1]. Their typical applications are considered for military uses like reactive fragments, respective bullets and reactive casings. This paper describes the manufacturing method for structurally robust RMSs, and shows the structural and energetic characteristics of the acquired RMSs. To acquire robust RMSs, we attempted kinetic spraying (i.e. cold spraying) of reactive material powders that is consisted of various compositions. As a results, we obtained tough RMSs of thickness over 1cm. The prepared RMSs were microscopy (SEM), X-ray diffraction (XRD) and universal testing machine (UTM). All RMSs show a porosity of less than 5% and a compressive strength of more than 250 MPa. To characterize energy releasing features under the environment of explosive detonation, the exothermic energy of each RMS was also analyzed using detonation calorimetric Analyzer (DCA). As a results, surprisingly, we found that RMSs can release more energy than conventional explosives.

**Multifunctional Foam Synthesis—Paradigm Shift Towards Next Generation 3D Printable Composites**

Maria A. Torres Arango²-¹, Domenic T. Cipollone² and Konstantinos Sierros²; ¹National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, New York, United States; ²Flexible Electronics and Sustainable Technologies (FEST) Laboratory, Mechanical & Aerospace Engineering, West Virginia University, Morgantown, West Virginia, United States.

Engineering photonic properties represents an important milestone in the synthesis of new composite materials with potential applications in photo-electronic devices. Moreover, it is pivotal for their sustainable processing and reliability, while providing a new window to explore and further understand fundamentals. Here, we will discuss our approach to novel materials synthesis, focussing on hierarchical-cellular-heterostructured-photonic composites, with control over their multifunctionality, for additive manufacturing. Particularly, we will present our most recent results on Ag-decorated TiO₂ heterostructures’ one-pot synthesis. We believe that this route is the foundation towards a series of multi-material-based 3D printable composites. Such multifunctional composites will trigger great advances in direct-write additive manufacturing, while leading to unprecedented developments in multi-functional materials and 3D processing for optoelectronics, environmental and energy related applications, and even regenerative medicine.

Recent Progress on Flexible, Intrinsically Stretchable and Healable Organic Electronics

Qibing Pei; University of California, Los Angeles, Los Angeles, California, United States.

The emergence of devices that combine elasticity with electronic or optoelectronic properties offers exciting new opportunities for applications, but brings significant materials challenges. This presentation will describe our latest results in the materials efforts in developing intrinsically stretchable conductors, semiconductors, dielectric polymers, and demonstrating integrated stretchable electronic devices. Specific examples include a polymer composite comprising surface-embedded silver nanowires with high transparency, high surface conductivity, and low surface roughness. The mechanical properties of the transparent composite electrode are determined by the polymer matrix employed, and demonstrated properties include flexibility, shape memory, self-healing, and rubbery deformation. Results on the healing efficiency of the healable composite with failure induced by both mechanical and electrical loading will also be presented. Touch panels were fabricated to demonstrate the applicability of the AgNW healable composite material.

Enhancing Flexibility of Highly Conductive and Transparent Platform with Buffered Conducting Polymer Layer

Devendra Singh and Gilles Lubineau, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

The design of new electronic system featuring flexibility and stretchability requires using advanced materials and microstructure. Classical inorganic materials are conductive but brittle in nature. On another side, organic materials are flexible but comparatively less conductive and are sensitive to environmental conditions. Here, we propose a novel approach to integrate the advantages of both inorganic (Indium tin oxide) as well as organic materials, here PEDOT:PSS (poly-(3,4 ethylenedioxythiophene): poly (styrene sulfonic acid)) as conducting polymer, for their conductive and flexible intrinsic properties, respectively. In this work, a PEDOT:PSS buffer layer is used between ITO layer and PET [polyethylene terephthalate] substrate such that during the deformation of the film, the stacked system retains its high conductivity with strong stability. The reason for using a PEDOT:PSS buffer layer is to substantially reduce the detrimental effects of cracks in the ITO layer in terms of an overall conductivity of the system. The highly conductive and transparent ITO films were sputter deposited on PET substrates at room temperature, and different configurations (with and without annealing and/or an intermediate layer of PEDOT:PSS) has been studied extensively. Structural, optical, mechanical and morphological studies have been carried out to understand the behavior of involved layers qualitative and quantitatively. We find that integration of an ITO thin film with PEDOT:PSS buffer layer results in robust synergetic behavior, showing a relatively low initial electrical sheet resistance that is very stable even under strong bending (value of bending radii down to 2.5 mm, repeated cycles up to 1000 cycles). This high stability can be attributed to an improvement of the electrical transfer at the delaminated interfaces due to supporting buffer layer. Results show that this highly conductive, flexible and transparent platforms can be used for advanced flexible devices.
suitable operations as defogging/deicing systems for an automobile side-view mirror and camera lens, transparent heating block systems for polymerase chain reaction (PCR) devices, and particulate matter (PM) detecting systems for PM2.5 sensors.

High Dielectric Constants of Transparent and Flexible Cellulose Hybrid Films Using Multidimensional Metal Nanostructures for Flexible Touchscreen Panels Sangyoon Ji, Jiuk Jang and Jang-Ung Park; UNIST, Ulsan, Korea (the Republic of).

Various forms of wearable electronics have been developed, including wrist bands, smart glasses, and watches, which are exposed extensively to outdoor activities. The key metrics for these rapidly-emerging, wearable electronics are high touch sensitivity and good mechanical and thermal stability of the flexible touchscreen panels (TSPs). The dielectric constants (k) of their protective cover layers are very important because they can determine touch sensitivities. Thus, studies on cover layers that are flexible and transparent and that have high-k dielectric films with outstanding mechanical and thermal reliabilities are essential for the success of future wearable electronics. Herein, we report an unconventional approach for forming flexible and transparent cellulose nanofiber (CNF) films. These films are used to embed random networks of ultra-long metal nanofibers that serve as nanofillers to increase the value of k significantly (above 9.2 with the high transmittance of 90%). Also, by controlling the dimensions and aspect ratios of these metallic fillers, we studied the effects of the fillers’ nanostructures and contents on the optical and dielectric properties of the resulting films. The length of the metal nanofibers can be controlled precisely using a stretching method locally to break the highly-aligned, ultra-long nanofibers. These nanofiber-embedded, high-k films are mechanically and thermally stable, and they have a better Young’s modulus and better tensile strength with lower thermal expansion than commercial transparent plastics. Our demonstration of highly-sensitive, flexible TSPs using high-k CNF film for smartphones suggested that this film has significant potential for use in next-generation, portable electronic devices.

4:00 PM PM02.01.08
High Performance Flexible Transistors and Thin Film Heaters via Simple Solvent Treatment of Ag Nanowire Networks Imnu Jin and Jaewoong Jung; KyungHee University, Yongin-si, Korea (the Republic of).

Silver nanowires (Ag NWs) have been extensively studied as the material of the transparent conductive electrode (TCE), as a promising replacement of conventional indium tin oxide (ITO). However, a typical polyl synthesis of Ag NWs employs insulating polymers as surfactants for the growth, stability and dispersion of silver, which limits efficient electron transport between each nanowire. Although the conventional post-treatments such as thermal welding process could improve transmittance and sheet resistance of Ag NWs networks, they usually require high temperature or complicated process that may limit the choice of substrate. In this presentation, we demonstrate the simple solvent treatment to enhance the optoelectronic properties of Ag NW networks. The solvent treatment effectively washes out the surrounding insulating polymer, which results in significantly improvement of transmittance and sheet resistance of Ag NW networks. By the optimization of the solvent treatment, we successfully fabricated a high performance TCE with a sheet resistance of 12.95 Ω/sq and a transmittance of 81.25% at 550 nm. The solvent treatment was also suitable for flexible substrate, leading to 16.29 Ω/sq and a transmittance of 78.76% at 550 nm. For the practical applications, transparent thin film heaters (TFHs) made of Ag NW networks followed by the solvent treatment was also fabricated. The TFHs exhibited a good performance of 155 °C at a bias of 5 V. In addition, the flexible TFHs based on Noland Optical Adhesive 63 as a substrate afforded a high performance flexible TFHs with a quick response time (15 s). This TFH exhibits good optoelectronic properties and outstanding mechanical robustness against deformation, such as flexibility and deformability. Therefore, this substrate can be used as a flexible and deformable heater and the temperature can exceed 110 °C at a bias of 4 V. This work clearly demonstrates the efficacy of simple solvent treatment for practical use of Ag NWs and to be formed into various shapes for TCE and TFHs.

4:15 PM PM02.01.09
Highly Conducting Transparent and Stretchable PEDOT:PSS Electrodes—Investigation of the Role of Additives Emilie Dauzon1, 2, Ahmed E. Mansour1, Fabrice Goubard2 and Aram Amassian1; 1King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 2Laboratoire de Physicochimie des Polymères et des Interfaces, Cergy, France.

Poly(3,4-ethylenedioxythiophene): poly(styrenesulfonate) (PEDOT:PSS) is a potential candidate as a transparent soft conducting electrode for electronic and bio-electronic devices. It has also recently emerged as a potentially stretchable electrode when prepared under certain conditions. Despite a significant growth of the interest in this material, there is still significant debate about the causes and mechanisms involved in significant conductivity improvements in PEDOT:PSS films when processed in presence of certain additives, such as dimethylsulfoxide (DMSO) and Zonyl-FS300. Understanding the effects of these additives is crucial to further progress in the field, as it pertains to the design of even better electrode materials with finely tuned functionalities. The addition of DMSO co-solvent significantly improved the conductivity and the carrier concentration by several orders of magnitude, as confirmed by Hall effect transport measurements. Addition of the Zonyl elastomer also improved the electrical properties, but to a slightly lesser extent. Importantly, it softens PEDOT:PSS significantly by reducing its Young’s modulus over more than an order of magnitude, making it increasingly stretchable and mechanically compliant. We show that these benefits can be combined to achieve excellent electrical, optical and mechanical properties. To understand the effect of these additives in isolation and in combination with each other, we have investigated the relationship between the transport properties of PEDOT:PSS and the morphology and microstructure of these films by performing atomic force microscopy (AFM) and grazing incidence wide-angle X-ray scattering (GIWAXS). Our analysis reveals distinctive impact of the two additives on the PEDOT and PSS components in the solid-state PEDOT:PSS films. The DMSO enhances the aggregation of PEDOT, while Zonyl introduces order into PSS domains. Both additives induce fibrillar formation in the film and the combination of the two additives only enhances the fibrillar nature and the aggregations of both PEDOT and PSS components of the film. In situ GIWAXS investigation performed during the spin-coating and annealing steps showed that the presence of the additives influenced the aggregation behaviors of the PEDOT and PSS components directly during the transition from wet to dry film, i.e., during solvent removal, and do not evolve further during subsequent annealing. These results indicate that the additives directly influence the self-assembly behaviors of PEDOT and PSS during the ink-to-solid phase transformation.

4:30 PM PM02.01.10
Modification of PEDOT:PSS with Triblock Copolymer and Sulfuric Acid for Stretchable Transparent Electrode Jinho Lee and Jeong Sook Ha; Korea University, Seoul, Korea (the Republic of).

In this study, we report on the fabrication of a highly conductive, stretchable, transparent electrode based on modified poly(3,4 ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) with triblock copolymer (PEO30-PPO90-PEO30, Phorone® P123) and post-treatment via sulfuric acid. Sulfuric acid post treatment is well known to increase the electrical conductivity of PEDOT:PSS via crystallization of PEDOT, conductive part of PEDOT:PSS. Since the sulfuric acid treated PEDOT:PSS film is not stretchable, however, we introduce P123 as a secondary dopant and plasticizer.
to enhance the stretchability via crosslinking as well as the electrical conductivity of PEDOT:PSS. The fabricated electrode shows high transparency of 89%, high electrical conductivity of ~1,700 S/cm, and minimal change in resistance of ~4% during repetitive stretch–release cycles by 40% tensile strain. By utilizing the high transparency and low resistance change with stretching of the electrode, a stretchable transparent touch sensor array with light emitting diodes is fabricated and it exhibits mechanical stability upon stretching by 30%. This work demonstrates the facile chemical modification to develop PEDOT:PSS based stretchable electrode with high transparency and high electrical conductivity.

4:45 PM PM02.01.11
Mechanically-Durable Printed Transparent Electrodes for Ultra-Flexible Organic Photovoltaics Zhi Jiang¹,², Kenjiro Fukuda¹,³,⁴, Sangjun Park³ and Takao Someya¹,²,³; ¹Thin-Film Device Laboratory, RIKEN, Hirosawa, Wako, Saitama, Japan; ²Electrical and Electronic Engineering and Information Systems, The University of Tokyo, Tokyo, Japan; ³Center for Emergent Matter Science, RIKEN, Saitama, Japan; ⁴Japan Science and Technology Agency, Saitama, Japan.

Conformable large-area optoelectronic devices are necessary for self-powered ultra-flexible applications to realize multi-functional systems, such as sensing, imaging, and healthcare-monitoring [1, 2]. Since conventional transparent electrodes, such as ITO, are brittle, novel transparent conductors owning good mechanical robustness are indispensable to these ultra-flexible photonic devices. Printing technology will make these novel ultra-flexible transparent electrodes closer to the step of their real application [3]; however, it remains challenging to obtain feasible printed transparent electrodes with ultra-thinness, good uniformity over a large area, and high conductance simultaneously [4]. There exists a trade-off between thickness and conductance. Highly conductive Ag mesh electrodes usually have a thickness in the range of 2-20 μm, which can limit the flexibility and inhibit utilization in ultrathin photonic devices. Reducing the thickness and keeping a high conductivity simultaneously is needed for ultra-flexible photonic devices.

Here, we present ultra-flexible and mechanically durable Ag mesh transparent electrodes fabricated by a reverse offset printing technique, which simultaneously achieved high conductance, high transparency, and good mechanical properties. Reverse-offset printing technology enabled high resolution (100 nm and 5 μm in thickness and width, respectively) and high uniformity of Ag mesh over a large area. The high uniformity comes from the good quality of Ag nanoparticle ink (good dispersion, ultrathin diameter, and uniformity of Ag nanoparticles), and small roughness of both glass cliché and PDMS transfer blanket. Consequently, the printed transparent electrodes exhibited a 17 Ω/sq sheet resistance at 93.2% transmittance. Furthermore, they showed an insignificant resistance increase (10.6%) after 500 cycles of 100% stretch/release deformation. The key mechanism for the mechanical robustness is the ultrathin thickness and buckling structure. Due to the total thickness of our printed ultrathin Ag mesh transparent electrodes is less than 1.5 μm, they can be easily used in ultra-flexible photonic devices. As a demonstration, organic photovoltaics (OPVs) are fabricated using our printed Ag mesh transparent electrodes, which showed a comparable power conversion efficiency (8.3%) to those using traditional ITO electrodes (8.6%).

The insight gained from the ultra-flexible printed Ag mesh transparent electrodes and their application in ultrathin organic photovoltaics will help to apply such novel transparent electrode into other ultrathin photonic devices, and even ultra-flexible systems.

Reference:
controlling ink spreading and penetration. This is shown to be more important than the larger scale inter-tow porosity governed by the weave. The importance of the fibre surface properties in controlling ink behaviour is further demonstrated through a comparative study of the interaction of a nanoparticle silver ink with cotton and polyester textile surfaces. The more hydrophilic cotton fabric shows greater spreading and infiltration of the ink than is observed with the polyester materials. Further hydrophobic chemical treatment of the fabrics using commercial water repellent finishes reduces the fabric surface tension, leading to reduced ink spreading and smoother ink deposition on the surface with higher areal ink concentration and improved electrical conductivity. Fibre architecture is shown to influence ink penetration and spreading in the longitudinal and transverse directions of a fibre tow with tighter fibre structures reducing lower levels of spreading.

Printed electronics has attracted considerable interest as an alternative manufacturing process to realize circuits or devices on paper or plastic considering its low material consumption and fast accessibility. Using metallic nanoparticles to create conductive traces for lower cost and faster process has been extensively investigated, but often limited by the sintering process. Plasma sintering is widely employed given its lower processing temperature and lower extent of damage caused to the substrate by avoiding the high temperatures of sintering. In spite of its advantages, the process suffers from skin effect due to the top-down treatment process which can hinder sufficient curing throughout the entirety of the printed patterns imposing either long-last processing times or the use of high-power plasma with potential for damage to the substrate.

Inkjet printing, a relatively new and promising technology for fabrication; its major advantages, compared with traditional photolithography, rely on fabrication costs reduction, reduced material waste output, and simpler manufacturing steps. This technology has gained increasing interest in the fabrication of thin films for flexible and stretchable electronics using new functional nanomaterial inks. Despite the established advantages of this technology, the electromechanical reliability of the fabricated material systems is still a key point to achieve competitive devices. In particular, bendable and stretchable electronics require electromechanical reliable interconnects as they are subject to mechanical loading which jeopardize the integrity of the material itself (the electrical interconnects) or that of the interfaces.

This work is focused on the electromechanical reliability of bendable and stretchable interconnects obtained through ink-jet printing by using a Dimatix material itself (the electrical interconnects) or that of the interfaces.

Here, we demonstrate a direct-write patternable water-based poly (3,4-ethylenedioxythiophene): poly (styrene sulfonate) (PEDOT:PSS) composite ink consisting of PEDOT:PSS, graphene oxide nanosheets and anionic polyurethane does readily not permeated into hygroscopic fabric, which resulted in an enough electrical pathway for charge carriers even though only 2.9 wt% of PEDOT:PSS existed in the composite film. The PEDOT composite film exhibited electrical conductivity of 4.6 S/cm, extremely high stretchability.
of 375% rupture strain, and high durability for repeated washing process with strong bleaching agent. Light emitting diode incorporated on the stretchable spandex with interconnects of the PEDOT composite pattern showed that LED light intensity was almost maintained even with stretching of PEDOT interconnects to 290%.

Direct Photochemical Deposition of Metallic Patterns on Polyimides for Development of Flexible Transparent Conductive Films
Kensuke Akamatsu, Yuma Yoshikawa, Yohei Takashima and Takaaki Tsuruoka; Konan University, Kobe, Japan.

Demand for the development of novel strategies for polymer metallization has been rapidly growing in the field of various flexible electronics applications, such as the liquid crystal displays, electronic paper, and solar cells. Polyimide film has been widely used to date for such applications as a low-k substrate, due to its chemical and thermal stability, and outstanding dielectric properties. Therefore, various processes for the metallization of polyimide films have been investigated for the development of flexible circuit elements in microelectronics applications. Additionally, adhesion strength between metal films and underlying polymer substrates becomes much more important when the device dimensions are in a sub-micrometer scale. The conventional approach to the fabrication of metal patterns on polyimide substrates utilizes a subtractive-based strategy, i.e., lamination metal films on polyimide films followed by patterning through lithographic methods, but this approach requires stringent environmental control, costly equipment, and complex, multistep processes such as resist-coating, lithography, and etching.

In order to sustain the demand for generating multichip packaging systems for future flexible electronic devices, it would be exceedingly useful to develop an additive-based strategy with high-throughput capability that would allow site-selective, direct metallization of flexible low-k substrates. In this contribution, we present surface modification-based strategy for the direct fabrication of microscopic silver circuit patterns on polyimide surface.

Deposition of silver patterns has been achieved by using ion-doped precursor films, through the process of chemical hydrolysis of polyimide by alkali treatment, doping of silver ions into the modified films followed by UV irradiation using photomasks. The high sensitivity of silver ions to UV light allows for direct area-selective photochemical reactions without the use of photocatalysts, providing granular nanostructures consisting of silver nanoparticles at metal/polymer interface. This granular structures ensure high adhesion between deposited metals and underlying polymer substrates. Subsequent electroless copper deposition provides copper circuit patterns on polyimide substrate, providing effective methodology for direct fabrication of circuit patterns on flexible polyimide substrate in fully additive based strategy. Specifically, the use of photomasks with square patterns (negative photomasks) provided flexible, transparent conductive films, which can be used as flexible displays and electronic papers.

10:45 AM PM02.02.07
Flexible, Foldable, and Wearable Carbon-Based Electronic/Electrochemical Devices on Paper
Muriel Santhiago, Mariane P. Perera, Cátia C. Corrêa and Carlos C. Bufon; Brazilian Nanotechnology National Laboratory, Campinas, Brazil.

In this work we will describe the fabrication of flexible, foldable, and wearable electronic/electrochemical devices using carbon-based materials. The first fabrication route is based on a direct, simple, and dry transfer method of graphite onto paper with unprecedented electrochemical features on paper. We have selected soft pencils to transfer graphite onto paper and achieved comparatively low sheet resistances. The sluggish electron transfer observed on bare pencil drawn surfaces was enhanced by two steps. The surface was first electrochemically oxidized and reduced. The origin of such unprecedented performance was characterized by atomic force microscopy, laser scanning confocal microscopy, X-ray photoelectron spectroscopy, Raman spectroscopy, and contact angle measurements. We observed that the oxidation process causes the formation of a few microcracks on the electrode surface. Also, different chemical groups are formed and reduced due to the electrochemical treatment. Some of the weakly attached graphite particles and carbon nanodebris are detached from the electrode surface after the electrochemical treatment. Our results suggest that oxidation process leads to chemical and structural transformations on the electrode surface, and these transformations are responsible for the electrode response improvements.

The second route to fabricate carbon-based devices on paper is based on the use of sacrificial adhesive layers. It is extremely challenging to fabricate carbon-based nanostructures on paper that has the potential to meet some of the recent demands of paper-based devices, namely: (i) low sheet resistance, (ii) high folding stability, (iii) flexible electrochemical cells with high performance and (iv) tunable electric properties to fabricate motion and wearable sensors. With this method it is possible to print different compositions of binder/carbon black with no extra care related to viscosity, particle size and solvent composition. The carbon black tracks have low sheet resistance and a high-record folding stability. I will also demonstrate the fabrication of a 3D paper-based electrochemical cell made from a single carbon-black track. Moreover, the ink was tailored in order to electrochemically detect biologically relevant molecules at low potentials. Flexible circuits can be fully crumpled and operated again with no significant response loss. Finally, we have created bioinspired motion and wearable devices by locally tuning the electrical properties of the conductive tracks.

11:30 AM PM02.02.09
Three-Dimensional Organic Conductive Networks Embedded in Paper for Flexible and Foldable Devices
Muriel Santhiago and Carlos Cesar Bufon; Brazilian Nanotechnology National Laboratory, Campinas, Brazil.

Flexible and foldable devices have gained much attention in the field of low-cost electronics and wearable devices. Among the flexible materials used as substrates, paper is an exciting candidate with several attractive advantages. For instance, paper is a natural polymer broadly available worldwide, lightweight, disposable, portable and foldable. Also, paper has the unique porous structure formed by cellulose fibers, which can drive solutions by capillary action. Here, we described the fabrication of three-dimensional (3D) conductive tracks through the porous structure of paper [1]. We combined paper microfluidics and gas-phase pyrrole monomers to synthesize polypyrrole-conducting channels embedded in-between the cellulose fibers chemically. By using the proposed method, foldable conductive structures can be created across the whole paper structure, allowing the electrical connection between both sides of the substrate. Our approach is a step forward towards the development of 3D-electronic devices on paper. As a proof of concept, Top-Channel-Top (TCT) and Top-Channel-Bottom (TCB) conductive interconnections, as well as all-organic paper-based touch buttons are demonstrated. By functionalizing the conducting tracks, we also created paper-based sensors to assess the local humidity changes in fully-enclosed paper microfluidic elements. The sensors exhibit excellent mechanical stability, with more than 600 bending cycles achieved. Additionally, we observed that the electrical resistance increases with relative humidity (RH) increase. Most importantly, the humidity sensor response is reversible. Our work essentially paves the way toward 3D fabrication of electrochemical devices [2], including sensors, capacitors, and energy harvesting systems. Several devices can be manufactured in parallel, and the fabrication process allows high-volume production.

Cellulose-based electronic textiles has promised as an interesting approach for the development of novel technologies, given its unique properties. Printed paper-based electronics have been usually accomplished by using standard printing methods, such as screen and inkjet printing. Some materials of interest for this field, however, are insoluble, hindering its use with solution-based direct printing techniques. This is the case, for example, of poly(P-phenylene vinylene) (PPV), a material that presents outstanding electrical, photo-luminescent and electro-luminescent properties, with great potential for applications. In this work we demonstrate the use of femtosecond laser induced forward transfer for creating high-resolution patterns of the conductive polymer PPV onto bacterial cellulose (BC) substrate, advancing the use of cellulose-based materials for printed flexible electronics, by offering a new approach for solid materials patterning. Such approach successfully allowed transferring PPV with resolution on the order of 10 µm and without materials degradation, which was subsequently doped to improve the electrical conductivity and exploited in the fabrication of functional devices. Our results open new avenues in the fabrication of paper-based devices, by combining high resolution and new classes of patterning materials.

Producing flexible, wearable circuitry relies on having robust electrical connectivity between components. The electrical traces must provide low resistance and predictable properties, especially over time, where a garment will see washing cycles and repeated mechanical stresses. Screen printing is a widely-used technique for making the conductive traces. Designing optimal inks in combination with various substrates for these applications requires control over several aspects of composites: 1) maintaining percolative conductivity; 2) control of the viscoelastic properties of the polymer binder and the substrate; 3) control over the adhesive interaction between the ink and the substrate; and 4) understanding the fracture behavior of this complex system. Industrial-academic partnerships, combined with internal research, provides a full context for working on and solving these problems. This presentation will show how the mechanical properties of the substrate and inks are interrelated and how that relationship affects electrical conductivity. We will also show the evolution of materials to more reliable, conductive compositions by applying lessons learned from extensive testing. Finally, we will discuss the current issues and where future work needs to be done.

The rising clinical and basic research interest in personalized and precision medicine promises to revolutionize traditional medical practices. This presents a tremendous opportunity for developing wearable devices toward predictive analytics and treatment. In this talk, I will introduce fully-integrated flexible biosensors for multiplexed in-situ perspiration analysis, which can selectively measure a wide spectrum of sweat analytes (e.g., metabolites, electrolytes, heavy metals, drugs and other small molecules) and allow us to gain real-time insight into the sweat-secretion and gland physiology. I will also demonstrate an integrated wearable sweat extraction and sensing system which can be programmed to induce sweat on demand with various secretion profiles. To demonstrate the clinical value of our platform, human subject studies were performed in the context of the cystic fibrosis diagnosis. These wearable and flexible devices open the door to a wide range of personalized diagnostic and therapeutic applications.

Cardiovascular disease is the leading cause of death in the United States. As a result, wearable health monitoring devices have become a heavily researched area. In order to provide long term monitoring of patients with heart-related diseases, electrocardiogram (ECG) studies employing textile-based wearable technologies. Concerns exist in these wearables in terms of data quality, power consumption, human design and manufacturing design. This work presents a systems-level approach towards the design of a self-powered ECG textile garment that seeks to resolve these issues. These garments are battery-less, open architecture sensor platforms that utilize continuous energy harvesting to ensure vigilant cardiac monitoring. Key stakeholder needs such as comfort, passive user-experience, accuracy, and data streaming were discovered during the NSF I-Corps program after interviewing patients, doctors, hospitals, and doctors. Component level integration and testing strategies are presented in the use of flexible interconnects, durable connectors, printed ECG electrodes, and energy harvesting integration. Finally, the garment design is considered based on understanding the use-cases in real-time cardiac monitoring health monitoring.

With the rise of wearable technologies there has been an unprecedented demand in finding suitable power supplies. As an alternative to conventional battery supplies, on-body energy harvesting is a promising avenue due to its ability to provide the location specific energy harvesting that is possible during long term (full day to multi-day) use, a key necessity to self-powered wearable systems.

In this paper, a high-sensitivity wide-range wireless strain gauge system is presented for simple structural health monitoring. The strain gauge contains a printable strain gauge, which is operated using a wireless system, can contribute to the inspection of deterioration rates in large-area infrastructure at low cost 

Biometrics are an effective way for technology to use signature indicators of a user’s body, such as the iris, facial features, or fingerprint, to create secure access methods. Especially, the recognition of fingerprints is one of the most popular techniques for mobile security applications. Capacitive fingerprint sensors have been widely used for contemporary portable electronic devices, including smartphones, with opaque sensor structures implemented in activation buttons or behind the phone. In the design of a device, the display occupies a relatively larger area of the total device size for improved usability. Except for the display, it would be optimal to reduce or completely remove other components (e.g., bezels, buttons, and sensors), from the front side of a product. As such, there has been a strong push for the development of invisible fingerprint sensors that are embedded in the display. However, the sheet resistance of conventional transparent electrode materials, such as indium tin oxide (ITO), carbon nanotubes, graphene, metal nanowires, or fine metal mesh patterns, are too high to allow high-frequency signals to drive the capacitive fingerprint sensors against noise from mobile devices. Here, we developed a transparent and flexible, capacitive fingerprint sensor array with multiplexed detection of tactile pressure and finger skin temperature for mobile smart devices. In our approach, random networks of hybrid nanostructures using ultra-long metal nanofibers and finer metal nanowires were formed as transparent and flexible electrodes of a multifunctional sensor array. The sensor array exhibited excellent optoelectronic properties (~ 1.03 Ohm/sq with an optical transmittance of 91 % in the visible light region) and outstanding reliability against mechanical bending. This resulting fingerprint sensor array has a high resolution (318 capacitors per inch) with good transparency (89%). This sensor offers a capacitance variation (between a ridge and valley) ~ 17 times better than the variation for the same sensor pattern using ITO electrodes, instead of the transparent hybrid electrode. This sensor with the hybrid electrode also operates at a high frequency (1 MHz) with negligible degradation in its performance against various noise signals from mobile devices. Furthermore, this fingerprint sensor array can be integrated with all transparent forms of tactile pressure sensors (sensing range from 10 kPa to 1.6 MPa) and skin temperature sensors (from 30 °C to 45 °C), to enable the detection of a finger pressing on the display. This will allow for the complete removal of any activation buttons on smart devices. Additionally, the capability to recognize artificial fingerprints further improves security. These results suggest the future promise of transparent and flexible devices for next-generation, interactive electronics.

This work proposes a printable strain gauge that exhibits high sensitivity (gauge factor < 100), a wide range (0.001% to 20% strain), and high durability (< a million strain cycles). The printable strain gauge is capable of detecting microcracks and microstrains simultaneously for long-term while conventional gauges lack the characteristic. A wireless system is installed, which further simplify structural health monitoring for maintenance, inspection, triage, and infrastructure remediation via the Internet of Things (IoT).

Current strain gauges are utilized to monitor microdeformation in concrete structures and to detect the risk of structural failures. Conventional reinforced concrete has a material breakdown limit of -10%–20% strain [1]. However, it deforms by -0.2%–0.2% strain per day. Conventional gauges do not provide a sufficiently wide measurement range [2]. The optimal gauge is selected as a function of strain range.

In this paper, a high-sensitivity wide-range wireless strain gauge system is presented for simple structural health monitoring. The strain gauge contains 83wt% of graphite. It was fabricated through screen printing on a polyimide substrate with a width of 0.5–2 mm and a scalability of < 1 m. A printed track was composed of highly conductive graphite fillers and a blended binder of poly-N-vinylacetamide (PNVA) and cellulose; this resulted in an electrical resistivity of 0.3 ohm cm. The printed track acts as a resistance-type strain sensor with the same sensitivity as that of a conventional gauge (correlative factor: over 0.99). Experimental results showed that PNVA, whose molecular structure consists of a strong network of hydrogen bonds, acted to improve performance under cyclic strain. As a consequence, the printable strain gauge exhibited high durability and retained its high sensitivity and wide measurement range even after < 1,000,000 strain cycles. It achieved long-term wireless monitoring in actual structural objects for over a month. Our printable strain gauge, which is operated using a wireless system, can contribute to the inspection of deterioration rates in large-area infrastructure at low cost.

All-Climate Aqueous Fiber-Shaped Supercapacitors with Record Areal Energy Density and High Safety Bin Wang and Jianli Cheng: China Academy of Engineering Physics, Chengdu, China.

Flexible fiber-shaped supercapacitors (FSSs) are promising energy storage candidates for wearable electronics. However, most of reported FSSs are flexible at room temperature and used the toxic flammable organic electrolyte or corrosive strong acid or base which may have safety hazards especially for wearable textiles directly sticking on the human skin at harsh environmental temperatures. Here we reported a new kind of aqueous symmetric FSSs with high safety and record high areal energy density at wide operating temperature ranging from -60 (14.2 µW h cm⁻²) to 75 degree (22.9 µW h cm⁻²) based on aqueous LCE-PVA based gel electrolyte and core-shell nanocrystalline polymer fiber electrode. The fabricated aqueous FSSs demonstrate high flexibility, high areal/volumetric energy density and stable cycle life at different operating temperatures, showing the potential application in all-climate.
work demonstrates the photoresist-etching-inspired new screen-printing technique that combines flexible conductive composite ink, water-soluble applications of graphene and derived structures for flexible electronics. CMOS devices. These array structure uses crosspoints as four-terminal switch and enables high complexity for logic synthesis compared to two-terminal structure can be applied for various switch designs. Nano-crossbar arrays are emerging structures as an area efficient state-of-art alternative to conventional integration of various printed devices such as batteries, supercapacitors, biofuel cells and sensors into stretchable and mechanical durable device can be created. This novel fabrication technique brings technological advantages of the inclusion of wide selection of materials in composite inks. Hence, a one-step to substrate and guided buckling by thickness control, complex 3D structures buckled from 2D planar design can be easily fabricated in few simple steps. Sacrificial material and mechanical buckling, allowing printed circuits to be stretchable and high-strain-enduring. Furthermore, utilizing selective bonding to substrate and guided buckling by thickness control, complex 3D structures buckled from 2D planer design can be easily fabricated in few simple steps. nanostructured flakes of rGO were produced from graphene oxide (GO). GO was prepared with modified Hummers’ method by chemically exfoliation and oxidation reactions. GO was washed, filtrated, centrifuged and vacuum-dried to obtain solid GO residue. Dry GO then powdered and sifted for further steps. Thermal treatment is applied for reduction of organic groups and expansion of GO into rGO, which took place in pure nitrogen flow (1 l/min.) with high heating rate and kept at high temperature (800°C) to form C:O structure with reduced oxygen content and high defects to be used in four-terminal switch device. The changes in structure and particle properties were investigated with scanning electron microscopy (SEM) for morphology, energy dispersive spectroscopy (EDS) for composition, X-ray diffraction (XRD) for crystal structure and stack layer quantifications, Brunauer-Emmett-Teller (BET) surface area analysis for effective surface area, Raman spectra for lattice distortions and defect structures and FTIR to identify functional groups. Besides that, fabrication of these switches require careful design features to perform symmetrically and accordingly. In this study, nanostructured flakes of rGO were produced from graphene oxide (GO). GO was prepared with modified Hummers’ method by chemically exfoliation and oxidation reactions. GO was washed, filtrated, centrifuged and vacuum-dried to obtain solid GO residue. Dry GO then powdered and sifted for further steps. Formation of Printable Granular and Colloidal Chains through Capillary Effects and Dielectrophoresis Zbigniew Rozyniec1,2, Ming Han3, Filip Dukta1, Piotr Garstecki1, Arkadiusz Jozefczak and Erik Luijten11, Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland; 2Faculty of Physics, Adam Mickiewicz University, Poznan, Poland; 3Applied Physics Graduate Program, Northwestern University, Evanston, Illinois, United States; 4Faculty of Physics, University of Warsaw, Warsaw, Poland; 5Departments of Materials Science & Engineering, Engineering Sciences & Applied Mathematics, Physics & Astronomy, Northwestern University, Evanston, Illinois, United States.

One-dimensional conductive particle assembly holds promise for a variety of practical applications, in particular for a new generation of electronic devices. However, synthesis of such chains with programmable shapes outside a liquid environment has proven difficult. Here we report a route to simply ‘pull’ flexible granular and colloidal chains out of a dispersion by combining field-directed assembly and capillary effects. These chains are automatically stabilized by liquid bridges formed between adjacent particles, without the need for continuous energy input or special particle functionalization. They can further be deposited onto any surface and form desired conductive patterns, potentially applicable to the manufacturing of simple electronic circuits. Various aspects of our route, including the role of particle size and the voltages needed, are studied in detail. Looking towards practical applications, we also present the possibility of two-dimensional writing, rapid solidification of chains and methods to scale up chain production.

From 2D to 3D—A Mechanistic Deterministic Approach for Stretchable Printed Electronics Lu Yin and Joseph Wang; Nanoengineering , University of California, San Diego, La Jolla, California, United States.

The world of electronics is shifting away from rigid, bulky and fragile to flexible, miniaturized and sturdy, underlining the need for stretchability in the design form factors. Screen printing, as the most widely used manufacturing technique for circuit boards, is low cost, high throughput and versatile. This work demonstrates the photosensitive-etching-inspired screen-printing technique that combines flexible conductive composite ink, water-soluble sacrificial material and mechanical buckling, allowing printed circuits to be stretchable and high-strain-enduring. Furthermore, utilizing selective bonding to substrate and guided buckling by thickness control, complex 3D structures buckled from 2D planer design can be easily fabricated in few simple steps. This novel fabrication technique brings technological advantages of the inclusion of wide selection of materials in composite inks. Hence, a one-step integration of various printed devices such as batteries, supercapacitors, biofuel cells and sensors into stretchable and mechanical durable device can be realized. Several fabrication examples including the reversible buckling of several 3D structures and the free-standing serpentine interconnected battery group is demonstrated, which exhibited minimal performance change even under 100% stretching deformation. The successful implementation of such fabrication technique offers a promising route for the wide adaption of stretchable device.

9:00 AM PM02.04.03
Direct Fabrication of Flexible and Stretchable Conductor by Electrohydrodynamic (EHD) Printing Jingyan Dong; North Carolina State University, Raleigh, North Carolina, United States.

Direct printing of flexible and stretchable conductors provides a low-cost mask-less approach for the fabrication of next generation electronics. In this work, an electrohydrodynamic (EHD) printing technology was studied for a number of functional materials (e.g. low-melting-point metal alloys, 1D silver nanowires) that are hard to be printed with traditional print methods. We successfully achieved high-resolution printing of these materials, which enables low-cost direct fabrication of metallic conductors with sub-30μm resolution. The EHD printed microscale metallic conductors represent a promising way to create conductive paths with metallic conductivity and excellent flexibility and stretchability. A stable electrical response was achieved after hundreds of bending cycles and during stretching/releasing cycles in a large range of tensile strain (0-70%) for the printed conductors with properly designed 2D
patterns. When using low-melting-point metal alloys as functional inks, due to their low melting point, the printed conductor demonstrated excellent self-healing capability, which recovered from failure simply by heating the device above the eutectic temperature of the metal ink and applying slight pressure. A few device demonstrations, including a high-density touch sensor array and AgNW heaters and electrocardiogram (ECG) electrodes, were fabricated to demonstrate the high-resolution capability of the EHD printing for the direction fabrication of flexible and stretchable devices.

Accelerating Design Through Flexible Hybrid Electronics Materials Data Collaboration Scott M. Miller, NextFlex, San Jose, California, United States.

Flexible Hybrid Electronics encompasses a rapidly growing set of technology and manufacturing capabilities that enable the creation of electronics with previously impossible form factors. The field combines printed electronic materials, additive processing, traditional semiconductor integrated circuits, and substrates that can bend, flex, and stretch. NextFlex, established in 2015 as America’s Flexible Hybrid Electronics (FHE) Manufacturing Innovation Institute, is a Public Private Partnership between the US Department of Defense and the private sector. The Institute brings together more than 85 companies and universities and 17 government organizations to shape the future of FHE, accelerate its development and commercialization, catalyze the manufacturing workforce of tomorrow, and ensure American manufacturing competitiveness in FHE. The Institute does this through a variety of mechanisms – jointly developing technology roadmaps; funding projects to advance the technology; performing technical projects to develop components, devices, and manufacturing processes; operating a low-volume production and prototyping fab; convening members of the ecosystem to collaborate; and developing education and training programs for both the next generation of talent and the current workforce.

One key challenge in FHE arises from one of its strengths – the abundance of materials that are available to use in designing and fabricating FHE devices. The material properties of common FHE materials are often dependent on the fabrication processes employed and the specific operating parameters used in those processes. The consequence is that a designer cannot look to a single data source for properties needed to conduct design, modeling, and simulation, and often requires an intimate knowledge of the fabrication process. In practice, design and fabrication often become linked by an iterative loop to arrive at the final design. This slows the design cycle for FHE devices. Furthermore, test methods are not standardized for FHE devices that undergo high strain, and these devices therefore require customized qualification testing.

This talk will present work that NextFlex has undertaken to address the data and design challenge by creating means for researchers, developers, and designers to collaborate. Tools like the NextFlex Material & Process Database provide a searchable repository for property data linked to specific labs or manufacturers, and specific processes. Examples of the use of this tool will be included. NextFlex funded projects that are developing design tools, test methods, and reliability testing will also be discussed.

Polymer-Assisted Metal Deposition for Soft Electronics Zijian Zheng, Hong Kong Polytechnic University, Hong Kong, Hong Kong.

Metal electrodes are indispensable element for most future soft electronic devices. One critical challenge in this field is how to fabricate highly conductive, adhesive, smooth, and soft metal conductors at low temperature under ambient conditions, and preferably in a roll-to-roll manner. Our laboratory recently develops Polymer-Assisted Metal Deposition (PAMD) to address this issue. PAMD allows ambient fabrication of flexible, foldable, stretchable, compressible, and wearable metal (especially Cu) conductors with very high conductivity. Importantly, PAMD is compatible with versatile substrates and different printing technologies at ambient conditions. This seminar will discuss the materials chemistry of PAMD and demonstrate their applications in several important soft electronic devices including circuits, solar cells, supercapacitors, and transistors.

11:00 AM PM02.04.06
Undercooled Liquid Metal Particle Inks for Flexible Conductive Traces Using Direct Writing Andrew Martin1, Christophe Frankiewicz2, Zach Martin2, Dipak Paramanik1, Ian Tevis2 and Martin Thuo1, 3, 4; 1Material Science and Engineering, Iowa State University, Ames, Iowa, United States; 2Safi-Tech LLC, Ames, Iowa, United States; 3Dep-All LLC, Ames, Iowa, United States; 4Microelectronics Research Center, Iowa State University, Ames, Iowa, United States.

Flexible electronics offer the promise of comfortable and less-intrusive bio-interfacing devices and affordable and rugged displays in packaging. Thermal sensitivity of the typical substrates used, however, makes it challenging to mount components or create conductive lines on these devices. Silver nanoinks have emerged as a lower-temperature processing alternative; although curing temperatures significantly above ambient eliminates use of a significant number of heat sensitive substrates. Advances in synthesis of core-shell undercooled metal, and associated heat-free lead-free solders, offers a new approach to ambient fabrication of conductive lines and component soldering. Herein, we demonstrate the adoption of undercooled liquid metal particles in fabrication of flexible electronic devices via direct write or screen printing. Devices ranging from MEM sensors, Wheatstone bridge, conductive traces and LED arrays are used to demonstrate versatility of this heat-free fabrication technique.

11:15 AM PM02.04.07
Hierarchical Self-Assembly in 3D Printable Carbon Nanotube (CNT) Based Links Shayandev Sinha, Yanbin Wang and Siddhartha Das; University of Maryland, College Park, Maryland, United States.

Compared to the traditional metallic materials CNT is known to have superior thermal and electronic conductivity. Printability of such CNT based inks thus can change the way we make electronic devices, composite materials etc. For any large-scale manufacturing, a chemical binder free CNT based ink will be useful but the bottleneck is the solubility of CNT in water - which is very low. Here we include graphene oxide (GO) which increases the dispersion of CNT inside the water. This ink is then printed using a syringe 3D printer with optimized pressure on a 3D printed soft surface made of an UV curable adhesive material (NEA 121) and sintered at 150 °C for 8 hours. The water evaporation during sintering causes the CNT and GO particles to assemble on the soft solid. A detailed electron microscopy study reveals a very interesting feature- hierarchical self-assembly of CNT and GO where CNTs self-assembled over nanoscale is sandwiched between layers of GO self-assembled over microscale. GO covers the whole printed line and exhibits flake-like behavior covering the internal CNT layers. Thus, the composition of CNT: GO ratio changes the whole procedure of self-assembly and reveals various highly intriguing internal structures. This also effects the electrical conductivity and the overall printability of the ink. We believe that such kind of inks will be key for fabricating embedded electronics inside the conformable composites.

11:30 AM PM02.04.08
Junction-Modulated Silver Nanowire-Elastomer Composite Films for Stretchable Transparent Conductors Jae-Chan Lee, Soyeon Lee, Philip Won,
Recent demand of reducing physical distance between devices and human have attracted considerable interests in flexible and stretchable devices for wearable electronics. Nanostructured metals, especially silver nanowires (AgNWs) have emerged as most promising transparent electrodes for stretchable and wearable devices owing to their high mechanical endurance. Many research groups have examined fracture strain of freestanding single nanowire. To develop commercially available AgNW films in stretchable and wearable electronics, it is necessary to investigate on the factors such as junctions and interaction between nanowires and elastomeric substrates on stretchability of entire AgNW films. However, there have been few researches on the factors affect to reliability of entire AgNW films in stretching conditions instead of single nanowire for transparent electrodes. Here, we investigate the effect of post treatment on tensile reliability by in situ tensile testing within scanning electron microscope (SEM).

Our results showed the potential of the use of Ag NWs in energy storage devices and the structures presented in this work is highly plausible and can be easily extended to other metal nanowire, metal oxide and conducting polymer systems.

11:45 AM PM02.04.09
Flexible Supercapacitor Electrodes with Silver Nanowire Networks
Recep Yuksel, Sahin Coskun and Husnu E. Unalan; Middle East Technical University, Ankara, Turkey.

Silver nanowires (Ag NWs) are appealing candidates for supercapacitor electrodes due to their high conductivity in addition to their allowance for all active materials to be in close contact to facilitate charge transport. All are very important to attain maximum charge accumulation provided that Ag NWs are electrochemically stable within the utilized potential window. In this work, high aspect ratio Ag NWs are used within a coaxial and/or network-like flexible nanocomposite structure in supercapacitor electrodes. Utilization of Ag NWs as conductive templates also results in rapid deposition of electrode active materials. We have fabricated supercapacitors using Ag NWs and their nanocomposites with molybdenum oxide (MoO3) (50.7 F g⁻¹) [1], nickel hydroxide (Ni(OH)₂) (1165.2 F g⁻¹) [2], polypyrrole (Ppy) (509 F g⁻¹) and some PEDOT derivatives (61.5 F g⁻¹). Highly conductive Ag NWs were utilized as the only current collectors and templates for these electrode active materials. Electrochemical properties of the fabricated Ag NW based flexible nanocomposite supercapacitor electrodes were investigated through galvanostatic charge-discharge, cyclic voltammetry, and electrochemical impedance spectroscopy. We will present a detailed analysis of utilization of Ag NWs in the fabricated supercapacitors to underline their charge transport behavior.

This talk introduces a technology platform for the development of large-area, ultrathin and lightweight electronic and photonic devices, including solar wraps and "sixth-sense" magnetoception in electronic skins. Air stable perovskite solar cells, only 3 µm thick, endure extreme mechanical deformation and have an unprecedented power output per weight of 23 W/g. Highly flexible, stretchable organic light emitting diodes are combined with photodetectors for on-skin photonics and pulse oximetry, providing electrical functionality in yet unexplored ways. Tactile sensor arrays based on active-matrix organic thin film transistors can be operated at elevated temperatures and in aqueous environments as an imperceptible sensing system that ensures the smallest possible discomfort for patients requiring medical care and monitoring. Combined with organic amplifiers and biocompatible conductive gels, we demonstrate in vivo recording of vital signals. E-skins with GMR-based magnetic field sensors equip the wearer with an unfamiliar sense that enables perceiving of and navigating in magnetic fields. These large area sensor networks build the framework for...
other attractive characteristics. The nano-patched graphene was exploited to demonstrate soft electronic skin sensors and organic field-effect transistors that have superior electrical properties. We believe that this nanopatch method would have a wide range of applications and contribute to development of soft organic devices that are robust and practical.

Mechanical deformability underpins many of the advantages of organic semiconductors in applications from flexible solar cells to wearable devices for healthcare and virtual touch. The mechanical properties of these materials are, however, diverse, and the molecular characteristics that permit charge transport can render the materials stiff and brittle. In this talk, I describe the ways in which molecular structure and solid-state packing structure govern the mechanical properties of organic semiconductors, especially of π-conjugated polymers. In particular, I describe how low modulus, good adhesion, and absolute extensibility prior to fracture enable robust performance, along with mechanical “imperceptibility” if worn on the skin. The discussion focuses on the mechanisms by which mechanical energy is either stored (i.e., elastically) or dissipated (i.e., by plastic deformation or fracture). Mechanical energy is mediated at the level of both the molecular structure (determined by synthesis) and solid-state packing structure (determined by processing techniques). Development of metrological methods are critical for the accurate determination of the mechanical properties of thin films of materials for which only small quantities are available from laboratory-scale synthesis. We often find that the interplay between the semiconducting polymer and the substrate influence the mechanical properties and the fracture behavior. Computational molecular dynamics simulations have been particularly helpful in predicting the molecular mechanisms responsible for deformation. The talk concludes with applications of organic semiconductor devices in which every component is intrinsically stretchable or highly flexible.

Recent research in organic electronics has focused on developing next-generation practical soft devices that use graphene materials, which are a single-atom-thick sheet of sp2-hybridized carbon atoms. However, currently-available graphene materials are too fragile to meet industrial requirements for mass production, but also for use of electrodes in soft organic devices. Therefore, a main challenge in this field is to increase the strength and chemical stability of such material without degrading its electronic properties. In this talk I will present our recent study about nanoscale organic layers to strengthen metal graphene sheets. We found that alkylthiol molecules can self-assemble on flaws in the surface of graphene and form nanometer-thick patches on them, in a phenomenon that resembles suturing of wounds. This process dramatically improves graphene’s mechanical durability while preserving its other attractive characteristics. The nano-patched graphene was exploited to demonstrate soft electronic skin sensors and organic field-effect transistors that have superior electrical properties. We believe that this nanopatch method would have a wide range of applications and contribute to development of graphene-electrode-based soft organic devices that are robust and practical.

Robust flexible conductors are essential for the development of wearable electronics and soft robotics. While there are various types of compliant polymers such as elastomers that are highly flexible and moderately stretchable, the number of flexible functional materials is very limited. To address this challenge, we have developed stretchable thin-film conductors suitable for wearable electronics. The newly synthesized metallic conductors are composed of silver nanoparticles (AgNP) and eutectic gallium indium (EGaIn) alloy. This talk covers design, fabrication, and characterization of stretchable thin-film metallic conductors with applications in integrated electronic devices. The rapid manufacturing method developed for these flexible electronics is based on printing silver ink on a temporary tattoo paper (with a thickness of 5 microns) followed by deposition of EGaIn to the printed circuits. With a thin layer of EGaIn, the electrical conductivity and mechanical failure strain of the printed silver traces significantly improved. A volume conductivity of 4.8 × 10^6 Sm⁻¹ was achieved while the stretchability of circuits was enhanced as much as 20 times when compared to traces with pure silver ink. Extensive electromechanical characterization on the printed traces will be presented to demonstrate the practical potential of printed AgNP-EGaIn traces. Furthermore, functioning circuits with surface mounted microelectronic chips will be presented to show the performance of AgNP-EGaIn traces as soft, stretchable, skin-like electronics.

In the past two decades, the use of metallic thin films as principal conductive material has been extended from Silicon-based microelectronics to electronic circuitry on flexible substrates. This spans from bendable sub-micron sensors to meter-long displays. For commercial applications and wearable or implantable healthcare devices, however, one key point that is yet to be thoroughly addressed is their long-term reliability. Indeed, the lifetime of flexible devices is limited by performance degradation often due to fatigue failure of metallic conductors. In our work, we introduce a new concept for healing of metal films on flexible substrates while in operation. Integrating Ni/Al multilayers as latent heat sources, we demonstrate that the self-sustained solitary heat wave generated by the intermetallic-forming reaction can be harvested to locally heal cracks. Damage repair is activated on-demand at room temperature by a low energy current pulse that is compatible with standard current-voltage operation conditions of electronic circuitry. After healing, which is completed in a single microsecond, in-situ electrical probing shows a conductivity recovery as high as 90% for crack opening up to 500 nm in different metals, such as copper and gold. Intrinsic heat source healing represents a unique concept for rapid repair of metallic thin films, which can be applied to flexible electronics or even integrated in temperature-sensitive components in Si-based microelectronics.

In this talk I will present our recent study about nanoscale organic layers to strengthen metal graphene sheets. We found that alkylthiol molecules can self-assemble on flaws in the surface of graphene and form nanometer-thick patches on them, in a phenomenon that resembles suturing of wounds. This process dramatically improves graphene’s mechanical durability while preserving its other attractive characteristics. The nano-patched graphene was exploited to demonstrate soft electronic skin sensors and organic field-effect transistors that have superior electrical properties. We believe that this nanopatch method would have a wide range of applications and contribute to development of graphene-electrode-based soft organic devices that are robust and practical.

Robust flexible conductors are essential for the development of wearable electronics and soft robotics. While there are various types of compliant polymers such as elastomers that are highly flexible and moderately stretchable, the number of flexible functional materials is very limited. To address this challenge, we have developed stretchable thin-film conductors suitable for wearable electronics. The newly synthesized metallic conductors are composed of silver nanoparticles (AgNP) and eutectic gallium indium (EGaIn) alloy. This talk covers design, fabrication, and characterization of stretchable thin-film metallic conductors with applications in integrated electronic devices. The rapid manufacturing method developed for these flexible electronics is based on printing silver ink on a temporary tattoo paper (with a thickness of 5 microns) followed by deposition of EGaIn to the printed circuits. With a thin layer of EGaIn, the electrical conductivity and mechanical failure strain of the printed silver traces significantly improved. A volume conductivity of 4.8 × 10^6 Sm⁻¹ was achieved while the stretchability of circuits was enhanced as much as 20 times when compared to traces with pure silver ink. Extensive electromechanical characterization on the printed traces will be presented to demonstrate the practical potential of printed AgNP-EGaIn traces. Furthermore, functioning circuits with surface mounted microelectronic chips will be presented to show the performance of AgNP-EGaIn traces as soft, stretchable, skin-like electronics.

In the past two decades, the use of metallic thin films as principal conductive material has been extended from Silicon-based microelectronics to electronic circuitry on flexible substrates. This spans from bendable sub-micron sensors to meter-long displays. For commercial applications and wearable or implantable healthcare devices, however, one key point that is yet to be thoroughly addressed is their long-term reliability. Indeed, the lifetime of flexible devices is limited by performance degradation often due to fatigue failure of metallic conductors. In our work, we introduce a new concept for healing of metal films on flexible substrates while in operation. Integrating Ni/Al multilayers as latent heat sources, we demonstrate that the self-sustained solitary heat wave generated by the intermetallic-forming reaction can be harvested to locally heal cracks. Reliability of printed devices within the field of textile electronics is a significant roadblock to their widespread market adoption. This problem is further exacerbated by the lack of test methods for evaluating the failure modes of printed devices such as interconnects under mechanical strain. A simple but effective thermo-electro-mechanical method for identifying cracks within printed conductive pathways on textiles and on planar films laminated on textiles is presented. This method utilizes resistive Joule heating to isolate conductive areas where cracks can form in-situ. It requires only a DC power source, thermal imaging device, tensile testing setup, and printed conductive samples. It has been shown that along a printed interconnect, cracks can form along print directions that endure high localized strain such as at curved junctions or at connection points for many sinusoidal based interconnect geometries.

Compared to post visual inspection utilizing optical microscopy, SEM microscopy, or atomic force microscopy which can be time-consuming and expensive, our method is simple and cost-effective as a first pass for identifying the localized area wherein a crack has formed in-situ. In this talk we will show results for printed devices on films and conductive pathways ‘embedded’ into a textile by direct-write printing.

Tensile and Fatigue Ductility Testing of Free Standing Cu Films and of Cu Films on Polyimide Substrates Ulrich R. Memmert and Roland Herold; Aitech Deutschland GmbH, Berlin, Germany.

Mechanical properties like the ductility of Cu structures are often discussed in the context of reliability considerations. Often experimental data for free standing films of around 50 µm thickness are used. The influence of the layer thickness or of the interactions with the substrate or the surrounding materials is often not known.

Thin Cu films were investigated as free standing films (Cu thickness 10 µm – 60 µm) and deposited on polyimide (PI) substrates (Cu thickness 2 µm – 60 µm) by tensile testing. The ductility and the yield strength were determined. Both sample types were also investigated for Cu thicknesses between 10 µm and 50 µm by a cyclic bending test. From these data the fatigue ductility was determined. For some of the samples the grain structure was investigated before and after tensile testing by secondary electron microscopy (SEM).

The measured tensile ductility varies significantly with layer thickness and is, at least for low layer thickness, also significantly affected by the presence of the PI substrate. For low layer thickness it decreases in the case of free standing films while it is significantly enhanced when in being contact to a PI substrate. The fatigue ductility decreases with decreasing layer thickness and shows no strong sensitivity to the presence of the PI substrate. SEM imaging shows the grain structure for the original layers to be rather independent of the layer thickness. After tensile testing a clear refinement of the grains is found.

Fatigue-Free and Self-Healing Stretchable Transparent Electrodes Chuanfei Guo¹ and Zhifeng Ren²; ¹Materials Science and Engineering, Southern University of Science and Technology, Shenzhen, China; ²University of Houston, Houston, Texas, United States.

Flexible transparent electrodes are key elements in flexible electronics and soft robotics. Stretchability is one of the most demanding mechanical modes of flexibility. A material that is optically transparent and electrically conducting is often not stretchable. However, a transparent conducting film can become stretchable if it is tailored to a network. In addition, one-dimensional materials that are intrinsically stiff can become stretchable when tailored to serpentine structures. We used a method that we call grain boundary lithography and successfully fabricated Au nanomeshes with curved ligaments, exhibiting indium tin oxide (ITO) level sheet resistance and transparency, together with exceptionally large stretchability.

We also demonstrate quantitative characterization of adhesion performance of conductive hydrogel on diverse substrates. This method will provide a simple yet truly useful and powerful tools for the fabrication of unprecedented devices in diverse fields.

Tough Bonding of Conductive Hydrogel to Diverse Substrates Akihisa Inoue¹, ², Hyunwoo Yuk¹, Baoyang Lu¹ and Xuanhe Zhao¹; ¹Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; ²JSR Corporation, Tokyo, Japan.

Conductive polymer, such as poly(3,4-ethylene dioxythiophene)(PEDOT) have been attracting great attention because of their biocompatibility, relatively softness and highly conductivity. In addition, conductive polymer hydrogel which have properties both conductivity and hydrogel, based on PEDOT or another conjugated polymer are highly attractive materials in biomedical application, soft robotics and sensors. However, there is limitation to fabricate them into such applications with reliability to use due to poor adhesion to another materials. There are a few known approaches to achieve better adhesion of PEDOT on substrate, but those methods require special EDOT monomer for adhesion improvement. Therefore, to provide useful and general method for tough bonding of conductive hydrogel to diverse substrates has remained as grand challenge in this field.

Here, we report a useful and remarkable promising tough bonding method of conductive hydrogel to diverse substrates, such as glass, PDMS, polyimide and metal. We also demonstrate quantitative characterization of adhesion performance of conductive hydrogel on diverse substrates. This method will provide a simple yet truly useful and powerful tools for the fabrication of unprecedented devices in diverse fields.
Reliability Assessment of Conductive Interfaces for Flexible Electronics

Kyunjin Kim, Gabriel Cahn, Saresh Sitaraman, Olivier Pierron and Samuel Graham; Georgia Institute of Technology, Atlanta, Georgia, United States.

Flexible electronics are next generation devices due to thin and light features that results in low manufacturing, installation and maintenance costs. These can be applied to wearable technology by allowing devices to conform to bodies while offering great utility. Additionally, silver ink applications have been developed recently as potential flexible circuits for consumer electronics, medical devices and alternative-energy solutions. In each case, reliability assessment is important at every stage of development to ensure reliable functionality for an adequate period of service. In this study, we focused on conductive materials that are (1) used in wearable flexible electronics or (2) fabricated on polymer substrates for flexible circuits. We first demonstrated the wearable conductive interfaces’ degradation under various in environmental and mechanical conditions and analyzed the data. A Garmin conductive pad, Zephyr conductive fabric, Polar T-shirt conductive pad were kept in deionized (DI) water, 3.5% NaCl solution and simulated perspiration, and conductance measurement were recorded until they completely degraded. Simulated perspiration was found to be the harshest condition for the Zephyr fabric, while the pad types were not affected by any of the solutions. Scanning electron microscopy (SEM) and X-ray photoelectron spectroscopy (XPS) were performed on the Zephyr fabric to image the surface degradation and predict the chemical reaction in NaCl and simulated perspiration conditions as compared to DI water. In addition to the above, the degradation of conductive inks on polymer substrates and the effect of barrier coatings on their degradation were studied further. A comparative in-situ microscopy tensile test and resistance measurement of a flake and a sintered-silver electric circuit pad on polymer substrate were conducted. The development of cracks in various types of polymer substrates was compared and analyzed using a depth-profiling technique in laser scanning confocal microscopy. The effect of atomic layer deposition (ALD) encapsulation layer on the development of cracks in the silver inks’ surface was also examined.

Fatigue Damage in Ag Nanowire Networks

Chongruang Liu, William Sampson and Brian Derby; University of Manchester, Manchester, United Kingdom.

Transparent conductive thin films (TCF) are widely used in electrical devices, especially for organic light-emitting diodes (OLED), screens & displays, solar cells and touch panels. TCFs must have low sheet resistance and high light transmittance. Generally, the materials used to make TCFs should behave as low sheet resistivity and high light transparency, typically the sheet resistance, $R_s$, should be $\leq 100 \Omega$ m² with optical transmittance, $T \geq 90 \%$. The current industry standard material that is used to define these standards is indium tin oxide (ITO). For applications in flexible and stretchable electronics, such films must be resistant to damage after significant strain, a requirement that cannot be satisfied using ITO TCFs. Potential replacement materials include conductive polymers, carbon nanotubes, metallic grids, graphene, and metallic nanowires. Silver nanowire networks (AgNW) can show lower sheet resistance with higher light transmittance than ITO thin films; they also display a much greater strain to failure and greater resistance to mechanical damage. This study investigates the optoelectric properties and flexibility of AgNW networks with the objective of developing a fuller understanding of their behaviour, damage mechanisms and how these can be developed into predictive models for their properties and lifetime.

Silver nanowires have been deposited onto flexible polymer substrates by spray coating to form a continuous stochastic network. Post-spraying treatment of either a low temperature anneal or a normal pressure is used to improve wire-wire electrical contact and reduce the network sheet resistance while maintaining optical transparency. The structural integrity of the film under repeated environmental service conditions has been assessed through repeated bending tests in a high cycle fatigue environment. Film electrical properties degrade with increasing cycle number, leading to a 40% increase in sheet resistivity after 5 × 10⁶ cycles through a strain of ± 1.7%. This change in film electrical properties is correlated with observations of distributed local fracture events observed after testing by SEM studies of the fatigued networks. The fibre fracture events visible on SEM images can be quantified using an image analysis routine to count the number of fibres fractured during the bending process. These data can be used in conjunction with a model for the sheet resistance of stochastic conducting networks to predict the increase in resistance as a function of mean fibre length and hence correlated with the number of fractured fibres.

Changes in the Conductivity of FDM Printed Commercial Graphene-Infused PLA Under Short and Long-Term Electrical Stresses

Adam Krajewski; Materials Science and Engineering, Case Western Reserve University, Cleveland, Ohio, United States.

The Graphene-Infused PLA is a material made by melt blending commonly used Polyactic acid (PLA) with a few weight percent reduced graphene oxide (r-GO) to create an electrically conductive filament for polymer additive manufacturing. Among the other possible uses, it allows printing conductive circuits inside 3D printed PLA models using dual-extrusion with no change in mechanical properties of the model and printing flexible conductive circuits on fabrics using a standard FDM printer. In the recent years there were multiple successful studies on adjusting its composition and processing methods to achieve high conductivity. However, none of the studies have investigated how this property change over time when the material is used in a working device, what can be crucial to reliability of such device.

In the course of this study, we have investigated changes in the conductivity of as-printed Graphene-Infused PLA under electrical stress conditions that could be found in the target applications. Over 60 samples of additively manufactured tracks with 1.26mm x 4mm cross-section and 90±5μm layer height were prepared on non-conductive PLA substrate using popular Ultimaker 2+ FDM printer. Samples were studied in two separate experimental setups. In the first one, 36 samples underwent long-term study in which they were placed in groups, with different constant potentials applied and monitored for multiple weeks. The goal was to investigate reliability, variability and performance changes that would happen over lifetime of low-power devices like wearable electronics. In the second experiment, samples underwent short-term 6 hour long tests in which conductivity was measured with higher frequency and electrical stress characteristics were varied over broader spectrum, in order to well investigate the process of conductivity change and help formulate a theory explaining it.
Indium Tin Oxide (ITO) is a widely used transparent conducting oxide (TCO). TCO films have been deposited by solution deposition process using ITO nanoparticle. However, it is difficult to obtain high quality ITO film at less than 200°C because of high contact resistivity. The electrical properties of nanoparticle TCO films deposited by solution process should be strongly affected by the residual surface acting agent. Therefore, in order to obtain the high-quality nanoparticles TCO films by solution process with low resistivity, the after annealing temperature should be higher than 300°C. In this study, ITO films were deposited on substrates by mist deposition process. The deposition rate was almost equal to the one deposited by conventional sputtering depositions. The mist deposition process using a nanoparticle should be one of the most possible techniques for atmospheric pressure deposition, because these films were consist by high crystalline crystal grain.

ITO nanopaticles were dispersed in H2O solution with surface acting agent by ultrasonic dispersion (20kHz). H2O solution which include the ITO nanoparticle was atomized by ultrasonic transducer (2.4MHz). The solution mist were transported to substrate by carrier gas such as Ar or N2. The sheet resistivity was around 100 Ω/sq, where the post annealing temperature was 150°C. All the films showed more than 80% transmittance in the visible region. The transmittance increased in the near-infrared region where the reflectance was decreased. Moreover, the electrical resistivity decreased in the near-infrared region. The reflectance is increased. This behavior can be explained in terms of the variation in plasma oscillation in the near–infrared region, which is well known in highly degenerate TCO films. Capacitive touch-sensing device was fabricated by Nanoparticle ITO. Lozenge-patterned ITO films were created by FPD Lithography Systems.

Highly Sensitive Crack-Based Strain Sensor on Elastomer Fabricated by Laser Transfer of Silver Nanoparticles

Wooseop Shin1, Younggeun Lee1, Suwoong Park1, Seongie Park1, Jaemook Lim1, Junyeo Yeo2 and Sukjoon Hong1; 1Optical Nanoprocessing Lab, Department of Mechanical Engineering, Hanyang University, Ansan, Korea (the Republic of); 2Novel Applied Nano Optics Lab, Department of Physics, Kyungpook National University, Daegu, Korea (the Republic of).

Precise detection and control of strain at micro-nano scale is important for upcoming technologies such as robotics, automation factory and wearable medical applications. Fabrication of sensitive strain sensor on elastomer is key to monitor physiological information like human voice. Among various elastomers, polydimethylsiloxane(PDMS) has been studied for wearable devices since PDMS has a number of advantages such as biocompatibility, cost-effectivity, transparency in visible region and conformal adhesion to versatile geometries given that the PDMS is sufficiently thin. However, preparation of a sensing unit on the PDMS has been remained as a difficult task to date because of its low surface energy and poor wettability.

In order to fabricate a sensitive strain sensor on the PDMS, we suggest a facile method to fabricate unstable metal micro lines on a PDMS by selective laser transfer of silver (Ag) nanoparticle (NP) ink. This instability enables controllable generation of cracks on the metal micro lines whose gap, or its overall electrical resistance, is easily changed by small external disturbance such as external pressure/strain or vibration. The detailed experimental methods are summarized in the following section.

Firstly, prepare sufficiently thin PDMS with ~500 μm thickness to be adhered to substrate conformally. Secondly, coat Ag NPs ink on a separate glass by spin coater at 1000 rpm for 60 seconds. Thirdly, attach the PDMS on the top of Ag NP ink coated glass and irradiate 532 nm continuous wave (CW) Nd:YAG Gaussian laser at 0.21W power and 130mm/s scanning speed through 5X objective lens. Finally, detach the PDMS film from the glass. Sintered Ag patterns are transferred to the PDMS along the scanned path as a resultant.

Given that the laser power is sufficient, it is observed that the transfer of the sintered Ag NP to the PDMS film only happens when the scanning speed exceeds certain threshold, and we presume this result is stemmed from rapid thermal expansion and contraction of PDMS film. Thermal expansion coefficient of PDMS (907X10^-6/K) is known to be much larger than that of Ag (19X10^-6/K) or glass substrate. (4X10^-6/K) Consequently, large temperature gradient induced by rapid scanning is expected to cause a shear stress between these layers to promote the transfer of Ag NP towards the PDMS film.

The performance of the resultant sensor is related to the configurations of cracks which are derived from the detaching process. Among various factors, it is known from the previously reported that the crack spacing can affect the performance of the sensor in a controllable manner. In this study, the crack density is altered by exploiting the cylinders with different diameter to attain various bending curvature radii for the detaching process. The resultant crack-based strain sensor on elastomer at its optimum crack density has proven to be compatible to highly sensitive applications such as sound wave recognition.

Highly Stretchable/Bendable Skin-Mimic Organic Transistors

Hwasung Lee; Hanbat National University, Daejeon, Korea (the Republic of).

Stretchable electronics have recently been extensively investigated for development of highly advanced human-interactive devices, by using elastomeric templates. However, mechanical properties of transistor components cannot keep up with the high stretchability of the elastomeric substrate, resulting in a problem that the device electrical performances are drastically decreased. Herein, a hard parylene-C layer was deposited on the pre-strained Ecoflex surface to fabricate a corrugated substrate which is a structure that can prevent damage against the external force. The metal electrode, the dielectric (parylene-C), the organic semiconductor (DNTT) layers were formed thereon. As the results, a maximum and average field-effect mobilities of 0.83 and 0.65 cm2/Vs, respectively, were measured, and these device performances were maintained up to 30% strain. In particular, the results remained stable even when 20% tensile was repeatedly applied 1000 times.

Investigation of Charge Transfer Ability of Nanocomposites Based on Cellulose Nanowhiskers, Silver Nanoparticles and Electrospun Nanofibers

Keileane B. Teodoro1, Flavio Shimizu2, Vanessa P. Scagioni1 and Daniel S. Correa1; 1Nanotechnology National Laboratory for Agriculture (LNNA), Embrapa Instrumentacao, Sao Carlos, Brazil; 2Sao Carlos Institute of Physics, University of Sao Paulo, Sao Carlos, Brazil; 1PPGQ - Department of Chemistry, Federal University of Sao Carlos, Sao Carlos, Brazil.

Novel sensors and biosensors have been fabricated with nanostructured materials in order to provide specific chemical functionalization and enhance their sensing properties. For instance, cellulose nanowhiskers (CNW) has been combined with functional materials as silver nanoparticles (AgNP) to application in sensor devices [1]. Combining these nanostructures with polymeric nanofibers becomes interesting once CNW can work as scaffolds for nanoparticles deposition. In this work, polyamide 6 electrospin nanofibers were combined with CNW and AgNP employing distinct strategies and were deposited onto fluorine doped tin oxide electrodes (FTO) surface. A hybrid material composed of CNW and AgNP resultant of previous study was also employed as strategy (CNW/Ag) [2]. The distinct nanocomposites were produced as follows: i) neat polyamide 6 fibers - (PA6), ii) PA6 fibers containing CNW in the bulk - (PA6/CNW)bulk, iii) PA6 fibers containing CNW/AgNP in the bulk - (PA6/CNW/AgNP)bulk, iv) PA6 fibers coated with CNW/Ag - (PA6/CNW/AgNP)sheet, v) fiber coated with AgNP (PA6/CNW/AgNP)sheet. Samples (i – iii) were produced by electrospinning from PA6 solution (10% w/v) and a mixture of PA6 solution and CNW or CNW/Ag (1 %w/v), using formic acid as solvent. Experimental parameters used for electrospinning were: feed rate of 0.02 ml h⁻¹, electrical field of 20 kV, working distance of 5 cm, interval deposition of 7 minutes. Otherwise, samples (iv – v) were resultant of 2 hours-immersion of
Air-Liquid Interfacial Polymerization of Lacey Polypyrrole Thin Films by Luciano Santino1 and Julio M. D'Arcy1, 2; 1Department of Chemistry, Washington University in St. Louis, St. Louis, Missouri, United States; 2Institute of Materials Science and Engineering, Washington University in St. Louis, St. Louis, Missouri, United States.

Conducting polymers are commonly thought of as rigid materials with high glass transition temperatures, making them less attractive for flexible electronics. We report on developments in the vapor-liquid interfacial synthesis of a large area lacey (macroporous) polypyrrole films with submicron thickness. These lacy films are translucent, conductive, and continuous. Their porosity keeps them flexible under extreme conditions like immersion in liquid nitrogen, bypassing the limitations imposed by the high glass transition temperature of polypyrrole. The polypyrrole laces float on water due to the surface tension created by the wetting of their segregated pores, allowing for easy deposition onto substrates from solution. The freestanding films can be manually twisted into micron-diameter strings of highly porous and conductive polypyrrole, which exhibit exemplary tensile strength. A detailed mechanistic investigation shows the initial nucleation and polymerization of pyrrole vapor on aqueous oxidant forms an interconnected polymer skeleton. As the reaction progresses, the skeleton grows laterally, confined by Langmuir-Blodgett forces at the air-liquid interface. Lacey polypyrrole is shown to have impressive electrochemical energy storage abilities without the use of any conductive substrate backing.

Printed Biocompatible and Bioinspired Electrodes for Flexible Light-Emitting Chemical Cells by Martin Held1, 2, Daniel Ehjejij1, Johannes Zimmermann1, 2, Stefan Schlische1, 2, Tobias Rödlimier1, 2 and Gerardo Hernandez-Sosa1, 2; 1Light Technology Institute, Karlsruhe Institute of Technology, Karlsruhe, Germany; 2Innovation Lab, Heidelberg, Germany; 3Heidelberg University, Heidelberg, Germany.

Electrodes in light-emitting chemical cells (LEC) do not supply the necessary drive current, but need to provide sufficient transparency for the emission. Designing the entire device to be fully printed, biodegradable and compatible with the human body presents an additional challenge. While PEDOT:PSS electrodes are transparent and considered biocompatible, their relatively high sheet resistance produces high turn-on voltages in fully biodegradable printed LECs. To overcome this limit, inkjet printed gold grids are imprinted into the substrate below the PEDOT:PSS electrodes in various symmetric, deterministic and nature-inspired patterns. Inkjet printing supports full freedom of pattern design and scalability to industrial processes. Their contribution to the conductivity and reduction in transmittance is estimated with a simple model and experimentally confirmed. Different stretchable substrates with increasing ultimate strain from thermoplastic cellulose acetate to parylene to biodegradable elastomers are utilized to test the benefits and contribution to the conductivity and reduction in transmittance is estimated with a simple model and experimentally confirmed. The inks used are characterized by their electrical conductivity. The electrical performance of these inks varies significantly with substrate properties. For example, when supported by TPU, with a modulus of 100 MPa, the trace resistance was measured to triple. This disparity only increases with recovery after strain-induced damage. PI supported inks showed decreasing recovery, from approximately 100% after 1% strain, to 50% after 15% strain. By PI and PET, which have elastic moduli of 2.5 GPa and 3.5 GPa, respectively, at 5% strain the measured resistance approximately doubles from a mean strain or strain rate. Given these findings, there is a strong link between electrical performance of 5025 and its supporting substrate. Designers must be aware of these relationships when selecting supporting materials for specific applications.

Influence of Semiconductor Deposition Pattern in the Fabrication of Organic Field-Effect Transistors by Inkjet Printing Technique

Cristina Stefanello, João Henrique Rocha Matos, José Alberto Giacometti and Roberto M. Faria; São Carlos Institute of Physics, University of São Paulo, São Carlos, Brazil.

In the last years, the organic electronics has attracted great efforts at fundamental and technological researches. The organic electronics enables large-area fabrication, the use of flexible substrates, solution processing at low temperatures, and deposition by printing techniques. Moreover, several technological devices, such as, flexible displays, disposable sensors, RFID tags and wearable electronics can be produced using organic materials. To make possible these applications, is needed the production of field-effect transistor, an essential circuit component, which is used to amplify and switch digital and analog signals. Due to its importance, there is great interest at fabrication of field-effect transistors (OFETs). Among the developed printing technologies, inkjet is one of the most appropriate for microelectronics. It is a noncontact technique which uses low amount of material to print defined patterns, avoiding waste; furthermore it enables to change the printed pattern with easiness. Here, we present OFETs fabricated at the bottom gate-top contact architecture with the semiconductor deposited by inkjet printing technique. The semiconductor used was the 6,13-bis(trisopropylsilylethyl)pentacene (TIPS-pentacene), a promising material as p-type semiconductor, due to its high mobility, air stability and solution processability. In this work, the transistor performance was evaluated changing the distance between drops and printing patterns. The semiconductor was deposited on the organic dielectric layer. Different printing patterns of parallel lines were deposited with respect to direction of electronic conduction. Transistors presented higher performance for the pattern with same dispensing direction, achieving mobilities on the order of 10^2 cm^2/V.s and on/off ratio of 10^4. Similar features were obtained for the distance between drops of 250 µm. The better OFETs performance is associated with the printed film morphology, due to homogeneous semiconductor layer and oriented crystallization on the direction electronic conduction.

Strain Effects on Electrical Performance of Polymer Supported Dupont 5025 Conductive Ag Ink

Gabriel Cahn, Samuel Graham and Olivier Pierron; Georgia Institute of Technology, Atlanta, Georgia, United States.

Improvements in materials science and precision printing technologies have given rise to flexible hybrid electronics, allowing for the creation of components that are lightweight, and able to conform to non-planar and amorphous surfaces. Unlike conventional rigid printed circuit boards, the application space of flexible electronics includes high strain use cases. Polymer supported conductive inks have become principle building blocks of flexible electronic assemblies, and ongoing academic research endeavors to optimize electrical performance of such inks against induced strain. This work investigates DuPont’s 5025 ink, comprised of 80% by volume silver flakes in a polymer matrix. The ink is separately screen printed onto Kapton Polyimide (PI), Thermoplastic Polyurethane (TPU), and Polyethylene Terephthalate (PET), and subjected to strains in tension while measuring resistance of a circuit trace pattern. As strain increases, resistance rises at a rate dependent upon the stiffness of the supporting substrate. For example when supported by PI and PET, which have elastic moduli of 2.5 GPa and 3.5 GPa, respectively, at 5% strain the measured resistance approximately doubles from a preloaded condition. When supported by TPU, with a modulus of 100 MPa, the trace resistance was measured to triple. This disparity only increases with strain. In-situ optical microscopy revealed channel cracking of the ink as the primary cause of the increase in resistance, over that of length and cross-sectional area changes in the conductor due to the Poisson Effect. Of particular note is that cracking did not occur within the Ag flakes themselves, but rather at the flake/matrix interface. Post-mortem SEM imaging confirmed these findings. Furthermore, these channel cracks were observed to nucleate and grow more rapidly in inks supported by the softer TPU substrate. After loading, specimens were unloaded to assess the potential of electrical performance recovery after strain-induced damage. PI supported inks showed decreasing recovery, from approximately 100% after 1% strain, to 50% after 15% strain. PET samples decreased in a similar manner from 100%, but stabilized at approximately 65% recovery beyond 10% strain. TPU, having proved the most susceptible to strain damage, was shown to only recover 80% of its original performance after 1% strain, decreasing rapidly to a 25% recovery rate beyond 10% strain. Strain cycling conducted on PET supported inks indicates that strain amplitude has the greatest impact on electrical performance, above that of mean strain or strain rate. Given these findings, there is a strong link between electrical performance of 5025 and its supporting substrate. Designers must be aware of these relationships when selecting supporting materials for specific applications.

Preparation of Cu Nanoparticle Colloid from a Cu Ion Solution by Using Protein Surfactant

Masatoshi Sekiizuchi, Kei Oikawa, Mizuki Nakahara, Yuusuke Inaba, Taiyo Maeda, Akinori Matsui and Hiroki Ishizaki; Saitama Institute of Technology, Fukaya, Japan.

Recently, metal nanoparticles colloid had many problems such as the aggregation of nanoparticles, oxidation resistance and non-uniformity of nanoparticles. In order to dissolve many problems mentioned above, we support that oxidation and aggregation will be improved by using casein contained in milk as a polymeric surfactant. In this investigation Cu nanoparticle colloid will be grown from the aqueous solution containing Cu ion and casein. Also, high purity water by liquid phase reduction method was used. As a preparation method, copper sulfate, citric acid, and urea were dissolved in ultrapure water, and an aqueous copper ion solution was made strong alkali with an aqueous sodium hydroxide solution. Next, the copper ion aqueous solution, the surfactant solution and the reducing agent were stirred to prepare a copper nanoparticle precursor solution. The copper nanoparticle precursor solution was kept at 80 ° C. for 20 minutes to prepare an aqueous copper nanoparticle colloid solution. For the actual results, the concentration of the nanoparticle colloid will be controlled by the surfactant concentration. Since the wavelength of the absorption spectrum shifts to the shorter wavelength side, the size of the nanoparticle colloid is considered to be smaller.

Improved Stability and Adhesion of Printed Graphene and Silver–Copper Composites for Circuits on the Foldable Substrates

Hui Jae Choi, Gyeong Seok Hwang, Ohyoung Kim, Dong Hyun Lee and Byung Doo Chin; Dankook University, Yongin, Korea (the Republic of).

Soft conductive materials, such as graphene and silver-based composites, are ideal for the electronic components of circuits and electrodes on the flexible, foldable, and even stretchable devices. Recently, stability against significantly smaller curvature and larger mechanical stress for repeated operation became a key factor to obtain a successful manufacturing of the commercial application of foldable electronic devices. Here, we have demonstrated the printed circuits on the foldable substrate with graphene ink and silver-copper nanocomposites. Few layer graphene powder nano-platelet, Angstrom materials graphene N002-PDR, was dispersed in solvents with appropriate binders to formulate a screen-printable paste. The paste was also modified for an electro-hydrodynamic jet printing toward a fabrication of fine line patterns on the foldable paper substrates and flexible polynime films. In order to modify the surface toward smoothness at foldable operation, poly(4-vinylphenol) coating on the commercial paper substrate was employed. In case of graphene/silver composites printed, circuit showed superior performance as well as folding stability; decrease of relative conductance for -90° and -180° folding (toward inside direction) was only 5% and 12%. Moreover, the conductance was maintained about 80% of initial value after 1000 cycle of continuous folding. For higher conductance circuit, silver-copper composite inks were printed and compared with graphene-based composites. In order to further improve the stability against continuous folding and unfolding deformaition, paper and plastic substrates were treated with primer containing the Joule-heater and touch screen panel.
flexible additive, poly(ethylene glycol) diacrylate (PEGDA). The folding stability of circuit conductance, employed as auxiliary electrode of green organic light emitting diode, was significantly improved by the enhancement of adhesion between PEGDA primer layer, foldable paper, and printed circuits.

*Fabrication of Ultra-Light Porous Boron Nitride/Polyimide (BN/PI) Composite Films with High Thermal Diffusivity and Low Dielectric Properties*

Yang Kwansoo1,2, Dong Gyun Kim2, No Kyun Park1, Jong Chan Won1,2 and Yun Ho Kim1,2; 1Korean Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2University of Science and Technology, Daejeon, Korea (the Republic of).

As modern electronic devices become functionalized, miniaturized, more integrated, and exhibit higher performances, one of the most important issues is to efficiently remove heat generated by high-power integrated circuits. In addition to the high thermal conductivity, the low values of dielectric properties such as the dielectric constant (\(\varepsilon\)) and dielectric loss (\(\tan \delta\)), are another important factors for future electronic devices using a high-frequency band, particularly for the 5G communications using frequencies above 2.8 GHz.

Here, we report a simple fabrication of ultra-light porous boron-nitride-(BN)/polyimide-(PI) composite films with high thermal diffusivities and low dielectric constants by combining high-internal-phase Pickering emulsification (HIPPE) and subsequent hot-pressing. BN nanoparticles in composite foams were well dispersed and three-dimensionally connected following the surface of the PI skeleton used as the polymer matrix. The BN contents in the BN/PI composite foams were adjusted in the range of 20–80 wt%. The porosities of the composite films were controlled according to the hot-pressing conditions such as the temperature. The internal porous morphologies of the BN/PI composite foams and films were characterized by scanning electron microscopy. The 400°C-hot-pressed BN/PI composite films had higher thermal diffusivities than those of BN/PI composite films prepared by the conventional solution blending method, despite the presence of internal air pores reducing the thermal conductivity. In addition, the internal pores provided lower dielectric constants of the BN/PI composite films.

The porous BN/PI composite films exhibited high thermal diffusivities of 0.059–1.033 mm²/s and low dielectric constants of 2.08–3.48 at 1 GHz for BN contents of 20–80 wt%. In particular, our porous BN/PI composite films had extremely low dielectric loss values, close to zero (< 0.002) at high frequencies regardless of the BN content and pressing conditions, which is essential for the 5G communication technology. Therefore, our porous BN/PI composite films with high thermal diffusivities and weak dielectric properties are promising for applications as packaging materials for integrated and miniaturized microelectronic devices.

TUTORIAL: Flexible Hybrid Electronics
November 25 - November 25, 2018

* Invited Paper

**TUTORIAL**
Flexible Hybrid Electronics
Sunday Afternoon, November 25, 2018
Hynes, Level 2, Room 206

Flexible Hybrid Electronics promises to deliver high performance and reliable systems in novel forms and functions. It is achieved by utilizing high performance silicon based semiconductor devices assembled on flexible (flex) substrates using optimized materials and additive processes. Integration of electronic devices on flexible substrates is starting to enable dramatically new approaches to traditional applications including: information displays, lighting, sensors, solar energy conversion and diagnostic medicine. The course will look at the fundamental aspects of three approaches: coating and printing (Mastropietro), chip-on-flex and micron scale thin-film devices on flex (Poliks) and sub-micron scale self-assembled/imprinted device based coatings on flex (Watkins).

1:30 PM
**Coating and Printing** Michael A. Mastropietro; ACI Materials

Selecting the right print method for additively manufactured circuits require a fundamental understanding of performance metrics of printed conductors and functional materials. The selection of the appropriate printing method is also key. This section will review the fundamentals of direct write methods: inkjet, aerosol-jet, extrusion, micro-dispensing; printing methods requiring a master: screen printing, flexo, gravure, gravure offset; and coating methods: slot-die and Meyer rod, as well as the technical challenges of drying and curing functional inks.

3:00 PM BREAK

3:30 PM
**Chip-on-Flex and Micron Scale Thin-Film Devices on Flex** Mark D. Poliks; Binghamton University, The State University of New York
In the second section emerging methods for integration of thin semiconductor devices, sensors and transducers, including creation of thin die, thin die handling, die attach, interconnection and encapsulation on flexible substrates will be presented. Die function can also be integrated into micron scale thin-film electronic device fabrication directly on flexible non-silicon-wafer surfaces. Engineered polymer films such as PET, PI, PEN, as well as thin flexible metal foils and glass are all viable substrates for this technology. Key substrate properties include: dimensional and thermal stability, low moisture uptake, ultra-low gas and moisture transmission rates and nano-scale surface roughness. This part of the talk will examine how some of the basic semiconductor manufacturing processes can be adapted for use with flexible substrate materials and suggest a means for roll-to-roll manufacturing of flexible hybrid electronics. Advancements in manufacturing processes such as roll-to-roll handling, slot-die coating, vacuum deposition, photolithography and wet processing will be described.

4:15 PM
Sub-Micron Scale Self-Assembled/Imprinted Device Based Coatings on Flex James J. Watkins; University of Massachusetts-Amherst

The third part of this course, will discuss emerging technologies in printed and flexible electronics that can enable next generation performance. Nano-scale fabrication techniques, including the self-assembly of hybrid (inorganic/organic) materials and imprinted patterning using polymers, hybrid polymer/inorganic resists and crystalline nanoparticle ink systems, can resolve challenges associated with large area production of sub-micron device features leading to very high integration densities as well as cost-effective production of functional device components. Applications include printing of 2-D and 3-D crystalline inorganic structures for light and energy management, printed micron scale transistors and printed microfluidic sensors. In addition, printing of functional structures to modify the performance and behavior of adjacent components.

SESSION PM03.01: Transistors and Devices
Session Chairs: Nikos Kehagias and Shelby Nelson
Monday Morning, November 26, 2018
Hynes, Level 1, Room 108

8:15 AM PM03.01.01
Homojunction Transistor with Superior Electrical Characteristics Hinting the Feasibility of Solution for Roll-to-Roll Process Junhee Lee1, Jinwon Lee1, Jintaek Park1, Sung-Eun Lee1, Keon-Hee Lim1 and Yoon Sang Kim1; 1Seoul National University, Seoul, Korea (the Republic of); 2University of Illinois at Urbana Champaign, Urbana, Illinois, United States.

Growing attention has been given to solution deposition techniques, considered as one of the promising deposition procedures for roll-to-roll process due to its properties of a continuous and large-scale deposition processing. However, further research is needed to apply a solution process into roll-to-roll process because of its several drawbacks such as inferior electrical characteristics of solution-grown electronics such as thin film transistors compared to vacuum-processed ones. To date, various efforts have been made on eliminating causes of lowering electrical performance such as impurities and a small number of orbital overlap. While the outcomes exhibit a moderate increase in electrical characteristics, their performance still does not reach that of vacuum-processed thin film transistors. In order to address this issue, thin film transistors with double-stacked layers hold great promise among other approaches because of their superior electrical performance. Recent studies have proposed heterojunction transistors showing an average high field effect mobility of 30 cm²V⁻¹s⁻¹, an analogous performance with devices made by vacuum process. However, further development of double-stacked transistors is hindered by limitations particularly with regards to their turn-on voltage of ~40 V which is unsuitable for the switching devices. Herein, we overcome this restraint by proposing a renovated structure called homojunction thin film transistors consisting of a channel layer and a channel electron modulation layer. Not only do we achieve the highest field effect mobility of approximately 50 cm²V⁻¹s⁻¹, but a turn-on voltage of the device can also be effectively controlled from -80 V to 0 V through modifying each layer. Moreover, this exceptional electrical performance of homojunction transistors are maintained more than 50 days under ambient conditions, and other device traits such as uniformity and reliability are validated. Through five analyses, including x-ray diffraction, atomic force microscopy, x-ray reflectivity, x-ray photoelectron spectroscopy and transmission electron microscopy, the solution-grown thin films in our structure have few electron trap sites and thus afford fast electron transportation, showing unprecedented field effect mobility and excellent hysteresis characteristics. These outstanding results are attributed to the high film quality of oxide films with a thickness less than 6 nm. On the contrary, thick oxide films of more than 6 nm forms a relatively poor film quality because an oxidation process at ambient conditions is
disturbed. Lastly, we have also demonstrated the n-type metal oxide semiconductor inverter making up of the homojunction transistors. Our solution-based electronics with superior electrical performance suggest the possibility of a low-cost and manageable solution process being applicable for future deposition techniques including roll-to-roll process.

8:30 AM *PM03.01.02
Free-Standing and Transparent Printed Organic Field Effect Transistors and Integrated Circuits with Sub-10 V Operation Elena Stucchi1,2, Giorgio Dell’Erba1 and Mario Caironi1,1, Istituto Italiano di Tecnologia, Milano, Italy; 2Politecnico di Milano, Milano, Italy.

Organic electronics enables the fabrication of flexible and lightweight electronic circuits, creating a clear path toward the realization of portable and wearable devices. In the last decades, organic field effect transistors (OFETs) have been extensively studied, aiming at the development of low cost, large area, flexible electronic systems, fabricated by means of industrially scalable techniques onto cheap plastic substrates.

In this work, we show the successful fabrication of organic transistors and circuits onto different substrates, namely 125 µm-thick polyethylene naphthalate (PEN) and 3 µm-thick parylene films. In the latter case, devices have been encapsulated with a parylene film of the same thickness, thus allowing for the realization of free-standing, conformal devices with improved stability in air.

We fabricated OFETs in a top-gate/bottom-contact (TG/BC) configuration with inkjet printed PEDOT:PSS source and drain electrodes. Inkjet printing has been used also for patterning poly(N,N'-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl)-alt-5,5'-(2,2'-bithiophene)) (PNDI2OD-T2) and poly[2,5-bis(7-decylnonaaddexy)pyrrolo[3,4-c]pyrrole-1,4,2(H,5 H)-dioneÊ–(E)-1,2-di(2,2'-bithiophen-5-yl)ethene] (29-DPP-TVT), which have been employed as p- and n-type semiconductors.

One of the factors hindering the diffusion of these devices onto the market is related with their high operating voltages, affecting their power consumption and stability. We addressed this issue by focusing on the development of a thin dielectric layer for low voltage, transparent, flexible OFETs. We used parylene C as gate dielectric material, both alone and combined with other low-k dielectrics into multi-layered structures, limiting in all cases the thickness of the dielectric layer to 100 nm.

The employed dielectric allows transistor operation in the sub-10 V regime, with very low leakage current density despite the reduced thickness of the dielectric layer. An array of optimized OFETs has been fabricated and the devices show high yield, uniform performances, high transparency and stable output characteristics up to at least 1000 bending cycles.

We have successfully demonstrated the integration of p- and n-type devices onto the same substrate, and we have been able to fabricate well-balanced CMOS inverter logic gates. These devices have been further integrated into more complex circuits, such as ring oscillators and D-Flip-Flops, and their correct operation has been demonstrated with voltages as low as 2 V.

The results presented in this work, exploiting scalable deposition processes, offer a viable and cost-effective path for the fabrication of all-polymer, transparent, flexible electronic devices operating at low voltages, which can easily be integrated into consumer products.

8:45 AM *PM03.01.03
High-Speed, High-Resolution Printing of Inorganic Devices Vivek Subramanian and William J. Scheideler; University of California, Berkeley, California, United States.

In recent years, there has been increased interest in printed inorganic devices. This has been driven by the high performance that has been demonstrated in these systems, with field-effect mobility >10 cm²/V-s having been achieved in several solution-processed FETs based on inorganic semiconductor materials. Some of these materials are additionally attractive due to their optical transparency. Printing is a key issue in these systems. Due to the material constraints of these systems, inks formulated from these materials are often limited in their rheological tenability. Here, we review our work developing materials and processes for printing of inorganic devices, and present the resulting device data showing the achievement of high-performance devices using a range of high-speed and high-resolution printing techniques. We have realized transparent conductors and fully transparent FETs using these techniques. We have also developed material system and inks that enable fabrication of such devices at low-temperature, enabling the use of a wide range of substrates.

We report on our development of printed thin film transistors, conductors, and sensors based on these materials.

9:15 AM *PM03.01.04
Zone-Cast Printed Crystalline Organic Thin-Film Transistors and Circuits with High Mobility Paul Heremans1,2, Robby Jameck1,2, Dimitrios Karagiannis1,3, Thomas Nowack1,2, Hany Ali1,2, Florian De Roose1,2, Jan Genoe1,2, and Cedric Rolin1, imec, Leuven, Belgium; 2ESAT, KU Leuven, Leuven, Belgium; 3KU Leuven, Leuven, Belgium.

We develop a meniscus-guided printing technique for organic transistors with high mobilities. In our zone-casting technique, a solvent meniscus with dissolved organic semiconductor is formed, that coats a crystalline thin-film of semiconductor in a continuous way. We acquire in-depth understanding of the process by modelling the film formation for different solvents, solute concentrations, temperatures and printing speed, and correlating the results with experimental findings for two different small molecules C8-BTBT and TIPS-pentacene. Next, printed crystalline films of C8-BTBT with charge carrier mobility exceeding 5 cm²/Vs are used to fabricate TFTs, both in top contact geometry and in bottom contact geometry. We show a reproducible and accurate process for patterning the semiconductor by photolithography and etch down to channel lengths of 3 micron. The patterning process does not impact the transistor performance. Using the bottom-contact geometry, robust 19-stage ring oscillators with 5-micron transistors are shown that comprise 80 TFTs, having an operating frequency of 630 Hz at an operating voltage of 10 V.

9:45 AM BREAK

10:15 AM *PM03.01.05
Horizontal Alignment of Carbon Nanotubes Using Roll to Roll Processing Ken R. Carter; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

One-dimensional objects which have aspect ratios greater than 5 such as carbon nanotubes (CNTs), microtubes nanowires, microfibers, fibers, nanorods, microrods, whiskers, and the like, are generally bundled or entangled into aggregates or agglomerates when disposed on a surface. It is difficult to separate these objects and to orient them because their high aspect ratios permit them to overlap with one another when they are stored. This overlapping is generally random and often results in entanglements which produce the aggregates and agglomerates. The entanglements make it difficult to separate the one-dimensional objects from one another and to orient them in any particular direction.

Oriented one-dimensional objects can find utility in a variety of applications in electronics, conductive plastics, catalysts and the like. It is therefore desirable to find a method of orienting one-dimensional objects. We report a method where CNTs can be directed to horizontally align when coated on a patterned substrate. A dispersion of one-dimensional objects in a liquid mixture is deposited on a substrate that has channels create by NIL or Roll-to-Roll NIL techniques. The CNTs orient in a direction that is perpendicular to the walls of the channel. By changing the shape of the channel, different orientations of the one-dimensional object can be obtained. The orientation of the one-dimensional objects can therefore be controlled by controlling the shape of the channels. Using this method, large areas of horizontally aligned CNTs can be fabricated with ease and high throughput.
During the drying process, the magnitude is determined by the surface free energy (SFE) of the substrate and surface tension (ST) of the ink. This interaction mainly affects the contact angle (CA) of a single drop and thus the smallest possible printed feature size. For these reasons, substrates need to be chosen carefully. Therefore, the interaction between the ink and the substrate has a strong influence on the wetting behavior, pinning effect and film formation. A particular ink is usually developed for a particular set of surface properties and generally has to be reformulated when changing the substrate.

Light emitting diodes (OLED) or organic field-effect transistors (OFET) are to be deposited on non-porous and non-ink-absorbing substrates. Therefore, we introduce a controlled nanoscale roughness onto the substrate surface to define wetting and pinning properties without changing the ink. The deposition of solution processable functional materials with printing techniques offers the possibility to prepare low-cost electrical devices like organic light emitting diodes (OLED) or organic field-effect transistors (OFET). These devices are to be deposited on non-porous and non-ink-absorbing substrates. Therefore, the interaction between the ink and the substrate has a strong influence on the wetting behavior, pinning effect and film formation during the drying process which magnitude is determined by the surface free energy (SFE) of the substrate and surface tension (ST) of the ink. In addition, this interaction mainly affects the contact angle (CA) of a single drop and thus the smallest possible printed feature size. For these reasons, a particular ink is usually developed for a particular set of surface properties and generally has to be reformulated when changing the substrate.

Increasing Organic Semiconductor Crystal Width with the Dimensions of Inorganic Polymer Micropillar

Jeongchan Lee and Steve Park; Korea Advanced Institute of Science and Technology, Daegon, Korea (the Republic of).

Solution coating process using organic semiconductors (OSCs) are a promising technique for large-area, low-cost and flexible transistor application. Therefore, a variety of solution coating processes have been developed over the past few decades such as spin coating, slot-die coating, ink jet printing and solution shearing. The key requirement of organic electronics is the formation of high quality organic semiconductor thin-film over a large area in a facile manner. However, the crystal orientation, crystallinity and crystal size of OSCs, which affects the performance of transistors, are difficult to control because of uncontrollable nucleation and chaotic fluid flow. Therefore, the system is needed that controls the nucleation process during the solution coating.

Herein, we demonstrate that organic crystal size can be manipulated simply by changing the shape and dimensions of the microstructures on the blade during solution shearing. We tuned the shape of the meniscus by tuning the micropillar shape and size, by which nucleation rate was controlled. The mobility of the thin-films increased with increasing crystal size to as high as 3.56 cm²/Vs. Such a new way to manipulate the crystal size adds another useful parameter that can be utilized to tune the property of organic thin-films and is potentially applicable to other materials systems. We also demonstrate for the first time the use of an inorganic polymer (AHPCS) as the microstructured blade for solution shearing. Currently, microstructured silicon is used, which is expensive and difficult to fabricate, and is very brittle. On the other hand, AHPCS can easily be microstructured via molding and is mechanically durable. Furthermore, unlike elastomers such as PDMS, AHPCS is highly resistant to various organic solvents. The use of AHPCS for microstructured blade is therefore highly advantageous for industrial applications where low cost and durability are of great importance.
Another important aspect is the master fabrication and its upscaling to large-area imprint tools. Here we introduce a Step & Repeat UV-NIL technique.

For optical polymer components such as free-form micro-lenses or light outcoupling / reflecting structures the tenability of the refractive microfluidics are a sufficiently high surface energy to allow for a fast and long distance filling of analytes, the ability to be bio-functionalized and low wicking) energy surfaces and it should have low enough viscosity to allow for large-area coating. Special requirements for the channel forming resin in this scenario. It should be tunable in terms of elasticity and surface tension to account for easy demolding and for low (water-repellant) as well as high (water-reflecting) effect coatings.

In this study we report the set-up of a custom made R2R-UV-NIL pilot machine which is able to convert 10 inch wide polymer web with velocities up to 50 m/min. For imprint as well as polymer working stamp material UV-curing resins based on urethane acrylates and thiol-ene chemistry were designed to meet the requirements of R2R-UV-NIL processes being strong adhesion to polymer substrates, fast curing speed and high imprint fidelity. The mechanical properties, surface chemistry and refractive index of these UV imprint resins can be tuned over wide ranges by choice and ratio of urethane acrylate oligomers and acrylate or thiol monomers – and surface active dopants. We have achieved Young’s moduli between 5 MPa and 5 GPa, refractive indices nD25 between 1.4 and 1.7 and surface energies between 15 mN/m and 60 mN/m. Furthermore, new strategies have been developed to achieve excellent abrasion resistance and utmost weathering stability of the nanoimprinted biomimetic polymer surfaces in harsh outdoor applications.

Roll-to-Roll UV imprint lithography (R2R-UV-NIL) gains increasing industrial interest for large area nano- and micro-structuring of flexible substrates because it combines nanometer resolution with many square meter per minute productivity. Besides the classical application fields of nanoimprint lithography like micro-electronics and micro-optics currently biomimetic micro- and nano-structured surfaces get increasing attention for e.g. viscous drag reduction (shark skin effect), water and dirt repellence (lotus effect) and anti-reflection (moth-eye effect) coatings.

In this study we report the set-up of a custom made R2R-UV-NIL pilot machine which is able to convert 10 inch wide polymer web with velocities up to 50 m/min. Replication and Surface Properties of Structures with a Novel 3D Topography Namrata Salunke1, Douglas McBain2 and Alamgir Karim3, 4, 5; 1The University of Akron, Akron, Ohio, United States; 2Chemical and Biomolecular Engineering, University of Houston, Houston, Texas, United States; 3Laird Technologies, Cleveland, Ohio, United States.

Surface texture is known to play an important role in altering and potentially improving surface properties of the material for different applications related to hydrophobicity, cleanability, heat transfer, lubrication, adhesion and friction. Traditionally, it is believed that the alterations in properties arise from increased roughness and waviness, but understanding in more specific terms is lacking. In the past decade, the importance of pattern shape has been gaining recognition. Several studies have focused on how patterns of various shapes (cubes, channels, cylinders) with similar surface roughness values show dissimilar properties. Recently, there has been an increased effort in developing technologies to fabricate patterns with increased geometrical complexities. In this talk, we discuss such a complex and a less conventional pyramidal pattern shape. A study using various processing techniques to obtain this less conventional pattern in the millimeter and micron range is reported. We will discuss traditional milling techniques and its limitations and proceed towards new innovative additive manufacturing and lithographic techniques.

3:45 PM PM03.02.05

Wrinkling is a ubiquitous surface phenomenon that occurs at a wide range of length scales from kilometers to nanometers. Particularly, micro/nano-scale wrinkles have found applications in stretchable electronics, tunable optics and coatings with controlled wettability and adhesions [1,2]. Although various techniques including thermal treatment [3], swelling [4], mechanical stretching [5], and UV curing [6], have been developed for wrinkle fabrication, little attention has been paid for continuous manufacturing over large scale. Bearing this in mind, here, we investigate wrinkling on a roller, both experimentally and theoretically, with the aim of developing a scalable roll-to-roll (R2R) manufacturing process. This technique takes advantage of the various geometrical shapes and curvatures defined by the 3D printed rollers to induce well-defined strain fields to manipulate the final wrinkle patterns on compliant polymer substrates. First, we study wrinkle formation on a thick polydimethylsiloxane (PDMS) film wrapped around a roller, followed by oxygen plasma. The wrinkle features show a strong dependence on the geometrical parameters of the roller, thickness of the film, and other processing parameters. We then explored to achieve continuous wrinkling under ambient conditions by applying a UV-curable polymer onto PDMS as the skin layer, followed by UV curing along with rotation of the roller. Based on this principle, we demonstrate one-dimensional (1D) gratings, two-dimensional (2D) herringbone and labyrinth patterns over large areas using different roller shapes, and the wrinkle wavelengths span from hundreds of nanometers to tens of microns. The use of rollers to control the generation of wrinkles paves the way for R2R manufacturing of surface wrinkles for a wide range of applications.

Transition to Superwetting for a Nanostructured Surface Nikolai K. Mandberg1, Agnieszka Telecka1, Tao Li2, Emil Ludvigsen3, Sokol Ndomi4, Rosa Di Mundo5, Fabio Falumbo5, Jackie Fiutowski5, Serguei Chirita6 and Rafael Taboryski6; 1DTU Nanotech, Kongens Lyngby, Denmark; 2Dept. of Electronic and Electrical Engineering, University College London, London, United Kingdom; 3Dept. of Chemistry, Politecnico di Bari, Bari, Italy; 4NANOTEC, National Research Council, Bari, Italy; 5Mads Clausen Institute, University of Southern Denmark, Sonderborg, Denmark.

According to traditional Wenzel theory, superhydrophilicity emerge when introducing roughness on an intrinsically hydrophobic surface. However, recent studies have shown a deviation from this behavior [1]. Understanding the failure mechanism will aid the design of surfaces that exhibit superhydrophilic behavior. In particular, moderately hydrophilic materials, such as polymers and other low energy materials, need a careful design, as they are particularly prone to failure.

In this study, we employed block copolymer nanolithography [2] with a subsequent injection molding replication in poly(methyl methacrylate). Compared to the flat reference, the roughness increased the water contact angle (from 67.6° to 99.4°); a contradiction to the traditional Wenzel theory. For moderately hydrophilic substrates, a nanoscopy pillar-built surface has a Laplace pressure barrier that prevents droplet spreading. Increasing intrinsic hydrophilicity could lower the barrier to allow superwetting. Consequently, we characterized the transition by applying a low-pressure Argon plasma to increase the surface free energy in a continuous fashion. Using apparent contact angle to probe the transition, we found a threshold of 55°.

Furthermore, we demonstrate how macro- and microscopic wetting phenomena are interconnected. As an example of the barrier implications, we study the condensation of water on both sides of the threshold. While flat surfaces and untreated, structured surfaces both show indelible dropwise condensation, the plasma treated, structured surface gives rise to filmwise condensation. Using a transparent polymer and designing structures to be below the diffraction
limit for visible light, the threshold defines the emergence of anti-fogging properties relevant to a plethora of optical applications such as endoscopy [3].

4:15 PM PM03.02.07

Rapid, high throughput patterning in three dimensions with nanoscale resolution has long remained an elusive target for materials scientists. Optical interference lithography has been an attractive technique to cheaply and rapidly pattern three dimensional features in polymer photoresists despite both resolution and feature size being limited by diffraction. In the past few years, Stimulated Emission Depletion Microscopy (STED) inspired lithography schemes have shown the ability to direct-write features well below the diffraction limit using visible light. However, the high light thresholds required for effective photoinhibition renders them unsuitable to be used for interference lithography and limits their use to point by point writing. Recently, we have shown that combining the reversibly saturable photoisomerization of spirothiopyran with thiol-Michael addition chemistry can be used to formulate a super-resolution writing system with desired low light thresholds for photo inhibition, thus enabling them to be used for parallel patterning using interference lithography. Adapting the spirothiopyran writing chemistry for self-assembled monolayers on glass substrates allows us to fabricate switchable photosensitive surfaces that can be activated and deactivated for patterning with maleimide functionalized molecules using UV (365 nm) and green (532 nm) light respectively. By exploring the kinetics of photoisomerization of bound spirothiopyran and subsequently tuning their chemical environment, we experimentally demonstrate large area nanopatterning with sub-diffraction resolution and molecular thickness using a 2-color interference lithography setup. The lateral feature size of the written patterns is shown to be tunable by controlling the relative intensity of the initiation and inhibition wavelengths. The resultant nanopatterns formed are characterized using super-resolution microscopy. Secondary conjugation on regions patterned with bifunctional maleimide linker molecules can be used to tailor the nanostructured surfaces to desired chemical functionalities. These experiments demonstrate the versatility of spirothiopyran based writing systems for rapid high-throughput nanopatterning. Efforts are currently underway in our laboratories to apply spirothiopyran mediated 2-color interference lithography for 3D nanopatterning in bulk polymeric gels.

4:30 PM PM03.02.08
High Resistive State Retention in Room-Temperature Solution-processed Biocompatible Memory Devices for Health Monitoring Applications Aishita Mishra, Henam Sylvia Devi, Soumen Saha, Abhishek Dixit and Madhusudan Singh; Indian Institute of Technology Delhi, New Delhi, India.

Wearable and bio-implantable health monitoring applications require flexible memory devices that can be used to locally store body vitals prior to transmission or to support local data processing in distributed smart systems. In recent years, non-volatile resistive random access memories composed of oxide-based insulators such as hafnium oxide and niobium pentaoxide have attracted a great deal of interest. Unfortunately, hafnium and niobium are not low-cost materials and may also present health challenges. In this work, we have explored the alternative of using titanium dioxide as the insulating oxide using a low-cost solution-phase deposition process. Aqueous sol deposited titanium dioxide thin films were deposited on standard RCA-cleaned commercial thermal silicon dioxide (500 nm) wafer (500 um). Patterned bottom contacts Cr/Au (~200/300Å) using shadow masks were deposited on the substrate using successive DC sputtering, and thermal evaporation, respectively at 5 x 10-6 Torr. A sol was prepared using titanium (IV) butoxide as precursor hydrolyzed under water and ethanol to form a colloidal solution (sol) at 50°C under constant stirring. Powder X-Ray Diffraction (PXRD) scans of calcined (from sol at 750°C) nanoparticles show a mixture of anatase and rutile phases, confirming the composition of the material. The sol was slowly cooled to room temperature before being spin coated at low rotational speeds on the substrate in multiple steps involving several spin coating and drying steps to form a uniform film. Top contacts (Ag) of thickness (~500Å) were deposited on the sol-deposited thin films using thermal evaporation. The resulting devices were coated with a thick layer of polydimethylsiloxane (PDMS) using a 10:1 ratio of base elastomer and curing agent respectively. After drying the PDMS, resistance measurements were carried out using Keithley 6514 electrometer. A high resistance state was detected prior to electroforming in the air at ~27 GΩ, which remains nearly unchanged (~24 GΩ) when dipped in a pH 7 buffer solution (equivalent to human blood’s pH reference value ~7.4). Unencapsulated devices were further characterized in air using a Keithley 4200-SCS semiconductor parameter analyzer in dual sweep mode to observe repeatable hysteresis behavior with a large difference between trace and retrace R-V characteristics (~50:3% over a pristine device), which compares favorably with recent data in the literature on high-performance sputtered TiO2 memristors. Unchanged retention ratio using biocompatible device materials and encapsulation suggests that these devices can be used for biomedical implantable sensor electronics.

SESSION PM03.03: Integration
Session Chairs: Shelby Nelson and Mark D. Poliks

8:00 AM PM03.03.01
Flexible Nanogap Diodes for GHz Radio Frequency Energy Harvesting Applications Kalaivanan Loganathan, Emre Yengel, Hendrik Faber, Zainab Felemban, Emre Yaral, Thomas D. Anthopoulos; Material Science & Engineering (MSE), King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

The emergence of the Internet of Things (IoT) device ecosystem is expected to impact many aspects of our daily lives including health via accurate sensing & monitoring of our environment, transportation, logistics, and entertainment, to name but a few. Despite the tremendous potential, however, numerous technological and economic barriers still exist. One such technology roadblock with significant economic implications is how to reliably power the myriad of these IoT devices without increasing the environmental impact (e.g. battery disposal/recycling). Among the various green options is harnessing the omnipresent radio frequency (RF) energy using Wireless Energy Harvesting (WEH) systems. The most crucial components of a WEH system is the rectifier circuits and the RF antenna as they determine the frequency of operation, operating distance, and ultimately the power conversion efficiency of the system. In order to satisfy these requirements, the rectifier circuit should be inexpensive to manufacture and able to operate at frequency ranges compatible
with the widely available RF networks (>1 GHz). This is the reason why recently considerable effort focused on the development of diode technologies that can satisfy both the performance and cost requirements. Here, we report the development of sub-20 nm co-planar asymmetric nanogap electrode Schottky diodes manufactured on arbitrary substrate materials using adhesion lithography (a-Lith) as an alternative nano-patterning technique. As the semiconductor we employ different metal oxides as they combine solution-processability with excellent electron mobility while as the electron Ohmic contact we employ Ti as its native oxide (TiO₂), which forms spontaneously upon semiconductor deposition, is thin (~2 nm) and semiconducting and as such does not compromise electron injection. For Schottky contacts, we find that both indium tin oxide (ITO) or Au yield large electron injection barriers and serve as good blocking materials. Using this rather simple nano-gap device architecture in combination with the attractive properties of metal oxides, we demonstrate diodes with operating characteristics significantly higher than 1 GHz. The manufacturing of the diodes can be further simplified through the use of an innovative photonic processing scheme that allows sub-10 second conversion of the metal oxide precursor to a highly polycrystalline semiconducting layer even on temperature sensitive substrates materials such as plastic, without compromising the diode’s performance. Our work paves the way to a radically new diode technology that has the potential to significantly impact the IoT device ecosystem.

Site-Specific Growth and In Situ Integration of Different Nanowire Materials on a Single Chip for Electronic Nose Applications Guillem Domènech-Calí, Lukas Harachowina, Antonio Pardo, Michael S. Seifner, Isabel Gràcia, Carles Cané, Sven Barth and Albert Romano-Rodriguez; *1University of Barcelona, Barcelona, Spain; *2In2UB, Barcelona, Spain; *3TUW, Wien, Austria; *4CNM, Bellaterra, Spain.

Many of our daily habits contribute to disperse toxic and harmful gases to the atmosphere, both in indoor and outdoor environments. For this reason, there is an increasing concern about the presence of these gases in the ambient and the need to fabricate systems to monitor them. There are many types of gas sensors for this application and among them, solid state gas sensors are an excellent choice. These sensors offer low manufacturing cost and low power consumption thanks to MEMS technology. Even though gas sensors based on semiconducting nanowires offer remarkable performances in terms of sensitivity and response time, they usually lack in selectivity, showing cross-sensitivities with environment conditions (e.g. humidity or temperature) and being only able to distinguish among oxidizing or reducing gases. A way to solve this issue is using pattern recognition from arrays of sensors with different materials or operating at different temperatures, giving rise to an electronic nose (e-nose) configuration. Based on a modification of the chemical vapor deposition method, a new procedure to site-selective synthesize nanowires on top of micromembranes has been developed. This method allows to grow the material with nanowire morphology and different compositions on one single chip surface and can be easily tailored offering an adjustable fabrication process for the direct integration of different nanowire-based resistive multifunctional devices. The use of chemical vapor deposition techniques is compatible as a CMOS post-processing and, therefore, the impact of preparing gas sensors on any kind of chips for multifunctional devices is unimaginable. In this work, we demonstrated for the first time the site-specific growth and in-situ integration of different materials in form of nanowires for sensing applications on a single chip in a well-defined geometry, with little interference on the growth parameters caused by the prior deposition of other nanostructured material. This proof-of-concept is exemplified by the deposition of SnO₂, WO₃ and Ge nanowires on the membranes of one single chip and their gas sensing responses towards different concentrations of CO, NO₂ and humidity diluted in synthetic air are presented. The measured responses allowed to discriminate between all three analytes using the well-known Principal Component Analysis (PCA) representation, as it allows gas separation and identification and, thus demonstrate that the system is suitable for environmental monitoring.

8:30 AM *PM03.03.03
Scalable Manufacturing for Flexible Hybrid Electronics Benjamin Leever; Air Force Research Laboratory, Wright Patterson AFB, Ohio, United States.

Flexible Hybrid Electronics (FHE), which combine additive manufacturing processes with silicon chips, will enable applications such as wearable, assistive soft robotics, conformal and embedded sensors for condition-based maintenance, and wear-and-forget medical monitoring devices. The Department of Defense along with industrial and academic partners established NextFlex in 2015 to move these concepts from the lab to the manufacturing floor in the United States by developing or maturing key manufacturing processes in the areas of device integration & packaging and printing. This presentation will describe our roadmaps, which detail the capabilities identified by the FHE community over the next five years to enable the variety of envisioned applications. In addition, the presentation will highlight the FHE design and manufacturing flow through examples such as an FHE Arduino as well as specialized manufacturing tools developed through NextFlex projects such as modular systems that combine surface pre-treatment, inkjet printing, and encapsulation. Finally, the talk will address future prospects for applying roll-to-roll processes to FHE manufacturing.

9:00 AM *PM03.03.04
Hydration Sensor Patch for Human Performance Monitoring Azar Alizadeh; GE Global Research, Niskayuna, New York, United States.

GE Global Research, Niskayuna NY 12309

Maintaining proper hydration is paramount for maximizing performance and minimizing health risks for laborers, warfighters, and athletes. Currently, there are no commercially high resolution solutions for accurate, non-invasive and continuous assessment of hydration in a wearable device format. Laboratory gold standards for hydration assessment are based on total body water and plasma osmolality under controlled conditions of stable and equilibrated body fluids. In practice, body mass losses are used as an indirect measure of fluid content, but continuous assessment of an individual’s body mass fluctuations in the field during a mission is unrealistic. Similarly, blood (or urine) osmolality measurements are invasive and require sophisticated equipment and training for analysis. In this talk, we will present our approach towards developing a fully wearable system composed of bio-impedance and sweat sensors for dynamic and non-invasive assessment of hydration. The presentation will also include recent results from field testing of these devices at the U.S. Air Force Academy in Colorado Springs.

This work is sponsored by NextFlex, NBMC and AFRL and is a collaborative effort between GE Global Research, AFRL, UES, Dublin City University, University of Connecticut, University of Massachusetts, American Semiconductors Inc., and University of Arizona.

9:30 AM *PM03.03.05
Printed Image Sensors Based on Organic Phototransistors Ana C. Arias; University of California, Berkeley, Berkeley, California, United States.

Image sensors are ubiquitous and used in a wide variety of applications ranging from consumer products to healthcare and industrial applications. The signal-to-noise ratio (SNR) of an image increases with larger pixels, which is costly to scale using silicon and wafer-based microfabrication. Solution-processed phototransistors can substantially advance the performance of image sensors. Phototransistors exhibit large photoconductive gain and a sublinear responsivity to irradiance, which enables a logarithmic sensing of irradiance that is akin to the human eye and has a wider dynamic range than photodiode-based image sensors. A solution-processed phototransistor composed of a heterostructure between a high-mobility organic semiconductor and an organic
bulk heterojunction is presented here. The device efficiently integrates photogenerated charge during the period of a video frame then quickly discharges it, which significantly increases the signal-to-noise ratio compared with sampling photocurrent during readout. Phototransistor-based image sensors processed without photolithography on plastic substrates integrate charge with external quantum efficiencies above 100% at 100 frames per second. In addition, the sublinear responsivity to irradiance of these devices enables a wide dynamic range of 103 dB at 30 frames per second, which is competitive with state-of-the-art image sensors. The fundamental operation of image sensors using intra-pixel charge integration will be introduced and the figures of merit for these systems reviewed.

10:00 AM BREAK

10:30 AM PM03.03.06 Roll-to-Roll Fabrication of Conductive Copper Patterns on Flexible Substrates Using Maskless Lithography and Electroless Plating \textsuperscript{U} Okoroanyanwu, N. Mehta, S. Brandso, M. Lepine, J. Morse and James Watkins; Department of Polymer Science and Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States.

We report scalable roll-to-roll manufacturing processes for fabricating conductive copper patterns on flexible polyimide and PET substrates using a combination of maskless lithography and two approaches for patterning the seed layer, followed by electroless plating. A roll-to-roll processing platform comprising in-line surface cleaning, corona treatment, coating (gravure), and direct write lithography modules was used to pattern positive tone photoresist-coated polyimide and PET substrates. In the first approach, silver nanoparticle ink was deposited within the resist patterns and then sintered by photonic curing, to obtain silver seed layer for subsequent electroless copper plating steps. In the second approach, reactive Cu(II)-bearing ink and reducing ink were simultaneously deposited into the resist patterns and air-dried at room temperature to obtain a verifiable reactive catalyst for subsequent electroless copper plating. Immersion of the silver seed layer and the catalyst bearing substrates into electroless copper plating baths resulted in deposition of conductive copper patterns over the lithographically defined silver seed layer and reactive copper catalyst patterns, respectively. Lastly, the photoresist pattern was lifted off the substrate in acetone, resulting in well-defined copper patterns. The obtained copper patterns were characterized with optical and scanning electron microscopy, X-ray diffraction spectroscopy, and energy dispersive X-ray spectroscopy. The resistivity, solderability and adhesion strength of the copper patterns obtained with the two approaches were determined and compared, and will be presented, as will the performance of the copper patterns on an actual flexible hybrid electronic device.

10:45 AM *PM03.03.07 Novel Substrates for Applications of Roll-to-Roll Printed and Hybrid functionalities Jukka Hast, Markus Tuomiskoski, Jussi Hiltunen, Marja Välimäki, Olli-Heikki Huttunen, Johanna Hiitola-Keinänen, Marko Juvansuu and Tiina Pöldör; VTT Technical Research Centre of Finland ltd, Oulu, Finland.

In this presentation, we discuss opportunities of novel substrate materials for roll-to-roll (R2R) printed and hybrid electronics and diagnostics applications as well as future production aspects. Traditionally standard substrates have been PET, PEN, PC, PMMA etc or stretchable polyurethane films. However, application requirements, especially wearable electronics and diagnostics, and sustainability issues are setting new demands for the future. Firstly, we present R2R thermal imprinting method to fabricate integrated polydimethylsiloxane (PDMS)-paper micro-fluidics for molecular diagnostics, which demonstrated in on-chip amplification of viral ribonucleic acid (RNA) with loop-mediated isothermal amplification (LAMP). Secondly, we discuss about new bio-based and recycled materials that include introduction of novel interactive cellulose fibre acoustic RGB-LED panel that is manufactured using R2R printing, chip assembly and foam forming technique. Moreover, to improve the sustainability, performance and consumer acceptance of printed and hybrid electronics we will introduce these functionalities on recycled, bio-based and biodegradable substrates and compare their functionality against traditional PET/PEN substrates. Third part of the presentation introduces PrinToNode industrial internet platform, which has been ramped-up recently. The aim of the PrintoNode is to explore challenges and solutions how to utilize collected process data in printed and hybrid electronics manufacturing and product lifetime towards novel data based business models.

11:15 AM *PM03.03.08 High Resolution Screen Printed Circuits for Low Cost Hybrid Systems Goran Gustafsson\textsuperscript{1}, Peter Andersson Ersmann\textsuperscript{1}, Roman Lassnig\textsuperscript{1}, Jan Strandberg\textsuperscript{1}, Robert Forchheimer\textsuperscript{2}, Deyu Tu\textsuperscript{1}, Isak Engquist\textsuperscript{1} and Magnus Berggren\textsuperscript{1}; \textsuperscript{1}RISE Acreo, Norrköping, Sweden; \textsuperscript{2}ISY, Linköping University, Linköping, Sweden; \textsuperscript{3}ITN, Linköping University, Norrköping, Sweden.

Printed electronics devices and systems built up from organic and inorganic electronic inks, promise for a low-cost technology platform that enables widely distributed electronics possible to add onto stickers, labels, posters, packages, smart cards, construction elements, solar cells etc. However, the functionality and reliability that can be achieved is still not enough for most products. Hybrid Printed - Si labels have the potential to fulfill the requirements above but are still awaiting their breakthrough. One reason for its slow market evolution is that the price is too high for low margin products, e.g. packaging. There is a strong need for a strategy to make such hybrid integration cost effective. We will present a technology platform that merges Si-based components with printed electronics, aiming at twinning the benefits of the two. The technology includes printed, low voltage, devices and circuits such as drivers and MUX/DEMUX that release Si from expensive input/output circuitry, thus making Si-labels into a low-cost technology. The technology platform is based on electrochemical devices such as transistors and displays printed at high resolution, by standard screen printing equipment. The major advantages of these printed electrolyte-based components are that the manufacturing can be performed outside the clean room facility that typically is used for most other transistor and display technologies. The resulting devices are operated at low voltages, less than 3 V, and are thereby compatible with printed batteries. The device manufacturing is further simplified by that only a small set of materials is employed, for instance is the very same conducting polymer utilized as the active material in both the electrochemical transistors and the electrochromic displays. In the presentation we will describe this platform in detail and also hybrid product demonstrators at different levels of integration.

11:45 AM PM03.03.09 Silver Nanowire Inks for Direct-Write Electronic Tattoo Applications Nicholas Williams\textsuperscript{1}, Steven Noyce\textsuperscript{1}, Jorge Cardenas\textsuperscript{1}, Matthew Catennacci\textsuperscript{2}, Benjamin Wiley\textsuperscript{2} and Aaron D. Franklin\textsuperscript{1,2}; \textsuperscript{1}Electrical and Computer Engineering, Duke University, Durham, North Carolina, United States; \textsuperscript{2}Chemistry, Duke University, Durham, North Carolina, United States.

Integrating electronics with biological systems is a critical step toward ubiquity for the ever-growing field of wearable electronics. The ultimate in custom integration will be to print functional electronics onto biological surfaces without any buffer or transfer layers – a directly written electronic tattoo. However, the development of such direct-write capabilities is severely limited by the absence of a conductive ink capable of printing directly onto biological surfaces. Current ink formulas typically require significant post-processing to achieve conductive traces, such as sintering at temperatures incompatible with living organisms (~40°C), ultraviolet curing, or rinsing with hazardous solvents. In addition, the electrical performance of printed traces
designated for low-temperature curing generally degrades rapidly when the substrate is flexed, even when the curvature is minor. Silver nanowires offer a promising solution to these challenges as their high aspect ratio allows for the high conductivity of traces to be retained when the supporting substrate is flexed. In this work, we demonstrate room-temperature aerosol jet printing of highly conductive silver nanowire traces onto both biological and non-biological substrates, including Kapton and an oak leaf, with near-identical electrical performance on both substrates. The printed traces maintain a conductivity within 10% of its initial value when the substrate is completely folded (bending radius <0.1 mm). We also show that the resistance of the printed traces was independent of nanowire length. As a result of these unique characteristics, we demonstrate how our water-based, silver nanowire ink is capable of providing direct-write electronic tattoos on sensitive biological surfaces, such as the petal of a flower. These results open the way for the tattooing of functional electronic components, from antennas to circuits, directly onto the surface of virtually any organism, such as the skin of an animal.

Roll-to-Roll Processing of Perovskite Photovoltaics

Maikel van Hest; National Renewable Energy Laboratory, Golden, Colorado, United States.

Metal halide perovskites have emerged as a highly promising solar cell technology with high light to electric power conversion efficiency and low processing cost due to their solution processability. However, to make perovskite solar cells commercially viable, particularly to compete with or build upon the traditional silicon dominated photovoltaic market, substantial progress is needed in improving their process techniques and scalability. Fabricating perovskite devices and modules in a roll-to-roll process on flexible substrates will enable high throughput manufacturing, and it will also allow the application space to be extended beyond what is available to rigid geometries. We developed chemistries, contact and absorber layers, that can be deposited in a roll-to-roll fashion using scalable slot-die coating. As part of this development we investigated the performance of flexible perovskite solar cells with various transparent conductors, including flexible indium tin oxides (ITO) and indium zinc oxides (IZO), on thin (100μm) flexible glass substrates. Progress of scaling up perovskites to larger area, sheet-to-sheet and roll-to-roll, on flexible substrates will be reported. Insight will be given in module performance and the stability of such modules. For device structures of flexible glass/ITO/TiO2/mixed cation perovskites/Spiro-OMeTAD/MoOx/Al, a power conversion efficiency of 18% has been demonstrated.

2:30 PM *PM03.04.02
Flexible Glass Applications and Process Scaling

Sean Garner, Sue Lewis, Gary Merz, Alexander L. Cuno and Ilia Nikulin; Corning Research & Development Corporation, Corning, New York, United States.

Substrate choice is critical for overall flexible electronic device and process optimization. Flexible glass, ≤200μm thick, offers several advantages for web manufacturing of electronic devices. Compared to alternatives, glass substrates offer advantages of dimensional and thermal stability, hermeticity, transparency, and surface quality. Similar to other web materials, flexible glass is appropriately conveyed through fabrication equipment using roller systems. This paper discusses flexible glass properties that enable high-performance devices using roll-to-roll (R2R) processes. With a specific focus on mechanical reliability, use of glass web has been demonstrated in key R2R building block processes such as: vacuum deposition, lamination, laser patterning, printing, photolithography, and solution coating.

A disruptive industry ecosystem for flexible glass manufacturing is emerging with new equipment sets being specifically optimized for glass R2R processing. This paper provides specific examples of scaled-up glass web processing at manufacturing widths, lengths, and conveyance speeds for glass web. New demonstrations of flexible glass R2R microreplication, flexographic printing, and high temperature vacuum deposition are discussed. These processes go beyond the previous lab scale activities and highlight glass web R2R processing at 1m-width, 100m-length, and 30m/min conveyance speed.

3:30 PM PM03.04.05
Ambient Roll-to-Roll Slot-Die Fabrication of Flexible Organic Photovoltaics with Non-Fullerene Acceptor

Yu-Ching Huang¹, Hou-Chin Cha², Yun-Ming Sung², Tsui-Yun Chung² and Cheng-Si Tsao²;¹ Ming Chi University of Technology, New Taipei, Taiwan;² Institute of Nuclear Energy Research, Taoyuan, Taiwan; ³Department of Materials Science and Engineering, National Taiwan University, Taipei, Taiwan.

Solution-processed organic photovoltaics (OPVs) have shown a dramatic progress in enhancing power conversion efficiency (PCE) by using non-fullerene acceptors. The non-fullerene based OPVs recently achieved over 14% PCE [1-3], and the promising PCE demonstrated the great potential of commercialization. One of the most attractive advantages of OPVs is the printable capability into large-area devices. The high throughput slot-die coating process is the most suitable candidate for the mass-production technology. Our previous study has developed a universal roll-to-roll (R2R) slot-die coating approach to fabricate high-PCE OPVs [4]. Here, we demonstrate the promising photovoltaic characteristics of flexible OPVs based on a combination of PBDB-T and non-fullerene ITIC. We successfully R2R slot-die coated the flexible OPVs devices with high PCE over 9% under irradiation of simulated sunlight (AM 1.5G, 100 mW/cm²). In this study, we present systematical research on the morphology evolution of PBDB-T:ITIC bulk heterojunction (BHJ) films deposited by spin and slot-die coating processes. Our results indicates that the processing parameters significantly affect the morphology and nanostructure of PBDB-T:ITIC BHJ film. These results provide significant insights into the essential knowledge towards highly-efficient OPVs for R2R slot-die process.

Meniscus Guide Slot-Die Coating for Roll-to-Roll Fabricated Perovskite Solar Cells

Daniel Burkitt, Peter Greenwood, David Richards, David Beynon and Trystan Watson; Swansea University, Swansea, United Kingdom.

Slot-die coating has been proposed as a potential fabrication method for many of the layers of perovskite solar cell stacks and a growing number of publications are emerging on this topic. Slot-die coating is a versatile coating technique able to coat a range of ink rheologies and as a pre-metered coating method slot-die coating results in little ink wastage. It is compatible with both flexible and rigid substrates and can be used in both roll-to-roll or batch processes, is capable of simple patterning, such as stripes or patches and can achieve considerable line speeds. The use of a meniscus guide as part of the slot-die head, to help bridge the gap between the coating head lips and substrate, has been reported to improve stripe definition [1] and has often been employed in the fabrication of both organic photovoltaic and perovskite devices. To help understand the role of the meniscus guide and how it’s dimensions impact on coating quality we have performed coating trials and produced process windows with a range of inks and assessed if the onset of coating defects, low flow limits- ribbing, discontinuous films, can be predicted using the visco-capillary model of slot-die coating proposed by Carvalho [2]. We also present observations regarding the onset of flooding/leaking for different meniscus guide lengths and how these can be used to control stripe definition under different coating conditions and ink rheology.

We present results of how this understanding is used to develop improved roll-to-roll slot-die coating methods for perovskite solar cells in a P-1-N configuration using a sequential deposition process for the perovskite layer. The lead iodide ink used in the perovskite layer is formulated in a non-toxic solvent and results in a film readily converted to perovskite through slot-die coating of methylammonium iodide without any other pre-treatments. The choice of solution for the MAI ink is optimised by considering how the rheology and volatility of the formulation impact on the conversion to perovskite.

Finally, these developments will be used to demonstrate how slot-die coating can be used to produce the full perovskite device stack in a continuous roll to roll process.

Scalable Strategies to Enhance Mechanical Stability in Efficient, ITO-Free, R2R Printed OPV Devices Processed in Ambient Conditions on Flexible Substrates

William Greenbank, Elodie Destouesse, Jani Lamminaho and Morten Madsen; The Mads Clausen Institute, University of Southern Denmark, Sonderborg, Denmark.

Organic photovoltaic (OPV) solar cells have been explored by research groups across the world as a promising form of next-generation solar energy technology. In addition to their potential to reduce the costs of PV solar energy, they also open up a range of new applications to solar energy. The major point of difference for OPV is that they can be fabricated using roll-to-roll (R2R) printing processes onto flexible substrates in ambient conditions, drastically reducing the energy payback time of the device. Despite all this promise, OPV are only just beginning to be commercialised on any significant scale, and efforts to scale up OPV production have been slow. Much of this stems from issues of low efficiencies and short lifetimes of devices – particularly when attempts are made to replicate laboratory-scale studies at commercial scales. In recent years, laboratory-scale OPV device efficiencies as high as 15% have been reported, and while this represents remarkable progress, devices with such high efficiencies are often produced using techniques that do not translate well to commercial production, and do not retain their high efficiency over time. This is compounded when attempts are made to replace expensive components of the device like indium tin oxide (ITO), or deposit on flexible plastic substrates.

At the SDU NanoSYD nanoscience centre at the University of Southern Denmark we explore an integrated approach to OPV research, spanning the spectrum from highly controlled, small scale device studies, to medium-scale slot-die coated modules, to large-scale R2R printed modules. In this way our work aims to help bridge the gap between the laboratory scale and the industrial scale. This strategy has already proven successful. Recently we successfully produced ITO-free OPV devices incorporating non-fullerene acceptors (NFAs) that were entirely air-processed on flexible polyethylene terephthalate (PET) substrates with 6% PCE using scalable slot-die coating. These devices showed impressive stability when properly encapsulated, demonstrating a viable route for the implementation of a highly efficient polymer-NFA system in industrial-scale OPV production.

One of the key areas that we focus on is improving the lifetime of OPV modules, in particular the mechanical stability of flexible modules. This is often an under-researched area for OPV stability, but vitally important for many of the anticipated applications of OPV technology. Much of the mechanical instability in devices arises from poor adhesion between chemically-incompatible layers that then easily delaminate when only small amounts of stress are applied to the device. In our work we explore strategies to improve layer compatibility without compromising device performance that can be easily applied to commercial-scale production. Although our focus is principally on OPV devices, the techniques we employ have the potential to be applied to any solution-processed organic electronic device.
investigated a hybrid approach which combines the polymer and ceramic into a composite electrolyte to achieve both processing and performance requirements. There is a significant need to understand how we can tailor the solid electrolyte to promote effective transport. Herein, we demonstrate a custom-made benchtop multi-material slot-die system that can print solid electrolytes with graded structures. Initial results have shown that the nano-scale interactions in the ink phase impact the macroscopic ink properties and the coating structure [1, 2]. This work focuses on demonstrating the fine feature capabilities in slot-die coating system and understanding how pathways can be engineered for efficient transport.

4:30 PM PM03.04.09
A Scalable Dry-Powder Spraying to Manufacture Lithium-Ion Batteries from Electrodes Towards the Entire Battery

Jin Liu1, Yan Wang1, Heng Pan2, Brandon Ludwig3, Yangtai Liu4 and Zhangfeng Zheng1; 1Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2Mechanical and Aerospace Engineering, Missouri University of Science and Technology, Rolla, Missouri, United States.

An advanced power-based spraying technology was developed by us to fabricate electrodes for the lithium-ion batteries to analytically lower 20% of the manufacturing cost. Gas-driven spraying guns were chosen to address a direct dry-powder laminating of the electrode structures onto the current collectors without involving solvents. Through removing the usage of these organic solvents and related recycling procedures, the entire processing of electrodes is shortened and found to be more precisely controlled, which results in product electrodes with higher bonding strength, structural integrity, and materials homogeneity. We have demonstrated this technology with a wide range of compatibility on producing electrodes, including cathodes (LCO, LMO, NCM), anodes (Graphite), advanced architecture designs (Ultra-low binder recipe (<1%), high-energy thick electrodes (>280um), hierarchical micro-structured).

In addition, the flexible arrangement strategy of spraying guns promoted the development of hierarchical designs to be practically available to the lithium-ion market. Dry-powder sprayed electrodes with a multi-layered structure, outperformed single layer ones at electrochemical performance and mechanical properties. This technology is currently developing to be grafted onto the existing roll-to-roll fabrication of electrodes for lithium-ion batteries at the pilot scale, and finally aiming to achieve an integrated direct manufacturing of the entire energy storage devices (batteries) accustomed to flexible designs.

4:45 PM PM03.04.10
Roll-to-Roll Fabrication of High Performance Conformal Thermoelectric Generators

Yining Feng1, 2, Zamaan Bagban1 and Na Lu1, 2, 4; 1Lyles School of Civil Engineering, Purdue University, West Lafayette, Indiana, United States; 2Birck Nanotechnology Center, Purdue University, West Lafayette, Indiana, United States; 3School of Aeronautics and Astronautics, Purdue University, West Lafayette, Indiana, United States; 4School of Materials of Civil Engineering, Purdue University, West Lafayette, Indiana, United States.

Thermoelectric generator (TEG) is a solid-state technology that can convert thermal energy directly into electricity through the Seebeck phenomenon. Over 2.5 quadrillion BTU/year of energy generated in US is wasted as a form of heat, which can be reclaimed as electricity using flexible TEG to power sensors and other microelectronics for civil communications and Internet of Things (IoT) technologies. Unfortunately, the current TEG technology is suffering from its rigid device structured, low efficiency and high cost in both device fabrication and installations.

In this work, a novel roll-to-roll production line of conformal thermoelectric generator (cTEG) will be reported. In-line fabrication includes several micro-deposition processes on a roll-to-roll equipment for a continuous manufacturing platform. The specific activities include: (a) depositing top metal contact layers using screen printing technique; (b) creating micro-porous channels on polymer substrates using pulsed laser irradiation system; (c) filling of micro-channels with p- and n-type TE materials using pipet dispensing systems or similar technique for nanoparticles depositions; (d) laser sintering of p- and n-type TE materials for in-situ crystallization with minimal thermal damage, followed by screen printing the top layer metal contacts to achieve high power output of conformal TEG as power sources for sensors. Thermo-plastics with low thermal conductivity (i.e. kapton, PDMS, polyamide etc.) will be used as substrate and insulating materials between p-n legs.

The cTEG with polymer substrate and insulating materials lead to maximum heat gain to reach high efficiency at the device level for power generation. The performance of cTEG will be discussed with regards to the materials quality and manufacturing process. The fundamental science developed here will have a broad interest to flexible electronic and nanomanufacturing community.

Hybrid Roll-to-Roll Manufacturing of OLEDs

Pim Groen1, 2; 1Holst Centre, Eindhoven, Netherlands; 2Aerospace engineering, TU Delft, Delft, Netherlands.

Hybrid production methods offer the possibility to exploit the benefits of different technologies in a single manufacturing process. In this contribution, this strategy will be highlighted using the example of the roll-to-roll (R2R) production of large area organic light emitting diodes (OLEDs) on flexible polymer substrates. Two opposing strategies are available to deposit the functional layers in an OLED device stack: The “dry” approach uses vacuum based methods such as thermal evaporation and sputtering, whereas the “wet” approach relies on the coating and printing of functional inks. The R2R production of OLEDs based solely on vacuum techniques has been demonstrated and can provide efficient and stable devices. By contrast, preparing OLEDs exclusively by R2R “wet” methods is generally hampered by the limited materials purity and undesired interactions between the functional layers during deposition. A number of R2R production steps from solution, however, are already well established and allow the high throughput production with good control over the resulting layer quality. We have designed an OLED architecture which can be prepared in a hybrid manner by combining elements of wet and dry R2R processing technologies. Starting with a roll of barrier substrate, indium tin oxide (ITO) is first deposited uniformly by R2R magnetron sputtering as a transparent conductor. Hereafter, an insulator is applied from solution with patterned slot die coating to separate the electrodes. This eliminates the need to pattern the ITO. A conductive and semiconducting inks is then employed, to enable the external power supply and planarise the ITO surface, respectively. These steps have been demonstrated at web speeds of 10 m/min and above. The slot die coated planarisation layer allows the following step (R2R evaporation of the active OLED materials) to be carried out targeting significantly lower layer thicknesses, thereby saving precious materials and speeding up the entire process. At current state, the efficiencies of the hybrid OLEDs still lag behind compared to fully evaporated reference
devices (20 vs. 45 lm/W at 1000 cd/m²), but with further process optimisation, it is foreseen that the increased process speed and more efficient materials use can compensate for a somewhat lower performance.

8:45 AM PM03.05.02
OLED Manufacturing on Flexible Substrates Towards Roll-to-Roll Christian May; Fraunhofer FEP, Dresden, Germany.

Besides to display technology, OLED also has unlikely potential for lighting applications. Where extremely thin, flexible or transparent light sources are desired, OLED can exploit its potential as a supplement to the LED. The improvement of flexible OLED is currently the focus of worldwide research activities. Thin substrates of primarily barrier-coated polymer films, but also metal foils or ultra-thin glass, were tested for use in OLED production and have advantages and disadvantages. OLED prototypes on polymer substrates as well as ultra-bright glass were realized by Fraunhofer FEP. The main development areas are the improvement of device stability and brightness. This includes intensive work on encapsulation as well as the development of stacked OLED architectures on flexible substrates.

Metal foils have also been utilized for several years as substrates for thin-film photovoltaics and batteries. Now metal foils are getting interest as substrates for flexible organic electronic devices. In contrast to substrate materials like glass or plastic web an extra smoothing layer on typically rough metal foils are necessary to reach sufficient device stabilities, in particular for large area OLED lighting. An advantage of metal foils in the organic electronics is the comparatively good electrical and thermal conductivity. This allows for homogenous large-area lighting surfaces with current densities of more than 10 mA/cm². Additionally, metal foils can be applied as top encapsulation on OLED devices on glass or plastic substrate to improve the temperature management during device operation, combined with excellent barrier properties of metal foils. Those benefits of improved temperature management on the OLED device lifetime and better illumination homogeneity will be outlined in the presentation. First results on a full roll-to-roll process chain enabling later high throughput production will be presented.

In future, the focus will be on the development of integration solutions in functional devices and surfaces using established technologies. Fraunhofer FEP works on processes along the entire value chain to produce flexible OLEDs in both, sheet-to-sheet and roll-to-roll processes. The requirements for the materials and technologies as well as the associated challenges will be introduced using latest results by Fraunhofer FEP. Solutions and application possibilities will be presented.

9:15 AM PM03.05.03
High Volume Manufacturing of Advanced Optical Elements Theodor Nielsen¹, Alicia Johansson¹, Iija Czolkos¹, Niklas Hansson² and Brian Bilenberg¹; ¹NIL Technology ApS, Kongens Lyngby, Denmark; ²NILT Sweden Filial, Gothenborg, Sweden.

Advanced optical element such as diffractive optical elements (DOEs) are expected to revolutionize the compact optics market for imaging and non-imaging systems by enabling low weight and low cost optical systems. Today we are in the beginning of a transition period when bulky optical systems consisting of classical lenses are going to be replaced by advanced optical elements using only a single flat optical element with an advanced micro- and nanostructured surface topology.

NIL Technology ApS specialises in supplying high-quality nanostructured masters and nanoimprinting solutions for customers worldwide. The key to high-volume and low cost production is replication and NIL are experts in replication techniques such as nanoimprint lithography, hot embossing and injection moulding.

Since 2010, NIL Technology has developed methods to implement advanced micro-and nanostructures on steel inserts for injection moulding of low-cost polymer parts. The applications range from super-hydrophobic lenses to consumer products with structural colors and lab-on-chip systems. Over 100,000 nanostructured parts have been replicated by injection moulding without any degradation of the nanostructured mould surface which demonstrates the potential for production of very high volumes at low cost.

In this presentation, NIL Technology will demonstrate advanced multi-level DOEs replicated in low cost materials suitable for high volume applications. Methods for future in-line quality control will also be presented. Focus will be on nanostructured steel injection moulding tools made by nanoimprint and the tools use in injection moulding process.

9:45 AM PM03.05.04
3D Printed Polymer Photodetectors Ruitao Su, Sung Hyun Park and Michael C. McAlpine; Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, United States.

Organic optoelectronic devices have witnessed significant advances in both material development and device performance over the past several decades. Recently, additive manufacturing has been applied to the fabrication of optoelectronic devices via utilizing various functional inks that are compatible with an extrusion-based 3D printing process. This has enabled the ability to additively print complex 3D optoelectronic architectures without the need for any traditional microfabrication processing techniques. Here, polymer photodetectors with high performance are fully 3D printed and thoroughly characterized. Specifically, functional inks are carefully selected for the constituent layers of the photodetector and semiconducting polymer ink is optimized for the active layer, achieving an external quantum efficiency of 25.3% and a specific detectivity of $8 \times 10^{12}$ cm$\cdot$Hz$^{1/2}$/W. Significantly, these metrics are comparable to those of traditionally spin-coated counterparts, yet are fabricated solely via a one-pot custom built 3D printing tool housed under ambient conditions. The devices were integrated into image sensing arrays with high sensitivity and wide field-of-view, by 3D printing interconnected photodetector arrays onto flexible substrates and directly onto hemispherical surfaces. It is further demonstrated that this approach can be extended to create fully integrated multifunctional devices consisting of optically coupled photodetectors and light emitting diodes which are both fully 3D printed on a single platform, showing for the first time the multifunctional integration of multiple semiconducting device types on an integrated platform. The 3D printed optoelectronic devices introduced here simplify fabrication procedures by eliminating the need for any conventional microfabrication facilities, enhancing the flexibility for the design and manufacture of next-generation wearable and 3D structured optoelectronics, and validating the potential of 3D printing to achieve integrated active electronic materials and devices.

10:00 AM BREAK

10:30 AM PM03.05.05
Digital Printing of Organic Photodiodes Comprising Non-Fullerene Acceptors—Device Architecture and Ink-Formulation Noah Strobel¹,², Felix Lindheimer¹,², Tobias Rödlmeier¹,², Mervin Seiberlich¹,², Stefan Schliske¹,², Manuel Pietsch¹,², Uli Lemmer¹,² and Gerardo Hernandez-Sosa¹,²; ¹Light Technology Institute, Karlsruhe Institute of Technology, Karlsruhe, Germany; ²Innovation Lab, Heidelberg, Germany; ³Institute of Microstructure Technology, Karlsruhe Institute of Technology, Karlsruhe, Germany.

Organic photodiodes (OPDs) have in recent years reached a level of performance comparable to inorganic devices. This has considerably fueled the development of printing processes for the fabrication of single and multi-device systems. However, in order to achieve adequate rheological properties
while maintaining optical and electrical device functionality, heavy investment into ink-formulation and process parameter evaluation is necessary even for small changes in material properties like the absorption range. For instance, in systems comprising a polymer donor and a fullerene acceptor the viscoelastic and optical properties are mostly defined by the polymer and are thus intrinsically coupled. To overcome this challenge, we are working with non-fullerene acceptors, which offer an additional adjustment screw to tune the optical properties of our devices without strongly affecting the viscoelastic behavior.

First, we present OPDs comprising poly(3-hexylthiophene) (P3HT) and the non-fullerene acceptor (NFA) IDTBR, having an indacenodithiophene core with benzo[k][1,2,5]thiadiazole and rhodanine flanking group. The devices show a photo-response up to 800nm and reach record responsivities of 400mA/W as well as cut-off frequencies surpassing 4MHz. To combine the gained spectral flexibility with the freedom of design, the fabrication is transferred to digital printing techniques (i.e. ink- and aerosoljet printing) to process opaque and transparent devices of comparable performance. Furthermore, we demonstrate successful decoupling of the optical and rheological properties by using visibly transparent polymer donors and color-selective non-fullerene acceptors. This approach offers spectral flexibility without the need for a variation in process parameters. By the selection of NFAs with energetic compatibility, we fabricated devices with color selectivity in the range of 400-600nm as well as 500-800nm.

10:45 AM *PM03.05.06
Novel and Scalable Concepts for Efficient, Bright and Low-Cost Light-Emitting Electrochemical Cells
Ludvig Edman; Umea University, Umea, Sweden.

The light-emitting electrochemical cell (LEC) features mobile ions in the active material, and it is the action of these ions that distinguishes the LEC from other light sources such as the OLED, and which enables for a number of attractive properties. For instance, it is possible to fabricate LECs from solely air-stable materials and employ a relatively thick single-layer as the active material. These attributes promise to pave the way for an unprecedented low-cost fabrication, and we have demonstrated how functional LEC devices can be fabricated by slot-die coating, inkjet printing, and spray-sintering directly on a wide variety of substrates -- including paper, metal, and textile -- under uninterrupted ambient-air conditions. We have also performed a cost analysis that predicts that solution-based high-volume R2R fabrication methods can allow for the realization of flexible LEC patches at a low cost of ~11 €/m², which deliver bright light emission at 3.6 mcd/1.7

The redistribution of the mobile ions during the initial operation of LECs causes electrochemical doping of the active material (p-type at the positive anode and n-type at the cathode), so that a light-emitting p-n junction forms at steady-state. It is thus in-situ formed doping structure that allows for the simple device structure and the low-cost fabrication, but at the same time it has represented a significant challenge from both a conceptual and performance perspective. More specifically, the doping regions comprise high concentrations of electron and hole polarons, and the direct interaction of these polarons with excitons formed in the p-n junction region will result in a quenching of the excitation before light emission. Thus, it has been questioned whether an LEC ever can become efficient at strong light emission. However, in a recent study we have demonstrated that this issue can be resolved with a triplet-emitting host-guest active material, designed with equally deep electron and hole traps, a balanced hole and electron mobility, and an optimized concentration of mobile ions. Such a carefully designed single-layer LEC featuring air-stable electrode materials and equipped with an outcoupling structure delivers strong green luminance of 1910 cd/m² at a efficiency of 99.2 cd/A, which corresponds to a record-high external quantum efficiency of 27.5 %.8

Inkjet Printing of Small Molecular Phosphorescent Emitters at the Controlled Surface of Confined Geometry
Youjung Kang, Ji-lye Kim, Robert Bail and Byung Doo Chin; Polymer Science and Engineering, Dankook University, Yongin, Korea (the Republic of).

Significant progress has been achieved in the area of full color organic light-emitting diodes (OLEDs) in terms of their high performances. However, stable ink materials and accurate fine line patterning by printing is an essential core as an alternative candidate of expensive fine metal mask-aided RGB side-by-side patterning or multi-stack (tandem) high efficiency white technology for the large area OLEDs. We have prepared a suitable combination of soluble host material compounds with an effective ink formulation technology. The bipolar phosphorescent host materials based on diphenyl phosphine oxide, pyrroloindole, and carbazole-based structure were dissolved in a solvent mixture, and various conditions for the solvent composition and drying of films were examined. Homogeneous dot and line patterns with controllable surface condition at the confined geometries of light emitting pixels were obtained, where the precise pinning at the coverage of light emitting region was accomplished by use of the photo-patternable pixel define layer. Proper thickness and smooth surface were obtained from a mixture of chlorobenzene and other organic solvent with higher viscosity than chlorobenzene. During the inkjet process, several issues such as control of drop injection density, reduction of line-edge roughness, and the role of the mixed solvent properties were studied in detail. These results show the potential power of inkjet printing as a low-cost patterning method for low molecular weight emitters at high resolution or large area OLEDs.

11:30 AM PM03.05.08
Polychromatic Quantum Dot Light-Emitting Diode Array Fabrication Using Omni-Resolution Immersion Transfer Printing Technology
Tae Won Nam and Yeon Sik Jung; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Diverse integration of depositing and patterning colloidal quantum dots (QDs) to demonstrate individual red-green-blue (RGB) QD pixels has been developed in past years to realize electroluminescent QD light-emitting diodes (QLEDs) as next-generation displays. Among numerous display products from televisions to mobile displays, the inception of virtual reality (VR) display demands for sub-micrometer pixel resolution due to the requirements of extremely high pixels per degree (PPD) far above those of the conventional displays. However, previously reported patterning technologies have limitations in demonstrating large area, full-color pixel arrays of sub-micrometer feature size with high fidelity and pixel quality such as edge-roughness. Here we present a novel transfer-printing technique which allows patterning and printing of QD array in omni-resolution scale; QD array in single-particle resolution to entire film can be fabricated and transfer-printed. Polychromatic array with unprecedented resolutions up to 200 PPD is demonstrated by utilizing sequential aligning and printing of individual RGB pixel arrays. Conventional transfer-printing techniques adopt flexible polydimethylsiloxane (PDMS) mold on which topological pixel information is written; expensive high resolution patterning on flexible media cannot
extend its functionality from prototype to industrial fabrication because the repeated use of soft PDMS transfer mold at pressure-assisted stamping step is no-longer possible due to accumulated deformation. Conversely, we used the pattern information on hard Si master template to control the capillary-force self-assembly patterning process of colloidal QDs occur in single step. After the ordered QD arrays are delivered to transfer media, hard master template can be reused permanently. Another advantage of using hard master is extremely low edge-roughness of QD pixels as the QDs are strictly confined in hard master trench with minimal edge-roughness when they undergo capillary-force self-assembly. At the final delivery stage of QD pixels, mere minimal contact between the pixels on transfer media and final substrate is necessary therefore avoiding pressure induced defect formation at QD solid. Our transfer-printing technique effectively reduces trade-offs of conventional QD patterning method thereby suggests possibilities for fabrication of full-color electroluminescent QLED displays in industrial scale.

11:45 AM PM03.05.09
Direct-Write Assembly of Freeform Colloidal Structures Alvin Tan, Justin Beroz, Mathias Kolle and A. John Hart; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Evaporative self-assembly can be used to assemble colloidal building block particles with varying degrees of order and scale. These particles, when assembled into a solid, can attain emergent properties, such as an electronic or photonic band gap. However, to date, self-assembly of colloidal materials is limited to planar films on substrates. Extending colloidal self-assembly to three dimensions would enable new applications uniquely enabled by macroscale colloidal crystals. Here, we demonstrate a direct-write technique capable of on-chip assembly of colloidal particles into centimeter-scale freestanding structures. Using a custom-built liquid dispense apparatus, we precisely extrude an aqueous polystyrene particle suspension from a fine needle onto a temperature controlled substrate. By balancing the rate of dispense with the rate of water evaporation, the polystyrene particles are continuously assembled into a crystalline solid. We propose that direct-write assembly has the potential to be adapted to a vast library of building blocks for building functional materials such as photonic crystals, quantum dot solids, and metamaterials.

SESSION PM03.06: Device Fabrication

Wednesday Afternoon, November 28, 2018
Hynes, Level 1, Room 108

1:30 PM *PM03.06.01
Stretchable Hybrid Packaging for Skin Electronics and Electronic Textile Takao Someya1, 2; Hanbit Jin3 and Tomoyuki Yokota1; 1Electrical and Electronic Engineering and Information Systems, The University of Tokyo, Tokyo, Japan; 2RIKEN Center for Emergent Matter Science, Saitama, Japan.

In this talk, we will report recent progress of stretchable hybrid packaging for skin electronics and electronic textile. First, we have fabricated a skin display, which is an array of micro LEDs embedded in a thin rubber sheet. The display is stretchable by 45 percent of its original length. A skin display is much more durable to stretching and twisting than previous wearable displays. It is built on a novel structure that minimizes the stress resulting from stretching on the junction of hard materials, such as the micro LEDs, and soft materials, like the elastic wiring—which is a typical reason of damage in the past. Similar stretchable hybrid packaging is used to integrate rigid electronic elements and stretchable wires on textiles for smart apparel. Finally, we will describe remaining issues and future prospects of stretchable hybrid packaging.

2:00 PM *PM03.06.02
R2R Gravure as an Additive Manufacturing Technology for the Fabrication of Large Area Flexible and Inexpensive Devices Gyoujin Cho;
Sunchon National University, Suncheon, Korea (the Republic of).

Over the last decade, roll-to-roll (R2R) printing has been pursued with the expectation of developing a commercially viable, high throughput technology to manufacture flexible, disposable and inexpensive printed electronics. However, in recent years, pessimism has emerged due to the barriers faced when attempting to fabricate and integrate thin film transistors (TFT) using R2R printing. In this presentation, for the first time, I will report a way of manufacturing TFT based large area, flexible and inexpensive devices via a fully R2R gravure printing process with Ag nanoparticle based conducting ink, BaTiO3 nanoparticle based dielectric ink and single walled carbon nanotubes (SWCNT) based semiconducting ink. Using R2R gravure system including those inks and poly(ethylene terephthalate) (PET) as the substrate, we obtained about a 92 % device yield in 15 x 0.25 m2 of PET roll with the printing speed of 6 m/min and extracted the scalability factors needed for a feasible manufacturing process. The R2R gravure printing process addresses several barriers in the fabrication and integration of printed TFTs, circumventing or surmounting challenges associated with the alignment of source-drain and gate electrodes, threshold voltage (Vth) shift, stability and overall device yield, proving that R2R printing is indeed a viable advanced manufacturing technology that can enable high throughput production of inexpensive smart packaging.

2:30 PM BREAK

3:30 PM *PM03.06.03
Flexible and Printed Organic Electronics Development for IoT Sensor Applications Shizuo Tokito, Yamagata University, Yamagata, Japan.

Flexible and printed organic electronics technology has garnered increasing attention and resources in research and development because of its potential for low-cost, environmentally-friendly electronic devices. In particular, there is an immense need to deploy sensor frameworks for the so-called Internet of Things (IoT). These applications are envisaged as thin-film transistor (TFT) devices with various types of sensors fabricated using a variety of printing processes on thin plastic film substrates. Here, we report briefly on recent advancements in printable electronic materials, printed OTFT devices used in integrated circuits and IoT sensor applications. We have successfully fabricated pseudo-CMOS inverters using p-type OTFT devices, as well as NAND logic gates, which exhibited ideal characteristics at low operating voltages and high gains. True CMOS inverters using both p-type and n-type OSC materials are essential for low-power, high-speed operation, and for circuit designs with compact layouts. Using our newly developed n-type OSC material (TU-3) and a commonly used p-type OSC material (dI-F-TE-ADT), we successfully demonstrated a CMOS inverter that employed a stacked TFT device construction. Based on this CMOS inverter design, an operational amplifier, as well as ring oscillators and D-flip flop circuits, were also fabricated. To realize very short-channel OTFT devices and higher performance integrated circuits, we employed the reverse-offset printing method to form narrow channel lengths below 10 µm, resulting in good electrical characteristics. Pressure sensors based on ferroelectric polymer (PVDF-TrFE) materials are superior in detecting vital signs for the human body. We previously succeeded in the precise detection of pulse waves with a wearable patch-type sensor, which was fabricated on a plastic film substrate using printing methods. Our goal is to develop a smart sensor device that can be connected wirelessly to the
Internet, which combines printed integrated circuits and one or more sensors. More recently, we are developing flexible hybrid electronic (FHE) devices, which use silicon-based LSI die for the signal processing and wireless communication circuits and are integrated onto a flexible plastic film substrate. We patterned the sensor element, interconnect layer, and antenna with screen or inkjet printing methods, after which we mounted Si-LSI die and resistors on the same flexible film substrate, whereby we employed both Near Field Communication (NFC) or Bluetooth Low Energy (BLE) wireless communication protocols. We successfully demonstrated a wearable temperature sensor using a PEDOT:PSS sensor element.

4:00 PM PM03.06.04
Rapid Production of Large-Area, Transparent and Stretchable Electrodes Using Metal Nanofibers for Wearable Electronics
Jiuk Jang, Sangyoon Ji, Byeong Wan An and Jang-Ung Park; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Recently emerging electronic devices, including displays, light-emitting diodes (LEDs), touch screens, smart windows, and heaters requires transparent electrodes with high optical transmittance (T) and low sheet resistance (Rs). Although the indium tin oxide (ITO) shows the excellent electrical and optical properties, its brittleness limits many potential applications in stretchable and wearable electronics. There are numerous studies for high-performance, stretchable and transparent electrode to substitute the ITO-based transparent electrode, however, most of them are virtually unavailable to the industry because of their low production rates, high process temperature and lack of reliability.

Here, we report the rapid electrosprinning process that can directly form one-dimensional (1D), ultra-long Ag nanofibers (AgNFs) as a large-area, and continuous network for stretchable electrodes. The electrosprinning process is simple and cost-effective because AgNFs can be formed directly on a substrate while minimizing the waste of functional inks. Since this process is based on a roll collector, it enables the roll-based rapid production of a large-area and transparent electrode film that is composed of AgNF network. In this work, the electrode film exhibits superb electrical characteristics (Rs of ~1.3 ohm/sq) with high optical transmittance of ~90% in a visible regime and outstanding mechanical properties (90% stretchability and minimum bending radius of curvature of 70 μm). In addition, the annealing temperature of AgNF network relatively low (~150 °C), suggesting that the polymer substrate such as polyethylene terephthalate (PET) can be used directly without any transfer process. For a continuous roll-to-roll process, a photonic annealing of functional inks has been utilized and the production speed was 4.5 to 12 m/min. As an application of this high-performance transparent electrode, we fabricated a stretchable and transparent heater in a large area (300 mm x 300 mm) using the roll-to-roll process. The heater presents high temperature (250 °C) at a low operating voltage and excellent temperature reliability under large strain. Furthermore, we integrated the heater with wireless operation system by connecting Bluetooth module so that the temperature is controlled directly using smart devices. According to the target purpose, temperature also can be automatically controlled by applying logic circuit to the micro-controller unit. We believe that this approach presents a promising strategy for future wearable electronic devices.

4:15 PM PM03.06.05
Laser Patterning of Flexible Nanogap Schottky RF Diodes Via Adhesion Lithography
Hendrik Faber, Kalaiavanan Loganathan, Zainab Felemban, Emre Yengil and Thomas Anthopoulos; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

A major part of the envisioned Internet of Things device ecosystem will rely on wireless smart tags and sensor nodes for application areas as diverse as health care, wearables or logistics. All these devices rely on radio frequency (RF) signals for communication or wireless energy harvesting, and a crucial component for that are rectifying diodes capable of operating at the required frequencies typically beyond 1GHz. Therefore, developing novel manufacturing paradigms that successfully combine the ability to produce such RF diodes over large areas and flexible substrates, can truly make a substantial impact.

We have recently introduced adhesion lithography (a-Lith) as an innovative patterning technology that enables the fabrication of ultrafast planar RF Schottky diodes based on a variety of semiconductors [1-3]. A first metal layer (M1) is deposited and patterned via standard lithography procedures. Afterwards the M1 surface is treated with a self-assembled monolayer to weaken the adhesive forces towards a subsequently deposited second metal film (M2). Due to the weak adhesion, the second metal can then be peeled off where it overlaps M1 using a liquid glue or adhesive tape, resulting in the formation of a small inter-electrode gap of typically ~15nm at the boundary between M1 and M2. Because of the nm-sized gaps and the possibility to use dissimilar metals for M1 and M2, a-Lith is perfectly suited to create fast coplanar Schottky diodes. Such devices have been demonstrated using solution processed ZnO in Al-Au nanogap electrodes, reaching cut-off frequencies well above 20MHz [2]. For a-Lith the most involved step is the use of photolithography to structure M1. In this work we therefore investigated an alternative patterning approach to streamline the whole diode manufacturing process. Using a commercial laser scriber system (~1080nm), the desired pattern is achieved by selectively removing areas of M1 via laser ablation with sub-50 micron precision. With optimized process parameters the metal film can easily be patterned according to digital designs that can be realized quickly followed by the a-Lith steps. Using this innovative combination of laser ablation and a-Lith 50nm-nanogap coplanar ZnO diodes with on-demand size and shape are realized. Despite the simplicity of the approach, resulting diodes are found to exhibit excellent operation including high current rectification (~104) and cut-off frequency (~1GHz). Most importantly, the proposed manufactured methodology is compatible with a wide variety of electrode materials including Al, Au, Ti, ITO, Cu, as well as substrate materials such as glass and plastic. The easy adaptability of the diode designs and compatibility with flexible substrates makes the combination of laser ablation and a-Lith an ideal tool to prototype advanced RF devices and circuitry.

Wafer-Recyclable, Environment-Friendly Transfer Printing Methods for Fabricating Large-Scale Thin-Film Nanoelectronics
Bongjoong Kim1, Dae Seung Wie1 and Chi Hwan Lee1, 2; 1Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States; 2Biomedical Engineering, Purdue University, West Lafayette, Indiana, United States.

Thin film nanoelectronics that can offer performances beyond traditional bulk systems but on diverse substrates or surfaces in lightweight, low-cost, and/or flexible forms could enable many emerging applications. Example devices include flexible complementary metal oxide semiconductor (CMOS) systems, multifunctional nanosensors and optoelectronics, and high-speed nanowire circuits. Conventional approaches in transferring thin film nanoelectronics from their fabrication wafer to arbitrary surface of interests commonly requires chemical etching on the sacrifice of wafer, but also is limited by defects with a low yield. Here, we introduce a high-fidelity transfer printing process that enables the wafer-scale separation of high-performance thin film nanoelectronics from their fabrication wafer in a defect-free manner that allows multiple reuse of the wafer. This interfacial delamination is enabled through a controllable cracking phenomenon triggered by liquid at room temperature or electrochemical reactions. The physically liberated thin film nanoelectronics can be then pasted onto arbitrary places of interest, thereby endowing the particular surface with desirable add-on electronic features. Systematic experimental and theoretical studies reveal the underlying mechanics mechanism and guide manufacturability for the transfer printing process in terms of scalability, controllability, and reproducibility.
Aerosol jet printing (AJP) offers a promising digital, direct-write printing technology for device applications with broad materials compatibility, high resolution, and versatile integration capabilities. Despite its potential, ink design and printer operation for AJP has relied to date on empirical methods for highly curved surfaces. So far, very few efforts have been made to realize devices over a curved surface. Fabrication of optimized direct printed on inductor coil, these soft ferrite layer in WPT module plays important roles in (a) enhancing magnetic coupling between the inductor coils transmitting and receiving the magnetic field, and (b) preventing the magnetic field from reaching any conductive object, electronic devices, or human bodies near the WPT module. Laser annealing using an IR laser with various laser fluences was applied to enhance the magnetic property of the soft ferrite layer printed on the highly curved surface. The performance of the printed WPT module on the highly curved surface was demonstrated by transmitting wireless power to various electronic devices through the magnetic resonant coupling. This work may find potential applications, including wearable electronics, optoelectronics, biomedical devices, sensors, and Three-Dimensional (3D) electronics.

In each case, general principles of ink design derived from a simple numerical model are applied to identify suitable solvent systems. Standard calibration

Direct Printing of Wireless Power Transfer Module with Metal-Coil/Ferrite Layer/Capacitor Configuration on Highly Curved Surface Rajaram Kaveti and Jihoon Kim; Kongju National University, Cheonan, Korea (the Republic of).

Direct printing on curved surfaces is a newly emerging challenge in printed electronics due to the difficulties in developing the suitable inks and fabrication methods for highly curved surfaces. So far, very few efforts have been made to realize devices over a curved surface. Fabrication of optimized direct printing inks is highly significant for the production of high-quality printing on curved surfaces. The effect of solid, solvent, and dispersant on the printability and ink rheological properties such as viscosity, storage modulus, yield stress, thixotropy and viscoelasticity of various inks were tuned and investigated by rheological tests under steady and dynamic shear conditions. Here, for the first time, we demonstrate the direct printing of magnetic resonant coupled wireless power transfer (WPT) modules and ceramic layers directly onto the highly curved surfaces (hemispherical glass substrates with a radius of curvature ~ 50) with viscoelastic conductive, ceramic, and magnetic inks designed for the highly curved surface printing. WPT module consists of an inductor coil (Ag), and capacitors (Ag/BaTi2O3/Ag) are used to realize a parallel resonant LCR circuit. Furthermore, a soft ferrite layer (NiZn-Ferrite) direct printed on inductor coil, these soft ferrite layer in WPT module plays important roles in (a) enhancing magnetic coupling between the inductor coils transmitting and receiving the magnetic field, and (b) preventing the magnetic field from reaching any conductive object, electronic devices, or human bodies near the WPT module. Laser annealing using an IR laser with various laser fluences was applied to enhance the magnetic property of the soft ferrite layer printed on the highly curved surface. The performance of the printed WPT module on the highly curved surface was demonstrated by transmitting wireless power to various electronic devices through the magnetic resonant coupling. This work may find potential applications, including wearable electronics, optoelectronics, biomedical devices, sensors, and Three-Dimensional (3D) electronics.

Architected Porous Media Designed for Flexographic Printing

Michael A. Gallegos1, 2, Chelsea M. Garcia2, Madeline Van Winkle1, Kristianto Tjiptowidjaja2 and Bryan Kaehr1, 2; Sandia National Laboratories, Albuquerque, New Mexico, United States; Dept of Chemical and Biological Engineering, The University of New Mexico, Albuquerque, New Mexico, United States.

The development of printed and unconventional electronic devices to meet application-specific needs requires innovation in printing technologies. Flexography (flexo), a rubber-stamping method developed in the 19th century, has proven scalable (meters per second) for graphic arts but is underdeveloped for printed electronics, particularly transistor and transparent electrode applications, due to limited feature resolution (>50 µm).

Although much work has gone into understanding the structural and fluid mechanics of the ink transfer processes, little attention has been paid to the actual stamp, typically fabricated via polymer replication of a hard master. The elastomeric stamp is top-side inked and compressed on a substrate, a process that has inherent limits for materials transfer and results in uneven pixel quality (poor feature resolution) due to compression-induced spreading. However, consider a porous stamp that undergoes precise deformation such as negative Poisson’s ratio (NPR) during this process. Here, ink transfer could be a metered process with the pore-space being the reservoir and the mechanical deformation being the “metering pump”. Moreover, a stamp that exhibits a slight NPR may allow for controlled expulsion and sharper transfer foot print (minimal line-edge roughness). Only recently has it been feasible to produce such engineered structures at high resolution, for example, using multiphoton-induced, direct laser writing (DLW). Here we investigate how precisely architectured (e.g., NPR and a structured pore size distribution), 3D porous media can control the fluid saturation/capillary pressure characteristics upon mechanical compression to enable high fidelity/metered material transfer for high speed printing. In this study, we systematically investigate the effects of porosity, pore size distribution and microstructure compression on flexographic ink transfer using iterative arrays of high-resolution (<1 µm feature size). DLW structures converge on optimized forms. Fluid dynamics simulations of defined poroelastic media provide further insight into metering ink transfer during compression. Overall, this work illustrates the design flexibility and precision control of micro-features/fluid dynamics enabled using form-fabrication of flexographic forms.

Engineered Nanocomposite Material Properties Through Embedding of Smaller Nanoparticles in a Polymer Matrix

Sanjoo Gupta, Alex Henson and Brendan Evans, Western Kentucky University, Bowling Green, Kentucky, United States.

Organic and inorganic nanoparticle reinforcements have garnered widespread attention for polymer nanocomposites to yield properties enhancement useful for wide ranging modern technologies including photovoltaics, catalysis, optics, and renewable energy. Recent experiments and computational simulations revealed the macroscopic properties are governed by mesoscale structure and interfacial layer dynamics due to the interactions between the polymer matrix (host) and nanoparticle reinforcements (guest). However, a clear fundamental understanding of the role of size, shape, loading (volume fraction) in controlling the structure and dynamics of polymer-nanoparticle interfacial layer is limited. Moreover, “forward” engineered polymer-nanoparticle composites targeting specific applications often require higher volumetric density and better dispersions remains a challenging task. We report on developing polymer nanocomposites engineered to minimize dielectric losses and investigating structure and dynamics of interfacial layer to predict macroscopic properties. The nanocomposites will consist of poly(2-vinylpyridine) (P2VP) polymer matrix with (~2-5 nm diameter) and (2) planar nitrogereated graphene nanoribbons (~20 nm wide), having dimensions comparable to polymer matrix characteristic length i.e. gyration radius (Rg = 5 nm). This approach will enable improved nanocomposites and identify key molecular parameters governing non-linear dielectric loss mechanisms while studying structured deposition using broadband dielectric spectroscopy and wide-angle X-ray scattering. The transmission electron microscopy will reveal microscopic structure and the lattice bonding, interfacial stress transfer and conjugation length will be determined from micro-Raman spectroscopy. The exact loading and glass transition temperature, Tg, will be obtained using thermogravimetric analysis and differential scanning calorimetry, respectively. We will gain fundamental insights into the interfacial layer and diffusion dynamics above and below Tg and establish quantitative structure-property correlations, while predicting macro-scale properties. We acknowledge KY NSF EPSCoR REG subaward Grant.

Polyaniline/Carbon Nano Hybrid Composites for Monitoring and Detection of Flexible Alkali Sensor

Do Hun Kim, Jin Sun Yoo, O Hwan Kwon and Woo Seok Yang; Korea Electronics Technology Institute, Seongnam-si, Korea (the Republic of).

As the safety has been emerged as a major interest in chemical industry facilities, there have been many researches about sensors for detecting hazardous chemicals. In this study, especially, the sensor for detecting alkaline solution was developed and evaluated. The sensor was composed of carbon materials and polyaniline, which is a conductive polymer. The candidate carbon materials for sensor such as graphite and graphene nano platelet were examined. When graphene nano platelet was used, it showed insensitive reactivity to basic material. Also sensor films can better overcome sensor errors in moisture and water when using graphite than GNP. Finally, it was confirmed that the graphite was the best carbon material for the alkali sensor and it was coated on PET to enable flexible sensor.

PM03.07.09
Enhanced Photo-Luminescence from Highly Interconnected Porous QD/BCP Nanocomposites Formed via Controlled Spinodal Decomposition of Block Copolymer

Geon Yeong Kim, Yeon Sik Jung and Duk Young Jeon; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

In this poster, highly interconnected porous QD/BCP nanocomposites was demonstrated in order to achieve enhancement of photo-luminescence. The QD/BCP nanocomposites with strong emission has the potential to be used in photo-luminescence devices of display application with simple and cost-effective fabrication method. Block copolymer (PS-b-P4VP) forms highly interconnected porous structure via the mechanism of spinodal decomposition
during the evaporation of solution when dimethylformamide (DMF) and water exist together. Here, the composite film was fabricated by simple spin-coating with the humidity control. The porous QD-BCP nanocomposites effectively enhanced absorption of quantum dots inside the block copolymer matrix by the multiple light scattering and trapping effect inside film, resulting in enhanced photo-luminescence. A one of current obstacles towards high-performance QD devices is reducing energy transfer nearby quantum dots, which is called Fluorescence Resonance Energy Transfer (FRET). The quantum dot was functionalized with hydroxyl ligand for the conjugation with BCP. The hydrogen bonding between hydroxyl ligand and nitrogen atom of P4VP block was successfully established. Consequently, by the self-assembly properties of block copolymer, the dispersion of quantum dots was induced, which indicated reduced Fluorescence Resonance Energy Transfer (FRET) effect. With the synergetic effects of light scattering from porous structure and dispersion of quantum dots from conjugation effect, the 21-fold enhancement in photo-luminescence was achieved compared to reference quantum dot film.

PM03.07.10 Fabrication of Robust Superhydrophobic Surfaces with Modified Siloxane Resin Kibeom Nam and Dong Yun Lee; Kyungpook National University, Daegu, Korea (the Republic of).

The superhydrophobic surfaces have received a significant attention for decades because of their wide spectrum of applications such as self-cleaning, anti-icing, separation of liquids, and anti-corrosion. We achieved durable water repellent surface through a spray coating method. This technique is possible to fabricate superhydrophobic surfaces with multiscale of roughness over large area. Spray coating is conducted by spraying the nanoparticles (NPs) onto the substrate with some binders in it; The NPs are gathered each other and form multiscale structures on the substrate and the binder which has low surface energy acts as an adhesive. This superhydrophobic surfaces has not only an excellent water repellency and superb solidity. In addition, it shows a heat resistance even at 300 celsius degree, and solvent resistance. To achieve such superhydrophobic surface through spray coating, we should consider various factors that influence on degree of superhydrophobicity, for example NPs size and content, binder content and the amount of coating solution. Especially, it is important to control the aggregated size of NPs in solution, that highly affect the surface morphology after coating process. The superhydrophobic surface means the surface that has high contact angle over 150° and low slide angle under 10°. It is well established that the superhydrophobic surfaces came from an association of low surface energy and multilevel of surface roughness (i.e., hierarchical structures). It is explained by two theoretical models (Wenzel and Cassie-Baxter); Both models explain a superhydrophobic surface that has rough surface with low surface energy. If liquid drops on Wenzel model, liquid fills up all grooves however, air pockets are formed between the surface and water droplet in Cassie-Baxter state. Because of such differences, they show different wetting properties, water droplet can be pinned on the Wenzel surface and do not roll off easily. By contrast Cassie-Baxter drops are fall form the surface because they sit partially on air. These structures are vulnerable to mechanical forces form the surrounding like water impact, or finger touching. When the structures are demolished, it lost its hydrophobic property. However, we introduce a method for fabricating the mechanically durable superhydrophobic surfaces by spraying robust siloxane resin as a binder. The resin can be synthesized through hydrolysis-condensation reaction of silanes and cured with amino-silanes. Furthermore, surface morphology is controlled by adjusting distribution and mount of NPs in the coating solution.

PM03.07.11 Superhydrophobic Functionalization of Textile Surface Using Roll-to-Roll Chemical Vapor Deposition Mehmet Gursoy; and Mustafa Karaman; Selcuk University, Konya, Turkey.

In most cases, functional polymeric thin films are essential parts for the production of many devices with electronic or other advanced functionalities, including transistors, memories, physical and chemical sensors, photovoltaic cells, photo detectors, energy storage devices, displays, lighting, biomimetic surfaces and flexible-hybrid electronic devices. Today, the interest in wearable devices is increasing rapidly, making it necessary to integrate device parts on flexible textile surfaces. Usually, the surfaces of textiles are not compatible with the other parts of the devices, which could be overcome by imparting a functional thin film on textile surface. The desired properties of a device-quality textile include flexibility, breathability, durability, ease-of-manufacturing, aerium and mechanical properties. To achieve such a high-throughput production, making it as a suitable mass production equipment such as roll-to-roll process. In this study, a pilot roll-to-roll iCVD system was designed and operated to produce thin films of poly(hexafluoro butyl acrylate) on bamboo fabric surfaces. In this way the surface of bamboo was modified with silver and copper nanowires are used to make transparent heaters because of their high electrical conductivity as well as high optical transmittance in the near infrared spectrum. The superhydrophobic surfaces have received a significant attention for decades because of their wide spectrum of applications such as self-cleaning, anti-icing, separation of liquids, and anti-corrosion. We achieved durable water repellent surface through a spray coating method. This technique is possible to fabricate superhydrophobic surfaces with multiscale of roughness over large area. The resin can be synthesized through hydrolysis-condensation reaction of silanes and cured with amino-silanes. Furthermore, surface morphology is controlled by adjusting distribution and mount of NPs in the coating solution.

PM03.07.12 Direct Write of Micro-Circuitry via Micro Cold Spray Ryan Mocadlo1, Victor Champagne1, Jianyu Liang2 and Richard Sisson2; 1U.S. Army Research Laboratory, Aberdeen, Maryland, United States; 2Materials Science & Engineering, Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Micro-cold spray (MCS) is a process that can achieve the solid-state deposition of metal powders through capillary focusing. In this process, metal powders are accelerated, using high pressure helium, through a capillary nozzle to impact on a substrate, and subsequently deposit in micrometer lines. Fine feature sizes have been a long-standing aspiration of the cold spray community, but have remained elusive despite extensive efforts. Recent developments in micro powder feeding has enabled the use of the MCS as a direct-write technology to deposit conductive materials for use in printed electronics. In addition, the MCS process has shown the ability to deposit materials on flexible substrates, allowing for the possible use in the fabrication of flexible electronics. This work describes the extensive effort on understanding the impact of nozzle design, and process gas temperature on the final deposition. Computational fluid dynamics models were employed in the preliminary design of the capillary nozzles, with the goal of maximize particle velocity, while minimizing the particle beam diameter. The insights gained through experimental studies were used to help optimize the computational models for future use.

PM03.07.13 Transparent Thin-Film Heaters Based on Atomic Layer Deposited Oxides onto Copper Nanowire Networks Dogançan Tigan, Sevim Polat Genlik, Bilge İmer and Husnu E. Unalan; Middle East Technical University, Ankara, Turkey.

Transparent heaters utilizing random metallic nanowire networks received great attention in recent years due to their significant performance. Commonly, silver and copper nanowires are used to make transparent heaters because of their high electrical conductivity as well as high optical transmittance in the near infrared spectrum.
In this study, we succeed in patterning the anodized aluminum oxide layer by the photolithography technique. The minimum resolution of the patterning is less than 10 μm. To pattern the anodization oxide layer, first we patterned the photo resist on the connection wires. By covering the connection wire with copper nanowires, we successfully fabricated transparent thin film heaters using copper nanowires with oxide shells through simple means.

PM03.07.14 Reducing Fresnel Reflection Losses in Chalcogenide Based Infrared Optical Fibers via Direct Nanoimprinting Mikkel Lotz, Christian R. Petersen, Christos Markos, Ole Bang, Mogens Jakobsen and Rafael Taboryski; 1DTU Fotonik, Technical University of Denmark, Kongens Lyngby, Denmark; 2DTU Nanotech, Technical University of Denmark, Kongens Lyngby, Denmark.

Fresnel reflection at the glass-air interface in chalcogenide glass based optical components generally constitutes a significant portion of the overall losses due to the high refractive index (2-3) of the glass. In arsenic triselenide (As$_2$Se$_3$) based mid-infrared optical fibers the Fresnel reflection losses surmount to about a 40% reduction in transmitted power. Traditionally, mid-infrared optical systems have relied on antireflective dielectric coatings to solve this problem, but only a limited number of materials are chemically and thermo-mechanically compatible with chalcogenide glass. Nevertheless, we recently reported on the progress towards fabricating broadband mid-infrared antireflective moth-eye nanostructures on the surfaces of commercially available As$_2$Se$_3$ optical windows by thermal nanoimprinting. We now present a study into a more cost-effective method of reducing the Fresnel reflection losses in As$_2$Se$_3$-based optical fibers by nanoimprinting antireflective nanostructures directly on the end-facets.

Based on a simulation approach using rigorous coupled-wave analysis we first design a hexagonal array of moth-eye nanostructures optimized for the mid-infrared. A silicon master containing the moth-eye nanostructures is then fabricated using DUV lithography to create an etching mask and dry-etching to fabricate the structures in the silicon substrate. A nickel mold is then made by depositing a nickel-vanadium seed layer to the silicon master and subsequently electroforming it with nickel. The nickel mold is released by dissolving the silicon master in a potassium hydroxide solution. The negative relief mold of nickel (Ni shim) is then coated with Perfluorodecyltrichlorosilane (FDTS), which acts as an anti-stiction coating using Molecular Vapour Deposition (MVD).

Using a mid-infrared supercontinuum laser source with a radiation spectrum from 2.4-2.6 μm, we observe >30% improvement to the transmitted optical power (from 56% to almost 90% of incident power) as a result of nanoimprinting the input and output facets of a As$_2$Se$_3$ multi-mode fiber and a single-mode fiber, using the fabricated Ni shim.

PM03.07.15 Damage Induced Surface Texturing of PDMS Composites, a Single Fiber Insertion Study Navid Namdari and Reza Rizvi; Mechanical Engineering, The University of Toledo, Toledo, Ohio, United States.

Damage and mechanical failure are detrimental for materials in engineering applications. However, recent studies have shown that properly designed debonding and pullout phenomena in composite fractures can be implemented to introduce added functionalities by damage induced surface texturing (DIST). In this approach, randomly oriented or aligned fibers are incorporated in a polymeric matrix, followed by transversal shearing of the surface. As a result, the shear-fractured surface will have protruded fibers on it because of the debonding followed by subsequent pullout. The protruded fibers play a key role in imparting new functionalities to the cut surface. To date, two important applications have been affected by the introduction of DIST. The first application is in enhancing the ice friction coefficient by as much as 900% in carbon-based styrene butadiene styrene (SBS) composites. Furthermore, DIST has also shown a significant potential in hydrophobic surfaces where the water droplet contact angle increased by 30% in SBS reinforced with carbon fiber (CF) composites. DIST is a simple, economical, and a scalable method compared to lithography, hot embossing, and laser ablation. In addition, there is no need to use costly and time-consuming post-processing stages to introduce anisotropic properties into the material. Tailoring the pullout length can directly affect the functionality of the surface. Thus, selecting appropriate process parameters plays a key role in designing an optimized surface. The aim of this study is to investigate the effect of fiber type, polydimethylsiloxane (PDMS) modulus of elasticity, fiber stiffness, and fiber/matrix interface on the pullout length of the fiber. A PDMS with varying hardness of 10, 20, 30, and 50 was selected as the compliant material that will incorporate carbon and poly[p-phenylene-2,6-benzobisoxazole (PBO)] fibers. A single fiber insertion method was carried out with a sequential alignment of eight single fibers on a frame placed in a cubic mold before casting the PDMS. The samples were cut transversely to the direction of alignment with a custom-built cutter once the PDMS was cured. The protrusion lengths were measured with an image processing software (ImageJ) from the scanning electron microscopy (SEM) micrographs of the cut surface. Smaller protrusion lengths were observed by increasing the matrix modulus, according to the predictions of the model proposed by Wells and Beaumont [1]. Moreover, using regular and high-modulus PBO fibers brought to light the fact that increasing the fiber stiffness can enhance the pullout length. Finally, we evaluate the effect of epoxy sizing, plasma treatment, and no sizing on the pullout length of the carbon fiber.

PM03.07.16 Anodization Patterning for Organic Electronic Circuits with Low Operation Voltage Tomovski Yokota, Hirosi Jinno and Takao Someya; The University of Tokyo, Tokyo, Japan.

Organic circuits are much attracted in realizing the flexible and bendable electronics such as flexible display and flexible sensor systems. The important technology for realizing the high yield and high performance organic circuits with low operation voltage is anodized oxide gate dielectrics. Recently, many groups reported the low operation voltage organic transistor with anodized oxide gate dielectrics layer [1, 2]. Compare with a plasma-formed aluminum oxide layer, an anodized alumina oxide layer shows higher mechanical durability [1]. One of the biggest problems of anodization process is patterning. Normally, anodization process needs to connect the all electrodes to form the oxide layer. For this reason, it is very difficult to make the complicated circuit with anodized oxide gate dielectrics. Although some novel method of anodization patterning were developed [3], it is still difficult to apply these methods to organic integrated circuits.

In this study, we succeed to pattern the anodized aluminum oxide layer by the photolithography technique. The minimum resolution of the patterning is less than 10 μm. To pattern the anodization oxide layer, first we patterned the photo resist on the connection wires. By covering the connection wire with...
Automated Fabrication of Uniaxially Aligned Nanofibers via Beltspinning

Dave Jao and Vince Beachley; Rowan University, West Berlin, New Jersey, United States.

This study proposes a continuous and straightforward method for fabricating suspended micro- and nano-diameter polymer fibers by using an automated single step drawing system. Tangled beltspinning, fiber alignment, diameter, and morphology can be controlled by varying draw ratio, rotational belt speed, and polymer solution properties. The belt spinning device is inexpensive and simple to operate as it does not require an electric field. The device can draw single or multi-filament arrays of nanofibers from any kind of polymer and solvent. Fibers are continuously spun by the direct contact and mechanical drawing between the two rotating belts. The automated track can produce continuously aligned fibers along a single linear axis, which is advantageous for building uniaxially aligned scaffolds for tissue engineering. To demonstrate, fibers were manually pulled from polymer solutions containing 10, 20, and 30% w/v PVAc and 7, 10, and 13% w/v PE. As the system rotates and cycles, the viscous liquid polymer solution applied to the belt begins to evaporate and form semi-solid fiber bridges. The polymer bridges then proceed down the angled track where the fiber is further stretched and elongated over a wide range of fiber diameters. Polymer nanofibers with diameters as small as 400 nm with a length of 30 cm were produced using this technique. Controlling the drawing parameters, all kinds of polymeric materials (polymer melts and solutions), and biopolymers (protein materials), and polymer composite materials. The setup is inexpensive to implement, nozzle-less, easy to scale up, and the tracks can be patterned/textured for aligned fiber arrays. The ability to draw various materials into uniaxially aligned nanofibers opens the door to applications associated with 3D nanostuctures and development of new nanodevice configurations, while also providing opportunities in a wide variety of 3D substrate geometries that have been difficult or impossible to obtain, such as tissue engineering scaffolds. The preferential alignment of nanofibers can also lead to the formation of nanostructured materials with highly anisotropic behavior and new features, such as electrical, magnetic, ferroelectric, ferromagnetic, and structural mechanical. For example, drawing polymeric fibers can increase chain alignment and crystallinity, it is a conventional method to improve the thermal conductivity of the polymer along the axial direction of the nanofibers. While electrospraying has been successfully used in preparing many kinds of polymer fibers with high thermal conductivity, it has some disadvantages, such as the need for polar solvent carriers that are relatively high in electrical conductivity to spin highly resistive polymer materials, such as PE. Since studies have shown that the thermal conductivity of the mechanical drawn PE nanofiber is comparable to the electrosprun PE nanofiber, the automated drawing process can be implemented via beltspinning.
fabricated on Si substrates using a ZrO₂ gate dielectric and In₂O₃ semiconductor that are converted with a total annealing time of just 2 minutes. The devices exhibit a high carrier mobility (μ > 9 cm²V⁻¹s⁻¹) and on/off ratio (Ion/off > 10⁶) than the same TFT device structure made using a UV-ozone assisted metal oxide conversion plus thermal annealing at 250 °C with a total processing time of 3 hours (μ = 1.4 cm²V⁻¹s⁻¹, Ion/off = 10⁴). The sol-gel to metal oxide transformation process is characterized by XPS, FTIR, and ellipsometry. Photonic curing is further explored to convert sol-gel oxide films on polyethylene naphthalate (PEN) substrates. The increase in processing speed will be crucial to enabling high-throughput roll-to-roll manufacturing of metal oxide electronic devices.

8:15 AM PM03.08.02
Roll-to-Roll Ion Beam Assisted Deposition of Single-Crystalline-Like Conductive TiN Buffer Layer Directly on Metal Substrate for Thin-Film Optoelectronic and Electrical Applications  Sicong Sun, Ying Gao, Yongkuan Li and Venkat Selvamanickam; Department of Mechanical Engineering & Texas Center for Superconductivity and Advanced Manufacturing Institute, University of Houston, Houston, Texas, United States.

Single-crystalline-like buffer layers made by ion beam assisted deposition (IBAD) have been used to grow highly epitaxial functional layers on inexpensive metal and flexible glass substrates. Most commonly-used single-crystalline-like buffer structures consist of oxide materials such as LaMnO₃/MgO. While such oxide layers have led to high-performance epitaxial superconductor tapes, GaAs photovoltaics and Si and Ge-based flexible electronics, they isolate the active layers from the substrate. This architecture has a few drawbacks including possibility of thermal destruction in the event of an overcurrent situation and the need to fabricate lateral back contacts by etching and photolithography. Single-crystalline-like buffer structure of a conductive material is a very desirable design since they allow electrical and thermal contact between the active layers and the substrate which allows high thermal dissipation ability and the ability to fabricate back contacts on the substrate without the need to etch the active layers. TiN has been reported as a promising material for developing conductive buffer layer to replace oxides because of its good electrical conductivity and high thermal stability. Here we report a new method to grown biaxial-textured single-crystalline-like TiN thin film on polished metal tape by continuous roll-to-roll ion beam assisted deposition. Single-crystalline-like TiN has been directly realized on low-roughness metal tape surface (Rₘₐₓ 0.35nm, 1µm scale) without any seed layer at room temperature. In-plane texture Δφ of 5.6° and out-plane texture Δω of 1.8° are achieved in the homoepitaxy TiN on IBAD TiN. Such electrically- and thermally-conductive single-crystalline-like TiN have been used for epitaxial growth of active layers for photovoltaics, flexible electronics and superconductor applications by roll-to-roll manufacturing.

Ultra-Rapid Transformation of Materials Characteristics via Photonic Processing  Demosthenes Koutsogeorgis, School of Science and Technology, Nottingham Trent University, Nottingham, United Kingdom.

Humankind has always been fascinated by light. But, besides just mesmerising us, light can also be a powerful tool for manipulating matter and its characteristics. Light is no longer limited to just a diagnostic for probing materials’ characteristics, but has also become an engine for manipulating materials’ properties. This presentation is about using light in order to process thin films and manipulate their characteristics. As an alternative to conventional thermal annealing, photonic processing enables the use of temperature sensitive substrates without any loss in the effectiveness of a high temperature treatment. Photonic processing is amenable to the demands of R2R, providing a highly localised and ultra rapid thermal treatment, which targets the material of choice only and has minimal influence onto the surrounding materials. The 10 parameters that affect the outcome of photonic processing will be presented in detail, offering a description of how they may affect the outcome of the processing and transform the characteristics of thin film materials. Several examples of successful application of photonic processing to thin film materials will be presented. Examples include the processing of materials for effective dopant activation, control of crystalline structure, creation of ohmic contacts, fabrication of plasmonic nanoparticles, localised photo-chemical conversion of sol-gel precursors.

SESSION PM03.09: ALD and Printing
Session Chairs: Gyoujin Cho and Shelby Nelson

Roll-to-Roll Atmospheric Atomic Layer Deposition Technology for Thin Films and Flexible Electronic Applications  Kamrun Ali1 and Kyung H. Choi2; Qatar Environment and Energy Research Institute, Hamad Bin Khalifa University, Doha, Qatar; 1Department of Mechatronics Engineering, Jeju National University, Jeju, Korea (the Republic of).

Since the inception of Atomic Layer Deposition (ALD) Technology in 1974 by Dr. Tuomo Suntola, it has been adopted by numerous industries for variety of applications. ALD has earned a reputable status in electronic industry especially in the sectors of solar cells, displays, and energy storage devices etc. Although, the conventional ALD technologies are quite capable to produce good quality thin films of wide variety of materials, yet the sequential introduction and purging of precursors and inert gases prevent their application for mass production under atmospheric conditions. In this research work, a novel technology of roll-to-roll atmospheric atomic layer deposition (R2R-AALD) has been implemented for the increased production of Al₂O₃ thin films on movable web of polyethylene terephthalate (PET) substrates at low temperatures (< 100 °C), and the films were also implemented for the encapsulation of organic Poly (4-vinylphenol) (PVP) flexible memristor devices as for their life time enhancement. Trimethylaluminum (TMA) and water has been used as precursors. A compact multiple silt gas source head has been used to transport the precursors and the inert gas to the surface of the substrate and to efficiently remove the bye products and the unreacted gases from the reaction zone. The films deposition has been carried out under the working pressure of 740 Torr, which is very near to the atmospheric pressure. Thin films were developed under a promising growth rate of ~1 Å/cycle at a carefully optimized web velocity of 7 mm/second. The deposited Al₂O₃ thin films showed good morphological, chemical, and optical properties. The films demonstrated very low root mean square roughnesses (Rq) of ~1.73 nm. The fabrication of Al₂O₃ thin films was confirmed through X-ray photoelectron spectroscopy (XPS) analysis and its characteristic peaks of Al 2p, Al 2s and O 1s were appeared at the binding energies of 74 eV, 119 eV and 531 eV, respectively. The compositional study was also supported by conducting Fourier transform infrared spectroscopy (FTIR) analysis. The optical transmittance of more than 85 % in the visible region was observed for the films. The electrical characterization of memristor devices showed that the Al₂O₃ encapsulation has a prominent influence on their performance, and life time. The results reveal that the R2R-AALD technology has a great potential for mass production of thin films and has a promising future in the field of flexible electronics.

9:15 AM PM03.09.02
Hybrid Thin Films Prepared by Solution Processing and ALD for Ambipolar Thin-Film Transistor Devices  Jaspreet Kainth1, Martyn A.
Hybrid active layers comprising of both inorganic and organic semiconducting materials are becoming more promising due to the ability to produce inexpensive, versatile and tailored electronic devices such as thin film transistors (TFT) or photovoltaic (PV) devices. By combining the advantages of the single components, it becomes possible to produce devices with the high stability of inorganic and the mechanical flexibility of organic materials. TFTs generally exhibit unipolar behaviour, where the dominant charge carrier in the channel is either electrons or holes. However, recent work has demonstrated the use of a hybrid layer consisting of poly(3-hexylthiophene-2,5-diyli) (P3HT) on top of ZnO in TFTs which exhibits ambipolar behaviour. These solution processed devices exhibit lower saturated mobilities compared to their single component counterparts, however well-balanced electron and hole mobilities are achieved in their hybrid devices. There is scope for further optimisation of these devices, including reversing the active layer order and exploring alternative deposition techniques.

Atomic layer deposition (ALD) is a thin film deposition technique which produces thin, conformal films due to the precise control over the thickness and composition of films on the atomic scale. The ability to grow ZnO films with such precision and at low temperatures results in ALD having good compatibility with organic materials. The growth of ZnO relies heavily on the surface chemistry therefore varies with the type of substrate. As a result, the nucleation and growth of ZnO on different polymers results in variations in morphology and electrical properties. Previous studies have explored the growth mechanism of ZnO onto P3HT via ALD, showing that the precursors are able to vapour diffuse into amorphous regions of the polymer thin film resulting in incorporation of ZnO within the polymer nanostructure. Such hybrid structures have also been successfully incorporated into PV devices. In this contribution we investigate the well-studied P3HT/ZnO systems to develop the growth of oxide layers directly onto polymer thin films in TFT devices, comparing their performance with their single component counterparts. Our methodology is simple, first depositing P3HT from solution and subsequently ZnO by ALD. We demonstrate an ambipolar charge transport for these hybrid TFTs. Following this, the growth behaviour of ZnO onto alternative p-type semiconducting polymers, such as poly[p-phenylene vinylene] and poly(9,9-diocetylfluorene-alt-benzothiadiazole), are explored. The observed effects of polymer variation is investigated by examining the crystallographic and morphological characteristics, and their potential ambipolar properties are studied by investigating their electronic properties.

Hierarchically structured solid scaffolds are often used to improve light absorption and carrier collection in thin-film photovoltaics. The structure can simultaneously optimize the rates of light absorption, carrier collection at the semiconductor-liquid junction, and mass transport of reactants to improve the effective energy conversion properties of the material. However, the scaffolds require a continuous transparent, conductive coating to function as an electrode and maintain electrical contact to the entire, tortuous surface. The electrochemically robust transparent conducting oxide (TCO) fluorine-doped tin oxide (FTO) can only be grown by line-of-sight physical deposition methods such as RF sputtering or spray pyrolysis, which in general prevents the deposition of uniform thin coatings of FTO on the interior of a hierarchically structured scaffold. Other TCOs (tin-doped indium oxide (ITO), aluminium-doped zinc oxide (AZO)) can be grown conformally by surface specific methods such as atomic layer deposition (ALD). ITO and AZO films are only stable at near-neutral pH, limiting their use in photocatalytic energy conversion. Here, we describe a strategy for improving the stability of ALD-deposited AZO films for anodic operation in alkaline electrolytes. The addition of a conformal, nanoscale TiO2 coating preserves a conductive AZO film for more than 24 hours at pH > 13. This is an improvement of several orders of magnitude compared to the lifetime of pure AZO films. Although the TiO2 coating is not significantly conductive alone, we observed an improvement in the conductivity of the layered AZO/TiO2 film. The TiO2-coated AZO film can be used as an electron collector on hierarchically porous scaffold formed from close-packed inorganic silica spheres. The improved electrochemical stability suggests that this approach will greatly benefit the fabrication of ultra-thin film photoanodes based on alkaline-stable semiconductors, such as the ternary metal oxide systems NiMnO4 and BiVO4.

Atmospheric Pressure Plasma Enhanced Spatial ALD of Silver from a New Halogen-Free Precursor

Plasma enhanced atomic layer deposition (PE-ALD) affords excellent-quality thin-films for various applications [1]. However, conventional ALD is vacuum based and imposes limits toward high-throughput and low cost manufacturing. To overcome these limits, spatial PE-ALD at atmospheric pressure has been introduced [2]. We have shown outstanding gas diffusion barriers and semiconductor thin-films grown by spatial PE-ALD, recently [3,4]. For the PE-ALD of metals, reducing plasmas are needed. As of yet, work on spatial PE-ALD of metals at atmospheric pressure is very limited, as is the choice of suitable Ag precursors. In this work, we report on the growth of Ag by spatial PE-ALD at atmospheric pressure from a novel halogen-free, monomeric and volatile carbene-based Ag precursor at substrate temperatures as low as 80°C. The results are compared to those obtained from the more established precursor [Ag(fod)(Pet3)] (FOD), which contains fluorine, phosphorous and oxygen. An atmospheric pressure dielectric barrier discharge with Ar/H2 as working gas is used as reducing agent for both compounds. Using Rutherford backscattering spectrometry, a growth rate of 2.1 * 10^11 atoms cm^-2 cycle^-1 (corresponding to an equivalent of 0.36 Å cycle^-1) was obtained for the new precursor, as opposed to 0.3 Å cycle^-1 for the FOD precursor.[5] The slightly enhanced growth rate could probably be attributed to the higher reactivity of the carbene based Ag precursor. X-ray photoelectron spectroscopy confirmed that Ag films from the FOD precursor deposited by atmospheric pressure spatial PE-ALD contained a high level of fluorine residues. These residues could be efficiently avoided by using the new carbene-based precursor. Furthermore, growth characteristics in dependence of process parameters like deposition speed and substrate temperature as well as saturation of the precursor were investigated. The substrate temperature was reduced to temperatures as low as 80°C to reduce the mobility of the silver atoms on the substrate surface and thus the percolation threshold. The prospects to use these grown Ag layers to create semi-transparent electrodes for thin-film optoelectronic devices are discussed.

References:
During the last few years, atomic layer deposition (ALD) has been highlighted in the semiconductor industry. As device performances have been enhanced, the topography of the device structures have become more complex, and consequently, the requirements on the step coverage have become much more important. ALD is one of the best techniques to deposit conformal films on topographically complex structures. Also, the dimensions of the features have become smaller and narrower. Consequently, the required thickness of the films becomes less, thus low growth rate, one of the main drawbacks of ALD, is becoming less important. When the ALD technique was in the research phase for semiconductor applications, almost all studies were executed with single-wafer processing type reactors. However, as ALD is finding their way into high volume semiconductor manufacturing, the processing cost becomes an important factor to be taken into account. This has resulted in an introduction of batch-type ALD systems, particularly in dynamic random-access memory and flash memory fabs that are cost-sensitive.

As increasing the volume of the batch-type ALD reactor to enhance throughput, it became more difficult to deposit uniform films over the whole wafers, i.e., decreased within-wafer (WIW) uniformity and wafer-to-wafer (WTW) uniformity. We observed that the WIW and WTW uniformities are affected by the pulse step in ALD process. In this study, we developed a dynamic purging process and achieved excellent WIW and WTW uniformities at more than 80-wafer batch size. The dynamic purging process is composed of cyclic steps with purging and vacuum pumping. As comparison studies, we also checked the WIW and WTW uniformities with normal purging processes. We deposited Al2O3 films using tri-methyl aluminum (TMA) and ozone as Al and O sources, respectively, with N2 as a purge gas. With the dynamic purging process, we obtained enhanced WIW and WTW uniformities more than 50%. The dynamic purging process can be applied to all types of ALD reactors to increase uniformity, resulting in enhanced throughput.

Assembly of microscale objects with ever-decreasing sizes is essential for automated production of integrated electronic devices such as micro-LED displays. Here, we introduce a new engineered surface, comprising carbon nanotube (CNTs) forests coated with nanometer-scale ceramic layers, for dexterous pick-and-placement manipulation solid objects using electrically switchable adhesion. We describe the electromechanical contact behavior of the nanosurface components, which are mechanically soft, have low intrinsic adhesion, and can be rapidly switched using with 100x greater adhesion by application of an electric potential to the CNTs. The large range of tunable adhesive strength accompanied by the low intrinsic adhesion allows manipulation of objects whose small sizes dictate surface forces dominate over gravity. We demonstrate pick-and-place manipulation of a variety of objects including colloidal particles (metal, ceramic, polymer) with diameters from 0.5-30 μm, silver nanowires (~12 μm long), and unpackaged light emitting diode (LED) chiplets (~170 μm). These manipulations do not require chemical/thermal surface modification or additional adhesives, demonstrating the versatility of this new approach.

There is a growing industrial need for manufacturing technologies that can print devices with high resolution (< 10 microns) and at high throughput. Conventional flexography is limited in resolution due to the instabilities in the ink loading and transfer mechanisms. A recent invention from our research group, engineered nanoporous stamps composed of polymer coated carbon nanotube (CNT) forests, are highly porous (~90%) and can retain the ink within their volume rather than on their surface only and has been used to print micro-scale features with highly uniform ink layer thickness.

In this talk, we explore the liquid transfer behavior from engineered nanoporous printing stamps using a high-speed visualization system and discuss the governing physics enabling the high-resolution high-speed printing. We conducted experiments using a custom-built printing apparatus which enables printing on flat and curved substrates by precisely controlling the force and printing speeds while observing the printing process in the time scales of milliseconds using a high magnification high speed imaging system. We observe all the steps in printing and describe the details of liquid meniscus evolution that lead to the ink transfer. Then we theoretically and experimentally study the dynamics of liquid spreading and receding, emphasizing the effects of approaching and retraction speeds. Finally, we discuss how our understanding of ink transfer physics can be applied to the process control of contact printing for the precision electronics manufacturing.

Large-area, layer-by-layer transfer molding requires an adhesion strategy that facilitates transfer to the substrate by maximizing interlayer bond strength while minimizing stamp demolding force. A size dependence on transfer rate was observed for plasma bonding at the nano-scale in both batch and continuous processes using a conventional plasma cleaner and corona treatment, respectively. We study the possible contributions to this size dependence by transferring poly(dimethylsiloxane) (PDMS) lines with periods down to 140 nm into woodpile structures from perfluoropolyether (PFPE) stamps at 10-30 sec exposure times of 1-3 seconds showed successful bonding, while brittle delamination occurred at the more conventional longer exposure times of 30-60 seconds. In addition, demolding force displayed significant anisotropy depending on peel orientation with respect to the line direction. The results presented here offer insights into plasma bonding at the nanoscale and offer a pathway to rapid, scalable bonding strategies for printing and microfluidics applications.

Technologies for Multi-Material Additive Manufacturing of Embedded Heating Devices for Printable Sorbent in Life-Support Systems in Space Travel Applications

Jamie Thompson1, 2, 3, Charlotte Bellejean4, Camille Petit5 and Gregory Whiting4; 1NASA Ames Research Ctr, Moffett Field, California, United States; 2Materials, Imperial College London, London, United Kingdom; 3EMDL, Xerox PARC, Palo Alto, California, United States; 4Mechanical, University of Colorado at Boulder, Boulder, Colorado, United States; 5Chemical Engineering, Imperial College London, London, United States.
Kingdom.

Life support is the most essential process in human space flight. Currently, on board the International Space Station (ISS), carbon dioxide is removed via a four-bed molecular sieve system. The involved processes are heavily dependent on heating large containers of sorbent material during sorbent regeneration at a large energy cost. Therefore, any technologies that minimize the power requirements or turnover time of life support processes are invaluable for human space exploration.

Printed sorbent heater composites produced via additive manufacturing can be used for in-space CO2 capture and conversion processes. Through the development of multi-material printing technologies for ceramics and conductors, a heating element was successfully embedded within a printed sorbent device, allowing for more efficient and quicker localized heating from within the sorbent material. Embedded heaters will significantly minimize energy consumption during sorbent regeneration. Devices are manufacturable with a single print process and only require a post-printing heat treatment before being ready for use in a sorbent bed system. The processes are compatible with both terrestrial and space manufacturing techniques.

The evolution of these technologies explored the use of both metallic and nonmetallic conductor inks, as well as ceramic-conductor composite inks. Binders were also explored as part of the ink development to assess their role in both extrusion and drying/curing post processes. Pre-printing ink preparation methods capable of producing foams directly from homogenous solid phase solutions were developed to allow tunable porosity with minimal effects on printability. Changes to the nano, micro, and macrostructure of the sorbent materials were characterized to assess the extent of activation/deactivation caused by preparation, printing, and heat treatment steps.

Development of a Conductive Biodegradable Ink for Multi-Process Additive Manufacturing Madhur Atreya1, Gabrielle Marinick2 and Gregory Whiting3; 1Mechanical Engineering, University of Colorado Boulder, Boulder, Colorado, United States; 2Chemical and Biological Engineering, University of Colorado Boulder, Colorado, United States.

Widely distributed electronic systems for environmental monitoring can enable the collection of large data sets useful for resource optimization in areas such as agriculture. However, the use of such sensor systems is limited by a number of factors including unit cost and the potential for creating significant amounts of persistent electronic waste in the environment.

Continued research into transient electronic materials and devices has led to a number of available options for biodegradable conductive materials. However, development of biodegradable high-conductivity materials suitable for digital additive manufacturing under ambient conditions remains a challenge.

Building on previous work, we have created solution-based, conductive direct-write inks consisting of various metal particles (such as tungsten) and biodegradable polymeric binders (such as poly(lactic acid)). These printed conductors degrade under a combination of microbial action and water solubility in a predictable manner. Combining the direct-ink writing (DIW) process of these conductors with other digital additive processes, such as fused-deposition modelling (FDM), allows for the fabrication of three-dimensional electronic structures and complex geometries that enable the control of degradation time and mechanical properties.

Based on these materials and processes, a degradable sensor package for examining soil moisture was evaluated, with electronic properties, degradation characteristics and ecotoxicity of resulting by-products systematically analyzed.

Processing and Characterization of Reinforced Polymer Matrix Nanocomposites with Graphene and h-BN Nanoflakes Arab H. Hussein, Assimina Pelegri, Stephen D. Tse, Bernard Kear and Zhizhong Dong; Rutgers University, Piscataway, New Jersey, United States.

In this study, graphene (G) and hexagonal boron nitride (h-BN) microscale powders are exfoliated to nanoscale flakes in a liquid phase of poly-methyl methacrylate (PMMA) solution by an in-situ high shear process. G and h-BN are separately investigated for exfoliation and improvement of performance properties with the polymer. With pure PMMA as a reference, mechanical characterization, including nanoindentation test (strength and stiffness) and dynamic mechanical analysis (DMA), were conducted on the reinforced polymer matrix nanocomposite systems. The surface morphology and nanoflake interface within the polymer matrix are investigated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Raman spectroscopy is used to determine the number of layers and the dispersion of the 2D flakes in the matrix, via the distribution of peak positions and intensities as a function of wavelength. The results demonstrate improvement in the final mechanical properties. During processing, changes in the viscoelastic behavior during exfoliation of graphene in the polymer is noted, along with G being more reactive than exfoliated h-BN within the polymer matrix.

Characterization of Hierarchical Composites with Glass Fiber/Carbon Nanotube using Alternating Current Electrophoretic Deposition Dae Han Sung1, Sagar Doshi1, Andrew Rider1 and Erik Thostenson1; 1Department of Mechanical Engineering and Center for Composite Materials, University of Delaware, Newark, Delaware, United States; 2Defense Science and Technology Group, Melbourne, Victoria, Australia.

The introduction of nanomaterials like carbon nanotubes (CNT) to conventional fiber-reinforced composites creates hierarchical structures where reinforcing fibers, which usually have diameters in the micrometer scale, are surrounded by nanoscale materials. In this research, we used an alternating current electrophoretic deposition (AC-EPD) technique to deposit CNTs directly onto the glass fibers. We expected that AC-EPD would reduce the influence of water electrolysis by which trapped hydrogen or oxygen bubbles made the gap between substrate fibers and electrodes, thereby facilitating a denser CNT network within fiber bundles and filaments as compared to direct current EPD. We compare two different aqueous CNT dispersions, anodic and cathodic, using a novel ozonolysis and ultrasonication technique that results in dispersion and functionalization in a single step. In the anodic solution system, ozone oxidation makes CNTs negatively charged (anions) with functional groups such as hydroxyl and carbonyl groups. On the other hand, in the cathodic system CNTs were functionalized with a polyethyleneimine (PEI) dendrimer where the amine groups protonate under acidic conditions and, in turn, became cations. Anions and cations moved to positively charged electrode (anode) and cathode, respectively, when electric potential was applied in each system. Characterization of the coated fiber surfaces and composites revealed a uniform coating of carbon nanotubes and penetration between the bundles. AC-EPD is novel and simple approach to modify interface properties of CNT hierarchical composites and has great potential to scale
up hybridizing process of nanomaterials which can be utilized as multifunctional applications.

Continuous Production of Carbon Nanotube-Grafted Carbon Fibres—A Route to Manufacture Hierarchical Composites

Hugo De Luca1, David B. Anthony2, Chengyin Liu1, Suresh Kumar Raman Pillai3, Emile Greenhalgh1, Alexander Bismarck1, M. B. Chan-Park1 and Milo Shaffer1; 1Materials, Imperial College London, London, United Kingdom; 2Chemical Engineering, Imperial College London, London, United Kingdom; 3Aeronautics, Imperial College London, London, United Kingdom; 4School of Chemical and Biomedical Engineering, Nanyang Technological University, Singapore, Singapore.

The mechanical properties of fiber-reinforced composites depend on the properties of the fiber/matrix interface where stress concentrations prevail. Grafting of carbon nanotubes to produce a “hairy” or “fuzzy” carbon fiber creates hierarchical reinforcements, combining two different reinforcement length scales, in this instance micrometer and nanometer. This approach improves the interaction between fibers and polymer matrices, and can enhance thermal and electrical functionality of the final composite. Generally, hairy fiber production is limited to batch processes due to harsh synthesis conditions (e.g. high temperature, inert environment) inherent to chemical vapor deposition, and have only recently been scaled-up to continuous production. Carbon nanotube-grafting finally meets industry prerequisites for its implementation in carbon fiber production lines. In this work, the continuous production of carbon nanotube-grafted-carbon fibers was performed in an open chemical vapor deposition reactor with continuous in-line catalyst deposition. This patented technology can be adapted to different fibre types, including as whole tows, while ensuring that the substrate's initial mechanical properties are retained. At the single fiber level, the presence of a uniform 200 nm long carbon nanotubes coverage on the surface of carbon fibers led to an increase in interfacial shear strength of up to 7.5% (96.7 MPa) when compared to the baseline unsized material (89.4 MPa). Epoxy, stiffened through the addition of single-walled carbon nanotubes (up to 1 wt.%), dispersed with an epoxide containing tri-block (PMACEP-PI-PMACEP), showed a further improvement in interfacial shear strength of up to 3.5% (100.2 MPa) when compared to carbon nanotube-grafted carbon fibers in neat epoxy. The use of a nano-engineered epoxy, with continuously produced “hairy fibres” effectively displaces the weaker phase from the surrounding matrix interphase directly to the CNT/carbon fibre interface, demonstrating a synergistic effect and improved interfacial properties.

Multifunctional Structural Energy Storage and Stiffening of Fibre-Reinforced Polymer Composites Through Aerogel Addition

David B. Anthony1, Sang N. Nguyen1, Hui Qian1,2, Shi Xu1, Aryaman Singh1, Alexander Bismarck1,2, Milo Shaffer1 and Emile Greenhalgh1; 1Imperial College London, London, United Kingdom; 2Materials Science and Engineering, City University of Hong Kong, Kowloon, Hong Kong; 3Chemistry, University of Vienna, Vienna, Austria.

The desire to reduce overall weight in devices is a key driver for development; the ability to combine composites with energy storage which provide, simultaneously, structural integrity has the potential to replace single function components. To achieve this ambition, the multifunctional component must perform both functionalities sufficiently, but often there is a trade off in performance which is a significant challenge to overcome.

The performance and application of polymer-matrix fibre composites is often limited by matrix-dominated failures, both mechanical and functional. There is, therefore, considerable interest in the use of nanocomposite matrices, for example using resins filled with carbon nanotubes or graphene, to introduce both intralamellar and interlamellar reinforcement of the resulting hierarchical composites. The objective is to improve delamination resistance, through-thickness properties, and compression performance, without compromising the in-plane tensile response. The potential to improve thermal, fire retardance, as well as solvent and electrical conductivity, offers additional opportunities especially for multifunctional materials. However, due to processing constraints, the nano-reinforcements are typically present only at low loading fractions and in discontinuous form, limiting the level of enhancement.

Here, we present an alternative strategy, to form a rigid bicontinuous reinforcing network throughout the matrix volume. A suitable precursor is first infused into a structural fibre weave or other preform, then converted to form a porous monolithotic aerogel/xerogel matrix, with characteristic lengthscales around a few tens of nanometres. The presence of the reinforcing fibres allows the aerogel/xerogel to form a stable, handleable, structure. Both the rigid network and the porosity are bicontinuous, allowing a second matrix resin phase to be infused. This second phase may be a soft multifunctional phase, for example, one that can support ion conductivity for use in structural supercapacitors.

Pore purely mechanical properties can be investigated when the second phase is a conventional structural epoxy resin. We have studied two analogous systems, one combining carbon aerogel with carbon fibres, and one combining silica aerogel/xerogel with glass fibres, in both cases adding a secondary epoxy resin. In the carbon system, there are increases in compressive and tensile stiffness respectively, but drops in interlaminar, compressive and tensile strengths, due to poor fibre-matrix interfaces after processing. Measurements focussing on matrix performance, using +/-45° tests indicate intrinsic improvements. In the glass system, the interface quality is retained, such that interlaminar and compression properties are all maintained or improved. These initial studies highlight a family of bicontinuous nanostructured matrix systems for hierarchical composites, which have great potential and are worthy of further study.

2:30 PM PM03.10.05
Ultraitlight Xylem-Like Conductive 3D Porous Composite with Cellulose Nanofiber and Ag Nanowire

TaeGeon Kim1, Jongbeom Kim1, Seungmin Hyun2 and Seung Min J. Han1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Korea Institute of Machinery and Materials, Daejeon, Korea (the Republic of).

Ultra-light porous structures demonstrating high strength-to-weight ratio and large surface area and porosity has been of recent interest especially due to their potential application as structural material such as the framework of airplane or vehicle (high strength to weight ratio), catalyst supports (large surface area), thermal insulation, and shock damping or acoustic absorption (high porosity). In order to fabricate such a structure, direct foaming of the melt or powder metallurgical (PM) technique is commonly used by blowing a gas in the liquid alloy or by admixing of foaming agents with reactive sintering. However, Metallic foam made by PM techniques represent only 65 - 90 % of the porosity that showed limitation of lightweight in the structure. Recently, freeze casting method was suggested to solve the limitations of conventional fabrication methods, which uses ice crystal as a template instead of light-induced polymer templates. Pore orientation of the structure can easily be controlled by directional freeze casting method to yield geometrically patterned structures. Therefore, in this study, we propose a xylem-like structure using a composite of cellulose nanofiber and Ag nanowire that satisfies both the high strength enhancement of metal and ultra-light weight of organic with small relative density.

To fabricate the xylem-like 3D porous structure, a mixture of cellulose nanofiber (CNF) and Ag nanowire solution was used in the one-step freeze casting process. CNF (diameter: ~20 nm, length: a few microns) is a fibrous material that demonstrates significantly higher modulus compared to conventional polymer or organic materials that makes CNF more suitable as a structural support for free standing structure. In addition, CNFs can form continuous 2D wall via strong hydrogen bonds and van der Walls forces as they fill in the empty remaining space in between the ice crystals, and thus CNF is chosen as a backbone in the 3D composite, which is further strengthened by the addition of Ag nanowires. This study successfully fabricated a CNF + Ag nanowire porous structure in the bulk form with controlled pore orientation through a low cost process of directional freeze casting. The strengthening effect of the amount of the Ag nanowire addition was achieved 14.3 times higher compressive strength (from
7 kPa to 100 kPa) below 1% of total relative density for xylem-like CNF + Ag nanowire structure. Especially, addition of 0.29% of relative density for Ag nanowires in xylem-like CNF structure showed same order of compressive strength with higher scalability compared to Ni metallic microlattice in micro scale. In addition, more than 5mg/cm3 of Ag nanowire embedded 2D CNF wall is also able to offer sufficient conductivity that maybe suitable for a variety of electronics applications such as battery or supercapacitor electrode.

**Damage-Tolerance in Medium- and High-Entropy CrCoNi Alloys**  
Robert O. Ritchie1, 2, Jun Ding2, Mark Asta1, 2, Bernd Gludovatz3, Easo P. George1 and Qing Yu1; 1Materials Science & Engineering, University of California, Berkeley, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 4University of New South Wales, Sydney, New South Wales, Australia; 5Zhejiang University, Hangzhou, China.

Damage-tolerance is an essential characteristic of structural materials as it defines the combination of strength and toughness, properties that are often mutually exclusive. Certain medium- and high-entropy alloys, the equiatomic Cantor alloy CrMnFeCoNi and its derivatives such as CrCoNi, all of which are single-phase, fcc solid solutions, display exceptional combinations of strength (~1 GPa), ductility (~60-90%), and toughness (~200 MPa.m1/2), properties which are further enhanced at cryogenic temperatures. *In situ* TEM observations of fracture at 293K and 93K identify multiple deformation mechanisms, associated with these alloys' high friction stress yet low stacking-fault energy (SFE), that are activated at different stages of deformation and act synergistically to contribute to strength, ductility and toughness. For example, TEM studies on CrCoNi show that a hierarchical twin network is established at 293K associated with its low SFE. This network generates substantial 3-D barriers to dislocation motion, contributing to high strength and marked strain hardening, yet at the same time, the network provides multiple pathways for the easy dislocation motion, which provides for ductility - the perfect ingredients for exceptionally high damage-tolerance. We further examine the fundamental origin of these exceptional damage-tolerant properties by focusing on the potential effect of local chemical ordering in these alloys. Although difficult to observe experimentally, our DFT-based Monte Carlo simulations show that variations in the state of local chemical order can have a profound effect on the SFE, the twin boundary energy, the energy difference between the face-centered cubic and hexagonal-close packed phases (which affects the occurrence of transformation-induced plasticity), and even the energy of formation of vacancies and interstitials, all features that can have a marked influence on the mechanical properties. These results highlight the possibility of “tuning order in disorder” to ultimately achieve the science-based design and optimization of new high-entropy alloy systems with specifically desired combinations of macroscale mechanical properties.

9:00 AM PM04.01.02  
**Low-Temperature Deformation Pathways of a High-Entropy Alloy by In Situ Neutron Diffraction**  
Muhammad Naeem1, Haiyan He1, Bing Wang1, Stefanus Harjo1, Takuro Kawasaki2, Si Lan1, Zhenduo Wu1, HaiLong Huang1, Fan Zhang1, Zhouping Lu1 and Xin-Li Wang1; 1Department of Physics, City University of Hong Kong, Kowloon, Hong Kong; 2Japan Proton Accelerator Research Complex, Japan Atomic Energy Agency, Tokai, Japan; 3State Key Laboratory for Advanced Metals and Materials, University of Science and Technology Beijing, Beijing, China.

High-entropy alloys, which consist of five or more alloying elements in equal molar ratios, are among the most promising new class of structural materials. Despite the complex chemistry, they can form a single phase solid-solution with an incredibly simple lattice, CrMnFeCoNi is a face-centered cubic (FCC), for example. Several deformation mechanisms are known to operate in high-entropy alloys. At room temperature, CrMnFeCoNi deforms like a conventional FCC alloy, showing clear stages of dislocation slip and dislocation entanglement. At liquid-nitrogen temperature, the dominant deformation mechanism changes from dislocation to twinning, leading to high strength and large ductility. Here we show that, at even lower temperature, the serrated deformation dominates. Deformation behavior of CrMnFeCoNi high-entropy alloy was studied at 15K by *in-situ* neutron diffraction, to obtain insights of the effect of low temperature on the underlying deformation mechanism and the corresponding evolution of structure. Due to the highly penetrating power of neutrons,
Bulk Cantor alloys were successfully manufactured through spray forming and yttrium oxides were introduced into Cantor alloys, exhibiting clear grain rich particles with size of 150 nm were observed in Cantor alloys. Additional yttrium oxides serve as pinning points to dislocation movement, and further refining and strengthening effect. Further research will focus on investigating creep resistance and irradiation response of HEAs and y-doped HEAs.

Nano scale yttrium oxides and chromium-rich particles were observed with bimodal size respectively in y-doped Cantor alloys. Whereas only chromium-rich particles were observed with bimodal size respectively in y-doped Cantor alloys. Furthermore, the effect of grain size on yield strength, both alloys show good combination of strength and ductility.

A yttrium-free and yttrium-doped (y-doped) Cantor alloys both displayed equiaxed FCC structure with average grain size of 10 and 5 μm respectively. A yttrium together with oxygen source is known to form dispersed yttria, leading to grain refinement and oxide dispersion strengthening in alloys. Y-24 (high mass flow rate) and powder metallurgy (refined microstructure) and is thus well-suited for manufacturing complex compositional alloys. Addition of yttrium to HEA (which is also called Cantor alloy), is the most extensively investigated one and exhibits many unique properties (e.g. good combination of strength and ductility down to 77 K, exceptional fracture toughness, and good ultimate tensile strength. Based on the alloy composition or thermo-mechanical processing, solid solution strengthening, precipitation strengthening, transformation-induced plasticity (TRIP) effect, twinning-induced plasticity (TWIP) effect can each contribute to strain hardening in FCC HEAs. The relative contributions of each of these mechanisms, however, have not been systematically investigated. In the current work, we designed two new FCC HEAs with high strain hardening rates but different solid solution strengthening levels. The deformation substructures of the two HEAs at specific strain levels were investigated by using electron channeling contrast imaging (ECCI) combined with electron backscatter diffraction (EBSD). The HEA with higher solid solution strengthening level showed not only higher strength but higher ductility as well. We attribute this abnormal solid solution strengthening effect to the different defect evolution behaviors of the two FCC HEAs. The origins of this observation were systematically studied and will be presented in this talk.

High strain hardening rate plays a key role in enabling face centered cubic (FCC) high entropy alloys (HEAs) to have excellent ductility, high fracture toughness, and good ultimate tensile strength. Based on the alloy composition or thermo-mechanical processing, solid solution strengthening, precipitation strengthening, transformation-induced plasticity (TRIP) effect, twinning-induced plasticity (TWIP) effect can each contribute to strain hardening in FCC HEAs. The relative contributions of each of these mechanisms, however, have not been systematically investigated. In the current work, we designed two new FCC HEAs with high strain hardening rates but different solid solution strengthening levels. The deformation substructures of the two HEAs at specific strain levels were investigated by using electron channeling contrast imaging (ECCI) combined with electron backscatter diffraction (EBSD). The HEA with higher solid solution strengthening level showed not only higher strength but higher ductility as well. We attribute this abnormal solid solution strengthening effect to the different defect evolution behaviors of the two FCC HEAs. Universal Relation Between Critical Resolved shear Stress and Mean Square Atomic Displacement in Random High Entropy Alloys Shigenobu Ogata; Haruyuki Inui; Wei Wang; Osaka University, Osaka, Japan; ESISM, Kyoto University, Kyoto, Japan; Kyoto University, Kyoto, Japan;
High-entropy alloys (HEAs), are multi-component random solid solution alloys with nearly an equiatomic composition, have been receiving tremendous attention due to the excellent cryogenic temperature ductility, superior mechanical strength and good wear resistance, exceptional damage tolerance. Design and development of new HEA having further excellent mechanical properties is one of the challenges in these days. Since trial and error methods take long time and need cost, a general rule predicting mechanical response based on computable value by first-principles is truly desired. In our current study, we focus on critical resolved shear stress (CRSS) of HEA. It is well-known that CRSS of HEA is much higher than single element pure metals. Using molecular dynamics (MD) simulations with root-mean-square atomic displacement (RMSAD) tunable Jennard-Jones potential, we computed a normalized CRSS by shear modulus as a function of a normalized RMSAD by Burgers vector length for different concentration and component of random alloys at zero temperature. The results uncover that almost linear one to one relation between the normalized CRSS and RMSAD, which stands over very wide RMSAD range, in addition the relation depends quite weakly on the concentration and component of alloys. The universality of relation is also confirmed by MD using more realistic EAM potential and available actual experimental data. This implies that RMSAD computable by first-principles can be a general CRSS predictor of random alloys, that may strongly support high-throughput design of high strength random alloys.

11:00 AM PM04.02.02 Property Targeted Quantitative Design of Complex Concentrated Alloys Hyunseok Oh1, SangJun Kim1, Khoroglkhhus Odbudakhirh2, Wookha Ryu1, Kookhoon Yoon1, Sai Mu1, Fritz Körmann2, Yuji Ikeda1, C. Cem Tasan1, Dirk R. Raabe1, Takeshi Egami2 and Evun Soo Park1; Seoul National University, Seoul, Korea (the Republic of); 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Max-Planck-Institut für Eisenforschung, Düsseldorf, Germany; 3Joint Institute for Computational Sciences, University of Tennessee and Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 4Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 5University of Tennessee, Knoxville, Tennessee, United States.

Despite their unique combinations of mechanical and functional properties the property targeted quantitative design of complex concentrated alloys (CCAs) is difficult due to the complex local atomic environment. Here we present an effective quantitative design approach predicting the solid solution strength of complex concentrated alloys based on the quantum mechanically driven atomic level pressure approximation. We show that the dominant factor for the solid solution strengthening in single phase face-centered cubic complex concentrated alloys consisting of 3d transition metal elements is the variation in the atomic level pressures and discuss (i) which alloy constituents dominate the atomic level pressure, and (ii) how to rationalize configurational fluctuations of the atomic-level pressure. Finally, we establish a design recipe which uses elemental atomic-level information without explicit electronic-structure calculations as an efficient vehicle for more systematic and constitutive structure-property design of CCAs.

11:15 AM PM04.02.03 Variable Chemical Order Opens a New High-Entropy Playground Ong-Jie Li1, Howard Sheng2 and Evan Ma1; 1Johns Hopkins University, Baltimore, Maryland, United States; 2Department of Physics and Astronomy, George Mason University, Fairfax, Virginia, United States.

High-entropy alloys (HEAs) were presumed to have a configurational entropy as high as that of ideally mixed solution of multiple elements in near-equal proportions. However, inevitable enthalpic interactions render such chemically disordered solid solution (SSs) rare and metastable, except at very high temperatures. Here we highlight a different “high entropy” signature that sets HEAs apart from traditional solvent-solute SSs. We show that HEAs can be defined as concentrated SSs offering an unusually large configurational space for (local) chemical ordering (LCO) and hence rich property possibilities. Our atomistic simulations with realistic empirical interatomic potentials for NiCoCr demonstrate that at a given overall composition the LCO changes conspicuously with alloy processing. The variable LCO gives rise to a broad spectrum for any generalized fault energy, in terms of both its sample-average and spatial variation (local fault energy on nanometer scale), significantly influencing the dislocation mechanisms and strength. As such, the partial chemical order in a single-phase HEA opens a vast playground not accessed by either random SSs or ordered intermetallics.

11:30 AM PM04.02.04 Tunable Stacking Fault Energies by Tailoring Local Chemical Order in CrCoNi Medium-Entropy Alloys Jun Ding1, Qin Yu1, Mark Asta1,2 and Robert O. Ritchie1,2; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2University of California, Berkeley, California, United States.

High-entropy alloys (HEAs) are an intriguing new class of metallic materials due to their unique mechanical behavior. Achieving a detailed understanding of structure-property relationships in these materials has been challenged by the compositional disorder that underlies their unique mechanical behavior. Accordingly, in this work, we employ first-principles calculations to investigate the nature of local chemical order and establish its relationship to the intrinsic and extrinsic stacking fault energy (SFE) in CrCoNi medium-entropy solid-solution alloys, whose combination of strength, ductility and toughness properties approach the best on record. We find that the average intrinsic and extrinsic SFE are both highly tunable, as the degree of local chemical order increases. The state of local ordering also strongly correlates with the energy difference between the face-centered cubic (fcc) and hexagonal-close-packed (hcp) phases, which affects the occurrence of transformation-induced plasticity. This theoretical study demonstrates that chemical short-range order is thermodynamically favored in HEAs and can be tuned to affect the mechanical behavior of these alloys. It thus addresses the pressing need to establish robust processing-structure-property relationships to guide the science-based design of new HEAs with targeted mechanical behavior. This work was supported by DoE-BES-DMSE, under Contract No. DE-AC02-05CH11231.

11:45 AM PM04.02.05 Lattice Distortion Measurement Using HR-STEM Yi Chou1, Chanho Lee2, Peter K. Liaw2 and Yi-Chia Chou1; 1Department of Electrophysics, National Chiao Tung University, Hsinchu, Taiwan; 2Department of Materials Science and Engineering, The University of Tennessee, Knoxville, Tennessee, United States.

High entropy alloys (HEAs) have attracted attention for its excellent mechanical properties, such as very high yield strength even at elevated temperature or radiated condition,[1] which can be applied to high temperature (up to 1000 celsius degree) casting and nuclear application. HEA are alloys containing 5 or more elements in equal or near equal atomic percent to maximize the mixing entropy. Lattice distortion results from the atomic configuration of HEAs is expected to contribute effects on mechanical properties. In this paper, we examine and measure the lattice distortion two HEAs, NbTaTiV and NbTaTiVZr. Average lattice distortion factor is the commonly used factor to describe the magnitude of lattice distortion, and it is related to effective distance of two atom d0 and the average of effective distance d. Both d0 and d can be obtained from theoretical calculations. The measurement can be carried out in synchrotron or neutron diffraction, where d is the experimental data collected from diffraction peaks. Here we perform the imaging in STEM and the measurements from STEM images to evaluate the average lattice distortion factor. The STEM samples were prepared using FIB equipped with in-situ pick up system, and the thin HEAs were attached to grids with platinum deposition to fix the position for reducing the drift. HR STEM HAADF images were taken when the drift rate is below 0.5 Å/min and fitted with 2D Gauss equation to
specify the atomic position and intensity. The intensity guides to calculation of the Z contrast of HAADF images, and it clarifies that the atoms distributes randomly. The atomic position provides the guide to measure the lattice distortion by calculating the atomic displacement from two orthogonal plane which was defined as \(d^{\text{st}}\), and the standard deviation was taken from the displacement which in turn was the average lattice distortion \(u^{\text{st}}\). With the method, average lattice distortion is directly obtained from STEM images. The average lattice distortion factor of NbTaTiV and NbTaTiVZr are in good agreement with theoretical and synchrotron diffraction results.

SESSION PM04.03: Elementary Deformation Mechanisms
Session Chair: C. Cem Tasan
Monday Afternoon, November 26, 2018
Hynes, Level 1, Room 105

1:30 PM *PM04.03.01
In Situ TEM Characterization on Deformation of NiCrCo Alloy at Room and Cryogenic Temperature Qian Yu1, Robert O. Ritchie2, Easo P. George1, Scott X. Mao1, Hongbin Bei1 and Bernd Gludovatz2; 1Zhejiang University, Hangzhou, China; 2University of California Berkeley, Berkeley, California, United States; 3Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 4University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

NiCrCo alloy shows good combination of strength and ductility at both room and cryogenic temperature. To understand how the strength-ductility trade-off can be defeated, we apply in situ, and aberration-corrected scanning, transmission electron microscopy to examine deformation mechanisms in the medium-entropy alloy CrCoNi that exhibits one of the highest combinations of strength, ductility and toughness on record. We find that a three-dimensional (3D) hierarchical twin network forms from the activation of the three twin systems. This serves a dual function: conventional twin-boundary (TB) strengthening from blockage of dislocations impinging on TBs, coupled with the 3D twin network which offers pathways for dislocation glide along, and cross-slip between, intersecting TB-matrix interfaces. The stable twin architecture is not disrupted by interfacial dislocation glide, serving as a continuous source of strength, ductility and toughness. However, as temperature deceases, multiple deformation mechanisms are activated which was thought unlikely since reduce of temperature usually increase the competition between different deformation modes.

2:00 PM PM04.03.02
In Situ TEM Straining Experiments in A3S and Cantor’s HEA Alloys at Liquid Nitrogen and Room Temperature Marc Legros1, Michal Mroz2 and Anna Fraczkiewicz2; 1CEMES CNRS, Toulouse, France; 2Ecole des Mines de Saint Etienne, Saint-Etienne, France.

The yield stress of a non-equiatomic HEA from the CoCrFeMnNi family (A3S® grade) is significantly increased compared to the equiatomic (Cantor’s) alloy of the same family. This behavior comes from a stable nanostructure, easily formed in the material after classical hot thermomechanical treatment (forging and annealing).

In situ TEM straining experiments were carried out in both alloys at liquid nitrogen and room temperature. Dislocations movements are analyzed with respect to the applied stress that is measured locally using dislocation curvature. Size effects due to the thin foil configuration are discussed. Strengthening mechanisms arise from classical dislocation/ obstacle (grain boundary, forest dislocations, twinning) interaction, but also from local distortions of the interface to the applied stress that is measured locally using dislocation curvature. Size effects due to the thin foil configuration are discussed. Strengthening mechanisms arise from classical dislocation/obstacle (grain boundary, forest dislocations, twinning) interaction, but also from local distortions of the interface. The atomic position provides the guide to measure the lattice distortion by calculating the atomic displacement from two orthogonal plane which was defined as \(d^{\text{st}}\), and the standard deviation was taken from the displacement which in turn was the average lattice distortion \(u^{\text{st}}\). With the method, average lattice distortion is directly obtained from STEM images. The average lattice distortion factor of NbTaTiV and NbTaTiVZr are in good agreement with theoretical and synchrotron diffraction results.

The transformation induced plasticity (TRIP) effect is an ideal deformation mechanism for designing and tuning high-strength and yet ductile metallic materials. A recently developed dual-phase high entropy alloy (HEA) with a nominal composition of Fe50Mn30Co10Cr10 (at.%) shows an extraordinary combination of strength and ductility mainly owing to its TRIP effect, i.e. a sequential displacive transformation from the face-centered cubic (FCC) matrix to the hexagonal close-packed (HCP) phase [1-3]. In this study, we reveal the fundamental mechanisms of the displacive transformation in the dual-phase HEA at atomic scales. A combination of transmission electron microscopy (TEM), scanning TEM (STEM) and in-situ experiments unravels the detwinning and formation of hierarchical nanolaminated structures in the dual-phase HEA. The in-situ experiments conducted under low angle annular dark-field (LAADF)-STEM imaging reveals that the detwinning effect, i.e. formation of coherent \(\Sigma_3\) boundaries, induces a displacive transformation preferably at coherent \(\Sigma_3\) boundaries. In addition, owing to the positive and yet very low stacking fault energy of this specific dual-phase HEA (\(\sim 5.2 \text{mJ/m}^2\)), reversible displacive transformation from the HCP back into the original host FCC phase can also be induced during mechanical loading, in addition to the forward transformation from the FCC to the HCP. This complex sequence associated with the forward and backward transformation creates a hierarchical nanolaminated structure, which is strengthening the HEA without sacrificing any ductility.

Light Weight High Entropy Alloys for Cryogenic Applications Kooknoh Yoon, Hyunseok Oh and Eun Soo Park; Seoul National University, Seoul, Korea (the Republic of)
High entropy alloy (HEA) has been studied due to its great mechanical properties such as strength, toughness, and so on. Moreover, it is reported that Cantor alloy, FCC HEA, shows extremely high toughness at cryogenic temperature due to nano-size twins that is formed under dynamic stress. In this context, many researchers are trying to utilize this novel material under cryogenic environments such as the Arctic, the outer space and so on. Meanwhile, cryogenic applications are closely related with weight-lightening, because materials for LNG carrier, space shuttle are used for transportations. Thus, in this study, we will report about an alloy design of TWIP/TRIP HEAs by controlling the stacking fault energy (SFE). In this, we developed a multiscale modeling approach for the simulations of mechanical behavior of HEAs. In the first step, the vacancy energy and stacking fault energy are calculated with density functional theory (DFT) methods. Based on the DFT calculations, we have developed an accurate embedded atom model (EAM) potential for large-scale molecular dynamics simulation of Al$_{0.1}$CrCoFeNi HEAs. The DFT calculation results for Al$_{0.1}$CrCoFeNi HEAs show that there is a large variation in stacking fault energy in a range of -79 to 46 m/Å$^2$, depending on the local atomic environments. The origin of the negative stacking fault energy is discussed from the thermodynamic metastability of FCC stacking sequence. The nano-twin generation and interactions during deformation are also explored preliminarily with the EAM potential.

**2:45 PM PM04.03.05**

**Multiscale Modeling of Mechanical Behavior of Al$_{0.1}$CrCoFeNi High-Entropy Alloy**

Yu-Chia Yang, Cuixia Liu, Chu-Nan Liu, Jeffrey Lloyd and Zhenhai Xu.

University of North Texas, Denton, Texas, United States; 2University of Texas at Dallas, Richardson, Texas, United States; 3Xian Technological University, Xi'an, China; 4Impact Physics, U.S. Army Research Laboratory, Aberdeen, Maryland, United States; 5Northwestern Polytechnical University, Xi'an, China.

High-entropy alloys (HEAs) have shown exceptional properties, including remarkable fracture toughness, high strength, and excellent resistance to fatigue. These properties of the HEAs result from their five-or more equiatomic components that lead to relatively high configurational entropy, relatively large lattice strains, and unique deformation mechanisms. However, the atomic-scale complexity presents challenges to explore the underlying mechanisms through computer simulations due to a lack of effective potentials. In this work, we have developed a multiscale modeling approach for the simulations of mechanical behavior of HEAs. In the first step, the vacancy energy and stacking fault energy are calculated with density functional theory (DFT) methods. Based on the DFT calculations, we have developed an accurate embedded atom model (EAM) potential for large-scale molecular dynamics simulation of Al$_{0.1}$CrCoFeNi HEAs. The DFT calculation results for Al$_{0.1}$CrCoFeNi HEAs show that there is a large variation in stacking fault energy in a range of -79 to 46 m/Å$^2$, depending on the local atomic environments. The origin of the negative stacking fault energy is discussed from the thermodynamic metastability of FCC stacking sequence. The nano-twin generation and interactions during deformation are also explored preliminarily with the EAM potential.

3:00 PM BREAK

**SESSION PM04.04: Microstructure Control for Mechanical Properties**

**3:30 PM *PM04.04.01**

**Microstructure Control and Resultant Change in Mechanical Properties in High Entropy Alloys**

Nobuhiro Tsuji, Tilak Bhattacharjee, Yu Bai, Nokeun Park, Shu Kurokawa, Pinaki Bhattacharjee, Rajeshwar R. Eleti and Shuhei Yoshida; 1Department Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Elements Strategy Initiative for Structural Materials, ESISM, Kyoto University, Kyoto, Japan; 3School of Materials Science and Engineering, Yeungnam University, Gyeongsan, Korea (the Republic of); 4Department Metallurgical and Materials Engineering, Indian Institute of Technology Hyderabad, Hyderabad, India.

High entropy alloys (HEAs) have a large capability for microstructure control through thermo-mechanical processing, since they are mainly composed of solid solution phases that are stable and deformable at wide range of temperatures. However, HEAs have been mostly studied in their as-cast or even as-homogenized states. In this presentation, some examples of microstructure controls in several kinds of HEAs are introduced. For example, fully-recrystallized ultrafine-grained microstructures with mean grain sizes of 200–400 nm could be obtained in CoCrFeMnNi and CoCrNi alloys. Such fine grain sizes are interesting from a viewpoint of nucleation of recrystallization. The ultrafine-grained HEAs showed very high yield strength compared with their coarse-grained counterpart, still maintaining excellent strain-hardening ability after yielding, which led to nice combinations of high strength and large tensile ductility. We have also succeeded in microstructure control in a eutectic HEA, AlCoCrFeNi2:1, through various thermo-mechanical processes and in enhancing the strength keeping adequate ductility.

**4:00 PM PM04.04.02**

**Design of Non-Equiatomic FeNiCoAl-Based High Entropy Alloys with Heterogeneous Lamella Structure Towards Strength-Ductility Synergy**

Cheng Zhang, Chaoyi Zhu, Tyler Harrington and Kenneth Vecchio; 1Materials Science and Engineering Program, University of California San Diego, La Jolla, California, United States; 2Department of NanoEngineering, University of California San Diego, La Jolla, California, United States.

Two non-equiatomic FeNiCoAl-based high entropy alloys (HEA) with heterogeneous lamella (HL) structures are fabricated through conventional thermomechanical processing. In the HL microstructure, fine-grain regions result from inhibited grain growth due to Zener pinning of boundaries by NiAl (B2) precipitates, while of coarse grained regions originate from grain growth within large deformation bands in the absence of precipitates. A back-stress strengthening mechanism, unique to deformation of heterogeneous microstructures, is verified through electron backscatter diffraction enabled geometrically necessary dislocation (GND) density analysis. Macroscopically, back-stresses in the current two HEAs with HL structures are measured from the loading-unloading-reloading experiment. This mechanism gives rise to the combination of both high strength and high ductility in HL-HEAs.

**4:15 PM PM04.04.03**

**Microstructural Design to Improve the Mechanical Properties of an Interstitial TRIP-TWIP High-Entropy Alloy**

Jing Su, Z. Li and Dierk R. Raabe; Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany.

High-entropy alloys (HEAs) have drawn considerable attention nowadays not only due to their massive solid solution structures and partly good mechanical properties but also for the reason that the concept uncovers a vast compositional space for future alloy development. Here we present a novel strategy of employing deformation-driven hierarchical microstructure design to enhance the mechanical properties of an interstitial carbon doped HEA. This is to combine the benefits of designing specific microstructure features with the compositional advantages of HEAs. The as-cast alloy was subjected to a sequence of thermo-mechanical processing including hot-rolling, homogenization, cold-rolling and tempering/annealing. A single FCC phase bimodal grain structure was obtained in the tempered specimen containing nano-grains (~50 nm) and large parent grains (10-35 μm) with pre-existing nano-twins.
Trinodal microstructures were produced upon annealing characterized by small recrystallized grains (<1 μm) associated with shear bands, medium-sized grains (1-6 μm) recrystallized through subgrain rotation or coalescence of parent grains, and retained large subgrain or plastic grains. A superior yield strength of 1.3 GPa with an acceptable ductility (~14%) was achieved in the bimodal microstructure owing to the presence of nano-sized grains and nano-twins. In the trinodal microstructures, the ductility was dramatically improved (~60%) compared to the bimodal structures due to the appearance of a multi-stage work hardening behavior. This important strain hardening sequence was attributed to the sequential activation of transformation-induced plasticity (TRIP) and twinning-induced plasticity (TWIP) effects as a result of the wide variation in phase stability promoted by the grain size hierarchy.

4:30 PM PM04.04.04 Pressure-Induced Phase Modifications in Al-Based High-Entropy Alloys Al_{x}CoCrFeNi (x=0.1, 0.3, 0.75, 1.5) Chenzhu Wang1, Cameron L. Tracy1, Suliye Park1, Chien-Hung Chen1, Tengfei Yang2, Congyi Li2, Yuguang Wang1, Yong Zhang1, Wendy L. Mao1 and Rodney C. Ewing1; 1Stanford University, Stanford, California, United States; 2The University of Tennessee, Knoxville, Tennessee, United States; 1Peking University, Beijing, China; 4University of Science and Technology Beijing, Beijing, China.

Pressure-induced structural modifications in high-entropy alloys with varying Al content, Al_{x}CoCrFeNi (x=0.1, 0.3, 0.75, 1.5), have been investigated at pressures up to ~50 GPa by synchrotron X-ray diffraction and transmission electron microscopy (TEM). In Al_{x}CoCrFeNi compounds with x<0.3, all of which exhibit initial pure fcc structures, the proportionality between the Al content and the transformation pressure is observed. This is attributed to the large size of Al atoms relative to those of the other constituent elements, which leads to more structural distortion in Al_{x}CoCrFeNi and subsequently an increase in the formation energy of the stacking faults. High-resolution TEM results show the variation of the stacking sequence from ABCABC (fcc) to ABABAB (hcp) in Al_{x}CoCrFeNi following exposure to high pressure. In Al_{x}CoCrFeNi, which exhibits an initial dual-phase structure, the result again shows the transformation to an hcp phase despite its higher Al content, which might be due to the presence of the bcc phase that is more amenable to the pressure-induced phase modification. However, the trend of transformation inhibition by increasing Al content is again observed, with Al_{x}CoCrFeNi retaining its initial structures up to the highest pressure achieved. High-pressure processing of this class of high-entropy alloys might allow for improvement and producing phases that are otherwise inaccessible.

4:45 PM PM04.04.05 Structural Screening of FCC and BCC Thin-Film HEAs Using Compositional Gradient Samples Azin Akbari, Artashes N. Ter-Ishahkayan and John Balk; University of Kentucky, Lexington, Kentucky, United States.

Combinatorial thin film samples of CrMnFeCoNiCu and TiVNbMoW were prepared by simultaneous magnetron sputtering of the alloying elements onto silicon wafer substrates. This arrangement yielded a wide composition gradient in the films and resulted in the formation of multiple phases. Some film regions exhibited the desired single-phase high-entropy alloy (HEA), albeit with non-stoichiometric compositions. In order to determine the extent of phase stability for these potential HEAs, multiple characterization techniques were utilized. Microstructure and composition of thin film samples were characterized via scanning electron microscopy and x-ray energy dispersive spectroscopy. Single-phase FCC and BCC regions were detected in the samples by x-ray diffraction and electron backscattered diffraction analysis. Mechanical properties of these alloys were screened across the composition range as well, using nanoindentation. Based on the results of this combinatorial approach, potential single-phase FCC and BCC HEAs were determined. Additionally, these alloys were cast in bulk form via arc-melting followed by thermomechanical processing, which yielded a homogeneous HEA in the FCC CrMnFeCoNiCu system.

PM04.05.01 Microstructure, Mechanical Properties and Wear Performance of Ultrafine-Grained CrFeNi-Based Medium Entropy Alloys Fuzeng Ren, Dingshan Liang, Weiwei Zhu and Canzan Zhao; Department of Materials Science and Engineering, Southern University of Science and Technology, Shenzhen, China.

Distinct from traditional alloy design strategy, metallic alloys with nearly equiatomic multi-principle elements, frequently referred to high-entropy alloys (HEAs), have attracted considerable interests in the materials science community as a new class of engineering materials with the unique mechanical properties. However, most of the present HEAs consist of coarse grained microstructure. Here, we have fabricated an ultrafine-grained (UFG) equiatomic medium entropy alloy (MEA) CrFeNi by a combination of mechanical alloying and spark plasma sintering. The obtained bulk CrFeNi consists of 98% FCC-based solid solution phase with an average grain size of ~740 nm and 2% BCC Cr-rich precipitates with the grain size of ~450 nm located at the grain boundaries. A close examination further reveals that the FCC-matrix consists of a Ni-rich zone and a Cr-rich zone. Such UFG CrFeNi alloy has tensile yield strength of ~650 MPa with elongation to ~30%. To further enhance its mechanical properties, 5 at% Nb was added to the CrFeNi matrix after which the strength was significantly increased to ~800 MPa and the hardness was increased from 390 HV to 540 HV. We then systematically investigated the tribological performance of the two alloys at elevated temperatures. The fabricated CrFeNi based MEAs have shown a comparable high temperature wear performance to that of the Inconel 718 superalloy. Based on an in-depth characterization on the worn surface morphology, wear debris and subsurface microstructures formed during wear, the wear mechanism was discussed. Due to an excellent combination of strength, plasticity and high temperature wear performance, the fabricated UFG CrFeNi-based MEAs are promising candidates as a new class of high temperature alloys.

PM04.05.02 Bicontinuous BCC HEA/Cu Nanocomposite Made by Liquid Metal Dealloying Process Kooknoh Yoon, Ilhwan Kim and Eun Soo Park; Seoul National University, Seoul, Korea (the Republic of). Due to its high melting point, high sputtering resistance, low deuterium/tritium retention, and high thermal conductivity, tungsten has been recognized as the most promising candidate of plasma facing materials (PFMs) for fusion reactors. Meanwhile, copper based alloys have been proposed as the heat sink materials behind the plasma facing material due to its excellent thermo-mechanical properties. The joining of W to copper based heat-sink (CuCrZr) remain a main problem in the development of plasma facing component (PFC) due to the large difference in the coefficient of thermal expansion (CTE) between these two materials.
On the other hand, refractory high entropy alloys (RHEA) containing W, Nb, Mo, Ta etc. is reported recently. This multi-component system exhibits higher strength and vice versa due to solid solution strengthening and lower ductility against neutron irradiation damage. In this research, therefore, we fabricated composites of RHEA and Cu by liquid metal dealloying (LMD) process. To utilize this technique, we prepared a precursor material which contains elements having positive and negative enthalpy of mixing with Cu simultaneously, and we immersed it into high-temperature liquid copper to form bi-continuous composite material. Finally, we analyze strength and thermal conductivity of the composite systematically.

**PM04.05.03**

Spacegroup Monte Carlo Method Applied on Configurational Entropy of High Entropy Alloys

Yu Cheng Chen, Guan-Rong Huang, J.P. Chou, Peter K. Liao, J.W. Yeh and Alice Hu;
Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; Physics Division, National Center for Theoretical Sciences, Hsinchu, Taiwan; Department of Mechanical and Biomedical Engineering, City University of Hong Kong, Hong Kong, Hong Kong; *The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; *Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu, Taiwan.

Researchers have calculated alloy configurational entropy with ideal gas mixing formula regardless of the intrinsic structure symmetry. How to define configurational entropy precisely for multi-component crystalline system is a tough question. The commonest topic related to such problem is using model which has only two kind of states (spin up/down) in the system. However, it becomes much more difficult to solve if we have more states in a system such as complicated compositions in high entropy alloys (HEAs). How can we deal with it? Here we develop an innovative method to solve this troublesome problem. By using the concepts in group theory and discrete mathematics, we can simplify the problem into Pólya counting problem. We also implement Monte Carlo method which speeds up computation time with just a little deviation from exact solution. And we will demonstrate how to apply this method to distinguish the configurational entropy for different structures of HEAs.

**PM04.05.04**

Tailoring Strength and Ductility of Non-Equiatomic Ti-V-Nb-Ta-Mo High Entropy Alloys

SangJun Kim, Hyunseok Oh and Eun Soo Park; Seoul National Univ, Seoul, Korea (the Republic of).

Recently, high entropy alloys (HEAs) with BCC structure composed of group-4 to group-6 elements (Ti, Zr, Hf, Y, Nb, Ta, Cr, Mo and W) were reported exhibit superior mechanical properties at high temperature above 1000 °C comparing Ni-based superalloy. However, it is known that the HEAs containing group-6 refractory elements (Mo and W) suffer from poor ductility at room temperature, while HEAs without group-6 refractory elements have high ductility at room temperature but show poor strength at high temperature. In this study, we investigated mechanical behavior of HEAs depending on the composition to develop HEA with high strength at high temperature and favorable ductility at room temperature. It is known that valence electron concentration (VEC) of BCC alloys has negative relationship with ductility, but elements with high valence electron (Mo and W) are responsible for high strength of the alloy. To balance the strength and ductility, Ti-V-Nb-Ta-Mo system, whose VEC is 5.0 in equiatomic composition, was selected. HEAs in equiatomic and non-equiatomic composition in the system were predicted to form single BCC phase by CALPHAD (calculation of phase diagram) approach, and experimentally confirmed to have single BCC phase. Mechanical properties of the HEAs were quantitatively analyzed in terms of VEC and solid solution hardening. The results could provide an effective guideline for tailoring mechanical properties of high entropy alloy with bcc structure, and developing promising HEAs for high temperature structural materials.

In Situ Grown Nanocrystalline High Entropy Alloy Oxide Particles on Reduced Graphene Oxide as Hybrid Electrode Material for Supercapacitor

S. Ramanruthu and Manita Sham Lal; Department of Physics, Indian Institute of Technology Madras, Chennai, India.

Supercapacitors are considered as one of the most promising electrochemical energy storage due to their high power density, large charge/discharge rates and long cycle life. A Hybrid electrode material is mainly a nanocomposite of carbon based nanomaterials and metal oxide nanoparticles. Reduced graphene oxide with high surface area and high conductivity shows electrical double layer capacitance behaviour whereas high entropy alloy oxides (HEAO) constructed with of five or more metal with equal or nearly equal quantities, shows pseudocapacitive behaviour. In this work, we successfully synthesized a novel hybrid electrode material, (CoCrCuNiAl) oxide nanoparticles uniformly embedded on reduced graphene oxide sheets (rGO) by simple in-situ sol-gel auto combustion method. The mixed (bcc and fcc) phase of the HEAO nanoparticles is confirmed from X-Ray Diffraction pattern while microstructure is studied using Transmission electron microscopy (TEM) wherein the average size of CCCNOA nanoparticle is ~20 nm. A solid-state supercapacitor with CCCNOA nanoparticle as electrode material is fabricated and the electrochemical energy storage performance is discussed.

Microstructure of a New Type of Co and Ni Based High Entropy Alloys

Daniel Laipple, Andreas Stark, Marcus W. Rackel and Florian Pyczak; Helmholtz-Zentrum Geesthacht, Geesthacht, Germany.

One frequent definition for High Entropy Alloys (HEA) is a material of single phase, this single phase being a solid solution of four or more alloying elements which are mixed in nearly equal content. Probably, partly due to the difficulty of generating such single phase materials this concept is often not followed strictly, by allowing certain amounts of a second phase which is often of an ordered intermetallic type. Along similar lines as for the single phase HEAs consisting of ordered phases can be designed. Instead of the whole single phase being of equiatomic composition of all alloying elements in the ordered phase, the principle can be applied on the sublattices of the ordered phase. Then all alloying elements occupying one sublattice have to be present on this sublattice in nearly equiatomic content. The resulting alloys are termed MOCCA standing for Multiphase and/or Ordered Constitutionally Complex Alloy. For their design pre-knowledge about the partitioning behavior of alloying elements between the different phases but also between the different sublattices is necessary. We studied initially the characteristics of six different such MOCCA high entropy alloys: (1) 77Co-8Al-8W-7Ta, (2) 77Co-6Al-6W-6Ta-6Ti, (3) 38.5Co-38.5Ni-6Al-6W-6Ta-5Ti, (4) 77Co-10Al-13W, (5) 38.5Co-38.5Ni-10Al-13W and (6) 77Co-8Al-8W-7Ti which were all based on the L12-Co3(Al,W) ordered phase. Information about partitioning between phases and sublattices is available from experimental and theoretical investigations and was used to design the alloys. The samples are manufactured by arc melting and were annealed at 1300°C for 12 h under Ar atmosphere respectively. Due to the results of the SEM investigations including EDX analysis, the compositions (3) and (6) were refined in a second step by (7) 36Co-39Ni-6.5Al-6W-6Ta-6Ti and (8) 77Co-9.5Al-9.5W-7Ti in order to achieve a single phase constitution. Again by evaluating the SEM results composition No (7) was refined in a third step by (9) 39Ni-37Co-7Al-7Ti-7Ta-3W.

High-Entropy Ceramics of Five-Component, Equimolar, Rare-Earth (RE) Oxides

Kuo-Pin Tseng and Waltraud M. Kriven; Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.
To investigate the influence of cation radii on synthesizing high-entropy ceramics, a new system of five-component high-entropy oxides are reported here. Much research has been conducted in defining high-entropy alloys. However, the cation selection rules for high-entropy ceramics are still unclear. In this research, four rare-earth (RE) cations were selected and fixed. The fifth cation with larger radius was chosen from another set of eight different rare-earth (RE) cations. According to the rules of thermodynamics, each group of five cations were mixed in equimolar ratios to maximize the mixing entropy. Using the concept of atomic size difference (6) in high-entropy alloys, the cation radii difference in this system ranges from 1.25 to 3.71. Synchrotron-sourced X-ray powder diffraction patterns were measured here. The results show that all of these eight rare-earth (RE) candidates change into simple disordered high-entropy oxides after heat treatment. This indicates that the well-distributed cations in cubic-bixbyite structure are established in each group of candidates. Even though the radius of the largest cation is 1.16 times larger than that of the smallest one, all these cations still uniformly share the same lattice sites. Meanwhile, high-entropy oxides have the ability to keep all the cations in the same oxidation states. As we all know in oxides, some of cations tend to transform between trivalent states and tetravalent states under different conditions of temperature and pressure. Surprisingly, the high-entropy configuration can prevent the same type of cation from moving and aggregating. As a result, the valence states of all the trivalent cations are retained. This research provides a preliminary guideline of cation selection for synthesizing high-entropy ceramics in order to explore the next generation of structure-stabilized ceramics.

Ordering in a Series of Al-Containing Refractory High Entropy Alloys Ta-Nb-Mo-Cr-Ti-Al Alexander Kauffmann1, Hans Chen4, Sascha Seils4, Torben Böll1, Sandra Kaufmann-Weiss2, Ian Harding1, Sharan Kumar1, Dorothée Vinga Szabo31, Sabine Schlachetski1, Christian H Liebscher1, Franz Müller1, Bronislava Gorč1, Hans-Jürgen Christ1 and Martin Heinmaier3, 1Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; 2Institute for Technical Physics (ITEP), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; 3School of Engineering, Brown University, Providence, Rhode Island, United States; 4Institute for Applied Materials (IAM-WK), Karlsruhe Institute of Technology (KIT), Karlsruhe, Germany; 1Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany; 2Institut für Werkstofftechnik, Universität Siegen, Siegen, Germany.

High entropy alloys (HEAs) based on the Ta-Nb-Mo-Cr-Ti-Al system are expected to possess high creep and oxidation resistance as well as outstanding specific mechanical properties due to comparably low density. However, we recently reported that these arc-melted and subsequently homogenized alloys exhibited a lack of ductility up to 600 °C depending on the specific alloy composition [H. Chen et al. in Metall. Mater. Trans. A 49 (2018) 772-781 and J. Alloys Compd. 661 (2016) 206-215]. In this presentation, we provide the results of comprehensive microstructural characterization of a series of Ta-Nb-Mo-Cr-Ti-Al derivatives for assessing ordering as potential origin for the observed lack of ductility. Backscatter electron imaging (BSE), energy dispersive X-ray spectroscopy (SEM-EDX and STEM-EDX) and atom probe tomography (APT) were used to prove uniform element distribution after homogenization in these alloys. X-ray diffraction patterns (XRD) of the Ta-free derivatives indicated W prototype crystal structure without the presence of significant superlattice peaks, whereas TEM diffraction experiments confirmed B2 order. The presence of thermal antiphase domain boundaries (APDBs) suggested that order resulted from a disorder-order solid-state phase transformation during cooling from the homogenization temperature. In MoCrTiAl, these APDBs were enriched in Cr and depleted in Ti as confirmed by STEM-EDX line scans as well as APT analyses. Based on these results, we present an experimental approach to determine the site occupation factors in order to refine the experimental XRD patterns of these alloys. These refinements provide the basis for a critical discussion of the conflicting absorption factors in XRD patterns in some HEAs while order is revealed by other techniques.

PM04.05.10
Possible Correlation Between Strength and Mean Square Atomic Displacement in Cr-Mn-Fe-Co-Ni High Entropy Alloys Makoto Asakura1, Kodai Niitsu1, Norihiko L. Okamoto1, Koretaka Yuge1, Kyosuke Kishida1, Haruyuki Inui1, Takashi Fukuda4 and Tomoyuki Kakeshita1, 1Center for Elements Strategy Initiative for Structural Materials (ESISIM), Kyoto University, Kyoto, Japan; 2Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 3Institute for Materials Research, Tohoku University, Sendai, Japan; 4Division of Materials and Manufacturing Science, Osaka University, Osaka, Japan.

High entropy alloys (HEAs) are equiatomic or nearly equiatomic solid solution alloys consisting of at least five elements, which crystallize into a single phase presumably due to the large contribution of configurational entropy to the Gibbs free energy. The equiatomic Cr-Mn-Fe-Co-Ni HEA with the face-centered cubic (FCC) structure has been reported to exhibit excellent ductility and exceptional fracture toughness at cryogenic temperatures. To date, these properties in HEAs have been explained within the framework of the classical theories of solid solution strengthening. However, the classical derivations for binary dilute alloys, such as Fleischer’s and Labusch’s models, are not applicable to HEAs because solute atoms in HEAs are no longer discernible. Very recently, Mean-Square Atomic Displacement (MSAD) is suggested to be a new parameter scaling the degree of solid solution strengthening. This is a value of lattice distortion averaged across whole crystal, and is evaluated by ab initio calculation with Special Quasi-random Structure (SQS) models. For polycrystalline equiatomic HEA and its derivatives, the positive correlation between their yield strength and MSAD0.5 values was reported [1]. However, since the yield strength in the form of polycrystals is anticipated to be perturbed by the grain boundaries and textures, critical resolved shear stress (CRSS) of the HEA crystal should be assessed with single crystals. In the present study, we fabricated single crystals of Cr-Mn-Fe-Co-Ni HEAs and its derivatives with which the composition of only one element is changed and the other four elements’ compositions are equiatomic by the Bridgeman method. Compression tests were performed on rectangular parallelepiped single crystals with the size of 2×2×5 mm3 with the [−123] loading axis at an engineering strain rate of 1.0×10−5 s−1 and at temperatures from 13K to 298K. MSAD values were calculated by ab initio method with SQS models. Bulk single crystals are successfully grown for all compositions. Positive linear relationship between CRSS and MSAD0.5 is elucidated as is previously reported for the relationship between yield stress and MSAD0.5 in the HEA polycrystals. In addition, this relationship is found to be even for non-equiatomic HEA derivatives; MSAD is anticipated to be an essential parameter scaling the degree of solid solution strengthening of broader class of FCC multi-component alloys.

PM04.05.11
Anomalous X-Ray Scattering Study of the Local Structure of Mo Atoms in FeCoCrNiMox (x = 0.11 and 0.23) High Entropy Alloys Haiyan He1, Bang Wang1, Si Lan2, Jacob Ruff1, Chen Tian Lin1 and Xin-Li Wang4, 1Physics, City University of Hong Kong, Hong Kong; 2Hong Kong University of Science and Technology, Hong Kong; 3Herbert Glieiter Institute of Nanoscience, School of Materials Science and Engineering, Nanjing University of Science and Technology, Nanjing, China; 4Cornell High Energy Synchrotron Source, Cornell University, Ithaca, New York, United States; 5Mechanical and Biomedical Engineering, City University of Hong Kong, Hong Kong, Hong Kong.

High entropy alloys which contain 5 or more elements often have a rather simple structure like body-centered-cubic (BCC) or face-centered-cubic(FCC). In spite of the simple average crystalline structure, the local atomic order of individual atomic species has remained an open question. In this study,
anomalous X-ray scattering was applied to determine the local structure of Mo in FeCoCrNiMox (x = 0.11 and 0.23), a high entropy alloy with FCC lattice. At the Mo absorption edge, the intensity of all diffraction peaks decreased, by nearly identical amount. Detailed analysis of the experimental data confirms that Mo atoms are randomly distributed instead of locally segregated in the FCC lattice.

The work was supported by the grant from the Research Grants Council of the Hong Kong Special Administrative Region [CityU 11215917]. Anomalous X-ray scattering was conducted at station A2, Cornell University, Cornell High Energy Synchrotron Source.

PM04.05.12
Plastic Deformation of Single Crystals of a Cr-Co-Ni Equiatomic Medium Entropy Alloy Kazuaki Fujihara1, Makoto Asakura1, Kodai Niitsu1, Haruyuki Inui1

Medium/high entropy alloys are a class of multi-component solid solution alloys with (nearly) equiatomic compositions, which are considered to be stabilized because of the large contribution of configurational entropy to the Gibbs free energy. Some of these alloys exhibit exceptional mechanical properties that their tensile elongation and fracture toughness increase with decreasing temperature simultaneously. Among various medium/high entropy solid solution alloys discovered so far, the Cr-Co-Ni equiatomic solid solution alloy with the face-centered cubic (FCC) structure has been reported to exhibit both the highest strength and highest elongation in a polycrystalline form. However, the detailed mechanisms endowing the excellent mechanical properties to the Cr-Co-Ni equiatomic alloy remain unclear in many aspects mainly because of the lack of fundamental studies using single crystals. In the present study, we prepared single crystals of the Cr-Co-Ni equiatomic solid solution alloy by directional solidification in an optical floating zone furnace and investigated the deformation behavior of the [-123]-oriented single crystals under uniaxial tensile and compressive loading as a function of temperature (13K to 1073K). Temperature dependence of the activation volume were investigated by strain rate change compression tests (1×10\(^{-5}\) to 5×10\(^{-3}\) s\(^{-1}\)). Stress-strain curves obtained from tensile tests at low temperatures exhibit a widely extended easy-gliding region (stage I) when it is compared to that for the Cr-Mn-Fe-Co-Ni equiatomic solid solution alloy. This is considered to reflect a relatively low stacking fault energy for the Cr-Co-Ni equiatomic alloy. The critical resolved shear stress (CRSS) of the Cr-Co-Ni equiatomic alloy is higher than that of the Cr-Mn-Fe-Co-Ni equiatomic alloy. The CRSS value increases significantly with decreasing temperature below room temperature and with increasing temperature above 873K. Activation volume of the Cr-Co-Ni equiatomic alloy is found to be much lower than those of binary FCC solid solution alloys.

PM04.05.13
Effect of Impurity Solute Atoms on Strength of α-Al (fcc) Single-Crystal Micropillars Soichiro Takeyasu, Naoki Takata, Asuka Suzuki and Makoto Kobashi; Department of Materials Process Engineering, Nagoya University, Nagoya-shi, Japan.

High-entropy alloys (HEAs) exhibit high ductility and strength and toughness with decreasing temperature, and it is widely known that CrMnFeCoNi is the fcc structure and maintains its single-phase, solid solution state at elevated temperatures. N. I. Okamoto et al. have recently demonstrated that single-crystal micropillars prepared from the HEA exhibit the size dependence of shear stress for the initial slip, which corresponds to pure fcc metals (Ni, Cu and Al). The study indicates the size dependence of strength would be independent of solid-solution atoms in fcc metals. In contrast, the size dependence of strength was scarcely reported in fcc solid-solution phases, whereby the influence of solid-solution atoms on the size dependence has not yet been elucidated even in fcc metals. In the present study, focusing on the commercial purity aluminum (2N purity) containing Fe and Si elements as impurity solute atoms, we have attempted to clarify the influence of trace solute atoms on the measured strength of microscale-sized pure aluminum. We have fundamentally examined the compression response of α-Al (fcc) single-crystal cylindrical micropillars with different diameters (approximately ranging from 1 to 10 μm) prepared on the sample surface of 4N and 2N purity Al sheets with the recrystallized microstructure. Micropillars were fabricated by FIB and compressed by the nanoindentation systems attached the flat punch (ϕ=20 μm). Slip systems were identified by crystal orientation analysis using electron back-scattering diffraction (EBSD) and scanning electron microscopy (SEM) observation. The compression tests for micropillars with various sizes demonstrated the flow stress of micropillars increases with decreasing pillar diameter. In the case of 4N purity Al, the observed size dependence of resolved shear stress for slip corresponds well to the previous studies on micropillars prepared from 5N and 3N purity Al sheets. The measured shear stress resolved onto a primary slip system (s) scaled by shear modulus (G) and the pillar diameter (d) scaled by Burgers vector (b) show the following correlation: \(\tau_s/G = 0.33d/b^{0.06}\). In the case of 2N purity Al, the size dependence of resolved shear stress is smaller than that observed in higher purity Al (5N, 4N and 3N). The resolved shear stress shows the following correlation with the normalized pillar diameter: \(\tau_s/G = 0.0062d/b^{0.19}\). These results indicate that the impurity solute atoms in pure Al would reduce the size dependence of strength. In the presentation, we will present the dislocations inside the micropillars observed by transmission electron microscopy (TEM) and discussed on the observed size dependence utilizing the single-arm dislocation source model. Furthermore, we will report the compression response of single-crystal micropillars of α-Al (Mg) solid-solution phases.

PM04.05.14
Micropillar Compression Deformation of Single-Crystal in CrMnFeCoNi High-Entropy Alloy Norihiko I, Okamoto1,5, Shu Fujimoto1, Yuki Kambara1,2,3,4,5, Hirokata Matunoshita1, Katsumi Tanaka1, Haruyuki Inui1,2 and Easo P. George2; 1Department of Materials Process Engineering, Nagoya University, Nagoya-shi, Japan; 2Center for Elements Strategy Initiative for Structural Materials, Kyoto University, Kyoto, Japan; 3Kobe University, Kobe, Japan; 4Center for Elements Strategy Initiative for Structure Materials, Kyoto, Japan; 5Ruhu University Bochum, Bochum, Germany.

High-entropy alloys (HEAs) comprise a novel class of scientifically and technologically interesting materials. Among these, equiatomic CrMnFeCoNi with the face-centered cubic (FCC) structure is noteworthy because its ductility and strength increase with decreasing temperature while maintaining outstanding fracture toughness at cryogenic temperatures. However, plastic deformation behavior has not been fully characterized, due to the difficulty of obtaining large single crystals of the HEA. Recent years, a method for micro-compression testing of single-crystal pillars prepared by focused ion beam (FIB) machining, making further investigation of plastic deformation behavior in HEA possible, has been developed. In the present study, we investigate the plastic deformation behavior of single crystals of the CrMnFeCoNi HEA by performing compression tests on micropillars at room temperature as a function of specimen size and crystal orientation, in order to deduce its bulk CRSS value and orientation dependence. We also characterize deformation mechanisms at low homologous temperatures by investigating the deformation behavior of bulk polycrystals at room temperature and 77K. Dislocation structure in a specimen deformed at 77K is investigated with Transmission electron microscopy (TEM). Stacking fault energy is thus deduced from the separation distance between the Shockley partials. The critical resolved shear stress (CRSS) in room temperature with bulk size is estimated to be ~33–43 MPa, ~10 times higher than that of pure nickel. CRSS depends on pillar size with an inverse power-law exponent of ~0.63, which is within the range reported in FCC metals (~0.5 to ~1.0) but close to the lower bound, and independent of orientation. The relatively low exponent of power-law in HEA corresponds to the high CRSS value, compared to those of the FCC metals. No orientation dependent is confirmed. Dislocations are smoothly curved without any preferred line orientation indicating no significant anisotropy in mobilities of edge and screw segments. Planar \(\frac{\pi}{2} < 111\) dislocations dissociate into Shockley partials whose separations range from ~3.5–4.5 nm near the screw rotation to ~5–8 nm near the edge, yielding a stacking fault energy of 30 ± 5 mJ/m². Although the stacking fault energy in HEA is not particularly low, compared to certain FCC alloys (e.g. Cu-Al binaries), the separations can be relatively large, due to its relatively high shear modulus. The large separation distance may account for the difficulty in cross slip and for the occurrence of deformation twinning at low
The shear-modulus-normalized CRSS of the HEA is not exceptionally high compared to those of certain concentrated binary FCC solid solutions. Its rough magnitude calculated using the Fleischer/Labusch models corresponds to that of a hypothetical binary with the elastic constants of our HEA, solute concentrations of 20–50 at.%, and atomic size misfit of ~4%.

Irradiation Behaviour and Response of High Entropy Alloys

Hongjun Fu1, Maak K. Patel1, Anna Kareer1, Karl Dawson1 and Karl R. Whittle1; 1University of Liverpool, Liverpool, United Kingdom; 2Materials, University of Oxford, Oxford, United Kingdom.

High Entropy Alloys (HEAs) have attracted interest within the nuclear context due to their predicted properties, and potential for tolerating radiation damage to high levels. The continued revolution of nuclear energy, coupled with increased utilisation of fuel, and reactor materials requires continued development of materials capable of tolerating high levels of induced damage within the core. Such increased utilisation of reactor materials, whether it be as cladding or as componentry within the core, can lead to enhanced operations of the reactor, with the potential for lifetime extensions of LWRs.

To this end we have studied four model HEAs Co1.5CrFeNi1.5Ti0.5Mo0.1, TaNbHfZrTi, AlCoCrFeNiSi0.1, and CoCrCuFeNi, for use within reactor cores. The impacts of radiation damage have been examined using ions as proxies for neutron damage. After irradiation with Au, Ni and He, the degree of damage has been examined by electron microscopy (SEM, TEM and EDX) to elucidate the microstructural changes, and grazing incidence X-ray diffraction (GIXRD).

High Entropy Alloys Beyond Configurational Entropy

Jorg U. Neugebauer, Fritz Koermann, Blazej Grabowski, Yuji Ikeda and Tilmann Hickel; Max-Planck-Institut fuer Eisenforschung, Duesseldorf, Germany.

The name-giving entropy contribution in high entropy alloys is configurational entropy. However, configurational entropy is only one out of several entropic contributions. In a real alloy electronic, magnetic, vibrational entropy, as well as local chemical order or defects can also play a role. Presently, the relevance of these contributions for the phase stability of bulk alloys, but also for deformation mechanisms such as the formation of stacking faults or twins, remains largely unknown. Combining ab initio calculations with advanced thermodynamic methods and statistical sampling approaches we are able to accurately determine the various contributions. A detailed analysis of the results shows that the conventionally assumed dominance of the configurational entropy is in general not valid. Thus, for a realistic description of the bulk phase stability, but also to identify suitable process conditions or alloy compositions - e.g. by adding interstitial atoms such as C - the various entropic contributions have to be included. Examples of quinary magnetic high entropy alloys where this approach has been successfully employed will be given.

9:00 AM **PM04.06.02**

From Symmetry to Entropy—An Inconvenient Truth of Crystal Configurational Entropy

C.H. Hu1, Yu Cheng Chen1, K.Y. Fung1, Peijun Yu1, Peter K. Liaw2, J.W. Yeh3 and Alice Hu4; 1City University of Hong Kong, Kowloon, Hong Kong; 2National Taiwan University, Taipei, Taiwan; 3National Chiao Tong University, HsinChu, Taiwan; 4The University of Tennessee, Knoxville, Tennessee, United States; 5National Tsing Hua University, HsinChu, Taiwan.

All along, researchers calculated configurational entropy with ideal gas mixing formula regardless which structure they are considering. However it is obvious that crystalline has symmetry while ideal gas does not. Therefore the very same ideal gas mixing value should not be assigned for all the other structures, such as body-centered-cubic (BCC), face-centered-cubic (FCC), hexagonal-close-packed (HCP), and others. Here we will show a precise definition how to determine configurational entropy for crystalline. Based on Burnside’s lemma in combinatorial mathematics and crystalline rotation-point-group, we successfully present the configurational entropy difference between FCC and HCP. This is the first time in thermodynamic science that we know how to distinguish configurational entropy differences, which cannot be known from density functional theory, molecular dynamics, or any other computational method. Therefore this result will initiate a whole new revision of all the entropy related theorem in all kinds of disciplines including calculations of phase stability in thermodynamic physics, diffusion in material science, molecule symmetry in chemistry, DNA entropy in biology, and even statistical mechanics. Included this research, we apply our result to explain a crucial example that how high entropy alloy phase transformation starts at cryogenic temperature from nanoscale region. This also indicates conventional physical metalurgy theorem may require serious modification efforts before appropriate application on HEAs.

Entropy Contributions to Phase Stability in Random Solid Solutions

Anus Manzoor1, Shubham Pandey2, Simon R. Phillpot2 and Dilipaneet S. Aidhy2; 1University of Wyoming, Laramie, Wyoming, United States; 2University of Florida, Gainesville, Florida, United States.

High entropy alloys (HEAs) contain multiple elements in large proportions that make them prone to phase separation. In the overall vision of designing HEAs for structural applications, in this work, using density functional theory (DFT) calculations, we elucidate the contributions of various entropies, i.e., vibrational, electronic and configurational towards the phase stability of random alloys. Taking examples of various alloy systems, we show that the entropy contributions could be quantitatively comparable to the mixing enthalpy; as a result including the entropy contributions is critically important in correctly predicting the alloy phase stability. We also show that while the configurational entropy always favors phase stability by reducing the Gibbs free energy, the role of vibrational entropy is not predictable. The configurational and vibrational entropies can either compete to destabilize or can collectively contribute to stabilize the solid solutions. As a result, even those systems that have negative mixing entropy can show phase instability revealed as a miscibility gap; conversely, systems with positive mixing entropy can have stable phases due to the entropic contributions. Finally, we show that the contribution of electronic entropy is minor compared to the other two entropies. This work contributes towards the computational framework necessary for predicting the correct phase stability of HEAs.

Deformation by Dislocations, Twinning, and Phase Transformations in Compositionaly Concentrated FCC Solid Solutions C. E. Slone, J. Miao, M. Ghazisaeidi and Michael J. Mills; Department of Materials Science and Engineering, The Ohio State University, Columbus, Ohio, United States.

The equiatomic NiCoCrFeMn alloy is an fcc solid solution that exhibits intriguing characteristics including very large strain hardening rates, large fracture toughness, and strong dependence of the yield strength at low temperature. These characteristics are closely linked to dislocation-mediated plasticity, yet little experimental work has explored dislocation dissociation, stacking fault energy, or core structures in these alloys. In this study, these dislocation characteristics have been determined in the NiCoCrFeMn alloy using scanning transmission electron microscopy techniques. In addition, substructure development at larger strain has been explored as a function of strain, and compared with the ternary NiCoCr equiatomic alloy. While twinning is prevalent at larger strains in NiCoCrFeMn, a transformation from the FCC structure to a fine-scale microtwin and hcp lath structure occurs in NiCoCr during large-strain deformation at room and cryogenic temperatures. In addition, first principles calculations using density function theory has been used to explore the relative phase stabilities and energy pathways for twinning and hcp phase formation. These modeling results are compared directly with atomic resolution scanning transmission electron microscopy evidence for these structures, and possible mechanisms by which they form are presented. In addition, the relationship of this phase transformation to the strength and work hardening behavior in these two alloys will be explored.

10:30 AM *PM04.07.02
Elastic Properties of Low, Medium and High Entropy Alloys with the FCC Structure Katsushi Tanaka, Takeshi Teramoto and Kazuki Yamada; Kobe University, Kobe, Japan.

Monocrystalline elastic constants of low, medium and high entropy alloys with the fcc structure have been analyzed systematically. According to our previous result, monocrystalline elastic constants of equiatomic quinary CrMnFeCoNi alloy show characteristic features indicating a relatively large elastic anisotropy and the existance of a strong directional interatomic interaction in the alloy. On the other hand, elastic constants of pure-Ni and FeNi low entropy alloy are analyzed as more metallic, that is a weaker directional interatomic interaction. In this study monocrystals of equiatomic low, medium and high entropy alloys with the fcc structure were grown by a modified Bridgeman method and the elastic constants were determined from liquid helium temperature to 1200 K using a ultrasound spectroscopy. The results show a systematic transition of the elastic properties from pure-metal to a high entropy alloy, though some scattering are observed depending on the alloying elements especially for midium entropy alloys.

10:45 AM *PM04.07.03
Study of Pseudo-Binary Diffusion in Single-Phase High-Entropy CrFeCoNi Alloys Adeline Durand1, Guillaume Laplanche1, Ying Yang2, Gunther Eggeler2 and Easo P. George2; 1Ruhr-Universität Bochum (RUB), Bochum, Germany; 2Materials Science and Technology Div, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

High-Entropy Alloys (HEAs) are single-phase alloys composed of multiple principal elements in relatively high concentrations. Consequently, traditional notions of solvent and solute do not apply, and it is not clear how this affects diffusion kinetics of the constituent elements. Sluggish diffusion is said to be an important characteristic of HEAs; however, it has been increasingly contested in recent years. The goal of this study is to investigate and better understand interdiffusion processes in HEAs.

We adopted the pseudo-binary model introduced by Tsai et al. [1] in which only two elements are diffusing against each other while the others are kept at a constant concentration. According to Tsai, in this situation, the interdiffusion, intrinsic and self-diffusion coefficients are assumed to be equal. In our experiments, all the constituent pseudo-binaries were studied at the same time with the help of suitable diffusion multiples. The following are our major results and conclusions:

(1) Up-hill diffusion was observed, proving that interactions between all constituent elements exist and should not be totally ignored in contrast to what was claimed in the model of Tsai et al. [1]

(2) No significant Kirkendall effect (voids or shift of initial interface) was noted, confirming that interdiffusion and intrinsic diffusion coefficients are indeed equal.

(3) The systematic study of all pseudo-binaries showed substantial differences between the diffusion speeds of a given element in different pseudo-binaries, which invalidates the assumption that intrinsic and self-diffusion coefficients are equal.

(4) Thermodynamic simulations are currently under way to rationalize our experimental observations.

In conclusion, even though some aspects of Tsai’s model have been disproven here and in the literature [2], the model still provides an efficient way to compare diffusion of elements in different conditions and can easily show the different interactions among them (e.g. whether certain elements enhance or slow down diffusion of others).

11:00 AM OPEN DISCUSSION

11:15 AM *PM04.07.05

High-temperature strength, toughness and oxidation resistance are exhibited by Ni-based superalloys. However, increasing the application temperatures for such alloys become problematic due to melting temperatures of around 1350°C. New class of materials that can withstand harsher conditions at elevated temperatures are therefore desirable.

High entropy alloys (HEA) based on refractory elements may achieve higher temperature operations with superior creep strength. At elevated temperatures, Mo based HEAs have been observed to exhibit good thermal and mechanical properties. Recently, a refractory Mo-W-Ta-Ti-Zr HEA was observed to exhibit greatly enhanced modulus of elasticity (3x at 300K) over near atomic cases and with higher moduli above 500K over commercial alloys (2.3x at 2000K).

In this study, periodic DFT and atomistic thermodynamic modelling is used to study the oxidation mechanisms in the Mo-W-Ta-Ti-Zr HEA. The special quasi-random structures (SQS) model was used to generate random structures in combination with the VASP DFT package. A Monte Carlo algorithm implemented in the ATAT package is used to match the correlation functions in the random structures for pairs up to the seventh nearest neighbor shells, triplets up to the fourth nearest neighbor shells and quadruplets up to the third nearest neighbor shells. The best representative random structure as shown in the figure below is used to create different surfaces and the most stable surface selected based on the calculated surface energy. The stable facets are subsequently reacted with oxygen to gain a detailed understanding of the surface oxidation process. A link between theoretical and experimental conditions are established by using a thermodynamic approach to establish different temperature and pressure regimes on the oxidized surfaces at different oxygen coverages.

11:30 AM PM04.07.06
High-Temperature Nanomechanical Behavior of HEAs for Service Under Extreme Conditions Youxing Chen¹, Eric D. Hintsala², Nan Li³, Douglas Stauffer⁴, Bartosz Nowakowski⁵ and Nathan Mara⁶; ¹University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; ²Bruker Nano Surfaces, Eden Prairie, Minnesota, United States; ³Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The potential good high-temperature mechanical performance of high entropy alloys (HEAs) has attracted significant attention for demanding nuclear applications. Although abundant high-temperature mechanical behavior data exists for bulk HEAs, high-temperature correlation of microstructure and mechanical properties, especially after exposure to ion irradiation, requires more investigation in order to continue optimizing performance. In this talk, we investigate two types of HEAs with different microstructures: fcc FeCoNiMn and dual-phase FeCrNiMnAl HEAs with a mixed fcc/bcc structure. The mechanical properties of both materials were studied before and after Fe ion irradiation at 500°C with a peak damage level of ~50 dpa. High-temperature (up to 500°C) mechanical maps of HEA alloys achieved by elevated temperature nanoindentation under a vacuum atmosphere clearly demonstrate mechanical contrast from different grains and phases. With increasing test temperature, both fcc and bcc phases soften to different extents, and radiation hardening for the fcc and bcc phases exhibit marked differences. The combined effect of temperature and radiation damage on mechanical behavior will be discussed in terms of dislocation-based hardening models and resulting defect populations at elevated temperatures.

FeMnNiAlCr High Entropy Alloys (HEAs) and Their Native Oxide Solar Absorbers for Concentrated Solar Power Systems Eldred Lee, Margaret Wu, Sheppard Somers, Ian Baker and Jifeng Liu; Dartmouth College, Hanover, New Hampshire, United States.

Concentrated solar power (CSP) systems enable efficient solar energy harvesting and large-scale storage in the form of heat, allowing to supply solar electricity even when the sun does not shine. This capability can mitigate the intermittency issue of solar electricity. Carnot’s Theorem dictates that a higher operation temperature of a CSP system lead to higher energy conversion efficiency. However, the maximal operation temperature of commercial CSP system is limited to 873K as common materials used for the tubing systems (e.g. stainless steel) cannot operate at higher temperatures due to challenges in mechanical & chemical stability. One challenge is the subpar creep resistance and excessive oxidation of currently used CSP tubing materials at high temperatures, leading to crack formation. Ni- & Ti-based and oxide-dispersion strengthened alloys can overcome the problems, but they are expensive. Another challenge is the receivers of CSP systems, where the sunlight is focused on solar selective absorber coatings. The receiver should absorb maximum solar radiation and convert it to heat with low thermal emittance loss at the IR regime. The conversion efficiency should ideally be >90% and stable at high temperatures (>973K). Yet the current coatings (e.g. Pyromark 2500) [1] have high emittance loss (~70%) & conversion efficiency below 90% under long-term at ~973K with a likely degradation in the thermal cycles of CSP systems. To address these challenges, we grow native oxides on two- & three-phase FeMnNiAlCr HEAs to lower the thermal emittance loss (<50%), increase the solar absorptance (>92%), and enhance the conversion efficiency (~91% at 973K). The formation of Fe-Mn oxides and surface microstructures contribute to the drastic enhancement of optical performances at high temperatures, as previously found with externally applied Fe-Mn oxide nanoparticle-based coatings [2]. The native oxides also act as protective layers via diffusion limited oxide growth, thereby enhancing the corrosion-resistance of the HEAs. Furthermore, these HEAs have a yield strength twice that of 304 stainless steel at 973K and a good balance between strength and ductility. When annealed at 1173K, the Vickers microhardness increases considerably due to the fine NiAl-enriched precipitates. The precipitates are stable at 973-1073K, further enhancing the creep resistance of the HEA tubing materials for CSP applications. Because low-cost Fe & Mn constitute ~70 at.% of our HEAs, they are inexpensive compared to Ni- & Ti-based alloys. Therefore, the unique synergy between the mechanical & optical properties of surface-oxidized FeMnNiAlCr HEAs provides a promising solution to cost-effective tubing materials for high-efficiency generation of CSP systems.

SESSION PM04.08: Mechanical Properties of FCC Alloys

Elementary Deformation Mechanisms in High- and Medium-Entropy Alloys Guillaume Laplanche¹, Joël Bonneville², Céline Varvenne³, Aleksander Kostka¹, William A. Curtin¹ and Easo P. George¹; ¹Institute for Materials, Ruhr-Universität Bochum, Bochum, Germany; ²Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; ³Institute of Mechanical Engineering, EPFL, Lausanne, Switzerland; ⁴CNAM, Aix-Marseille University, Marseille, France; ⁵Physics and Mechanics of Materials, Institut PPRIME, University of Poitiers,
Recent progress in understanding the fundamentals of deformation in high- and medium-entropy alloys is reviewed. This presentation focuses on one of the most thoroughly investigated material systems, the fcc CrMnFeCoNi alloys. They have been shown to exhibit fascinating mechanical properties, including increasing strength and tensile ductility with decreasing temperature, with composition having a strong effect. Here, two model alloys from the CrMnFeCoNi alloy system are used to highlight key microstructural aspects responsible for strength, work-hardening rate, and ductility. Since the alloys deform by dislocation plasticity initially and mechanical twinning at higher strains, quantitative evolution of dislocation and twin densities, together with the magnitude and strain-dependence of activation volumes, are used to identify the elementary deformation mechanisms responsible for macroscopic mechanical behaviors. The activation volume at initial yielding is found to reflect the interaction of dislocations with solutes, in agreement with recent theoretical predictions, while its strong decrease upon straining is associated with forest hardening. The role of stacking fault energy on twinning is discussed and related to deformation twinning, which enhances work hardening capability and ultimate tensile strength.

2:00 PM PM04.08.02
Phase Stability and Deformation Behaviors of High-Entropy Alloys Bing Wang1, Muhammad Naeem1-2, Haiyan He1, Si Lan1-2 and Xun-Li Wang1, 2City University of Hong Kong, Kowloon, Hong Kong; 3Herbert Gleiter Institute, Nanjing University of Science and Technology, Nanjing, China.

It is rather amazing that high-entropy alloys consisting of multiple alloying elements in equal molar ratios can form a single phase solid-solution with an incredibly simple lattice, e.g., face-centered cubic (FCC). We have conducted a systematic study of the phase stability and deformation behaviors of CrFeCoNiMox (x=0 – 0.3) FCC high entropy alloys, using in-situ neutron scattering techniques and electron microscopy. For x=0.3, measurements by small angle scattering show that high-entropy alloys are stable up to 800 C, beyond which significant growth of precipitates were observed, which is responsible for the reduced strength at high temperatures. At room temperature, the deformation of CrFeCoNi alloys are dominated by dislocation activities, from dislocation slip at small strains to dislocation entanglement at large strains (up to 40%). Analysis of the diffraction peak widths demonstrates that the dislocation substructures are responsible for the unusual three-stage hardening behavior observed in this alloy. At low temperatures, the alloys deform by serration, with a complicated deformation path which is fully captured by in-situ neutron diffraction measurements.

2:15 PM PM04.08.03
Investigation of the Microstructure Evolution in Al0.1CoCrFeNi High-Entropy Alloy Liu Zhichao and Chengwen Tan; Beijing Institute of Technology, Beijing, China.

The quantitative characterization of the microstructure evolution in high-entropy alloy (HEA) during deformation is of great importance to understanding its strain-hardening behavior. In the current study, in-situ high-energy synchrotron X-ray diffraction was employed to characterize the microstructure evolution in a Al0.1CoCrFeNi HEA during a tensile test. The stacking fault probability and twin probability at different strain levels were analyzed by the Rietveld refinement method. Al0.1CoCrFeNi HEA exhibits a high ultimate tensile strength with a superior uniform elongation and a high strain-hardening rate. The stacking fault energy (SFE) of the Al0.1CoCrFeNi HEA by the synchrotron measurements was estimated to be 35MJ/m2. The increased volume faction of nano-twins and twin-twin intersections, formed during deformation, has been confirmed by transmission electron microscopy analysis. The high strain-hardening rate can be attributed to the increased density of dislocations and nano-twins.

Solid Solution Limit in High-Entropy Alloys—Quantitative Prediction and Experimental Verification Ming-Hung Tsai1, 2, Jian-Hong Li1 and Ting Chang1; 1National Chung Hsing University, Taichung, Taiwan; 2National Tsing Hua University, Hsinchu, Taiwan.

The criterion for the formation of simple solid solution phases has been an important issue in the HEA community. Most of the existing criteria are semi-empirical, with the threshold values obtained from experimental data. Some of criteria are theoretical, the tendency of phase formation is obtained by the comparing different hypothetical thermodynamic states. In this work, a new thermodynamic-based theory is proposed to predict the solid solution limit (SSL) in simple solid solution HEAs. Then, the solid solution limits of various elements in a model FCC base alloy are experimentally measured. These experimental values are used to verify the accuracy of existing models and our model. The results show that existing models evidently overestimate the SSL in HEAs. Our model has significantly higher accuracy than existing models, which provides new insights to the behavior of these multi-component solid solutions.

3:30 PM PM04.09.02
Predictive Multiphase Evolution in Al-Containing High-Entropy Alloys Louis J. Santodonato1, 2, Peter K. Liaw3, Raymond R. Unocic1, Hongbin Bei1 and James R. Morris1, 3; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Advanced Research Systems, Macungie, Pennsylvania, United States; 3Materials Science and Engineering, The University of Tennessee, Knoxville, Tennessee, United States.

The mixing of five or more elements, in near equimolar concentrations, to form disordered substitutional solid solutions is a central feature of the class of materials known as high-entropy alloys (HEAs). It is now becoming clear that the most promising HEAs for practical applications may actually be those which undergo phase transformations and separations during cooling. The present talk describes an approach to guide the development of multi-phase HEAs, using a simple Monte Carlo model with parameters derived from first-principles calculations. These high-throughput simulations are compared with neutron scattering, in situ microscopy, and calorimetry measurements. We demonstrate that the present technique captures not only the qualitative features, but also gives accurate quantitative results for the intermetallic phase formation and microstructure evolution of the Al-containing HEAs. Work is underway to generalize the approach and study a wider range of compositions.

3:45 PM PM04.09.03
Quantification of Solid-Solution Phase Stability and Short-Range Ordering in High Entropy Alloy from Atomistic Simulations Zhenyu Liu and
High entropy alloy (HEA, also known as compositionally complex alloy) refers to simple-phase solid solution alloy that contains multiple principal components in equimolar or near-equimolar ratios. To computationally address the complexities of this type of high-order alloy systems, we have performed atomistic simulations to predict the solid-solution stability as well as the short-range ordering in CoCrFeNi and AlCoCrFeNi bulk alloys and CoNiRuRh nanoparticles. In our simulations, the interatomic interactions were described using a set of modified embedded atom method (MEAM) interatomic potentials for these alloy systems. First, we used atomic simulation methods to examine solid-solution phase formation rules for CoCrFeNi high entropy alloy. Using the Monte Carlo (MC) simulations based on the developed MEAM potentials, we sampled the thermodynamically equilibrium structures of the CoCrFeNi alloy and further predicted that the CoCrFeNi alloy could form a solid solution phase with high configurational entropy of 1.329 at 1373 K. Then, we examined the stability of this solid solution phase of the CoCrFeNi alloy against the well-recognized solid-solution phase formation rules by varying the MEAM potentials and thus tuning the atom size and mixing enthalpy in the alloy. Our simulation results revealed that it required atom size difference effect $\Delta a/a = 0.05$ and mixing enthalpy effect $-10$ kJ/mol $< \Delta H < 0$ kJ/mol for the modeled CoCrFeNi alloy to remain a single solid solution phase. Furthermore, we studied the stability of solid-solution phase of AlCoCrFeNi HEAs using the developed MEAM potentials and the atomistic MC simulation method. In our MC simulations, different constituent elements were allowed to exchange their positions and thus the modelled HEAs were relaxed to their thermodynamic equilibrium states after several millions MC steps at 1300 K. The mixing Gibbs free energy of the HEAs was calculated using adiabatic switching thermodynamic integration method. We predicted that the AlCoCrFeNi HEAs would form a single fcc solid-solution phase when $x < 0.21$, a single bcc solid solution phase when $x > 1.08$, whereas a mixture of fcc and bcc phases when $0.21 < x < 1.08$. Our theoretical results are quite consistent with experimental observation. Moreover, we investigated the formation of solid solution phase in Co$_{12}$Ni$_{20}$Ru$_{40}$Rh$_{20}$ nanoparticles with size ranging from 2 to 5 nm through a combined molecular dynamics (MD) and MC approach. Our simulation results indicated that the local severe lattice distortion could block the diffusion of atoms and hence lead to a stable solid solution phase during a carbothermal shock synthesis procedure. Consequently, we have demonstrated that atomistic simulation techniques as useful methods for understanding the composition-structure-property relation of novel high entropy alloys.

4:00 PM PM04.09.04

Accelerated Atomic-Scale Exploration of Phase Evolution in Compositionally Complex Alloys Alfred Ludwig$^{1, 2}$, Yujiao Li$^3$, Aleksander Kostka$^3$, Alan Savan$^4$ and Helge S. Stein$^1$; $^1$Institute for Materials, Ruhr-University Bochum, Bochum, Germany; $^2$ZGH, Ruhr-Universität Bochum, Bochum, Germany.

Single-phase compositionally complex alloys (CCA) may decompose into multiple phases at elevated temperatures or reactive environments. We present a new methodology to investigate their phase stability in an accelerated way using a combinatorial processing platform which enables: simultaneous synthesis of 36 identical atomic-scale-mixed films by combinatorial co-deposition of 5 elements on an array of 10 mm-diameter Si wafers; rapid phase evolution in the formed nanoscale reactors upon processing; direct atomic-scale analysis of phase evolution after each processing step by atom probe tomography, complemented by transmission electron microscopy. Using this approach, we efficiently elucidate phase evolution by monitoring the redistribution of individual atoms upon annealing. Exemplaric results from nanocrystalline CrMnFeCoNi show that this alloy is unstable and already decomposes after 1 hour at low temperatures of around 300°C. The combinatorial processing platform was also used to explore the oxidation of this CCA. This concept will accelerate the design of novel structural and functional nanocrystalline multinary materials with superior properties, as the phase space of multiple principal element alloys can be more quickly and efficiently explored, resulting in the knowledge of which phases form or decompose at different processing conditions.

4:15 PM PM04.09.05

Combinatorial Exploration of High Entropy Alloys Sebastian A. Kube$^1$, David Uhl$^2$, Amit Dutye$^3$, Aparva Mehta$^4$ and Jan Schroers$^4$; $^1$Yale University, New Haven, Connecticut, United States; $^2$Southern Connecticut State University, New Haven, Connecticut, United States; $^3$SLAC National Accelerator Laboratory, Menlo Park, California, United States.

High Entropy Alloys (HEAs) are compositionally complex and span a vast composition space with many compositions potentially forming single-phase solid solutions. The quantitative prediction of solid solution structure requires a basis of consistent experimental data covering a significant portion of the alloy space. Here, we create the basis for such predictions by fabricating and characterizing 2,478 quinary HEAs based on the elements Al, Cr, Mn, Fe, Co, Ni, and Cu through combinatorial co-sputtering and high-throughput EDX and synchrotron XRD. By mining the data, we show that the solid solution structure can be predicted through the atomic size difference and the content of BCC/FCC elements in the alloy. Also, we find that the BCC structure becomes increasingly favorable with increasing atomic size difference, because it accommodates atoms of various sizes more efficiently than FCC.

4:30 PM PM04.09.06

Electrochemical and Mechanical Properties of Al-Cr-Nb-Y-Zr Based Nitride Thin Films Kristina M. Johansson$^1$, Pavel Soucek$^2$, Ajshwarya Srinath$^1$ and Erik Lewin$^1$; $^1$Uppsala University, Uppsala, Sweden; $^2$Masaryk University, Brno, Czechia.

Recently multicomponent nitrides with five or more elements have attracted a lot of attention due to their excellent material properties such as high hardness, thermal stability as well as corrosion and oxidation resistance. These nitrides are based on the high entropy concept where the high entropy of mixing will favor the formation of a solid solution. In many cases, it has been shown that such nitrides can outperform their respective binary nitrides [1].

In this study, Al-Cr-Nb-Y-Zr-N thin films were synthesized to investigate the effect of nitrogen content on mechanical and electrochemical properties. The Al-Cr-Nb-Y-Zr-N system was chosen since binary and ternary nitrides based on Al, Cr, Nb and Zr have been extensively studied for their corrosion resistance and high hardness. Also, by addition of yttrium corrosion and oxidation resistance can be improved as previously studied for the Cr-Al-Y-N and Ti-Cr-Al-N systems [2-3]. The films were synthesized by reactive dc magnetron sputtering using elemental targets of the respective elements and an Ar/N$_2$ gas mix. The ratio of gases was varied in order to obtain films with varying nitrogen content, from pure alloy to nitride material. The films with no nitrogen was amorphous. For high nitrogen contents only one crystalline phase with NaCl-type structure is observed, indicating a solid solution material in analogy with the high entropy materials. The hardness increased up to 32 GPa for the films with highest nitrogen content, about 40 at.%. Corrosion resistance, studied by polarization measurements between -0.2 V to +1.5 V in a 1.0 M HCl aqueous electrolyte, showed improved corrosion resistance for all the studied samples, i.e. increased corrosion potential and lower current densities, compared to an industrial stainless steel reference sample (hyper-duplex stainless steel). Furthermore, the films with highest nitrogen content showed higher corrosion resistance compared to the metallic films. Thus, this material
system shows a potential for the use as protective coatings in harsh environments.

Pseudo High Entropy Alloys
Yonghua Meng, Jie Pan and Yi Li; Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China.

High-entropy alloys (HEAs) are defined as an alloy with at least five principal elements and equiatomic or near-equatomic composition. However, some so-called HEAs should be considered as pseudo-binary or ternary system due to similar properties of the constituent elements. Here we report our investigation of HEAs based on RE-Al-Co (RE = La, Ce, Pr, Nd Sm and Dy) elements with more than five principal elements. Our study shows that the microstructure changes from amorphous phase to multi-phases when the number of elements increases from 5 to 8. In addition, ZrTiHfTM (TM = Cu, Ni, Co and Fe) alloys exhibit the similar B2 structure with binary Zr6Cu38 alloy. These were attributed to possible decrease rather than increase in entropy because of mixing enthalpy of some elements (e.g. rare elements) is almost zero. In this regards, many of the HEAs should be considered as pseudo-HEAs.

Theory of Strengthening in BCC High Entropy Alloys
William A. Curtin and Francesco Maresca; Ecole Polytechnique Federale, Lausanne, Switzerland.

The refractory BCC High Entropy Alloys (HEAs) in the class of Mo-Nb-Ta-V-W are very strong (1-1.5 GPa) at room temperature and have exceptional retained strengths of 400-500 MPa at 1600°C. The mechanistic origin of these outstanding properties is not yet understood, in spite of extensive experimental studies of these and related alloys. Here, we present a parameter-free theory for the strength versus temperature in this class of BCC HEAs based on the motion of edge dislocations through the random energy landscape created by the solute fluctuations. Excellent agreement with results from direct large-scale atomistic simulations at T=0K is achieved for a range of alloys. Moreover, very good agreement with experiments is achieved for the same alloys at T=300°C, and for the two alloys MoNbTaW and MoNbTaVW that have been studied up T=1600°C. The fundamental origins of the high retained strength are achieved because of large barriers to edge motion. The motion of screw dislocations is also considered, and are also strengthened but by different physical emerging from the high randomness in the alloy. The edge theory enables computationally-guided design of new alloy compositions aiming for the highest retained strengths and strength-to-weight ratios in this family of alloys, and several compositions are proposed.

Body-Centered Cubic High-Entropy Alloys—Understanding of the Mechanical Properties and Associated Underlying Deformation
Mechanisms
Jean-Philippe Cousseau1, Guy Dirras2, Frederic Mompiou3, Daniel Caillard3 and Ivan Guillot1; 1ICMPE CNRS-UPEC, Université Paris Est, Thiais, France; 2LSPM CNRS, Sorbonne Paris Cité, Université Paris, Villetaneuse, France; 3CEMES-CNRS, Toulouse, France.

Thanks to an attractive concept, high entropy alloys are actually among the most studied materials in the metallurgical field. In addition to the exploration of new materials, they also provide the opportunity to revisit the basic concepts of metallurgy. Among the most studied high entropy materials, those with body-centered cubic system are particularly interesting as they mainly retain high mechanical properties and are candidates for structural applications under extreme conditions. The present talk provides an overview on the properties of single phase body-centered cubic high-entropy alloys. Analysis of the existing data from the available literature will be performed and trends relative to the mechanical behavior and underlying deformation mechanisms will be proposed. The emphasis will be put on recent experimental results aimed at bringing basic knowledge on the mobility of dislocations in such complex disordered solid solutions.

9:30 AM PM04.10.03
Development of Precipitation Strengthened CCAs in the AlCrFeNiTi System for High Temperature Structural Applications
Silas Wolff-Goodrich, Thorsten Meiners, Christian H Liebscher and Gerhard Dehm; Max Planck Institute, Düsseldorf, Germany.

The need to make energy generation and conversion more sustainable and to reduce the emission of harmful gases requires the development of novel high temperature stable materials. Several of the so-called compositionally complex alloys (CCAs) have been shown to possess unique property combinations and, in some cases, exceptional mechanical properties. There is much promise in the development of cost-effective CCAs with the necessary properties for use in high temperature applications. In particular, alloys with high degrees of both solid solution strengthening and precipitation of creep resistant ordered phases, such as the L2₁-Heusler phase, can be realised under this alloy development strategy.

In the present study we are exploring the AlCrFeNiTi system for alloys exhibiting a BCC solid solution matrix and hierarchically arranged B2-NiAl and L2₁-Ni₃TiAl precipitate phases. The goal is to obtain novel high temperature alloys with densities of approximately 6 g/cm³ and mechanical stability up to 900 °C. Using arc melted samples containing 5-35 at.% of each component, we have begun screening the composition space in this system. More than 15 unique alloy compositions have been produced and characterised in the as-cast state using XRD, DSC, SEM, and micro-hardness measurements. One particularly promising alloy with a composition of 25Al-15Cr-30Fe-20Ni-10Ti (in at.%) has been further investigated using high resolution TEM and STEM. We have observed a wide compositional range of stability for the L2₁ and BCC phases, with a strong trend to form higher L2₁ phase fractions up to ~70 vol.% for increasing Al content. Alloys with Ti concentrations of ~15 at.% tend to form large fractions of the Laves phase and for ~25 at.% Ti are almost entirely comprised of the Laves phase.

The trends thus far observed have guided us to the most promising region of the composition space in this system for the target application area, this region being (20-25)Al-(10-15)Cr-(30-35)Fe-(10-20)Ni-(5-10)Ti (in at.%). Upcoming work will include a comparison of results for arc melted compositions to results for thin film composition libraries, characterisation of vacuum-induction-cast (VIC) samples in both as-cast and heat treated conditions, as well as

SESSION PM04.10: Mechanical Properties of BCC Alloys
High-entropy alloys (HEAs) with a vast alloy-design space have offered new avenues to explore novel low-cost, high strength-to-weight ratio structural materials. However, to date, no satisfactory light-weight HEAs (LWHEAs) have been developed, due to the difficulty in balancing strength, ductility, and density. In this study, we investigate the phase stability and transformation behavior of a newly-designed light-weight Al1.5CrFeMnTi HEA. The coherent precipitation of the nano-sized L21 phase within the body-centered-cubic (BCC) matrix at intermediate temperatures was observed, and their size, shape, coherency, and spatial distribution can be tuned through selected annealing treatments. Moreover, the CALculation of PHase Diagrams (CALPHAD) and first-principles calculations successfully optimize the compositions of light-weight HEAs with a coherent nano-sized L21 precipitate-strengthened BCC two-phase structure. With the support of the optimized CALPHAD database, first-principles calculations and experimental efforts, novel light-weight HEAs, featuring lower density and lower cost, have been designed for high-temperature and cost-effective light-weight applications.

Solving the Strength-Ductility Trade-Off Dilemma of High-Entropy Alloys via Interstitial Hardening
Zhifeng Lei, Xiongjun Liu, Yuan Wu, Hui Wang and Zhaoping Lu; University of Science and Technology Beijing, Beijing, China.

Oxygen, one of the most earth-abundant elements, often appears as an undesired interstitial impurity in metallic materials. Even when providing strengthening it renders metals brittle, causing the strength-ductility trade-off dilemma, i.e., increasing the strength leads to decreasing ductility. Here, we report an anomalous interstitial strengthening effect of oxygen in a family of single-phase refractory high-entropy alloys (HEAs) at ambient temperature. In contrast to conventional interstitial strengthening, strength and ductility are both substantially improved when doping a model Ti2ZrHfNb HEA with 2.0 at.% oxygen, breaking the paradigm of the strength-ductility trade-off with an inexpensive and ubiquitous element. Alloying with oxygen leads to the formation of ordered oxygen complexes (OOCs) which pin dislocations and subsequently promote their cross slip and multiplication. This novel strain hardening mechanism improves work-hardening capability and thus ductility. This finding revises our current understanding of the effect of oxygen on the mechanical behavior of metallic materials and provides new pathways for the development of high-performing alloys which have the capability to access new performance regimes.

11:00 AM PM04.11.02
Development of Refractory High Entropy Alloys with Enhancing High Temperature Strength and Room Temperature Ductility
Ilhwan Kim, Hyunseok Oh and Eun Soo Park; Seoul National University, Seoul, Korea (the Republic of).

As science and technology has evolved, there exists an extreme environment where conventional materials are difficult to use. Refractory metals are one of the most promising candidates for extreme environment especially in high temperature condition. Tungsten is a widely used structural material exhibiting excellent physical properties in high temperature environment, with high melting point, high resistance against mechanical wear. For these properties, tungsten is currently being considered as structural materials in fusion power plants for plasma facing components (PFCs). However, refractory metals, including tungsten, have some drawbacks for using as structural materials. The first is a dramatic softening phenomenon in high temperature range. Their high strength and hardness in low temperature range cannot be maintained in high temperature range due to its softening phenomenon. The other is brittle behaviour below room temperature. Operating temperature of structural materials is determined above the ductile-to-brittle transition temperature (DBTT) below the recrystallization temperature. Therefore brittle behaviour at room temperature limits the application of refractory alloys because refractory alloy should be used above room temperature. In particular, the DBTT of refractory alloy is increased by small amount of adding elements. It means orthodox alloying concept cannot be answer to increasing strength and ductility of refractory alloys. Thus, it is required to develop a new-type refractory alloy to tailor these mechanical properties. In the present study, maintaining good properties of tungsten, we developed novel refractory alloys to enhance mechanical properties by utilizing design concept of high entropy alloys (HEAs). To design materials having high temperature strength and room temperature ductility, we use two parameters, atomic size misfit parameter for solid solution hardening and valence electron concentration. Because of mixing effects among the elements, tungsten based HEAs had enhanced mechanical properties than pure tungsten. To evaluate the high temperature mechanical properties, we conducted compression test and thermal conductivity measurement at high temperatures. As a result, tungsten based HEAs were improved to strength and ductility simultaneously. This study offers an explanation of the tendency between physical properties and configurational entropy. Moreover, the mechanical and thermal properties database provides us a better understanding of refractory alloys, which can suggest guidelines for tailoring refractory alloys.

11:15 AM PM04.11.03
Boundary Micro-Cracking in a Metastable High-Entropy Alloy Shaolou Wei, Jinwoo Kim and C. Cem Tasan; Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.
Mechanically-induced martensitic transformation can be a double-edged sword: depending on composition and processing it can either lead to various beneficial mechanical effects (e.g. transformation-induced plasticity, transformation-toughening), or cause local brittleness and damage nucleation. While several corresponding guidelines are present in steels research, controlling microstructure metastability has not been drawing attention in the fast-growing field of high-entropy alloys. In the present work, we investigated the damage mechanisms of a mechanically metastable Fe₄₅Mn₃₅Co₁₀Cr₁₀ high-entropy alloy under uniaxial tensile loading. Our integrated in-situ scanning electron microscopy / electron backscatter diffraction experiments revealed a twofold effect of the highly localized strain, induced by asynchronously transformed martensite, leading to boundary damage nucleation and dissimilarly oriented martensitic variant formation. The latter suppresses slip transfer between adjacent grains, further expediting the growth of the nucleated damage incidents. Based on these experimental observations and corresponding theoretical calculations, we discuss the underlying mechanisms and propose a sequence of micro-events that create the observed phenomena.

11:30 AM PM04.11.04
Carbon Supersaturated Refractory Multicomponent Nanostructured Coatings Stefan Fritz, Paulius Malinovskis, Lars Riskehr, Linus von Fieandt, Erik Lewin and Ulf Janson; Uppsala University, Uppsala, Sweden.

The combination of ceramic hardness with high ductility is a major challenge in the design of protective thin films and high entropy alloys (HEAs) are a promising pathway to achieve new high-performance materials. While HEA thin films have been studied to some extent by experimental and computational materials science, there is only limited information available about the influence of carbon on HEA thin films, especially when prepared with physical vapor deposition techniques. In this study, we report on the influence of carbon on the structure and properties of two different HEA alloys in the Cr,Nb,Ta,Ti,W system. The metal composition of these alloys includes a near-equimolar alloy and a Ta,W-rich composition.

We have deposited Cr,Nb,Ta,Ti,W-C thin films by non-reactive magnetron sputtering. The material properties were strongly depending on the composition and the best results were observed for Ta,W-rich films which crystallise in a bcc structure with a strong (110) texture. TEM analysis revealed that the films exhibit coherent grain boundaries with specific crystallographic directions. The addition of 8 at.% led to the formation of a meta-stable bcc supersaturated solid-solution without the formation of carbide precipitates. The main effect of the carbon addition was a significant grain refinement reducing the column width from 35 to 10 nm, which resulted in an increase in hardness from 14 to 19 GPa while the reduced E-modulus was unaffected. The enhanced hardness will be discussed in terms of solid solution hardening and grain refinement strengthening. Nanoindentation deformation studies revealed that the addition of carbon significantly reduces the plastic deformation around the indents without showing any signs of crack formation which is explained by the special arrangement of the grain boundaries. Finally, the effect of carbon addition on the corrosion properties was likewise investigated in 0.6 M NaCl environment. High pitting corrosion resistance was found for the Cr,Nb,Ta,Ti,W-C thin film composition, with a corrosion potential of 0.23 V (vs. Ag/AgCl) and a transpassive region equal to hyper-duplex stainless steel (i.e. SAF3207HD).

11:45 AM PM04.11.05
Mechanical Behavior and Oxidation Resistance of a Particle-Reinforced Fe-Al-Cu-Ni-Ti Alloy Manja Krueger, Volodymyr Bolbut, Georg Hasemann, Katja Wollgarten and Dmitry Naumenko; 1University of Magdeburg, Magdeburg, Germany; 2IK-2, Research Center Jülich, Jülich, Germany.

We introduce the compositionally complex alloy (CCA) Fe₂₅Al₂₅Cu₁₁:Ni₁₀,5Ti₄,5 which provides attractive mechanical properties and a density of 5.6 g/cm³, which is lower compared to well-investigated alloys of the Al-Co-Cr-Fe-Ni-Ta-W family. This novel material has a bcc matrix phase and is reinforced by finely dispersed intermetallic particles, which are stable up to about 1100 °C. Hardness measurements and compressive tests in a temperature range between room temperature and 1100 °C show the advanced mechanical performance of this novel CCA compared to high entropy alloys (HEAs). These first results demonstrate the high potential of this alloy as structural engineering material for high temperature applications. During oxidation tests at 900 °C the material shows a slight mass gain which is due to the formation of an alumina layer at the surface. This layer has a thickness of ~1 µm after 100 h of thermal treatment, which again grows during further thermal cycling. Cyclic oxidation experiments at 1000 °C and 1100 °C resulted in spallation of this oxide layer, which leads to a mass loss of the samples. An approach to overcome this problem by the addition of a sixth alloy component will be discussed.

1:30 PM PM04.12.01
Applying Combinatorial and High-Throughput Methods to Develop Compositionally Complex Alloys Alfred Ludwig, Jan Alters, Janine Pfetzing-Mücklich, Jan Alters and Sigurd Thielenhaus; 1Institute for Materials, Ruhr-University Bochum, Bochum, Germany; 2ZGH, Ruhr-Universität Bochum, Bochum, Germany.

Compositionally complex alloys (CCAs) offer an almost unlimited composition space for new materials, which cannot be explored efficiently by conventional methods. Therefore, the combinatorial fabrication of CCA thin-film materials libraries and their high-throughput characterization is discussed. Materials libraries consist of well-defined composition spreads fabricated by co-deposition from up to five magnetron sputter sources. Chemical (composition), structural (phase, microstructure), electrical (resistivity) and mechanical properties (Young’s modulus, hardness) are measured using high-throughput characterization systems. The aims are to find the compositional limits of the single-phase solid solution existence range and to identify the multiphase constitution beyond these limits. Results for different CCA systems (transition metals, refractory metals) are shown and the visualization of multidimensional datasets is discussed.

1:45 PM OPEN DISCUSSION

2:00 PM PM04.12.02
High entropy alloys (HEAs) are a class of alloys that contain multiple principle elements and display interesting mechanical properties such as increasing ductility with decreasing temperature and resistance to softening at elevated temperatures. Details of the dominant atomistic deformation mechanisms as a function of temperature are key to understanding these unique mechanical trends. Small-scale mechanical testing is well-suited to investigate deformation mechanisms and isolated microstructural features such as grain or phase boundaries. Here we present molecular dynamics simulations of compression of single-crystalline FCC and BCC HEA nanowires and HEA nanowires that contain a single FCC/BCC axially-aligned phase boundary. In single-crystalline HEAs, we identify dominant deformation mechanisms from 50 K to room temperature and investigate the role of heterogeneity in defected crystal structures. In phase boundary-containing nanowires, we also discuss dislocation-boundary interactions and the role of the FCC/BCC interface as a source, barrier, or sink for dislocations. We supplement these results with calculations of stacking fault energy and also compare observed deformation mechanisms to experimental results of compression of single-crystalline and FCC/BCC phase boundary containing HEA nano-pillars.

2:15 PM PM04.12.03
Laser Processing as a High-Throughput Method to Investigate Microstructure-Processing Relationships in a High Entropy Alloy Mu Li and Katharine Flores; Washington University in St. Louis, Saint Louis, Missouri, United States.

The compositional complexity of multiprincipal element alloys, consisting of 4 or more elements without a dominant solvent, presents a challenge for studying their microstructural development and stability. In the present work, we apply a direct laser deposition processing method to construct compositional and microstructural libraries in an efficient and high-throughput manner. Phase formation in an AlCoCrFeNi high entropy alloy was first examined over a wide composition range. As the Al content increased from x = 0.15-1.32, the crystal structure was observed to transition from FCC to BCC/B2. While the onset of BCC/B2 formation was consistent with previously reported results based on cast materials, the FCC structure was observed at larger Al contents in the laser-deposited materials, resulting in a wider two-phase regime. In addition to the presence of the expected phases, the laser-processed microstructure was surprisingly consistent with that produced by casting. The 2-3 orders of magnitude faster cooling rates inherent to laser processing resulted in feature sizes 2-3 times smaller than cast materials, however the morphology of the phases was similar. At low-to-intermediate Al contents, the two-phase alloy exhibited a cellular structure, while at higher Al content, the FCC structure was isolated and confined to the BCC/B2 grain boundaries. The BCC/B2 morphology was also similar to that observed in cast materials. Ongoing work continues to investigate the sensitivity of the microstructure to the laser processing conditions, and will be discussed. This study suggests that the high-throughput laser processing method is an ideal method for rapidly and efficiently evaluating multiprincipal element alloys.

SESSION PM04.13: Novel Synthesis and Mechanical Properties
Session Chair: Alfred Ludwig
Wednesday Afternoon, November 28, 2018
Hynes, Level 1, Room 105

3:30 PM PM04.13.01
Solid State Manufacture of High Entropy Alloys via the Metalysis Process Ian Mellor, Lyndsey Benson, Mike Ellis and Nader Khan; Metalysis Ltd, Rotherham, United Kingdom.

Historically Metalysis have produced tantalum, titanium and titanium alloy powders for high performance applications using their solid state electrochemical process. The route for alloy production involves initial preparation of a mixed metal oxide feedstock, followed by electro-deoxidation, to generate an intimately mixed alloy on a microscopic scale. This low energy intensive and environmentally friendly technology, has been used to demonstrate a number of High Entropy Alloys (HEA’s), with complex compositions and microstructures.

In most conventional cases, the manufacture of HEA’s involves high temperature melting, which puts all of the alloying elements into the liquid phase. This can lead to numerous problems and restrict the number of combinations, which can be reliably made. In particularly those where one needs to combine low melting and/or boiling point with refractory elements, and also where there are significant liquid density differences between the constituents causing melt segregation.

The aim is to present the preliminary work carried out by Metalysis, and to show how the solid state process, based on molten salt electrolysis, lends itself to the manufacture of the next generation of HEA’s. This study will focus on some examples whose constituent elements have large differences in both their melting points and liquid densities, for example, but not limited to, chromium, niobium, tantalum, titanium and aluminium.

3:45 PM PM04.13.02
Growth and Mechanical Characterisation of Single-Phase Single-Crystalline FCC and BCC High-Entropy Alloys Tim Lienig, Michael Feuerbacher and Carsten Thomas; Forschungszentrum Jülich GmbH, Jülich, Germany.

High-entropy alloys (HEAs) represent a novel class of metallic materials. Composed of at least five elements in equiatomic or near-equiatomic proportion they show crystalline long-range order while maintaining chemical disorder throughout their lattice. The simultaneous presence of topological order and chemical disorder is unique in metals and poses fundamental questions in basic materials science. Various alloy systems have been reported to form HEAs, crystallising in face-centred cubic, body-centred cubic, and hexagonal structure.

In-depth investigation of structure-property relations of HEAs requires high-quality single-phase, preferably single-crystalline samples. Single-crystalline samples allow the determination of intrinsic materials properties without the influence of secondary phases or grain boundaries.

We report on the mechanical characterisation of single-crystalline equiatomic fcc CrMnFeCoNi and our advancements in the production of single-crystalline bcc TiVZnNbHf HEAs. Single-crystals are grown by means of the Bridgman technique from master-alloys synthesised from high-purity elements by arc-melting and in an inductively-coupled levitation crucible. Mechanical characterisation was performed on a modified Zwick Z050 compression deformation rig.
CrMnFeCoNi single-crystals successfully produced by the Bridgman technique have a volume of several cubic centimetres and a maximum diameter of 20 mm, making the high-quality material accessible to most physical-property measurements. X-ray Laue back-scattering images taken across the surface are sharp and mutually consistent. SEM and light microscope images reveal a grain-free microstructure, with EDS measurements confirming the equiatomic composition of the crystal. Macroscopic specimens (2.5x2.5x5 mm³) prepared from the large single crystals are used to perform mechanical compression testing along different crystallographic directions. By incremental testing, e.g. stress relaxations and strain-rate changes, thermodynamic activation parameters of the plastic deformation mechanism are determined.

A growth route for equiatomic TiVZnNbHf single crystals is currently under development and will be presented additionally. Our previously published results reveal that this material is a homogeneous single-phase HEA with bcc structure that has a significantly lower melting temperature than TiZnNbHfTa bcc HEAs. Therefore single-crystal growth of TiVZnNbHf HEAs can be addressed by means of the Bridgman technique, and we expect to grow crystals of the same volume as CrMnFeCoNi single-crystals.

4:00 PM PM04.13.03
Microstructure and Phase Transformation in Al-Containing Refractory High Entropy Alloys SangJun Kim, Hyunseok Oh and Eun Soo Park; Seoul National University, Seoul, Korea (the Republic of).

Refractory high entropy alloys with BCC structure composed of group-4 to group-6 refractory elements (Ti, Zr, Hf, V, Nb, Ta, Cr, Mo and W) were reported to exhibit superior mechanical properties at high temperature above 1000 C comparing Ni-based superalloys. Recently, Al-containing refractory high entropy alloys were reported to have unique structure in which disordered BCC phase (A2) are precipitated in ordered BCC matrix (B2). In spite of exceptional high strength at high temperature, however, they showed low ductility due to the ordered matrix and Zr-based precipitates in grain boundaries. Here, we investigated the phase transformation behavior of Al-containing refractory high entropy alloys to control the microstructure for balancing strength at high temperature and ductility at room temperature. Microstructural evolutions of various alloys in (Ti,Zr,Hf)-(Nb,Mo)-Al system during heat treatment were analyzed in terms of phase equilibrium and decomposition of disordered and ordered BCC phase. Through systematic studies of thermal processing condition, refractory high entropy alloy in which ordered B2 phase are precipitated in disordered A2 matrix was developed. This result could provide an effective guideline for tailoring microstructure of Al-containing refractory high entropy alloys, and developing promising HEAs for high temperature structural materials.

4:15 PM PM04.13.04
Two Modes of Screw Dislocation Motion in an Equiatomic Alloy Yuri Osetsky1, James R. Morris1,2 and George M. Pharr1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 3Texas A&M University, College Station, Texas, United States.

Molecular dynamics simulations show two distinct mechanisms of \(\frac{\pi}{2}\times110\rightarrow\{\{111\} screw dislocation glide in an equiatomic Ni-Fe solid solution face centered cubic crystal structure (fcc). At high stresses (above ~130 MPa), it glides under "typical" friction-controlled conditions. At lower stresses, the dislocation moves in a very rough manner that cannot be described as continuous glide but rather a motion through a set of obstacles. We demonstrate that these obstacles are localized and can produce large pinning, yet the dislocation does not exhibit significant bowing as normally expected for strong, localized pinning. The threshold stress for transition between modes depends on the dislocation segment length and ambient temperature. At 300 K the flow stress saturates at ~130 MPa for length above ~140 \(\ell\) (\(\ell\) is the Burgers vector). We demonstrate that the statistical behavior is important, with rare events dominating the behavior. The nature of internal obstacles to dislocation glide is likely due to the low stacking fault energy and composition effects in the core energy: dislocation accommodates its width and shape for its Shockley partials contain more Ni atoms. Energy barriers between minimum energy configurations define the flow stress. The observations are discussed in terms of their potential relevance to the mechanisms of plastic deformation in single-phase high entropy alloys.

This work was supported by the US Department of Energy Office of Science, Basic Energy Sciences, Materials Science and Engineering Division.

4:30 PM PM04.13.05
Effect of Ti and C Additions on Microstructural Refinement and Mechanical Properties of Cast AlCoCrFeNi Compositionally Complex Alloys Alex Asabre1, Ulrich F. Volkert1, Oleg Stryzhyboroda2, Janine Pfetzing-Micklich1, Ulrike Hecht1 and Guillaume Laplanche1; 1Ruhr University Bochum, Bochum, Germany; 2ACCESS e.V., Aachen, Germany.

Hot forming tools need to exhibit good strength, high hardness and wear resistance at high temperatures, combined with an adequate ductility at high and low temperatures. Currently boron doped steels are used for such applications, however there is a growing demand of new materials with improved properties. In the present study, the influence of Ti and C additions on microstructure and mechanical properties of an as-cast multi-phase A12(C2O12C2F2F2N2) composition in at. % compositionally complex alloys is investigated. The alloys with various additions were arc melted and subsequently drop cast. The as-cast microstructures were characterized using scanning and transmission electron microscopy. Microstructural analyses revealed a Widmanstätten microstructure in all cast alloys consisting of face-centered-cubic (fcc) plates which formed upon cooling in a disordered body-centered-cubic (BCC) matrix containing ordered B2 precipitates. The additions of Ti and C resulted in microstructural refinement with the presence of titanium carbides at grain boundaries and inside the grains of the high temperature BCC matrix. This result in combination with thermodynamic calculations suggest that titanium carbides formed in the melt and acted as nucleation sites for heterogeneous nucleation during solidification. The volume fraction of the BCC phase slightly increases with increasing Ti and C additions while the Cr-, Fe-, Co-, and Ni-concentrations are decreased accordingly.

We present a high entropy alloy (HEA) from the system Al-Co-Cr-Fe-Ni-W:Mo-Si-C which was designed to allow for precipitation hardening by annealing in the temperature range from 600 to 900°C. The alloy development was performed using centrifugally casted specimens and supported by thermodynamic computations using ThermoCalc software and the TCFE9 database. The microstructure of two selected samples in as-cast and annealed
conditions was analysed using XRD, SEM, EBSD, EDX and TEM measurements. The as-cast microstructure consists of spinodally decomposed BCC dendrites enveloped by FCC/M23C6 eutectic. Upon annealing at 700°C for 24h nanoscale intermetallic phase precipitates form within the spinodal BCC as well as from FCC. Furthermore, the L12 phase precipitates within the FCC phase below 600°C. Precipitation is exquisitely uniform leading to an increase in microhardness from 415 HV0.5 in the as-cast state to 560 HV0.5 after annealing, making the material suitable for tooling applications. We investigated the stability and coarsening of this microstructure using (i) varying annealing temperatures and (ii) varying time for a constant temperature of 700°C. We will present the microstructure evolution during coarsening and the corresponding mechanical properties obtained from instrumented indentation experiments.

Field-Assisted Sintering—Microwaves, SPS and Flash Sintering
Sunday Afternoon, November 25, 2018
Hynes, Level 2, Room 208

1:30 PM
Field Assisted Processing of Advanced Materials Eugene Olevsky; Sand Diego State University

Sintering of powder materials is a widely used technological process, and, on the other hand, it is one of the most basic physical phenomena. The success of the industry in the development of computer-aided manufacturing made it possible to create a significant number of various devices for the processing of materials by the simultaneous action of heat, applied pressure, as well as electric current or electromagnetic field. These devices and processes belong to the area of so-called field-assisted sintering which offers fundamentally new materials processing conditions. Field-assisted sintering, which includes also the impact of electromagnetic factors, is, accordingly, a vivid example of a fundamental and multi-physics process. These sintering techniques enable materials and components with unique properties. Field-assisted sintering technologies thus represent an excellent experimental base for technologists engaged in the discovery of new materials. Simultaneously, field-assisted sintering opens up wide opportunities for modeling the processes of materials consolidation and synthesis taking into account numerous physical phenomena. The ninety minute tutorial will provide an introduction to sintering fundamentals as well as basics of field-assisted sintering techniques, including microwave and spark plasma sintering.

3:00 PM BREAK

Flash Sintering Rishi Raj; University of Colorado Boulder

In a 2010 paper it was shown that yttria-stabilized zirconia can be sintered in ~5 s at a temperature of 850oC. (Conventional sintering requires several hours above 1400 oC – flash sintering is about four orders of magnitude faster.) Since then many different ceramics, including those that are semiconductors, electronic conductors, ionic conductors and high insulators, have been processed in this way. The flash phenomenon occurs in powder pressed samples, polycrystals and single crystals. An abnormal increase in electrical conductivity, and electroluminescence (in addition to rapid sintering) are characteristics of flash. Results from in-situ experiments at Synchrotrons are starting to provide fundamental insights. Molecular dynamics models are showing the significance of phonon-electron interactions. A roadmap for flash manufacturing is starting to develop. This emerging new field cuts across, materials science, ceramics science, engineering and solid state physics.

4:30 PM
Open Discussion
Invited Paper

Superplastic Flow at Relatively Low Furnace Temperature can be attained in Dense Polycrystalline Oxide Ceramics such as Tetragonal ZrO2 Polycrystal (TZP). For the first time, by taking into account the explicit influence of the electric current effect on the SPS densification mechanism, the constitutive equations describing the electric current-assisted hot pressing of conductive powders are developed. The densification mechanism is determined by the inverse regression of the new SPS constitutive equations and by utilizing the experimental results on a conductive powder consolidation with and without the participation of the electric current effect. The developed model provides the theoretical basis of the new method of controllable interfaces which allows extending flash sintering/SPS to nearly all materials, controlling sample shape, and an energy efficient mass production of small and intermediate size objects.

Controllable Interface Approach in Field-Assisted Sintering

Reactive Flash Sintering

Potential Flash Sintering and Related Field-Enhanced Processing for Oxide Ceramics

Electric field enhanced sintering is gaining interest in recent years owing to the accelerated consolidation compared to conventional, pressure-less sintering. In particular, flash sintering, where densification occurs almost immediately (typically <10 seconds) under high electric field, has attracted extensive attention as an innovative sintering technique. The flash sintering has been demonstrated in various ceramics, and almost full density has been achieved at relatively low furnace temperature for very short time. The non-equilibrium, drastic densification under strong electric field results from accelerated diffusional mass transport triggered by flash event; electric conductivity of material is highly increased, and excess anion vacancies are generated beyond threshold field strength and temperature. We should note that the flash event is rather a common phenomenon in oxide ceramics; it has been reported that flash event takes place not only in powder compact but also in dense, polycrystals even in single crystal. By employing flash event, for instance, superplastic flow at relatively furnace temperature can be attained in dense polycrystalline oxide ceramics such as tetragonal ZrO2; polycrystal (TZP). For example, elongation to failure of more than 150% of nominal strain can be achieved in TZP at a furnace temperature of less than 1000°C and a strain rate of faster than 1×10⁻³ s⁻¹. Flash sintering and field-enhanced sintering-related phenomena can be innovative processing techniques, i.e. consolidation and near-net shaping, of ceramic materials.
Understanding and Controlling Flash Sintering—from a Case Study of ZnO to Other Ceramic Materials

This presentation will discuss a series of our recent studies of flash sintering. ZnO was used as our primary model system; TiO$_2$ and 8YSZ have also been studied. The effects of various doping, grain sizes (including single crystals) and sintering atmosphere have been systematically examined. A coupled thermal and electric runaway model has been developed to forecast the onset flash temperatures for ~20 cases with different materials, doping, particle sizes, and atmospheres [Acta Mater. 125:465 (2017)]. Using this new two-step flash sintering (TSFS) technology, fast densification with suppressed grain growth was achieved [Scripta Mater. 141: 6 (2017)]. Furthermore, various electric field/current effects on microstructural developments have been discovered and investigated. Interestingly, we recently demonstrated the feasibility of flashing ZnO at room temperature (without any furnace/external heating) to subsequently achieve ~98% densities in ~30 seconds with the adsorption of water vapor [Scripta Mater. 142: 79-82 (2018)]. This new water-assisted flash sintering (WAFS) technology represents an exciting opportunity for significant economic and cost savings.

The scientific questions and technological opportunities of flash sintering were discussed in a most recent Viewpoint article [Scripta Mater. 146: 260-266 (2018)].

11:00 AM *PM05.01.06
Insight into the Flash Sintering Process Mechanisms in Ceramics

Thomas Tsikalakos; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Flash Sintering (FS) utilizes the non-equilibrium rise in current under applied electric field to densify ceramic green body compacts in seconds. A new method, EDXRD Temperature Calibration, utilizes white energy dispersive x-ray diffraction (EDXRD) from a synchrotron source to track the lattice expansion of the ceramic during FS compared to the lattice expansion during conventional sintering (CS). The materials used in this study were ZnO, TiO$_2$, CeO$_2$ and BiFeO$_3$ oxides and BiC, TiB$_2$, ZrB$_2$, and BN nonoxides. This investigation analyzes the proposed mechanisms for the onset of the flash, the cause of the enhanced sintering kinetics during FS, and the temperature for each theory. The temperature has been measured directly as it causes a proportional thickening of the bonds, which increases the unit cell volume. For all materials the temperature during FS is close to that of CS. The new ways of performing FS experiments on ZnO by ramping the current linearly and by AC power supply, microstructural inhomogeneity, grain growth, and other physical properties will be also shown.

The FS of BiFeO$_3$ is a homogeneous process and since the FS takes place at quite low temperatures (350°C < T$_c$) it explains excellent dielectric properties. However, for CeO$_2$ and TiO$_2$, exhibited inhomogeneous lattice expansion from anode to cathode.

Energy Coupled to Matter for Field-Enhanced Processing

Raymond Brennan, Victoria Blair, Michael Kornecki, Nicholas Ku, Selva V. Raju, Franklyn Kelllogg, Michael Golt; Aubrey Fry and Carli Moorehead; U.S. Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States.

Energy Coupled to Matter (ECM) research at the U.S. Army Research Laboratory is focused on the study of material interactions with external fields to produce outcomes that are unattainable through conventional means, expanding materials-by-design and processing science capabilities beyond the current state-of-the-art. Research has been conducted to utilize these innovative technologies and material solutions for exploring structure-property relationships of ceramic materials based on their interactions with applied external fields (i.e. magnetic, electric, microwave, etc.). ECM research is focused on manipulation of microstructures, phase formation, and the overall behavior of materials subjected to controlled fields, which can enable rapid densification at reduced temperatures, grain and grain boundary modification, and crystallographic texturing. The ability to rapidly densify materials under less extreme processing conditions can allow for preservation of the nanoscale grain structure, providing the opportunity to improve mechanical properties including strength, hardness, and fracture toughness, which are vital to Army protection applications. Techniques for manipulating materials to make them more responsive to specific fields have also been investigated (ferromagnetic additives for magnetic fields, conductive second phases for electric fields, susceptor materials for microwave fields) to amplify these effects during processing. These strategies have combined experimental design, computational modeling, and in-situ characterization for development of unique ECM processes to enable field-enhanced production of improved components for protection, lethality, and energy-related (i.e. laser host, battery) Army applications.

2:00 PM PM05.02.02
Low Temperature Ceramics Processing Under Electromagnetic Fields—Decoupling Thermal and Field Effects

B. Reeta Jayan; Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

Understanding the coupling between electromagnetic (EM) fields and matter can advance low temperature processing of several materials including ceramics. It is hypothesized that the EM field depending on frequency and polarization modifies energy barriers for chemical reactions. This talk will demonstrate experiments that use thin conducting films to selectively localize EM field interactions. We aim to delineate processing-structure relationships by creating and probing instances where there can be specific field driven effects that can be distinguished from conventional thermal phenomena.

Specifically, our experiments will couple synthesis and characterization of binary ceramic oxide (e.g., ZrO$_2$) films on conducting (metal) layers under 2.4-2.5 GHz microwave radiation. The solution bath in which the growth happens remains below 250°C even during field exposure. We utilize synchrotron x-ray pair distribution function (PDF) analysis along with transmission electron microscopy (TEM) and Raman spectroscopy to study the crystallization and local atomic order in these thin films. By analyzing how EM field conditions (power, final temperature) influence the local atomic structure, we unlock the potential mechanisms underlying field-assisted phase transformations and the role of defects in these field-induced structural changes.
Defects from Two Perspectives—Microstructure and Impedance Spectroscopy Comparison of Flash Sintered 8YSZ Al2O3 and B4C tapes at room temperature using an electrical potential of 100 - 1500V/cm and a 100W 975nm CW laser to heat the sample. No additional Flash sintering is an energy efficient sintering technique, which has been extensively researched, in recent years. Most of the work reported is on joule bulk TiO2. For grain boundaries, we studied titanium diffusion by classical force field molecular dynamics. Ti diffusion is orders-of-magnitude faster close boundaries. In bulk, we predicted the equilibrium defect concentrations at various pressures and temperatures from first-principles calculations. Berry curing/sintering methods leading to energy-efficient manufacturing processes; even for materials like ceramics that conventionally requires high temperatures exceeding 500-2500 oC. Lower temperature processing can further be expanded to other delicate materials such as polymers and can even realize novel polymer-ceramic and metal-ceramic composites for biomedical use.

Open questions remain, however, which may be greatly elucidated by considering these material-specific defect behaviors. For example, in samples processed under DC fields, inhomogeneous grain growth has been observed, with its relation to polarity changing based on the material processed. Furthermore, while the thermal runaway model explains the onset conditions of flash, no work has fully or conclusively proven a mechanism responsible for the rapid mass transport evidenced. Meanwhile, it is clear that the high electric fields in the process must simultaneously interact with the defects present in the material as well as add to the defect populations.

In the interest of exploring these defect contributions, we present a study comparing the final properties of flash sintered 8 mol% yttria-stabilized zirconia (YSZ) pellets using DC and AC fields. Microstructure is examined using scanning electron microscopy (SEM), and the final electrical characteristics are considered using impedance spectroscopy. While SEM gives direct microstructural observation, impedance spectroscopy fills in the picture with smaller scale defect and impurity implications specific to the grain boundary and bulk. A comparison between the two forms of characterization as well as conventionally sintered 8YSZ lends insight into fundamental reorganization and creation of defects produced in ion conductors during flash sintering.

Defects from Two Perspectives—Microstructure and Impedance Spectroscopy Comparison of Flash Sintered 8YSZ Carolyn Grimley1, Andre Prette2 and Elizabeth C. Dickey1; 1North Carolina State University, Raleigh, North Carolina, United States; 2Lucideon Limited, Stoke-on-Trent, United Kingdom.

Field assisted sintering (FAST) has been demonstrated for multiple ceramic materials as a promising sintering technique in shortening consolidation time and lowering sintering temperatures. Mechanistically the interplay between electric field and the polycrystalline material is a complicated process and the governing factor for rapid densification during FAST is still under debate. In this work, we approached this problem from computational modeling in the model system of rutile TiO2. We separately quantified the effect of Joule heating and non-contact electric field on ion diffusion both in bulk and at grain boundaries. In bulk, we predicted the equilibrium defect concentrations at various pressures and temperatures from first-principles calculations. Berry phase calculation with electric field up to 8 MV/cm shows that electric field has negligible effect on both defect formation energy and migration barrier in bulk TiO2. For grain boundaries, we studied titanium diffusion by classical force field molecular dynamics. Ti diffusion is orders-of-magnitude faster close to the grain boundary. We also demonstrated the defect concentration change in space charge layer formed at grain boundaries with external bias. These results indicate that the local atomic structure and space charge layer profile of grain boundaries are important in understanding electric field effect on polycrystalline materials.

Computational Insight for Field Assisted Sintering of TiO2: Jing Yang, Minh A. Dinh and Bilge Yildiz; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Field assisted sintering (FAST) has been demonstrated for multiple ceramic materials as a promising sintering technique in shortening consolidation time and lowering sintering temperatures. In this work, we approached this problem from computational modeling in the model system of rutile TiO2. We separately quantified the effect of Joule heating and non-contact electric field on ion diffusion both in bulk and at grain boundaries. In bulk, we predicted the equilibrium defect concentrations at various pressures and temperatures from first-principles calculations. Berry phase calculation with electric field up to 8 MV/cm shows that electric field has negligible effect on both defect formation energy and migration barrier in bulk TiO2. For grain boundaries, we studied titanium diffusion by classical force field molecular dynamics. Ti diffusion is orders-of-magnitude faster close to the grain boundary. We also demonstrated the defect concentration change in space charge layer formed at grain boundaries with external bias. These results indicate that the local atomic structure and space charge layer profile of grain boundaries are important in understanding electric field effect on polycrystalline materials.

Computational Insight for Field Assisted Sintering of TiO2: Jing Yang, Minh A. Dinh and Bilge Yildiz; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Field assisted sintering (FAST) has been demonstrated for multiple ceramic materials as a promising sintering technique in shortening consolidation time and lowering sintering temperatures. Mechanistically the interplay between electric field and the polycrystalline material is a complicated process and the governing factor for rapid densification during FAST is still under debate. In this work, we approached this problem from computational modeling in the model system of rutile TiO2. into a steady state cycle with respect to its dynamic response. In this work, we explore the ability of coupled electric and magnetic field processing to develop a range of micro-architectures within a composite smart material system. The system consists of micron-sized barium hexaferrite (BHF) particles, which have strong magnetic anisotropy, embedded in various polymers including a relaxor ferroelectric (RFE) polymer having nano-crystalline domains. Externally applied electric and magnetic fields act orthogonally on the embedded barium hexaferite particles within the uncured composite due to the particles' planar shape and crystallographic c-axis magnetization, allowing multi-axis control of particle alignments. Furthermore, externally induced dielectrophoretic and magnetophoretic particle-particle interactions allow control of the arrangement of aggregates of particles, providing a second hierarchical level of control. Both levels have an inherent time dependence as well. The combination of BHF and the RFE polymer gives us, to varying degrees, the electrostatic response of traditional electroactive polymers coupled with the magnetostriuctive and magnetic-torque based response of magnetoactive elastomers. The microarchitectures formed, visualized using optical microscopy and SEM techniques, range from traditional chains of particles, to aligned clusters, to segregated agglomerations and are achieved within specific regimes of the processing parameter – constituent design space. The ability to tailor varying architectures is seen as a pathway to developing localized multi-material response, from a single set of constituents, through processing alone.

Non-Thermal Microwave Effects and the Role of Spin Entropy Configurations Darvoosh Vashae, Amin Nozariabzarnaz and Kelvin Dosouza; North Carolina State University, Raleigh, North Carolina, United States.

Today microwave radiation is quite often used to derive chemical reactions. Rapid and convenient heating, product selectivity, and better control over the product properties are some of the main advantages of using the microwave synthesis. In some cases, the reactions happened at rates several thousand times faster than what is achievable with conventional heating at similar average temperature. The observation of such extraordinary effects has been the subject of a fundamental question that whether there exist additional microwave specific effects. One of the main reasons that contradict the direct interaction of the microwave field is the significantly smaller energy of the microwave photons than the energy of the chemical bonds. Therefore, microwave excitations have been believed cannot dissociate the bonds and can merely heat the material by exciting the rotation or torsion of the dipoles a.k.a. dielectric absorption. As we will discuss this is not covering the whole story, and a fundamental study at the molecular level offers a better understanding of the energy transfers and the interaction of the material with the electromagnetic field.

In recent years, remarkable studies have been focused on understanding the microwave effects that cannot be explained by equilibrium thermodynamics. We will group some of these effects based on our experiments and the literature into (a) field-induced deccrystalization, (b) enhanced solid-state reaction, (c) densification, (d) solid solution alloy decomposition, and (e) field-induced reduction. After a brief discussion of the existing theories or hypothesis associated with each group, we will present a detailed study that due to its molecular approach permits application to numerous experiments. In particular, we solved the master equation to describe the time evolution of the system under microwave radiation. Gillespie’s exact stochastic method was used to model the chemical reactions occurring within the system considering the collisional energy transfers, spin degeneracy, microwave absorption/emission, and the chemical reaction. The vibrational and rotational states were evaluated while counting the densities of states. Notably, the energy split due to the Jahn-teller spin crossover lead to a change in the density of states and amplified absorption/emission of microwave radiation, which could not be explained otherwise. The outcomes demonstrated a noteworthy increment in the number of trajectories experiencing chemical dissociation contrasted with the system without the microwave. The resonance absorption and emission of the microwave photons inducing a transition between the states of different spin configurations increased especially the dissociation rate. These outcomes can clarify at least partially a number of the non-thermal influences of the electromagnetic interactions with materials.
required for complicated experimentation with processes of different physical nature. In this paper, we present a 2D multiphysics model mimicking the steady-state temperature solution as a function of incident power. We show that an EMHE with particular thickness and dielectric properties of the layers is built for a triple-layered (fluid-ceramic-fluid) EMHE and is capable of capturing the S- and SS-profiles of power response curve which determines the principle of the EMHE.

The complex dielectric properties of Aluminum Nitride-Molybdenum ceramic matrix composites around the percolation threshold (5-25% Mo by weight) are measured using free-space transmission methods in the W-Band frequency range (75-110 GHz) and temperatures between 20-1000 degrees C. These investigations of the high-temperature electromagnetic properties of ceramic composites at millimeter-wave frequencies enable predictions of the absorption properties of these materials under millimeter-wave irradiation. The ceramics are fabricated with hot pressing to obtain a range of composite samples having compositions ranging from 5-25% Molybdenum (by weight) in an Aluminum Nitride matrix. The relationship between the DC conductivity, grain boundary, and grain bulk conductivity of a ceramic matrix with distributed metal particles is compared with the measured complex dielectric constant to determine millimeter-wave absorption properties near the percolation threshold for electrical conductivity. In addition, thermal conductivity data is presented using differential scanning calorimetry to determine the heat capacity and laser flash method to determine the thermal diffusivity of each composition up to 1000 degrees C. Chemical and microstructural analyses are performed to identify mechanisms giving rise to millimeter-wave absorption and dielectric losses, and including scan electron microscopy, energy dispersive spectroscopy, x-ray diffraction, tomography, mass spectroscopy, temperature-dependent AC impedance (1 Hz-1 MHz) using a Solartron furnace, and DC conductivity measurements using a high temperature four-point probe up to 1000 degrees C. Millimeter-wave heating and interactions based on complex dielectric properties are investigated using a 100 Watt klystron source operating at 95 GHz to study the millimeter-wave interactions, including measurements of the throughput and reflected power, with temperature, for refractory ceramics at high temperature under free-space irradiation.

Electromagnetic fields are used constantly in industry and research to order or disorder a material’s crystal lattice on very short timescales, however the fundamental mechanisms that underlie these processes are still unknown. Primarily the existence of non-thermal effects (when the field couples directly with the lattice) and how they can be distinguished from thermal effects (when the field’s energy is first converted to thermal energy before inducing lattice changes) is still an open question. In an effort to identify these effects we have been studying the phase formation and coverage of zirconia (ZrO₂) thin films grown using microwave radiation. Formation of cubic and tetragonal zirconia (c-ZrO₂, t-ZrO₂), metastable phases that usually use yttria (Y₂O₃) doping to become stable, suggest non-thermal effects. These phases were identified using glancing incidence X-Ray diffraction. This suggests existence of a non-thermal effect, as our syntheses don’t exceed 250 °C and these phases are not stable below 1,170 °C. Our films are grown in the microwave by selectively heating a conductive layer via ohmic heating. Upon changing the pattern of this conductive layer (while maintaining the same area) the phase that formed as well as the coverage of this pattern by the thin film was changed. We hope to continue exploring this relationship by using a design of experiments approach. We are also in the process of modeling the scattering by the conductive layer to observe how its geometry influences heating and hope to use finite element modeling in future to expand on this model. Dielectric properties of ZrO₂ will also help describe how the films are growing, which we are obtaining using W-band free space characterization methods.

An electromagnetic heat exchanger (EMHE) is a device which converts electromagnetic (EM) energy into usable form of heat energy. The working principle of the EMHE is based on a collective effect of EM wave propagation, heat transfer and fluid flow, so the development of an efficient device requires complicated experimentation with processes of different physical nature. In this paper, we present a 2D multiphysics model mimicking operation of a layered EMHE that simulates the nonlinear interaction between EM, thermal, and fluid flow phenomena involved in the operation of the EMHE. The model is built for a triple layered (fluid-ceramic-fluid) EMHE and is capable of capturing the S- and SS-profiles of power response curve which determines steady-state temperature solution as a function of incident power. We show that a EMHE with particular thickness and dielectric properties of the layers can operate efficiently by keeping temperatures during thermal runaway under control. Overall temperatures increase rapidly as soon as the local maximum temperature reaches a critical value. This condition is held true both in absence and in presence of fluid flow. It is demonstrated that the efficiency of the EMHE dramatically increases when thermal runaway is achieved. It is also shown that, with appropriate length of the layered EMHE, thermal runaway can be achieved at a lower power level.
Flash sintering has attracted significant attention lately as its remarkable rapid densification process at low sintering temperature leads to the retention of fine grains and enhanced dielectric properties. However, the underlying mechanism of flash sintering and mechanical behaviors of flash-sintered ceramics remain poorly understood. Here, we report the microstructure of flash-sintered yttria-stabilized zirconia (YSZ) and TiO2 by transmission electron microscope (TEM) and their high temperature in-situ micropillar compression studies inside a scanning electron microscope (SEM). Our studies on flash-sintered YSZ show that YSZ exhibits high inelastic strain (~8%) primarily due to phase transformation toughening below 400°C. At higher temperatures, crack nucleation and propagation are significantly retarded and prominent plasticity arises mainly from dislocation activities. The holding time and current density limit after the onset of flash for flash-sintered TiO2 significantly affect the microstructure and mechanical behavior. High dislocation density and stacking faults have been observed in the flash-sintered TiO2 under TEM. The presence of high-density defects generated during flash sintering plays a major role in the overall microstructure and mechanical behavior of ceramics.

Low-Temperature Phase Transitions in Microwave-Assisted Synthesis---The Role of Oxygen Defects and Non-Thermal Effects
Nathan Nakamura1, Elizabeth Culbertson2, Han Wang3, Haiyan Wang4, Simon J. Billinge2,4 and B. Reega Jayant5; 1Carnegie Mellon University, Pittsburgh, Pennsylvania, United States; 2Columbia University, New York, New York, United States; 3Purdue University, West Lafayette, Indiana, United States; 4Brookhaven National Laboratory, Islip, New York, United States.

Electromagnetic (EM) radiation can significantly affect ceramic synthesis and processing, inducing rapid, low-temperature crystallization, non-equilibrium phase formation, and altered material properties. In particular, microwave radiation (MWR)-assisted synthesis has demonstrated the ability to crystallize high-temperature ceramic phases at significantly lower temperatures than conventionally required and impact local atomic ordering relative to furnace-based techniques. However, the mechanisms underlying these effects are not well understood. To understand these mechanisms, it is necessary to characterize EM field effects not only on crystalline phase formation, but also on non-crystalline local atomic order due to defects or amorphous components. It has been theorized that defect generation and transport may play an important role in promoting the effects seen under EM field exposure. Therefore, the relationship between synthesis and processing parameters (e.g., temperature, pressure) and the type, concentration, and response of defects is critical to the efficient design of these materials. An increased understanding of the potential mechanisms underlying EM field-assisted techniques will create the opportunity to utilize these methods to stabilize non-equilibrium phases or phase mixtures with desirable material properties.

To better analyze how EM fields influence phase formation and transitions, we utilize X-ray pair distribution function (PDF) analysis complimented by transmission electron microscopy (TEM) and Raman spectroscopy to study the crystallization and local atomic order in ZrO2, TiO2, and ZnO thin films. We demonstrate that the low-temperature crystallization and phase transitions observed during MWR-assisted synthesis are not a result of purely thermal effects. In all materials studied, we find that MWR helps to crystallize phases at much lower temperatures than conventionally required, and that the local order differs in MWR and furnace-grown films. This indicates a clear effect of MWR exposure on phase formation. By analyzing the local atomic order across various synthesis conditions, we find that thermal effects (e.g., reaction temperature, heating rate) do not fully explain the phase transitions observed. From our results, we are able to gain insight into the importance of defects and potential mechanisms underlying field-assisted phase formation.

In Situ Pair Distribution Function Analysis of Atomic Displacement in TiO2 During Flash Sintering
Bola Yoon1, Devinder Yadav1, Rishi Raj1, Emanuele Sortino1, Sanjít Ghose1, Pankaj Sarin4 and Daniel Shoemaker1; 1Materials Science and Engineering Program, Department of Mechanical Engineering, University of Colorado Boulder, Boulder, Colorado, United States; 2Energy Sciences Directorate/Photon Science Division, NSLS II, Brookhaven National Laboratory, Upton, New York, United States; 4Department of Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; School of Materials Science & Engineering, Oklahoma State University, Tulsa, Oklahoma, United States.

Flash sintering is a novel field assisted sintering technique, whereby ceramics can be sintered in just a few seconds. For example, 3 mol% yttria stabilized zirconia (YSZ) was shown to sinter in < 5 seconds at a furnace temperature of 850°C under electric field of 120 V/cm. Recently, flash sintering has been extended to synthesize unusual materials which are far from equilibrium. However, the mechanism of flash sintering is still controversial. Several mechanisms have been proposed for flash sintering, such as joule heating and defect avalanche. Here, we study atomicistic understanding of flash sintering on TiO2 to elucidate its underlying mechanism. For this purpose, in-situ experiments of total X-ray scattering has been conducted at the National Synchrotron Light Source II at the Brookhaven National Laboratory. We have measured atomic displacement of O and Ti atoms within a unit cell, and found the unusual displacements in O atoms which are far greater than that from thermal expansion. It might imply that these atoms movements are the precursors to the generation of Frenkel pairs.

Developing the Underlying Principles for Electric Field Assisted Sintering for Improved Ceramic Manufacturability
Clement Nicollet, Jing Yang, Minh A. Dinh, Harry L. Tuller and Bilge Yildiz; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Field assisted sintering (FAST) has demonstrated great potential in reducing temperature constraints imposed on ceramic materials during sintering. While there have been many phenomenological observations of FAST processes, mechanistic understanding of the effect of electric field has been understudied and remains open. In particular, quantifying cation diffusion at different temperatures and polarizations both in bulk and at grain boundary is important for resolving the densification process under electric field. To that end, we studied the effect of defect chemistry on the field assisted sintering of TiO2 by both sintering experiments and first-principles based modeling. Sintering experiments under electrical field were conducted inside a dilatometer to control the shrinkage of the material in real time. To separate out the Joule heating effect, we used controlled doping concentration and oxygen partial pressure to controllably vary the electronic conductivity of TiO2, thereby controlling the extent of the Joule heating contribution. By varying the main cationic defects between Ti vacancies and interstitials, as well as their concentrations, we studied their effect on the FAST process. In parallel, the equilibrium defect concentrations under relevant conditions were predicted utilizing a first-principles based computational framework. By combining equilibrium defect concentration with defect diffusivities obtained from force field molecular dynamics, we constructed Ti self-diffusion profiles as a function of temperature, oxygen partial pressure and electric polarization. The predicted Ti self-diffusion coefficient agrees reasonably well with experimental measurements and in both cases Ti interstitials contribute dominantly. Moving from bulk to grain boundary, we found a very weak space-charge effect and a three-order-of-magnitude increase in the diffusion coefficient due to decreased Ti migration barrier. This result implies that Ti diffusion is greatly accelerated at the grain boundary. Identifying these factors advances our understanding of the individual effects of Joule heating, bulk cation diffusion, grain boundary mobility and electric polarization on flash behavior, and thereby, guide better control of ceramic materials manufacturing by FAST technology.
Processes that utilize DC or low-frequency electric fields provide a driving force for ion migration in ionic materials. This is particularly true in electric-field-assisted sintering where both high fields and high temperatures are involved, which enhance the kinetics of ion migration. This talk will discuss the effects of sample and electrode boundary conditions on electric-field-induced ion migration and resulting stoichiometry gradients in the context of field-assisted sintering. The implications for conductivity evolution and microstructure development will be illuminated, with examples from field-assisted sintering of yttria-stabilized ZrO2 (YSZ) and BaTiO3. Lateral and axial microstructural gradients will be discussed with respect to the electrochemical, thermal and mechanical boundary conditions of the ceramic body during sintering. In addition, more complex composite systems, such as layered systems of YSZ and Al2O3, which exhibit interesting asymmetrical sintering behaviors, will be discussed.

Nanostructured ceramic materials have various structural and functional applications. Flash sintering has attracted significant attention as one of its remarkably rapid densification process at low sintering furnace temperature leads to the retention of nanograins. However, high-temperature mechanical behaviors of flash-sintered ceramics remain poorly understood. Here, we present the high temperature in-situ microcompression studies on ultrafine grained yttria-stabilized zirconia (YSZ) processed by flash sintering technique. At room temperature, the flash-sintered YSZ sustains a large strain before fracture due to the local temperature during this process. It is disputed whether the observed phenomena are thermal or non-thermal in nature. It is possible that coupling of microwave and matter can lead to localized heating, which would also result in rapid reaction/diffusion kinetics at preferential sites. But, this temperature inhomogeneity still does not explain the nucleation of meta stable phases under microwave. In this work, microwave radiation-assisted synthesis of TiO2 is performed with three different materials as substrate. In situ x-ray diffraction (XRD) is used to track the change in lattice parameters of both the substrate and the synthesized TiO2 powder during growth and crystallization. The lattice expansion was correlated with the actual temperature at the ceramic/substrate interface and within the ceramic itself. The temperature distribution and change in crystal structure is used to differentiate the thermal from the non-thermal contribution of externally applied fields during the process.

Microwave radiation-assisted synthesis reduces the reaction temperature and improves the yields compared to a conventional furnace synthesis. Additionally, it has been shown to alter the material properties of final product by incubating new phases, changing crystallinity, or modifying particle size distributions. For example, during an experiment involving synthesis of TiO2 on an indium tin oxide (ITO) layer under microwave radiation, a mixed phase structure consisting of a long-range anatase phase and a short-range amorphous phase was obtained. The results were linked to the formation of an oxygen-deficient meta stable phase under microwave irradiation. The exact mechanism, however, remains undetermined, as there is no direct method to measure the local temperature during this process. It is disputed whether the observed phenomena are thermal or non-thermal in nature. It is possible that coupling between microwave and matter can lead to localized heating, which would also lead to rapid reaction/diffusion kinetics at preferential sites. But, this temperature inhomogeneity still does not explain the nucleation of meta stable phases under microwave.

Microwave radiation-assisted synthesis of TiO2 is performed with three different materials as substrate. In situ x-ray diffraction (XRD) is used to track the change in lattice parameters of both the substrate and the synthesized TiO2 powder during growth and crystallization. The lattice expansion was correlated with the actual temperature at the ceramic/substrate interface and within the ceramic itself. The temperature distribution and change in crystal structure is used to differentiate the thermal from the non-thermal contribution of externally applied fields during the process.

In some wireless power transfer systems utilizing thermo-mechanical conversion methodologies, bulk susceptor materials are required to convert microwave or millimeter wave radiation to thermal power which is, in turn, converted to electrical power. These bulk susceptor materials may take the form of composites formed from a high thermal conductivity ceramic matrix in combination with a radiation-absorbing additive, such as lossy ceramic or metal particles. For ease of design, the effective dielectric loss of the susceptor composite should be dominated by the additive material. Additionally, the temperature-dependent dielectric loss of the composite should be as weakly exponential as achievable to limit the likelihood of thermal runaway effects and to better enable optimization over a wide range of operating temperatures. Ceramic composites present under investigation for use as mm-wave susceptors include aluminum nitride composed with molybdenum powder (AlN:Mo) and aluminum nitride composed with titanium diboride (AlN:Tib). Thermal properties, compositional and structural analysis, and high-temperature complex permittivity data will be presented for AlN:Mo compositions ranging from 0.25% to 4% Mo (by weight). Preliminary complex permittivity measurement data will also be presented for selected AlN:Tib formulations. Data presented on these AlN-based ceramic composites will be discussed in the context of suitability of these materials for use in future wireless power transfer experiments.

Dielectric Breakdown in Ceramics—Conduction Mechanisms, Conducting Filaments and Breakdown Toughness

Gerold A. Schneider and Pia-Kristina Fischer; Hamburg University of Technology, Hamburg, Germany.

Even though dielectric breakdown in ceramics is a limiting factor for the reliability of electronic devices and components and despite almost 100 years of research there is no commonly accepted understanding of this phenomenon. In this talk a Griffith-type dielectric breakdown model is presented. The difference to previous models is that it is based on space charge limited conduction (SCLC) and not on Ohmic conduction. It is shown that in a lot of ceramics SCLC is most likely the dominating conduction mechanism at very high electric fields. As the origin of dielectric breakdown it is assumed that tiny electrically conducting filaments get unstable at the breakdown field and grow to the well known breakdown channels. To investigate this hypothesis artificial conducting channels were prepared in borosilicate glass using a Focused Ion Beam. It will be shown that the breakdown strength is linearly dependent on the inverse square root of the lengths of these filamentations, which is in agreement with the prediction of the model. From these results a breakdown toughness for borosilicate glass can be determined. In summary it is possible to describe the size dependence and scattering of the breakdown strength with this approach.

Electrochemistry and Electro-Kinetics in Zirconia Ceramics

Field assisted sintering such as flash sintering and spark plasma sintering attracts much attention in the ceramic community. It is of particular interest to clearly identify non-thermal effects, to understand diffusion/phase-transformation kinetics and to control microstructural evolution, aided by an electric field and maybe enhanced by far-from-equilibrium defects. To echo and argue on such non-equilibrium effects, we shall present our recent work on how electric field influences zirconia’s microstructure and how we can understand it within equilibrium. We emphasize applied electric field can greatly change local thermodynamics, hence influencing kinetics indirectly.

Phenomenological correlation: By grain growth experiments, we show hydrogen and electrochemical reduction enhances grain boundary mobility and cation diffusion in zirconia and ceria. [1-2]

Electrochemistry: Anions and electrons set up local equilibrium. Zirconia is a fast oxygen ion conductor with little electronic conductivity. So electrode reactions at metal/zirconia interface are necessary to convert electron flow in outer circuit to oxygen ion flow inside zirconia electrolyte. Yet it must in the end become sluggish, creating huge overpotentials and shift equilibrated defect concentrations. Through continuum-level simulations, we obtain a step-like oxygen potential profile responsible for observed grain-size transition inside electrically loaded zirconia, and a flux discontinuity at grain boundary responsible for observed cavitation.

Electro-kinetics: Cation diffusion determines global microstructure evolution. Cation diffusion in zirconia and ceria takes place via a vacancy mechanism [3-4], yet it is enhanced by reduction, which according to defect chemistry decreases the concentration of cation vacancy. This conundrum has been resolved by our recent first-principles calculations. We found reduction-created electrons can greatly lower cation’s migration barrier. It suggests a critical role of minor electronic defects in determining mass transport for oxides (even as ionic as zirconia), which had been totally overlooked by classical nonstoichiometric defect chemistry.

Nano-structured and nano-grained materials are among the most promising applications of field-assisted sintering techniques, thanks to their characteristic ability to enhance densification and hamper grain growth through high heating rates and the aid of electric fields and current. The introduction of multifunctionality is also often made possible by combining tailored nano-architectures with such ultra-rapid processing methods. This study addresses the potential of spark plasma sintering for the production of advanced iron oxide-based ceramics with an enhanced combination of magnetic and mechanical properties. The green samples consist of organically-covered magnetite nanoparticles, with diameter below 18 nm and monomodal size distribution, self-organized into an extended tightly-packed supercrystalline lattice. The application of relatively low-temperature spark plasma sintering regimes leads to the controlled development of bulk nanocrystalline ceramic materials with tunable magnetic properties and a unique combination of strength, hardness, stiffness and toughness. 4:00 PM PM05.05.06 Polymer Patterning Via Electrohydrodynamic Instabilities Katherine E. Copenhaver and Jason H. Nadler; Georgia Institute of Technology, Atlanta, Georgia, United States.

Patterned polymer surfaces can provide high-index contrast over a periodic matrix with 3-dimensional element shapes. The dielectric contrast and array pitch and height can be tuned to control specular reflection and achieve specific scattering characteristics. Surfaces with tailored scattering characteristics in the aforementioned ranges could be useful in producing frequency-selective windows for glare reduction, anti-reflective solar cells with enhanced efficiency, surface waveguides and whispering gallery-mode resonator arrays for integrated photonics and sensors, and surfaces with controlled emissivity for direct heat dissipation. Electrohydrodynamic (EHD) instabilities can be induced in polymers by placing a polymer film above its Tg in a strong electric field between two capacitor plates or electrodes. The polymer experiences an electrostatic stress at the interface between the polymer and air due to a mismatch in their dielectric constants. This stress, along with thermal fluctuations, induces small magnitude capillary waves in the polymer film, and the minima and maxima of those waves experience slightly different electric field strengths. In a sufficiently strong electric field, the capillary wave maxima, where the distances between the polymer film and the top electrode(s) are the smallest, are eventually drawn up to the top electrode. The wavelength of the instabilities in the film and the ability of the polymer to be drawn upward is a dependent on the competition between surface tension forces and the electrostatic stress imparted on the polymer. While EHD instabilities are typically used to pattern polymer surfaces on a nanometer-scale, instabilities have been induced in polymer films with air gaps up to 500 μm. Upper electrodes with non-planar structures have also been used to induce instabilities in polymer films, resulting in patterned polymer surfaces without contact. Size, shape, arrangement, and placement of the upper electrode relative to the polymer film and lower electrode, as well as the processing conditions such as temperature and applied voltage, can all be modified to produce a desired array of structures with tailored performance characteristics.

4:15 PM PM05.05.07 Controlling Catalytic Reaction Pathways via Magnetic Heating Natalia da Silva Moura, Pragathi Darapaneni, Kerry Dooley and James A. Dorman; Louisiana State University, Baton Rouge, Louisiana, United States.

The catalysis market is responsible for more than 35% of the world’s GDP, and it is involved in the most successful industrial sectors: energy generation, chemicals, and pharmaceuticals. Despite the remarkable advances in catalytic technologies, the industry still faces thermal management issues and accumulation of heat on reactor walls. Alternatively, it is possible to overcome the activation barrier using in situ methods via iron oxide (Fe3O4) exposed to an alternating magnetic field. In this work, Fe3O4 nanoparticles will be used to convert alternating magnetic fields to heat to study the effects of localized energy on the chemical transformation in a reference alcohol condensation reaction. 20 nm iron oxide nanoparticle spheres, cubes, and truncated octahedrons of tunable sizes are exposed to RF fields to drive an alcohol dehydration reaction. The size and shape of these particles are controlled by varying surfactant to precursor ratio in thermal decomposition reactions. These facets allow for the tuning of surface activity and heat generation, key parameters for selectivity and activity engineering. The heat generated is dependent on the spin configuration on the surface, with minimum heating rates at least 34% higher than commercially available particles. Surface functionalization with hydroxyl groups is performed to increase the interaction of Fe3O4 with alcohols in dehydrogenation reactions. This localized heat generation can be used to control surface functionalization for dispersion in aqueous solutions and conversion of alcohols. For spherical particles, the GC-MS data shows production of aldehydes and esters via thermal routes while RF induced reactions result in longer alkenes, such as decene, which is dependent on the applied magnetic field. These results indicate changes in the reaction mechanism associated with RF activation. Furthermore, to investigate the role of the surface of iron oxide without any surfactants on the mechanism of the reaction, spherical nanoparticles are also synthesized via co-precipitation routes. The catalyst is characterized before and after functionalization and reaction steps to probe the crystal structure, oxidation states of iron and morphology of the particles, using XRD, XPS, and HRTEM respectively. The reaction products are characterized via GC-MS to elucidate the reaction mechanism.
The macroscopic properties of polycrystalline ionic ceramics are determined by the doping levels, point defects, and their interaction with the microstructure, as they are specified via processing and the target application. Here, the starting powders react, densify, and coarsen into microstructurally tailored grain topologies that are aimed to enhance (but sometimes limit) the performance of the device that are part of. The extent of these interactions varies with grain size, crystallographic orientation, and misorientation distribution, as well as applied fields, such as stress or electric fields. In order to understand the grain boundary characteristics, including their electrochemical properties and the driving forces that control grain coarsening, a thermodynamically consistent diffuse interface theory is being developed. The theory naturally incorporates the effects of drag as they are imposed by the interfacially accumulated charged defects on the grain growth of polycrystalline ceramics. Applications to materials such as YSZ, GCO, and STO (and comparisons against experimental results) are presented.

Electromagnetic (EM) heat exchangers are devices which absorb EM radiation converting it into thermal energy to do work, such as run a turbine. Applications involving both solar and microwave energy have garnered increasing attention but have yet to utilize the potential benefits of short-wave interactions when the wavelength is comparable to a material’s microstructure. It has been shown for a three-layer laminate the Bragg resonance that occurs at this scale can be used to control steady state temperature and thermal runaway effects. We investigate these effects in a mathematical model approximating a porous medium for use in a heat exchanger. Classical homogenization methods average over the microscale to obtain a macroscopic description of the material, however they are incapable of describing short-wave behavior. High-frequency homogenization methods have been developed but are restricted to cases incompatible with modeling heat exchangers, such as assuming a lossless medium, spatially uniform dielectric constants, and reducing Maxwell’s equations to the Helmholtz equation. We develop a high-frequency homogenization technique that relax these assumptions, considering a laminate geometry composed of alternating layers of lossy dielectric material and lossless fluid channels in the homogenization limit. This model advances the designing of porous materials for efficient collection of energy in electromagnetic heat exchangers.

Nucleation of metastable vaterite CaCO₃ is mediated by electric fields. Wenhao Sun and Gerbrand Ceder; Lawrence Berkeley National Labs, Berkeley, California, United States.

Vaterite is a transient metastable polymorph of calcium carbonate that often appears during the multistage crystallization of CaCO₃. Nucleation of vaterite prior to the equilibrium phase calcite should, according to classical nucleation theory, be facilitated by a lower surface energy of vaterite than calcite. We perform a thorough density functional theory investigation of calcite and vaterite surface energies, and find, contrary to expectations, that vaterite unequivocally has the higher surface energy of the two phases. Here, we present a novel mechanism to rationalize the preferential nucleation of vaterite. Because the vaterite crystal structure is composed of alternating Ca²⁺/CO₃⁻ planes in the [001] direction, nanoparticles of vaterite possess a permanent electrostatic dipole moment. We show that nuclei of vaterite can be stabilized relative to calcite under electric fields that are consistent with charge inhomogeneities on mineral surfaces, in biogenic macromolecules, and in aqueous electrolyte solutions. The role of electric fields in nucleating the polar polymorph of CaCO₃ can be more generally leveraged to synthesize metastable polar phases of other materials, potentially opening the door to materials with novel or superior functionality.

During "flash sintering," the application of an external electric field results in rapid densification at significantly reduced temperatures in many materials. The flash event is accompanied by a dramatic increase in the conductivity of the sample and an expansion of the lattice constants. I will discuss the microscopic processes contributing to flash sintering. In particular, I will discuss the coupling between a non-equilibrium carrier distribution and defects within the grains. I will present examples of density functional calculations of defects in yttria-stabilized zirconia and titania. This work was performed in collaboration with Noam Bernstein and Steven C. Erwin at the Naval Research Laboratory.

Additive manufacturing enables production of complex shapes and customizable designs, using a wide variety of materials. Direct layer-wise sintering of ceramics using additive manufacturing techniques, however, has been an elusive goal due in part to the rapid kinetics required to sinter ceramic powders together one layer at a time. Flash sintering research using conventional furnace heating has demonstrated that application of an electric field during furnace sintering results in very rapid densification of ceramics, in most cases decreasing over an hour of sintering time to seconds. The simultaneous application of an electric field with laser scanning of ceramic powders is investigated as a method of enabling the processing of ceramic powder using selective laser sintering.
Electrochemical Effects on the Microstructural Evolution of STO

Suryanarayana V. Karra, Rheinheimer Wolfgang and R. Edwin Garcia; Purdue University, West Lafayette, Indiana, United States.

Grain growth experimental studies on perovskites exhibit unimodal or bimodal microstructures as a function of temperature and dopant concentrations, as a result of the underlying point defects and their interaction with the grain boundaries. The extent of these interactions varies with grain size, orientation and misorientation distribution, as well as processing temperature and amount of doping. A theoretical formulation based on a thermodynamically consistent diffuse interface model has been developed to understand the effects of dopants on the grain coarsening of polycrystalline ionic solids. The theory is applied to Fe-doped Strontium Titanate (STO). At small Fe amounts and low temperatures the microstructures exhibit unimodal and coarse microstructures. An increase in Fe concentration or temperature results in a bimodal grain size distribution that affects the overall grain growth dynamics. In agreement with experimental results, the developed theory provides a starting point to understand the effects of the structural and electrochemical state of the grain boundary properties and its impact on the microstructural evolution of STO, including the possibility of abnormal grain growth.

Electric Field-Induced Softening (EFIS) of Alkali Silicate Glasses

Charles McLaren², William Heffner¹, Surapong Panyata¹, Bernhard Roling³, Rishi Raj¹, Nicholas Smith² and Himanshu Jain¹; ¹Lehigh University, Bethlehem, Pennsylvania, United States; ²Corning Incorporated, Corning, New York, United States; ³University of Marburg, Marburg, Germany; ⁴University of Colorado Boulder, Boulder, Colorado, United States.

Inspired by the observations of dramatic effects of electric field on sintering of ceramic powders, we investigated the effect of electric field on the softening of alkali silicate glasses that were heated at a constant rate under static load and fixed voltage. We observed abrupt softening and viscous flow at furnace temperatures well below the glass transition temperature, resulting in a new phenomenon, termed electric field induced softening (EFIS) of glass. The strain, the specimen temperature (obtained with a pyrometer), and the optical emission spectrum have been measured simultaneously as a function of time. Preceding the overall softening, localized hot spots are observed near the anode, which may meander before leading to an abrupt increase in electrical conductivity as well as photoemission. The effect is more pronounced (that is, it occurs at a lower temperature) with AC field of ~1 kHz than with DC electric field. Unusual events at the metal-glass interface, resembling dielectric breakdown are observed, which, however, are less localized in AC than in DC experiments. These observations suggest the following sequence of events: polarization of the sample from ion displacement under the application of electric field as in electro-thermal poling, formation of an alkali ion depletion layer, development of large internal electric fields across this layer, electrolysis and charge injection followed by dielectric breakdown, and very high localized heating near the anode, ultimately leading to thermal runaway and softening throughout the sample. The results suggest that AC electric field assisted softening may be better suited to practical applications of this phenomenon. The magnitude of EFIS is significantly larger in single alkali than in relatively lower conductivity mixed-alkali glass of same mole fraction of silica, raising the possibility that EFIS can be induced in highly conductive glasses even at ambient furnace temperature. Potential applications of EFIS will be presented.

Laser Fabrication of Single Crystal within Glass—Influence of Polarization

Volkmar Dierolf¹, Keith Veenhuizen², Courtney Au-Yeung¹, Sean McAnany¹, Lejla Hoxha¹, Khalil Tafiti², Bruce Atkén¹, Dan Nolan¹, Dmytro Savitskyy³ and Himanshu Jain¹; ¹Lehigh University, Bethlehem, Pennsylvania, United States; ²Lebanon Valley College, Annville, Pennsylvania, United States; ³Corning Incorporated, Corning, New York, United States.

Spatially selective heating of a glass using lasers allows to precisely control the conversion of a glass into a single crystal. In particular, we have shown that it is possible to perform this conversion without ever melting the glass. In such a solid-solid conversion, the growth conditions are highly constrained, which produce unusual crystallization characteristics. In this presentation, we will give an overview of the most unique features which include preferred orientation of seed crystals and controlled rotation of the crystal lattice orientation both along and perpendicular to the growth axis. These concepts will be introduced for crystallization on the surface of a chalcogenide glass using a cw-laser as well as for 3D-crystallization inside a lithium niobosilicate glass. The dependence of these phenomena on the properties of the laser irradiation, in particular the laser polarization will be discussed. We will report on how the polarization determines the orientation of the seed crystal as well as how it determines the crystal growth. Interpretations of these phenomena will be presented.

11:45 AM ANNOUNCEMENT PRESENTATION/POSTER AWARDS
Part of this study was carried under the research of SIP in JST (Japan Science and Technology Agency). Multi-component systems of the alloys, including both substitutional and interstitial elements. In case of Ti-Al-M1-M2 quaternary systems, for example, we develop novel heat treatments to optimize the interaction parameters to calculate the phase diagram in good agreement with experimentally determined phase diagram, by taking into account the influence of deformation and kinetic aspects.

Intermetallic Titanium Aluminid based alloys are considered for high-temperature aero and automotive engine applications. The advantage of this class of innovative high-temperature materials is their low density in combination with good strength and creep properties up to 850°C. A drawback, however, is their limited damage tolerance at room temperature, which is reflected in a low plastic fracture strain and fracture toughness. Advanced engineering Titanium Aluminid alloys are complex multi-phase materials which can be processed by ingot or powder metallurgy. Engine components can be manufactured by casting as well as additive manufacturing, e.g. electron beam melting. Each ingot production process leads to specific microstructures which can be optimized by thermo-mechanical processing, e.g. isothermal or hot die forging and subsequent heat treatments. Thermo-mechanical processing can provide balanced mechanical properties, i.e. a minimum ductility at room temperature as well as sufficient creep strength at elevated temperature. In order to achieve this goal, the knowledge of the occurring solidification processes and phase transformation sequences is essential. Therefore, thermodynamic calculations were conducted to predict the phase diagram of engineering TiAl alloys. After experimental verification, these phase diagrams provided the basis for the development of heat-treatments. To account the influence of deformation and kinetic aspects sophisticated ex- and in-situ methods have been employed to investigate the evolution of the microstructure during thermo-mechanical processing. For example, in-situ high-energy X-ray diffraction was conducted to study dynamic recovery and recrystallization processes during hot-deformation tests. Novel high-strength Titanium Aluminid based alloys, such as TNM alloys have been developed in the last decade to meet the advanced requirements of aero engines. These alloys are characterized by a high content of β-stabilizing alloying elements, such as Nb and Mo. Because Nb and Mo represent the decisive alloying elements, this alloy family, based on the γ-TiAl phase, has been named “TNM alloys” in order to distinguish them from the well-known and even stronger “TNB alloys” which rely on a high Nb concentration and small additions of B and C. At room temperature, strength levels > 1000 MPa can be achieved in advanced TiAl alloys by appropriate thermo-mechanical processing and subsequent heat treatments. It is important to note that also high temperature properties, such as creep resistance, were considerably improved, e.g. by implementation of precipitation hardening, which further extend the application range of Titanium Aluminid based alloys.

Advanced this talk, we present achievements and design approaches for the development of wrought TiAl alloys to be used for LPT and HPC blades. First, we built up a new database for phase diagram calculations in advanced TiAl alloys by appropriate thermo-mechanical processing and subsequent heat treatments. It is important to note that also high temperature properties, such as creep resistance, were considerably improved, e.g. by implementation of precipitation hardening, which further extend the application range of Titanium Aluminid based alloys.

Innovation of structural materials is urgently being required for contribution to worldwide issues on energy, environment, and high performance jet engine development with larger thrust-to-weight ratio is one of them, since more than 30,000 new airplanes are to be produced by 2030. A five-year National project of “Structural Materials for Innovation (SM4I)” in Cross-ministerial Strategic Innovation Promotion Program (SIP) starting from 2014 is currently going on in Japan. In this project of SM4I, a focus is placed on innovative structural materials applicable for jet engines, where author at Tokyo Tech is committed to as a technical leader and take responsibility for alloy design and development of TiAl alloys in collaboration with other universities (Hokkaido Univ., Osaka Univ.) and industries (Kobe Steel, Ltd and IHI Co.). In this talk, design approaches and achievements for the development of wrought TiAl alloys to be used for LPT and HPC blades are presented. First, we built up a new database for phase diagram calculations in multi-component systems of the alloys, including both substitutional and interstitial elements. In case of Ti-Al-M1-M2 quaternary systems, for example, we optimize the interaction parameters to calculate the phase diagram in good agreement with experimentally determined phase diagram, by taking into considerations of temperature, aluminum and M1/M2 concentration dependencies in the four phases of β-Ti, α2-TiAl, α-Ti and γ-TiAl phases. Based on the phase diagram calculations, we successfully proposed model alloys with excellent hot workability even at higher strain rate and room temperature ductility of more than 1%. It should be noted that an introduction of bcc b-Ti phase and microstructure design using a unique phase transformation pathway of β→α→γ→β'γ in the multi-component systems makes it possible to have excellent properties in both process and service temperatures. We revealed the alloy with lamellar microstructure decorated by β'/γ duplex microstructure at the lamellar colony boundaries show better crack initiation and propagation resistance than that with fully lamellar microstructure. The detailed microstructure control method using the phase transformations and toughening mechanism will be presented.

The present study applies a strategy of grain refinement on a γ-based Ti-45Al-7.5Nb intermetallic compound through high-pressure torsion (HPT) processing for 5 and 10 turns under a compressive pressure of 6.0 GPa at room temperature. Successful grain refinement was introduced in the duplex microstructure to have ultrafine lathes with thicknesses of 40-100 nm after 10 HPT turns. Exceptional hardness is recorded after the severe plastic deformation and the X-ray diffraction analysis confirmed the occurrence of phase transformation from γ-TiAl to α2-Ti3Al in the alloy. The close investigation demonstrated that hardness and texture evolution vary gradually from the sample surfaces to the core, thereby exhibiting a heterogeneous microstructure. Macroscopic plastic flow is estimated thorough the micro-mechanical responses by the nanoindentation technique for the TiAl alloy. This study demonstrates the promising feasibility of HPT processing for improving essential mechanical properties in the TiAl.

Low Pressure Turbine blades made of TiAl alloys are being used in three civil aircraft engine families (GEx, PW1000GTF, LEAP). The production process of TiAl semi-finished parts is based on three technological pathways: VAR ingot metallurgy, VAR Skull Melter homogenization and subsequent investment casting to oversized components followed by mechanical machining VAR ingot metallurgy, VAR Skull Melter homogenization and subsequent centrifugal casting in permanent moulds to small sized feed stocks for either forging or mechanical machining or direct mechanical machining:

- Plasma Arc Cold Hearth Melting to small sized ingots for direct mechanical machining
- In both processing routes b) and c), a substantial amount of valuable TiAl revert is being generated during the different processing steps. An industrial recycling process based on Vacuum Induction Skull Melting with subsequent centrifugal casting according to the technological pathway b) has been developed and commissioned at GfE. Appropriate revert preparation technologies prevent a detectable impurity pick-up from previous processing steps even for multiple use of revert. The corresponding revert preparation and revert conversion technology is approved and validated for the production of pre-materials for components for aircraft engines. The presentation addresses the origin of revert and the appropriate revert preparation technology. The recycling process via Induction Skull Melting is being introduced. Resulting products are indistinguishable from products resulting from the virgin production route via VAR Skull Melting with regard to chemical composition and microstructure.

Introduction of YSK-TiAl, Novel Wrought Alloy with High Strength and Advanced Producibility

Keiji Kubushiro, Yutaro Ota, Yohei Sakakibara, Shin Usui, Satoshi Takahashi, Kotaaro Tagawa and Masanobu Baba; IHI Corp, Yokohama, Japan.

This study demonstrates the promising feasibility of HPT processing for improving essential mechanical properties in the TiAl.
the present work we study at high temperature the mobility of defects controlling the mechanisms responsible for creep. However, the study is approached through mechanical spectroscopy by measuring the internal friction (IF) spectra between 300 and 1350°C. On one hand, the high temperature background (HTB) of the IF is closely related to creep behavior [1], and on the other hand, the relaxation peaks of the IF spectra offer valuable information about the atomic diffusion mechanisms involved in creep [2,3]. In particular, the developed nano-lamellar microstructure allow us to discover and analyze a new relaxation peak, which remains hidden in between the IF peak associated to Ti diffusion in α2-Ti3Al phase [2] and the HTB. We have measured the IF spectra at different frequencies and performed a deep analysis to decompose the IF spectra into the different contributions and isolate the relaxation corresponding to each individual atomic mechanism. This way we measured the activation energy of the hidden relaxation, E_a=3.7 eV, which is attributed to the Aluminum diffusion in γ-TiAl phase. Moreover, a new atomic relaxation mechanism is proposed to explain the characteristic of the observed IF peak. Finally, the importance of the discovered relaxation is discussed in terms of its relationship with the atomic diffusion processes involved in creep.

Density Functional-Based Kinetic Monte Carlo Approach to Ni Pipe Diffusion

Luke Wirth1, Amir A. Farajian1 and Christopher Woodward2; 1Mechanical and Materials Engineering, Wright State University, Dayton, Ohio, United States; 2Air Force Research Laboratory, Dayton, Ohio, United States.

Pipe diffusion along dislocations in metals can occur at faster rates than in bulk regions, expediting creep and contributing to device failure. We use density functional theory methods to calculate the vacancy-mediated diffusion coefficient along a <1-1 0-> screw dislocation in FCC nickel. A lattice Green’s function technique is used to accurately configure the atomic structure surrounding the dislocation core. Vacancy hop rates within this region are calculated using principles of transition state theory with activation energy barriers and vibrational properties obtained from our ab initio framework. A kinetic Monte Carlo model then uses these rates to describe mass transport within the region on representative timescales at various temperatures.

SESSION PM06.02: Silicides and Ultra-High Temperature Alloys

Monday Afternoon, November 26, 2018

Alloy Design of Refractory BCC-T2 Silicide-B2 Aluminide Multicomponent-Multiphase Alloys

Seiji Miura, Satoshi Takizawa and Ken-ichi Ikeda; Hokkaido University, Sapporo, Japan.

Refractory-metal based materials have attracted attentions for many years because of the increasing demand for high temperature components. In order to obtain such materials having superior properties for high temperature use, multicomponent-multiphase alloys are required. Authors have conducted studies on the mechanical and physical properties of BCC solid-solution phase, MoSi2-T2 silicide phase and B2 aluminide phase, together with phase equilibrium among these constituent phases. Authors have conducted the investigation on the effects of various additive elements on the strength and deformability of BCC solid solution. As (Nb, Mo)(Si, B), phase dispersion in Nb-Mo BCC solid-solution matrix has been studied by various researchers, we also try to understand the phase stability of T2 phase in alloys. Although silicide phases including (Nb, Mo)(Si, B) show superior oxidation resistance, we have focused on B2-aluminide coating because B2-NiAl coatings have been used for commercial Ni-based superalloys. To realize a three-phase alloys composed of refractory BCC, T2 silicide and B2 aluminide, phase equilibrium in ternary, quaternary and higher-order phase diagrams are experimentally investigated. Among them, brittle compounds such as Nb(Ni, Al)2 Laves phase form at the interphase boundary between NiAl and Nb-based alloys during high temperature heat-treatment. To avoid the formation of Laves phase, both the B2 phase composition and the BCC alloy composition were optimized based on the phase diagrams such as Nb-Al-Pd and Nb-Mo-NiAl, then a composition area at which BCC solid-solution phase equilibrates with B2 aluminide was found in Nb-Mo-Ni-Al-Pd quinary system. By the systematic investigation, it was found that the atomic size ratio of constituent elements is still an important key to understand the stability of ternary Laves phases including Al. For a further understanding of the substitutes behavior of elements in the Laves phase, electronic structure calculations based on the density functional theory (DFT) was performed on the alloy system including Si. This work was supported by the Advanced Low Carbon Technology R&D (ALCA) program of the Japan Science and Technology Agency (JST).

2:00 PM PM06.02.02

Role of Mo Solid Solution on Ultrahigh-Temperature Tensile Creep Deformation of MoSiBtic Alloy

KyoSuke Yoshimi1, Shihito Y. Kamata1, Shunichi Nakayama1, Sojirou Uemura2, Sadahiro Tsukerawa2, Gunther Egelier1 and Kouichi Maruyama1; 1Tohoku University, Sendai, Japan; 2Kumamoto University, Kumamoto, Japan; 3Ruhr-University Bochum, Bochum, Germany.

A Mo-Si-B-based alloy reinforced by TiC (65Mo-10Ti-5Si-10B (at.%)) shows high creep resistance estimated over the rupture time of 1000 h under 137 MPa at 1350°C and relatively good room-temperature fracture toughness over 15 MPa(m)1/2. The excellent mechanical properties arise from the high strength of Mo-Si-B (T2) and TiC, the good ductility of Mo solid solution, and the microstructural configuration of these phases. Under creep deformation, the resistance of Mo solid solution would be one of key factors controlling the overall strength of the material and the interfacial sliding between these phases would be the other factor. In this paper, the role of Mo solid solution on ultrahigh-temperature tensile creep deformation is addressed for the MoSiBtic alloy. The microstructural continuity of Mo solid solution was analyzed in terms of the percolation probability. It was clarified by the percolation probability analysis that both the Mo solid solution and brittle phases (T2 and TiC) were not 100%-continuous in the microstructure. EBSD and TEM observations for ruptured specimens presented dynamic recrystallization in Mo solid solution due to heavy plastic deformation during creep but much less plastic deformation in the brittle phases. These results represent that the creep strain was given by the dislocation creep of Mo solid solution and the interfacial sliding between the phases. The apparent activation energy of creep was estimated to be about 560 kJ/mol from the Arrhenius plot of the logarithm of the minimum creep rate against inverse temperature. The value is much higher than the activation energy of the self-diffusion of Mo. This strongly suggests that the rate-controlling process of this creep is governed by the bulk diffusion in Mo solid solution rather than interfacial diffusion. However, it is unlikely to be caused by Mo self-diffusion because of its lower activation energy, but it might be caused by impurity diffusion, for example, of interstitial (I)-substitutional (S) pairs. The role of Mo solid solution on ultrahigh-temperature tensile creep deformation of the MoSiBtic alloy will be further discussed with experimental data.

2:15 PM PM06.02.03
Density Reduced Mo\textsubscript{x}-(Mo,V)\textsubscript{y}Si\textsubscript{z}-(Mo,V)\textsubscript{y}SiB\textsubscript{z} Alloys Julia Becker\textsuperscript{1}, Ulf Betke\textsuperscript{1} and Manja Krüger\textsuperscript{2}; 1Otto von Guericke University, Magdeburg, Germany; 2IEK-2, Forschungszentrum Jülich GmbH, Jülich, Germany.

In terms of preserving resources and reducing environmental impacts, improving the efficiency of turbines for power plants and aircraft engines is an increasingly important research subject. Potential high performance materials are Mo-Si-B alloys. Consisting of a molybdenum solid solution (Mo\textsubscript{90}) phase and two intermetallic phases Mo\textsubscript{5}Si\textsubscript{3} (T\textsubscript{2}) and Mo\textsubscript{5}Si\textsubscript{3} those alloys present balanced room temperature fracture toughness, high temperature creep strength and oxidation performance. In this work vanadium as a lightweight element with a density of 6.1 g/cm\textsuperscript{3} has been identified as a potential alloying partner which can entirely be solved in the Mo\textsubscript{5}Si\textsubscript{3} phase as well as in the Mo\textsubscript{5}Si\textsubscript{3} and MoB\textsubscript{5} phase. To identify the role of vanadium in terms of strengthening the solid solution phase different Mo-XV (X = 5...50 at.%) alloy compositions were produced and evaluated by means of microhardness measurements. Additionally, quantitative values for solid solution hardening were determined by the approach of Labusch. Compared to other alloying concepts, e.g. Mo-Ti, vanadium affects a more balanced strength – ductility relation at room temperature, i.e. a slightly reduced strength but increased plastic deformability. In the next step, potential Mo-V-Si-B materials which provide a reduced density by about 20% as compared to reference alloy Mo-9Si-8B were investigated. Different alloy compositions were obtained by powder metallurgy to observe the effects of V as a solvent in the respective phases. The microstructure of the bulk Mo-40V-9Si-8B was characterized via SEM and XRD. From Rietveld refinements the preferred V sites in the lattices of the present phases were derived. The mechanical behavior was determined by microhardness measurements as well as constant displacement tests in the compressive mode between room temperature and 1100 °C. Three point-bending with notched samples as well as compressive creep tests reveal a high fracture toughness and acceptable creep strength of this new type of alloys. Therefore, the first results show a high potential as a lightweight version of Mo-Si-B alloys for structural applications.

2:30 PM PM06.02.04
A Phase Field Study on Script Lamellar Pattern of MoSi\textsubscript{2}/Mo\textsubscript{5}Si\textsubscript{3} Eutectic Chuanzi Zhu\textsuperscript{1}, Yuichiro Koizumi\textsuperscript{2}, Chuanqi Zhu\textsuperscript{1}, Akihiko Chiba\textsuperscript{1}, Kyosuke Kishida\textsuperscript{1} and Haruyuki Inui\textsuperscript{2}; 1Institute for Materials Research, Tohoku University, Sendai, Japan; 2Department of Materials Science and Engineering, Osaka University, Osaka, Japan; 3Center for Elements Strategy Initiative for Structure Materials (ESISIM), Kyoto University, Kyoto, Japan.

MoSi\textsubscript{2}-based alloys and composites have been considered as promising candidates for high temperature structural application. Directionally solidified (DS) Mo\textsubscript{5}Si\textsubscript{3}/Mo\textsubscript{5}Si\textsubscript{3} composites have a script pattern in which discontinuous Mo\textsubscript{5}Si\textsubscript{3} rods inclined to the growth direction are embedded within Mo\textsubscript{5}Si\textsubscript{3} matrix. Since a deeper understanding of pattern formation is crucial to the microstructure design for property optimization, a phase field model based on Multiphase-Field framework has been constructed to elucidate the responsibility of continuous nucleation on solid-liquid interface for the discontinuity of this pattern, which has a close relation to material toughness. Under solidification conditions with various growth rates, three dimensional computation results of microstructures reproduced the characteristics of script pattern observed by scanning electron micrography (SEM). In addition, the simulation results show good agreement in length scale of lamellar spacing with experimental images and analytical solutions obtained by Jackson-Hunt approach.

2:45 PM PM06.02.05
Printability of Mo-Si-B Alloys via Additive Manufacturing Janett Schmelzer\textsuperscript{1}, Silja-Katharina Rittinghaus\textsuperscript{2}, Andreas Weisheit\textsuperscript{2}, Martin Stobik\textsuperscript{3}, Jörg Paulus\textsuperscript{4}, Karl Gruber\textsuperscript{4}, Egbert Wessel\textsuperscript{4}, Manja Krüger\textsuperscript{2} and Christoph Heinze\textsuperscript{2}; 1Otto-von-Guericke-University Magdeburg, Magdeburg, Germany; 2Fraunhofer – Institut für Lasertechnologie, Aachen, Germany; 3NANOVAL GmbH & Co.KG, Berlin, Germany; 4Dr. Kochanek Entwicklungsgesellschaft, Neustadt a. d. Weinstraße, Germany; 5Institut für Energie- und Klimaforschung (IEK-2), Jülich, Germany; 6Siemens AG, Berlin, Germany.

Current research on high temperature metallic materials focuses on Mo-Si-B alloys which are candidates for novel turbine materials. For structural applications, an important phase field in the ternary Mo-Si-B system is located between the Mo solid solution phase (Mo\textsubscript{90}) and the silicides Mo\textsubscript{5}Si\textsubscript{3} (T\textsubscript{2}) and Mo\textsubscript{5}Si\textsubscript{3} (A\textsubscript{15}), which is known as the so-called “Berezik-triangle”. Near-eutectic Mo-Si-B alloys from this three-phase region exhibit outstanding creep properties, even above temperatures of 1100 °C, as well as a good oxidation resistance. However, ingot processing (IM) of this class of materials is challenging due to the high melting point of Mo-Si-B materials being typically > 2000 °C (eutectic Mo\textsubscript{90},Mo\textsubscript{5}Si\textsubscript{3},Mo\textsubscript{5}Si\textsubscript{3} alloys - 2000 °C). Different multi-step powder metallurgical processes (PM) were typically used in the past to produce dense Mo-Si-B samples under laboratory conditions. The introduction of a one-step processing route for this type of material via additive manufacturing (AM) or 3D printing represents an important innovation that will allow the production of complex bulk materials with net shape geometries (e.g. turbine blades). This work shows the feasibility of printing pre-alloyed near-eutectic Mo-Si-B powder materials via laser metal deposition (LMD). Therefore, Mo-Si-B powder was manufactured via gas atomization (GA) process out of solid raw materials meeting the requirements for AM regarding fluidability and particle size. The specific challenge is the ultra-high melting point of this type of alloys, accompanied by problems of interlayer bonding and defects that may occur during cooling. Compact multiphase Mo\textsubscript{90}Mo\textsubscript{5}Si\textsubscript{3}Mo\textsubscript{5}Si\textsubscript{3} builds containing low porosity could be manufactured. For further understanding of the microstructural evolution powder particles after GA were investigated and detailed analyses of the resulting microstructure were carried out. For purpose of comparison with PM and IM Mo-Si-B alloys first results of mechanical tests, e.g. hardness, compressive strength and creep response, are presented.

Room Temperature Deformation of Transition-Metal Silicides Investigated by Micropillar Compression Method Kyosuke Kishida\textsuperscript{1,2} and Haruyuki Inui\textsuperscript{1}; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Structural Materials (ESISIM), Kyoto University, Kyoto, Japan.

Transition-metal (TM) silicides have received considerable attention as promising structural materials for ultra-high temperature applications that can replace the currently used Ni-based superalloys because of their very high melting temperature above 2000 °C, good mechanical properties and good oxidation resistance. Extensive studies using bulk single- and poly-crystals have revealed that most TM silicides can plastically deform only at high temperatures above 1000 °C. The activation of various deformation modes has been reported so far, however, some ambiguity in the identification of operative deformation modes still remains mostly because of severe oxide formation on the specimen surface as well as dislocation climb, which is inevitable in the case of high temperature experiments. Recently, the micropillar compression method first introduced by Uchic et al. has been widely recognized as an attractive technique to investigate the mechanical response of not only pure metals but also various hard andbrittle materials at sizescales of tens of micrometers or less. Recently, we have applied the micropillar compression method to single crystals of various TM silicides such as TiM5Si2 (TM=Mo, Nb, Ta, V, Cr), TiM5Si3 (TM=Mo, Nb, Ti) and T2-Mo5SiB2 as a function of specimen size and loading axis orientation. For most of the TM silicides tested, plastic flow was observed if the specimen size is reduced to micron meter size. For T2-Mo5SiB2 phase, three different slip systems were identified to be operative at room temperature. The values of critical resolved shear stress (CRSS) for the three slip systems in T2-Mo5SiB2 are extremely high all exceeding 2 GPa. The CRSS value for each slip system increases with the decrease in the specimen size, following the inverse power-law relationship with an exponent much smaller than those reported for FCC and BCC metals. The dissociation scheme and glide plane (actual atomic
The microstructures are compared with respect to the nature and morphology of the phases, the chemical homogeneity and the porosity. The main detected temperatures; (4) bulk SPS samples with additional heat treatment (1500°C, 100 h). Quasi-static compression tests as well as creep tests, at 800°C and 1000°C, are presented.

This communication reports the study of an alloy with composition 43Nb-25Ti-3Mo-3Cr-6Al-20Si (at.%). The microstructure of this alloy has been investigated both experimentally through atomic-resolution scanning transmission electron microscopy imaging of their core structures and theoretically by first-principles calculations of the relevant generalized stacking fault energy curves.

Application of the single-crystal Ni base superalloys for turbine blades at temperatures of up to 90 % of their melting point already reached the limit of their development. Because of the beneficial physical and mechanical properties at high temperatures, Mo base alloys are very promising to substitute Ni base alloys. These materials possess high temperature strength and excellent creep resistance as well as acceptable fracture toughness. Nevertheless, the replacing of Ni base superalloys in turbine applications is still a difficult problem. This study is focused on FE calculations of the deformation of a simple turbine blade made of Mo based alloys under the typical loading conditions in comparison to conventional turbine blade materials, aimed to evaluate the feasibility of Mo base alloys.

The investigations of Mo base alloys displayed the best combination of the high temperature properties for alloys containing Si and B, specifically for the alloy family with a three-phase microstructure: ductile molybdenum solid solution phase and the two intermetallic phases Mo3Si and Mo5SiB2. However, an extensive knowledge about the physical and mechanical properties of each phase is not achieved yet. In this study, the creep properties of the individual phases are determined and applied for the estimation of the creep properties of the alloy in general. This provides a possibility for the advanced alloy design.

Phase Field Simulation of Spontaneous C11b-MoSi2/D8m-Mo5Si3 Eutectic Reaction in Directional Solidification Yuichiro Koizumi1, Chuanqi Zhu1, Toshihiro Yamazaki1, Akihiko Chiba1, Kurotaka Yuge2, Kyosuke Kishida1, Haruyuki Imai2; 1Tohoku University, Sendai, Japan; 2Osaka University, Suita, Japan. This model can take into account the elastic strain energy and the relaxation of strain by structural ledges. It is also possible to include interfacial segregation of ternary elements to the model. When spontaneous decomposition from liquid to C11b-phase and D8m-phase was assumed, inclined lamellar structures were formed under limited conditions, and the lamellar spacing decreased with increasing cooling rate as expected. It is suggested that the nucleation of DB6-Mo5Si3 is important for more quantitatively precise reproduction of script lamellar structure. The effects of nucleation will be presented by Zhu et al. elsewhere. Reference: [1] K. Fujiwara et al. Intermetallics 52 (2014) 72-85. [2] T. Yamazaki et al. Intermetallics 54 (2014) 232-241, [3] T. Yamazaki et al. Comp. Mat. Sci. 108 (2015) 358–366.

Microstructural Study of a Nb-Si Based Alloy Through the Different Steps of a Powder Metallurgy Route Virgil Malard1, 2, Stefan Drawin1, David Neumeyer3, Jean-Philippe Monchoux3, Anne Denquin1 and Alain Courtet1; 1ONERA, Châtillon, France; 2Paris-Saclay University, Saclay, France; 3CEMES/CNRS, Toulouse, France.

Niobium silicide intermetallic alloys are good candidates for applications as low-pressure turbine blades in aircraft engines for service temperatures between 800°C and 1000°C. The Nb-Si based alloys are multiphase materials constituted by a niobium solid solution Nbss, silicide phases of the NbSi3-α and / or Nb5Si3-β (tetragonal structure) and / or NbSi3-γ (hexagonal), sometimes NbSi type, depending on the heat treatments applied or the alloying elements added. The solidification structure is generally dendritic with more or less complex eutectic cells. Microstructure control during solidification and processing steps is essential to obtain good mechanical properties. This is difficult by conventional casting, knowing that forming processes (forging, etc.) require high temperatures for these materials which contain more than 50 vol.% of intermetallic phases. Powder Metallurgy (PM), thanks to the microstructural homogeneity it offers, and to easier shaping processes, is a manufacturing process that deserves to be studied.

Characterization Crystal Phase and Thermolectric Properties of Thin Film SrSi2 Kodai Aoyama1, Takao Shimizu1, Hideto Kuramochi2, Masami Mesuda1, Ryo Aikio2, Yoshiyuki Kimura1 and Hiroshi Funakubo1; 1School of Materials and Chemical Technology Department of Materials Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan; 2Advanced Materials Research Laboratory, Tosoh Corporation, Ayase, Japan.

This work has benefited from State support managed by the ANR under the "Investissements d'Avenir" program through the MATEMCA project (reference ANR-10-EQPX-37) and from ANR funding through the SYNOPSIS project (reference ANR-15-CE08-0042).

Characterization Crystal Phase and Thermolectric Properties of Thin Film SrSi2 Kodai Aoyama1, Takao Shimizu1, Hideto Kuramochi2, Masami Mesuda1, Ryo Aikio2, Yoshiyuki Kimura1 and Hiroshi Funakubo1; 1School of Materials and Chemical Technology Department of Materials Science and Engineering, Tokyo Institute of Technology, Yokohama, Japan; 2Advanced Materials Research Laboratory, Tosoh Corporation, Ayase, Japan.

Silicon based alloys with good thermoelectric property such SiGe, MgSi and Mn-Si system have been widely investigated not only bulk form but also thin film form. α-SrSi2 is also a promising candidate as a thermoelectric material because it consists of abundant nontoxic elements and a good thermoelectric power factor near the room temperature was reported by Hashimoto et al. [1]. However, the number of researches is limited compared with former widely
investigated silicide and there are no reports in film form. In this study, we firstly prepared α-SrSi2 thin films on insulating substrates and measured their thermoelectric properties. Thin films of Sr-Si system were deposited on c-Al2O3 substrate by using RF magnetron sputtering method at various deposition temperature and total pressure. Constituent phases strongly depend on the deposition temperature. The films deposited below 400°C consisted of amorphous phase. Metastable SrSi2 phase with CaSi2 structure was obtained between 500 and 600°C and finally stable α-SrSi2 above 700°C. Metastable SrSi2 phase with CaSi2 structure showed low power factor below 10 μW/(m K2) for the temperature range of 100-400°C. On the other hand, α-SrSi2 show good thermoelectric power factor beyond 700 μW(m K2) at room temperature. This much value is larger than observed value of Mg2Si (111) one-axis-oriented films prepared by the same deposition process, maximum 130 μW/(m K2) at 300°C. The present result shows that α-SrSi2 is one of the promising candidates as thin film thermoelectric materials. [1]K. Hashimoto et al., J. Appl.Phys. 102 (2017) 063703.

Microstructure Design for Enhancement of Room-Temperature Ductility in Multi-Component TiAl Alloys Ryosuke Yamagata, Yotaro Okada, Hirotoyo Nakashima and Masao Takeyama; Materials Science and Engineering, Tokyo Institute of Technology, Meguro-ku, Japan.

TiAl alloys are required high toughness and ductility for jet-engine applications. In previous studies, we clarified that introduction of the β-Ti / γ-TiAl duplex (DP) microstructure at the α2-Ti3Al / γ lamellar colony boundaries improves the stress intensity factor range threshold AK and decreases the Paris exponent m. Microstructure analysis revealed many slip lines exist in γ phase in DP region. This suggested that it is possible to enhance room-temperature ductility through controlling DP microstructure. Therefore, in this study, microstructure factors to enhance room-temperature ductility was investigated in multi-component TiAl alloys.

Multi-component TiAl alloys were used in this study. The microstructure was controlled by phase transformation of α → β + γ based on our phase diagram studies. Room-temperature tensile tests were conducted with a strain rate of 3 × 10^-4 s^-1 using an Instron-type universal testing machine. In order to removed surface strain that was introduced during machining, tensile test specimens were firstly electrical-polished. Microstructures observation was carried out using field-emission scanning electron microscopy. The room-temperature ductility changes from 0.1 % to 1.4 % with increasing of volume fraction of γ phase from 5 % to 80 %. However, γ single phase alloy did not show any ductility, less than 0.1 %. Microstructure analysis revealed that the key of factors for enhancement of room-temperature ductility are the large amount of γ phase (>70%) in DP region and the existence of β phase. The other techniques and mechanisms will be discussed in presentation. This study was supported by Strategic Innovation promotion Program (SIP) in Japan.

Microstructural Evolution in Mo-Alloyed Al-Rich Titanium Aluminides Reinhold Warthichler1, Frank Stein2, Martin Palm2, Helmut Clemens2 and Svea Mayer1;1 Department of Physical Metallurgy and Materials Testing, Montanuniversität Leoben, Leoben, Austria; 2Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany.

Titanium aluminides based on the intermetallic γ-TiAl phase are well-established lightweight structural materials within the temperature range from 600 to 800°C due to their high specific (creep) strength, low density and sufficient oxidation resistance. Increasing the aluminum content lowers the density even further while improving the oxidation behavior and leads to the formation of Al-rich intermetallic phases, such as γ-TiAl2. Although for an alloy with a...
The microstructural evolution and transformation behavior of titanium aluminides is a complex interplay in alloy design, process development and under due to their peerless combination of material properties at high temperatures, intermetallic titanium aluminides have already started to be implemented as a turbine blade material in the low pressure section of the turbine engine.

As turbine blades are attached to the turbine disk by a specific dovetail connection, metallic surfaces are inevitably in direct contact under harsh mechanical loads as well as thermal conditions. In this regard, friction and wear issues always occur and can strongly affect the overall lifetime of the components. Within the scope of this study a basic analysis of the friction and wear properties of two γ-based TiAl alloys, namely TNM-B1 and GE 48-2-2, has been conducted using a high temperature pin-on-disk apparatus. Hereby, tests were performed covering a wide temperature range (up to 800°C) under variation of the counterpart material to simulate conditions that are relevant for today’s turbine engines.

As oxidation plays a vital role in terms of high temperature sliding wear conditions being the decisive factor for the specific wear mechanism and rate, the basic oxidation behavior of the chosen TiAl alloys has to be additionally investigated. Isothermal exposures in air were conducted to determine the respective influence of the exposure time (up to 1000h) as well as the temperature. Conclusively, wear losses/rates were calculated and changes in the occurring wear mechanisms were identified using a profilometer as well as different metallographic techniques to depict differences in the overall tribological performance of both substrates.

Gamma TiAl alloys are gaining acceptance as a lighter weight alternative to nickel-based superalloys in certain high temperature applications. Further successful adoption of these alloys into new aero-engine components requires additional improvements to temperature capability and property balances. Comprehensive understanding of composition-processing-microstructure-property correlation is essential in aiding the selection of suitable alloy composition and the control of processing conditions. Although simulations tools have been developed for such a purpose, trial-and-error approaches are still widely used in alloy design and process optimization.

In this work, we will present our work in the development of a simulation tool that can be used to accelerate the development of gamma TiAl alloys. In particular, we developed a thermodynamic database for TiAl-based alloys using the CALPHAD (CALculation of PHAse Diagram) approach. This database contains 16 components which covers most of the major and minor alloying elements for TiAl-based alloys. We have also developed a high throughput calculation (HTC) in Pandat software through which calculations at numerous alloy compositions can be performed and alloy compositions that satisfy user-defined criteria can be searched through data mining of the simulated results. In this presentation, we will demonstrate how we can use HTC function and the thermodynamic database we have developed for TiAl alloys to understand the effect of various alloying elements on the properties of TiAl alloys and therefore identify the alloy compositions with good potentials for certain applications.

The microstructural evolution and transformation behavior of titanium aluminides is a complex interplay in alloy design, process development and under...
operating conditions. In-situ neutron and synchrotron X-ray diffraction deliver unique and complementary insight into the material’s response to high temperature, deformation and extreme conditions. Neutrons illuminate a larger bulk volume and reveal quantitative phase abundance, bulk texture, lattice parameter changes and other ensemble averaged quantities. In contrast, fine-bundled high-energy X-rays deliver reflections from a number of individual grains. For each constituting phase, their statistics and behavior in time reveal information about grain growth or refinement, subgrain formation, static and dynamic recovery and recrystallization, slip systems, twinning, etc. Features will be presented on selected examinations on titanium aluminides, especially to characterize phase evolution and crystallographic changes upon heating and during plastic deformation, and severe conditions.

Formation of Orthorhombic Intermediate Temperature Phases in Different Commercial and Experimental γ-TiAl Alloys Marcus W. Rackel¹, Heike Gabrisch1, Uwe Lorenz1, Andreas Stark¹ and Florian Pyczak1, 2; 1Helmholtz-Zentrum Geesthacht, Geesthacht, Germany; 2Brandenburgisch Technische Universität Cottbus-Senftenberg, Cottbus, Germany.

γ-TiAl alloys for aero engine blades can be produced by forging but the inherent brittleness of TiAl makes this difficult. A means to facilitate forging of γ-TiAl alloys is to stabilise the ductile soft disordered β phase at forging temperature. This is achieved by the addition of β stabilising elements as for example Nb, Mo or V and was successfully implemented in the TNM alloy. In the ideal case the β phase may be present at forging temperature but can be dissolved fully at service temperature where its presence is unwanted. Unfortunately, often not only the two phases γ and α2 are found at service temperature but additional stable or metastable phases are present. In an experimental Ti-42Al-8.5Nb alloy an orthorhombic phase constituent was identified which had the crystal structure of the O-phase and is a transformation product of α2-phase at temperatures below 650 °C. To unambiguously identify the phase and its transformation path high-energy X-ray diffraction (HEXRD) measurements at varying temperatures using in-situ specimen environments were performed. Based on literature knowledge the occurrence of O-phase is only expected for significantly higher niobium and lower aluminium contents.

Initially it was supposed that this O-phase is a feature of this very special experimental alloy composition. Nevertheless, screening tests over a wide variety of alloy compositions proofed that the O-phase can be found in a number of commercial as well as experimental alloys depending on composition and heat treatment history. In general it can be stated that alloy compositions with a combined content of β stabilising elements of 6 at.% or more and Al contents of 46 at.% or lower form O-phase to a greater or lesser extent. Minor alloying elements, such as boron or carbon exhibited no measureable effect on O-phase formation. The results can be valuable for the development of β stabilised TiAl alloys and the understanding of the long term behaviour of TiAl parts as the possibility of O-phase formation in the medium temperature range was until now disregarded for such alloys.

SESSION PM06.04: Titanium Aluminides III and Superalloys
Session Chairs: Alain Couret and Rui Yang

Hynes, Level 1, Room 104

1:30 PM *PM06.04.01
Influence of Solidification Condition on Boride Morphology in Cast TiAl Alloys Rui Yang; Institute of Metal Research CAS, Shenyang, China.

Boron additions are indispensable in gamma TiAl alloys designed for cast applications because borides of different structures, shape, and size or their mixtures limit grain growth during solidification, subsequent solid state phase transformation, and during hot isostatic pressing. Some forms of borides, such as very long ribbons, especially when concentrated and entangled, may degrade mechanical properties. In this talk, we attempt to classify the conditions for the formation of such borides according to alloy composition, cooling rate and solidification sequence. Experimental evidence will be presented from both cast turbine blades and wedge-shape samples with step thickness. Corresponding tensile test data will be discussed.

2:00 PM PM06.04.02
Phase Equilibria among β/α2/α/γ Phases and Phase Transformations in Ti-Al-Cr System at Elevated Temperatures Ali Shaaban¹, 2, Hideki Wakabayashi¹, Hiroyo Nakashima¹ and Masao Takeyama¹; ¹Department of Materials Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan; ²Surface Protection and Corrosion Control Lab, Central Metallurgical Research and Development Institute (CMRDI), Cairo, Egypt.

Designing of wrought TiAl alloys opens the window for a wide range of applications and it will not be exclusive to be applied as low-pressure turbine materials but also as high-pressure compressor materials. β-Ti phase in TiAl alloys allows excellent workability during processing and excellent mechanical properties in service temperatures. In other words, microstructure control using β-phase is a key to develop high-toughness wrought γ TiAl alloys. This can be accomplished by understanding the phase transformations involving β-phase. Effects of group V⁰ (V, Nb) and V⁰ (Cr, Mo) elements as β-stabilizers on phase equilibria of TiAl alloys above 1473 K were extensively studied by our group. It was found that V and Nb stabilize α2 against α. Also, the change in three-phase coexisting region β+α2+γ that exists above 1473 K to that of β+α2+γ occurs not just by the ordering transformation α→α2 (2⁰ order phase transformation) but by a transition peritectoid reaction β+α→α2+γ (1⁰ order phase transformation) at a temperature between 1453 K (the congruent temperature of α→α2) and 1400 K (the eutectoid reaction temperature of α→α2+γ) in Ti-Al binary system with decreasing temperature. Thus this phase transformation allows a unique transformation pathway for α→α2+γ in the ternary systems. However, it has not been clarified yet that the addition of group V⁰ elements (Cr, Mo) stabilizes either α or α2. Thus, in this study, the effect of Cr addition to TiAl alloy on the phase equilibria among the four phases and phase transformation pathways within the temperature range of 1473 K–1073 K were investigated using several alloys in the composition of interest. In between 1473 K–1373 K, the slope of β/a tie-line in the three-phase coexisting region of β+α2+γ remains basically unchanged where the Al content in β-phase is much lower than that in α-phase. However, this slope drastically rotates in a clockwise direction and the Al content between the two phases becomes nearly equal, in between 1373 K and 1273 K and below the eutectoid reaction temperature in the binary system (1400 K). This is a strong indication that thermodynamically α-phase exists even below the 1400 K, i.e. addition of Cr stabilizes α against α2 and the three-phase coexisting region of β+α2+γ at lower temperatures is formed through a ternary eutectoid reaction α→β+α2+γ with decreasing temperature. This three-phase tie-triangle moves towards lower Al content in alloys with lower Al content. In between 1173 K and 1073 K, no further shift was observed in the tie-triangle meanwhile it expands towards high Cr content in β-phase. Based on these information, a novel technique for developing a new wrought γ-TiAl with excellent workability during processing at elevated temperatures and excellent toughness in service conditions, could be proposed.

2:15 PM PM06.04.03
A Dislocation-Scale Characterization of the Evolution of Deformation Microstructures on a Bulk TiAl Alloy Antoine Guitton¹, 2, Hana Kriaa¹, 2,
Developing new materials and understanding how they deform is the main challenge of engineers in order to follow and predict the fast evolutions of our society. For instance, in a framework of energetic cost reductions, titanium aluminide (TiAl) alloys have attracted considerable attention due to their unique combination of properties such as high specific strength and stiffness, good creep properties and resistance against oxidation and corrosion, which make them suitable candidate materials for high temperature applications [1]. However, TiAl alloys are brittle at Room Temperature (RT), i.e. below their brittle-to-ductile transition temperature, which lies between 800°C and 1000°C [2]. Furthermore, their complex microstructures (multiphase, different types of microstructures, specific dislocation mechanisms…) with several impacts at different scales are puzzling the materials science community. Despite intense research, literature suffers from a lack of understanding of their elementary deformation mechanisms and the precise role of microstructures [2].

In order to address these questions, we report here, an original and an innovative approach bringing the necessary information, thus allowing linking the multiscale aspects of the mechanical behavior of TiAl alloys at RT. Particularly, we bring new breakthrough on the evolution of deformation microstructures at RT in the vicinity of interfaces in γ phase of a dual-phase bulk TiAl alloy. Plastic deformation is induced locally by μN-nanindentation. The evolution of the microstructures is characterized comprehensively by accurate Electron Channeling Contrast Imaging (αECCI) before and after deformation [3]. αECCI is a non-destructive groundbreakings procedure offering the ability to provide, inside a SEM, TEM-like diffraction contrast imaging of sub-surface defects (at a depth of about one hundred of nanometers) on centimetric bulk specimen with still unsurpassed resolutions [4]. Defects, such as dislocations, can be characterized by applying the TEM extinction criteria [5]. All features help to explain the poor ductility of the TiAl-based alloys at RT. Accommodation of the deformation is reported and a scenario is proposed [3].

Relationship Between the Microstructure and Atomic Relaxation Processes in the Last Generation of TiAl Intermetallics

Maria L. No1, Leire Uategui2, Thomas Klein3, Svea Mayer4, Helmut Clemens5 and Jose San Juan; 1Física Aplicada II, Universidad del País Vasco (UPV/EHU), Bilbao, Spain; 2Física de la Materia Condensada, Universidad del País Vasco, Bilbao, Spain; 3Materials Center Leoben, Leoben, Austria; 4Physical Metallurgy and Materials Testing, Montanuniversität Leoben, Leoben, Austria.

Engineering structural intermetallics exhibit outstanding stability at high temperature. Among the different families of intermetallics, γ-TiAl alloys are good candidates for propulsion systems in aero and automotive industries. Recently a third and a fourth generation bearing Nb and Mo in well-balanced quantities and small amounts of C and Si (TNM and TNM+ alloys) have been developed. Adequate thermal treatments of these alloys give a lamellar arrangement of α2/γ colonies that exhibits a good creep resistance at high temperatures, which has been studied by tensile creep experiments and mechanical spectroscopy /1,2/. A microstructural analysis before and after the mechanical spectroscopy experiments should give important information about the mechanisms responsible for the observed behaviour and this is the approach used along this study. In the present work two lamellar alloys were studied: Ti-43Al-4Nb-1Mo-0.1B (aT%) (TNM alloy) and Ti–43Al–4Nb–1Mo–0.1B–0.3C–0.3Si (aT+%) (TNM+ alloy) with a final aging thermal treatment at 1123K and 1173K respectively. Mechanical spectroscopy measurements between 850K and 1225K show the diffusion of several solute atoms at different temperatures. The activation parameters were determined by tensile creep and mechanical spectroscopy experiments. The regions of discontinuous precipitation surrounding the lamellar colonies were characterized by scanning electron microscopy (BSE, EDX, EBSD) technique. The lamellar α2/γ colonies and the small precipitates observed inside the lamellae were characterized by transmission electron microscopy (BF, DF, microdiffraction, nanodiffraction, STEM-HAADF, EDX) with a Titan Cubed 80-300KV working a 200KV. A good correlation between the mechanical spectroscopy results and the small precipitates characterized by TEM-STEM-EDX has been established through the corresponding models of precipitation and mechanical properties.

The Effect of Oxidation on Microstructure and Phase Stability in the Subsurface Zone of Titanium Aluminides Exposed at High Temperatures

Mathias C. Galletz, Anke S. Ulrich, Lukas Menigs, Alexander Donchev, Ceyhun Oskay and Diana Fähßing; DEHEMA Research Institute, Frankfurt am Main, Germany.

Titaniumaluminides had been in the focus of research for more than three decades before they finally took off as part of modern aircraft engines in 2011. Due to their density of about 4 g cm⁻³ they offer a high specific strength since they weigh only the about half in comparison to nickel-based alloys. Thus, a favorable advantage in efficiency, noise reduction and fuel consumption is achieved. Because of their properties they gained interest also for application temperatures beyond the present range of ~750°C. This limit is defined by the strong degradation of their oxidation resistance above that temperature. Best oxidation resistance and the mechanical properties are also affect, however, the origin of this phenomenon is still under debate. In addition, several authors reported an increase in oxygen and nitrogen concentration in the surface region of TiAl-alloys. It was shown that the loss of ductility can be restored by removal of the surface and subsurface layer following high temperature exposure. One issue related to that is, that the oxygen and nitrogen uptake within the alloy are not easy accessible. Recently developed TiAl alloys and applications such as TMB® and TMB®+ aim for even higher application temperatures and improved hotworkability. Beside γ-TiAl and α₂-Ti₃Al, such alloys additionally contain the β₂ phase, whose impact on the high temperature oxidation and mechanical properties after exposure is hardly investigated and shows the requirement of a deeper understanding of the subsurface changes in such alloys due to dissolved
Due to the low density in combination with a high melting point, vanadium demonstrates a great lightweight potential for turbines in aircrafts or energy industry. Since vanadium as a structural material is in focus of research only recently, the effects of several alloying elements on the materials properties are not or insufficiently examined yet. Therefore, various binary V-X and ternary V-Si-X-systems, that frequently contain intermetallic phases, have been studied. By means of ingot metallurgy, vanadium samples with different concentrations of alloying elements were manufactured. Resulting from this, single phase vanadium solid solutions (V₃ₓ), two-phase and three-phase alloys were produced. Microhardness measurements and compression tests were carried out to determine the mechanical properties in dependence on the alloying components. The combination between mechanical characteristics and microstructural investigations enables conclusions concerning the materials behavior and the efficiency of solid solution strengthening and second phase strengthening. Therefore, SEM (Scanning Electron Microscopy) and XRD (X-ray Diffraction) methods were used to examine the microstructure, to identify phases and to measure elements concentration in the respective phases. Results achieved within this study may help to assess the potential of novel vanadium-based structural materials regarding to high temperature applications.

An Attempt to Design a New Class of Co-Based Superalloy with Improved Oxidation Resistance and Creep Property 
Zhenghao M. Chen1, Norihiko L. Okamoto1 and Haruyuki Imai1; 1Kyoto University, Kyoto, Japan; 2Tohoku University, Sendai, Japan.

Recently, a new ternary L1₂ (γ′) phase Co₃(Al,W), coexisting with a fcc solid-solution phase (γ) based on Co, has been discovered. With precipitation strengthening by the γ′ phase, this class of Co-base superalloys exhibits an improved high-temperature strength, compared to that of conventional Co-based superalloys. However, the creep property in ternary alloy is still insufficient, due to the insufficient high-temperature strength and the lack of γ′ in volume fraction. Besides, the oxidation resistance is also an unresolved problem. In previous studies, the effect of some alloying elements on Co-base superalloys has been investigated. Ni, Ta and Ti are effective in improving the creep property by either increasing the γ′ high-temperature strength or the γ′ volume fraction. On the other hand, Cr and Si are proved to be effective in improving oxidation resistance, but providing a negative effect on creep property, by decreasing the γ′ solvus temperature, unfortunately. Thus, in the present study, we investigate the effect of co-addition of alloying elements Ni, Ta, Ti, Cr, Si on Co-base superalloys, attempting to find out a composition exhibiting both excellent creep property and sufficient oxidation resistance, simultaneously.

Ingots of (Co₀.₈, Ni₀.₂)ₐAlₐₜ₉Taₐₜ₉Tiₐₜ₉Crₐₜ₉Siₐₜ₉ (at.%; a, b, x, y≥0) were prepared by arc melting. These ingots were homogenized at 1200 °C for 24 h in vacuum, followed by heat treatment at a sub-solvus temperature for 96 h. The γ′ solvus temperatures were determined by differential scanning calorimetry (DSC), and the microstructures were examined by scanning electron microscope (SEM). Single crystals with selected compositions exhibiting exclusive γ′/γ two-phase cuboidal structure and reasonable γ′ solvus temperature were prepared by modified Bridgman technique, followed by heat treatment at 900 °C for 96 h. Creep tests were performed in tension under the conditions of 137 MPa/1000 °C and 428 MPa/900 °C. Oxidation resistance behavior at 1000 °C were investigated with cyclic oxidation test for 200 h (20 cycles).

Although Cr and Si alloying decrease γ′ solvus temperature drastically, substituting W (and Al) with Ta (or Ti) is an effective way to increase γ′ solvus temperature without precipitating any secondary phases (such as D₀₁₉). Oxidation resistance in multicomponent alloys are indeed to be improved, compared to non-Cr, Si alloyed Co-7Al-8W-Ta-4Ti. However, Rupture time of tensile creep at the condition of 900 °C /428 MPa in 4Ta and 8Ti are extremely short, only few hours. 2Ta6Ti6 exhibits relatively high creep property at the condition of 1000 °C/137 MPa (103h in rupture), but still not sufficient (approximately one-third to Co-7Al-8W-Ta-4Ti). It seems that, unfortunately, improving oxidation resistance and creep property simultaneously in Co-based superalloy to a utility-level may come out to be difficult, unless new type of alloying elements that increase γ′ solvus temperature more effective than Ta would be discovered.

Alloying of Cr-Base Alloys by Ternary and Quaternary Elements and Their Effect on Oxidation and Nitridation Resistance at High Temperatures
Anke S. Ulrich1, Ali Solimani1, Petra Pfizenmaier2, Uwe Glatzel2 and Mathias C. Galetz1; 1High Temperature Materials, DECHEMA-Forschungsinstitut, Frankfurt a.M., Germany; 2Lehrstuhl Metallische Werkstoffe, University Bayreuth, Bayreuth, Germany.

Due to the high melting points Cr-base alloys are future candidates for materials for high temperature applications beyond Ni-base superalloys. In addition, high Cr content alloys offer lower densities compared to the commonly used Ni-base superalloys. However, for a future successful application still an optimal alloy composition has to be defined with respect to the improvement of nitridation, oxidation, and mechanical properties at high temperatures. In this work, the influence of Si, Ge, Mo, and Pt alloying on the oxidation and nitridation resistance of Cr-rich Cr₉ₓ–Cr₉Si alloys was investigated using thermogravimetric analysis at temperatures from 1050°C – 1350°C. The samples were additionally analyzed using EPMA, SEM, and XRD analysis. Based on the binary Cr₉ₓSiₓ alloy [at.%] around 2 at.% Si were substituted by ternary elements (Ge, Mo, Pt). Before oxidation, all investigated alloys had a two phase microstructure consisting of Cr₉ and Cr₉Si₁₅ phase. During oxidation an oxide scale of Cr₂O₃ and SiO₂ formed and nitrides were found underneath the scale. However, alloying showed a significant influence on the oxide scale formation, nitridation, and oxidation kinetics. Ge substitution decreased the spallation of the oxide scale, reduced the parabolic weight gain (by oxidation and nitridation), and interestingly, also the linear weight loss induced by the formation of volatile species. In the ternary Cr-Si-X (X = alloying element) systems, Ge and Mo alloying were both enriched at the subsurface zone during oxidation and remarkably decreased nitridation and the formation of brittle Cr₇N compared to the binary Cr-Si system. Their combination in a quaternary alloy, in turn, neutralizes these positive effects. Pt acted as nitrogen getter in a ternary Cr-Si-Pt alloy by forming an antiperowskite phase which simultaneously led to increased nitrogen uptake by the sample when Pt is present at the substrate surface. In order to further optimize the alloy composition, the mechanisms of the respective elements on oxidation and nitridation behavior are proposed for the ternary and quaternary alloys.

A Combinatorial Study on Phase Formation and Oxidation in the Thin-Film Superalloy Subsystems Co-Al-Cr and Co-Al-Cr-W
Alfred Ludwig1, Wim Biekert2, Martin Weiser3, Steffen Salomon1, Helge S. Steinh 1 and Sannakaisa Virtanen2; 1Institute for Materials, Ruhr-University Bochum, Bochum, Germany; 2Materials Science, Friedrich-Alexander University Erlangen-Nürnberg, Erlangen, Germany.

In this work, the impact of high temperature exposure on the microstructure of TMB as well as the resulting effect on the mechanical properties at room temperature are investigated. For the latter, 4-point bending tests are conducted on samples before and after oxidation. Oxidation tests are carried out at 900 °C for varying times (24 h – 1000 h) in air. The evolution of the microstructural change (based on changes in phase fractions) in the subsurface zone is investigated over time. Based on EPMA and SEM the change of the microstructure in dependence of the distance from the surface is shown, quantified, and could be correlated to oxygen uptake. A mechanism for phase transition phenomena is proposed.
Two Co-based superalloy subsystems, Co-Al-Cr and the quasi-ternary system Co-Al-Cr-W with a constant amount of 10 at. % W, were deposited as thin-film materials libraries and analyzed in terms of phase formation an oxidation behavior at 500 °C in air. By combining energy-dispersive X-ray analysis and X-ray photoelectron spectroscopy high-throughput composition measurements, a detailed evaluation of the dependence between the initial multinary metal composition and the oxide scale composition which is forming upon oxidation on the surface of the thin film is established. Phase maps for both materials libraries are provided by high-throughput X-ray diffraction. In addition, the oxidation of a Co-Al-Cr-W bulk sample was analyzed and compared to a corresponding film in the library.

Micropillar Compression of Single Crystals of the Stoichiometric Ti₃Al and hcp-Ti
Kim Jingeum¹, Atsushi Matsumoto¹, Kyoosuke Kishida¹,² and Haruyuki Inui¹,²;¹ Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; ²Center for Elements Strategy Initiative for Structural Materials, Kyoto University, Kyoto, Japan.

Micropillar compression method has received a considerable amount of attention as a new method to investigate plastic deformation behavior of various crystalline materials in sub-micron scale. Previous studies mainly on single crystals of conventional FCC or BCC metals have revealed that various interesting features in micropillar compression experiments such as strain-burst behavior and size-dependent strength with a trend of “smaller is stronger”, which is generally described with an inverse power-law relationship between the strength and specimen size. Although various models to describe the size-dependent strength have been proposed, the validity of the proposed models and their applicability to other crystalline materials with low symmetry are still controversial. In order to understand the characteristic deformation behavior of single crystalline micropillars, systematic studies on various crystalline materials including those with lower crystal symmetry are considered to be important. In the present study, we focused on an intermetallic phase Ti₃Al with the hcp-based ordered structure of the D₀₁₉ type and its parent hcp-Ti in order to investigate how the size-dependent strength varies depending on the operative deformation modes and atomic ordering. Single crystal rods of the stoichiometric Ti₃Al and hcp-Ti were grown by directional solidification using an optical floating zone furnace. Micropillar compression tests of Ti₃Al and hcp-Ti single crystals were carried out as a function of loading axis orientation and specimen size. When the loading axis is parallel to a-axis, [1-100]<11-20> prism slip was confirmed to be activated in micropillars of both Ti₃Al and hcp-Ti. The values of critical resolved shear stress (CRSS) of the prism slip for both Ti₃Al and hcp-Ti. The power-law exponent for Ti₃Al was found to be much lower than that of hcp-Ti. Possible influences of the ordered structure on the difference in the size-dependent strength for the prism slip will be discussed based on the TEM observations of dislocations.

High-Resolution Electron Transmission Microscopy Study of Orthorhombic Phase in High Nb-Containing Lamellar γ-TiAl Alloy
Jian Sun; Shanghai Jiaotong University, Shanghai, China.

Recently, the formation of nano-scale modulated microstructure, consisting of orthorhombic phase and γₐ has been reported by several authors in high Nb-containing lamellar γ-TiAl alloys. However, the occurrence of such a unique modulated microstructure in high Nb-containing lamellar γ-TiAl alloys cannot be expected from the Al-Nb-Ti ternary phase diagram in the literature. Moreover, the formation mechanism and evolution of the modulated microstructure in high Nb-containing lamellar γ-TiAl alloys remain unclear and need to be investigated. In this work, we have proved that the orthorhombic phase is thermodynamically stable in the γₐ phase in high Nb-containing γ-TiAl alloys at high temperatures from the first-principles calculations. Transmission electron microscopy (TEM) studies showed that the formation of modulated microstructure takes place at temperature at and below 650 °C. The orthorhombic phase as a constituent of the modulated structure has the O₁ structure with a random occupancy of Ti and Nb atoms on the Wyckoff sites 8g and 4c2. The O₁ phase has a thin plate-like morphology with orientation relationships of [001]O//[0001]γ and <110>γ//[110]<110>α₂ at an initial precipitating stage. The habit plane for the O₁ phase lies at ⟨350⟩O//[130]α₂. TEM results further exhibited a remarkable enrichment of Nb in O₁ phase, indicating that the formation of the O₁ phase arises from a phase separation reaction in the γ₂ matrix, dominated by a diffusion mechanism. With an extension of annealing time up to 500 hours at 600 °C, the volume fraction of the O₁ phase increases remarkably, and the O₁ variants interact with each other and eventually develop into rectangle shape with perpendicular interfaces from the thin plate-like morphology. The retransformed α₂ phase at intersection points has been found to rotate by ~3.4 ° to the original α₂, leading to the formation of orthogonal habit planes for the single O₁ variant. The nano-indentation tests showed that the precipitation hardening effect of the O₁ phase is significant in the difference in the size-dependent strength for the prism slip will be discussed based on the TEM observations of dislocations.

Ordering and Disordering of β Phase in TiAl Alloys in Dependence of Alloy Composition
Victoria Kononikhina¹, Andreas Stark¹, Weimin Gan¹, Andreas Schreyer² and Florian Pyczk¹;² Helmholtz-Zentrum Geesthacht, Geesthacht, Germany; ³European Spallation Source ERIC, Lund, Sweden.

γ-TiAl based alloys recently have started to replace Ni-based superalloys as a material for turbine blades in the low pressure turbine section of aircraft engines. γ-TiAl based alloys are characterized by low density (4 g per cm³), good oxidation and corrosion resistance, and high specific tensile and creep strength. The presence of the γ and α₂ lamellar colonies is desirable for good mechanical properties. Cubic phase being in its disordered state (A₂ structure) improves the forging properties of the alloys because it increases the alloys brittleness at the working temperatures of about 700-800 °C and has bad creep strength. Therefore, knowledge about the presence of β phase and of its ordering/disordering temperature is of high importance for the development of alloys with improved processing properties and for a prolongation of the turbine blades working time. Currently the presence of ordered βₐ phase in the binary phase diagram is still under discussion and the influence of the different β stabilizing elements on the ordering/disordering temperature is not systematically investigated. We studied ordering/disordering transformation with in-situ synchrotron and neutron diffraction techniques. A good contrast of neutron diffraction between ordered and disordered βₐ/β phases was used to confidently determine the presence of ordered βₐ. Three binary TiAl alloys (Ti-xAl with x = 39, 42 and 45) and five alloys with additional alloying elements (Ti-42Al-2Y with Y = Nb, Mo, Ta, Cr and Fe) were investigated. Three ternary alloys with 2 at.% of Fe, Cr, and Mo contain correspondingly 12, 8, and 18 vol.% of the ordered βₐ phase. By synchrotron investigations we determined the degree of ordering
Effects of Ta and Nb Addition on the Microstructure and Mechanical Properties of MoSi2/Mo5Si3/Mo5Si3C Eutectic Composites

Kosei Takeda1, Yuki Kambara1, Hirokata Matunoshita1, Kyoysuke Kishida1,2 and Haruyuki Imu1,2,3, 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Structural Materials (ESISM), Kyoto University, Kyoto, Japan.

MoSi2, with the tetragonal C112 structure, has been considered as a promising material for ultra-high temperature structural applications because of its high melting point (2020 °C), excellent oxidation resistance, and relatively low density. However, poor fracture toughness at room temperature and insufficient high-temperature strength are still drawbacks to be improved for its practical applications. One possible way to solve these drawbacks is to form an in-situ composite with one or two strengthening phases. Among various candidates, we have recently focused on MoSi2/Mo5Si3 eutectic composites because of their high eutectic temperature (1900 °C for the binary alloy) and fine microstructures of the so-called script lamellar type formed simply by directional solidification (DS) and have studied the influences of ternary additions on the microstructure and mechanical properties of DS MoSi2/Mo5Si3 eutectic composites. Our previous studies have revealed that their high-temperature mechanical properties and fracture toughness values can be improved through refining the lamellar structure and controlling interfacial properties such as interfacial segregation of ternary elements and lattice misfits. We also have found that the DS ternary alloys with a small addition of C possess a homogeneous three-phase script lamellar structure composed of MoSi2, Mo5Si3, and Mo5Si3C and exhibit higher yield strength than the binary two-phase counterpart. In the present study, effects of Ta and Nb addition on the microstructure and mechanical properties of MoSi2/Mo5Si3/Mo5Si3C eutectic composites were investigated in order to establish a way to further improve the mechanical properties of MoSi2/Mo5Si3-based eutectic alloys. When part of Mo was substituted with Ta or Nb, a relatively homogeneous three-phase eutectic lamellar structure was obtained only at growth rates lower than 10mm/h during the DS process using an optical floating zone furnace, while a heterogenous eutectic microstructure with a cellular morphology was developed at higher growth rates. Nb atoms were partitioned mostly into Mo5Si3, while Ta atoms were partitioned into both Mo5Si3 and Mo5Si3C. Both volume fraction and average thickness of Mo5Si3 lamellae decreased in the Nb alloyed eutectic composites compared to those in the non-alloyed counterpart, which resulted in higher yield strength and better creep property of the Nb alloyed eutectic composites.

Phase Diagrams and Solidification Paths of MoSiBTiC Alloys

Kyoysuke Sawada1, Makoto Ohtsuka1, Haruki Nakashima1, Kyoysuke Yoshimi2 and Hiroyuki Fukuyma1, 1IMRAM, Tohoku University, Sendai, Japan; 2Graduate School of Engineering, Tohoku University, Sendai, Japan.

MoSiBTiC alloys are expected to be used for next generation high-pressure turbine blades. However, the phase diagrams of the alloys are still deficient. Our group has developed an ultra-high-temperature thermal analysis using blackbody radiation, which can be used above 2000 °C. In this study, MoSiBTiC alloys with several different compositions were thermally analyzed with this equipment to evaluate their phase transformation temperatures. In addition, the alloys were levitated and melted by electromagnatic levitation (EML) technique in a static magnetic field to observe solidification phenomena, and to obtain rapidly-solidified sample. The solidification paths of the alloys were studied from the thermal analysis and microstructures, and the partial phase diagrams of the alloys were constructed.

Each alloy powder was filled in a CaO-stabilized ZrO2 crucible having a blackbody cavity, and then heated and cooled in a radio-frequency furnace under Ar atmosphere. The heating and cooling rates were fixed at 10 °C / min. The sample was kept above 2000 °C for over 30 min to ensure homogenous melt, and then cooled. Temperature change during cooling was measured by a pyrometer, through the radiance from the blackbody cavity. The phase transformation temperatures were obtained from the cooling curves. On the other hand, each alloy was levitated and melted by EML technique in a static magnetic field of 10 T. The static magnetic field was applied to suppress convection in the melts. The temperature of the melts was measured by a pyrometer and controlled by adjusting the power of a heating laser. Multi-recalcescence was observed at the surface of the alloys during cooling. The phase diagrams of the alloys were constructed from the thermal analysis and microstructures, and the partial phase diagrams of the alloys were constructed.

Phase Equilibrium and Mechanical Properties of Cr-Mo-Nb-Si-B Alloys Composed of BCC and T-silicide Phase

Daisuke Goto1, Ken-ichi Kyogo Sawada1, Makoto Ohtsuka1, Haruki Nakashima1, Kyoysuke Yoshimi2 and Hiroyuki Fukuyma1, 1IMRAM, Tohoku University, Sendai, Japan; 2Graduate School of Engineering, Tohoku University, Sendai, Japan.

Cr-Mo-Nb-Si-B based alloys are promising materials for high temperature applications up to 800°C because of their light weight and high creep strength. However, the application of this material to jet engines is limited to the last stages of low pressure turbine blades due to low ductility and toughness for now. In order to apply this material to other parts such as high pressure compressor, toughening is essential. We performed fatigue crack growth tests on wrought TiAl alloys and revealed that introduction of β-Ti/γ duplex (DP) along α2-TiAl/γ lamellar colony boundaries increased the fatigue threshold, ΔKf, and decreased the Paris exponent, m. We proposed that the improvement of ΔKf is partly caused by the deformation of the DP microstructure. In order to verify this proposed mechanism, the quantification of deformation in each phase is important. In the present study, in-situ observation of tensile deformation in TiAl based alloys under an SEM at room and high temperatures is performed, and strain localization is measured by digital image correlation (DIC) technique. Three dimensional observation of the un-deformed and deformed materials is also conducted to observe the morphology of the microstructure and the crack stop points. The alloy with nearly lamellar (NL) microstructure, in which the volume fraction of DP is 7%, shows elongation of 0.14% at room temperature. Deformation is observed in both lamellar colonies and DP region in NL microstructure as a result of the strain localization measurement by DIC technique. In some favorably oriented lamellar colonies, strain localization along lamellae is more than five times as much as the macroscopic strain. The amount of deformation in each phase and the crack initiation and growth behavior during tensile will be discussed. This study was supported by Strategic Innovation Program Promotion (SIP) in Japan.

Phase Equilibrium and Mechanical Properties of Cr-Mo-Nb-Si-B Alloys Composed of BCC and T-silicide Phase

In some favorably oriented lamellar colonies, strain localization along lamellae is more than five times as much as the macroscopic strain. The amount of deformation in each phase and the crack initiation and growth behavior during tensile will be discussed. This study was supported by Strategic Innovation Program Promotion (SIP) in Japan.
MoSiBTiC alloy is systematically investigated at various temperatures, aiming to clarify the effect of Ti5Si3. The alloy was prepared by arc-melting and superior high-temperature strength and a high fracture toughness. The alloys have complicated microstructures consisting of molybdenum solid solution. The SEM observation and EPMA analysis revealed that the area fraction of constituent phases and their compositions in those Mo-Si-B-TiC alloys were measured to be in the range of 14.6~15.6 MPa (m) 1/2. There appeared no clear relation between the fractal dimension of dispersion [2] for almost no B solubility was found in BCC solid solution. With increasing Si in alloys, A15 silicide phase ((Cr, Mo, Nb)Si) and/or Laves phase are stabilized. This work was supported by the Advanced Low Carbon Technology R&D (ALCA) program of the Japan Science and Technology Agency (JST).

High-Temperature Oxidation Behavior of a Ti5Si3-Containing Multiphase MoSiBTiC Alloy
Xi Nan, Mi Zhao and Kyosuke Yoshimi; Tohoku University, Sendai, Japan.

The 1st-generation MoSiBTiC alloy (65Mo-5Si-10B-10TiC, mol.%) has great potential in high temperature structure application because of its comparable density with Ni-based superalloys (~8.8 g/cm³) and excellent high-temperature strength. However, its poor oxidation resistance, especially at intermediate temperatures (700-900°C) prevents them from practical uses. A recent work by Zhao et al. showed that the introduction of Ti5Si3 into MoSiBTiC alloy was able to improve the oxidation resistance, but without detailed oxidation mechanisms provided. In this study, the oxidation behavior of a Ti5Si3-containing MoSiBTiC alloy is systematically investigated at various temperatures, aiming to clarify the effect of Ti5Si3. The alloy was prepared by arc-melting and then annealed at 1700°C for 24 hours. Oxidation tests were carried out in a thermon-gravimetric analyzer (TGA) for different time periods. Microstructures before and after oxidation tests were characterized using X-ray diffractometry (XRD), scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX). The heat-treated 38Mo-20Ti-17Si-5B-10TiC alloy was composed of MoSS, Mo3Si, Mo5SiB2, Ti5Si3 and TiC phases. During oxidation test at 700°C, the alloy exhibited an initial transient stage of weight gain followed by an initial stage of weight loss. An initial transient stage, a steady state and an acceleration stage leading to catastrophic failure were observed at 800°C. The oxidation kinetic curves obtained at 900-1200°C showed continuous weight loss, including an initial transient stage and a steady state.

PM06.05.09
Topological Approach to Quantification of Microstructure in Mo-Si-B-TiC Alloys and Their Fracture Toughness
Sojirou Uemura1, Takateru Yamamura2, Kyosuke Yoshimi3 and Sadahiro Tsurekawa4; 1Department of Materials Science and Engineering, Kumamoto University, Kumamoto, Japan; 2Technical Division, Kumamoto University, Kumamoto, Japan; 3Department of Materials Science, Tohoku University, Sendai, Japan; 4Division of Materials Science and Chemistry, Kumamoto University, Kumamoto, Japan.

Mo-Si-B-TiC alloys are expected as a candidate for ultrahigh-temperature materials to replace Ni-base superalloys, because they have a low density, a superior high-temperature strength and a high fracture toughness. The alloys have complicated microstructures consisting of molybdenum solid solution (Mo3Si, Mo5SiB2, Ti5Si3, (Ti, Mo)C, and (Mo, Ti)2C phases and their eutectic phases. However, it has been still unclear how the microstructure affects mechanical properties of these alloys. It was reported so far that the topology like fractal analysis and percolation analysis were useful to correlate the microstructure with mechanical properties such as intergranular fracture. Accordingly, we applied the topological approach to evaluate microstructure in Mo-Si-B-TiC alloys and examined the correlation between topological parameters and the fracture toughness. For four distinct Mo-Si-B-TiC alloy ingots with the same composition (65Mo-5Si-10B-10TiC (at%)) were produced via conventional arc-melting (20g and 90g), drop-casting and plasma arc-melting techniques in an Ar atmosphere, followed by heat-treatment at 2073 K for 24 hours. Microstructure in those samples was observed by SEM, and then percolation and fractal analyses were performed on the binarized SEM-BSE images. The EPMA was used to evaluate the chemical composition of constituent phases. The fracture toughness, KIC, was evaluated using a three-point bending test based on the Irwin’s similarity relationship [1]. Three-points bending tests were conducted at a displacement rate of 5 µm/s. The specimens with the Chevron-notch had final dimensions of 2.5 mm (w) ×2.5 mm (h) ×12.5 mm (l). The Chevrons-notches were machined by electro-discharge machining with a brass wire of 0.1 mm in diameter. The SEM observation and EPMA analysis revealed that the area fraction of constituent phases and their compositions in those Mo-Si-B-TiC alloys were almost the same, but microstructures were different. The percolation probability of hard phases: Mo5SiB2, (Ti, Mo)Cx and (Mo, Ti)2C, was found to be more than 85%, whereas that of Mo5SiB2 was less than 20%. Accordingly, the microstructural feature of those alloys that the Mo5SiB2 clusters were distributed around the continuous hard phases, and then the fractal dimension of dispersion [2] of Mo5SiB2 phase was determined. The fracture-toughness of those alloys were measured to be in the range of 14.6~15.6 MPa (m) 1/2. There appeared no clear relation between the fractal dimension of dispersion [2] for Mo5SiB2 clusters and the fracture-toughness of those alloys. However, of particular importance is finding that the fracture-toughness monotonously increased with increasing a new parameter that was multiplied the fractal dimension of dispersion by the average perimeter of Moss clusters.

PM06.05.10
Oxidation Resistance and High-Temperature Strength of Cr-Added Novel MoSiBTiC Alloy
Tomonaka Hatakeyama and Kyosuke Yoshimi; Tohoku University, Sendai, Japan.

1st generation MoSiBTiC alloy, which mainly consists of Mo5SiB2, TiC and TiSi2-TiC four-phase alloy is expected to be a possible candidate for novel ultra-high temperature material because of its outstanding mechanical properties. However, its insufficient oxidation resistance at elevated temperature has caused barriers in practical application. In this study, we attempted to improve the oxidation resistance by two steps. First, by increasing Si with Ti content, a Mo5SiB2-TiSi2-TiC four-phase alloy was developed. The introduction of TiSi2 phase is aimed to increase a Si resource in the microstructure. Secondly, Cr was added on the four-phase alloy to reinforce its oxidation resistance especially at intermediate temperature around 800°C. The Cr addition maintains the constituent phases of the alloy in a compositional range, and thus a Cr-added four-phase MoSiBTiC alloy was successfully developed at a composition of Mo-10Cr-28Ti-14Si-6C-6B (mol%). As expected, newly developed MoSiBTiC alloy exhibited a much better oxidation resistance at 800°C than 1st generation one. The alloy composition modification led to the formation of protective Cr oxide below an outermost Ti oxide layer. In addition, this alloy has a much smaller density of about 7.1 g/cm³, resulting in about 20% improvement in the high-temperature specific strength at 1400°C compared with that of 1st generation alloy.
Effect of Ni, Ta Alloying on Yield Stress Anomaly in Co3(Al,W) Strengthening Phase with L12 Structure

Zhenzhao M. Chen1, Norihiko L. Okamoto2 and Haruyuki Imul1; Kyoto University, Kyoto, Japan; 1Tohoku University, Sendai, Japan.

Recently, a new ternary L12 (γ) phase Co3(Al,W), which can coexist with a fcc solid-solution phase (γ) based on Co, has been discovered. We have investigated the compression deformation behavior in polycrystals of the L12-Co3(Al,W) and found that Co3(Al,W) exhibits a positive yield stress-temperature dependence (yield stress anomaly: YSA) as in the case of Ni3Al and many other L12 compounds. However, our previous study of micropillar single crystals of L12-Co3(Al,W) has demonstrated that, the high-temperature strength of Co3(Al,W) is considerably lower than that of NiAl-based L12 compounds, due to a narrow temperature range of YSA in Co3(Al,W) (900-1100 K). Another study indicates that complex stacking fault (CSF) energy as well as γ' solvus temperature might be the key of improving the high-temperature strength of Co3(Al,W).

In the present study, we investigate the effect of Ni, Ta alloying on the anomalous temperature range in Co3(Al,W). Compression tests were conducted from 298 to 1423 K in vacuum. The onset as well as peak temperatures of YSA were thus determined from yield stress-temperature curves. Dislocations in specimen deformed at high temperatures were investigated with TEM. While, γ' solvus temperature was determined by differential scanning calorimeter (DSC). Slip trace formed at high temperatures was investigated by electron back-scatter diffraction. The result indicates that, with Ni, Ta alloying, reported to be effective to increase the CSF energy, the onset temperature of YSA shifts to the low temperature side. TEM observation reveals that dislocations introduced above onset temperature exhibit strong tendency to along in its screw orientation while that below onset temperature are curved and no special orientation preferred, indicating that YSA in alloyed Co3(Al,W) is also corresponding to the stress orientation lock. Thus, it is evident that alloying increasing CSF energy is effective in widening the YSA region by shifting onset temperature to the low temperature side. On the other hand, alloyed Co3(Al,W), possessing higher γ' solvus temperature, exhibits also higher peak temperature, compared to ternary Co3(Al,W). However, the correspondence between peak temperature and γ' solvus temperature is not strong among the alloyed Co3(Al,W), indicating that other effects, such as diffusion, may also influence on the mechanical properties at high temperature. Nevertheless, the slip trace analyses indicates that (111) slip plane makes the peak temperature range slightly above the temperature range and no slip plane transition occurs in the vicinities of peak temperature, unlike NiAl, in which the peak temperature corresponds to the (111)=[001] transition.

We confirmed that CSF energy is a dominant parameter of determining the onset temperature of YSA in both ternary and alloyed Co3(Al,W). On the other hand, γ' solvus temperature is a very important parameter, although may not be the only one, on peak temperature.

Effect of Multi-Elements Substitution on the Mechanical Properties of Intermetallic Compound

Suvi Yaramaka1, Ken-ichi Ikeda2 and Seiji Miura2; Department of Materials Science and Engineering, Hokkaido University, Sapporo, Japan, 2‘Division of Materials Science and Engineering, Faculty of Engineering, Hokkaido University, Sapporo, Japan.

It is well known that various elements substitute for a certain sub-lattice of intermetallic compounds. There are various experimental investigations on the effect of substitution elements on the mechanical properties, however, there are few reports on the effect of multi-elements substitution. In the present study, L12 type compound Ni3Al is selected as a model compound because of its substitution behavior is established. It was reported that various elements such as Co, Cu, Pt and Pr substitute for Ni-site, while Pt, Cu, Ga, Ge, Ti, V, Nb, Ta, Mo, W substitute for Al-site. These elements are expected to introduce local lattice distortion which may have effects on the motion of dislocations not only at room temperature but also at lower temperature region or higher temperature region. Several alloys composed of 5 or more elements including Ni, Co, Al, Mo, W are prepared using arc-melting machine and heat-treated at 900 ℃ for 168 h. Microstructures are investigated using FE-SEM (JEOL, JXA-8530F). Constituent phases are identified using XRD (PHILIPS, X’Pert Pro) and FE-EPMA (JEOL, JXA-8530F). Mechanical properties of phases are investigated using nano-indentor (Hysitron, Ti-950 Triboindenter) with a load of 10000 micro-N. Several alloys are found to include (Ni, Co)(Al, Mo, W, …) - L12 compound as one of the constituent phases. The hardness of these L12 phase investigated using nano-indentor are almost the same or higher than that of high strength Co3(Al,W) - L12 compound, and it is confirmed that multi-elements substitution is an effective way to improve mechanical properties of Intermetallic compound.

Effect of Ta Addition on Microstructure and Mechanical Properties of Dual Two-Phase NiAl-Ni3V Intermetallic Alloy

Kazushige Iorioi, Yasuyuki Kaneno and Takayuki Takasugi; Osaka Prefecture University, Sakai, Japan.

A dual two-phase intermetallic alloy exhibits microstructure composed of primary NiAl (L12) phase surrounded by a eutectoid microstructure comprised of Ni3Al and Ni3V (D022) phases which is formed by a eutectoid reaction from Al (fcc) phase. The intermetallic alloy with the dual two-phase microstructure shows attractive mechanical properties as high-temperature structural materials [1]. However, further increasing in mechanical properties is required to be used as advanced high-temperature structural materials. It has been reported that Ti and Nb not only stabilize the two constituent phases [2] but also play a role in effective solid solution strengtheners [3]. In this study, the effect of Ta addition which is other potential solid solution strengtheners in the dual two-phase intermetallic alloy is investigated. Ta was added to a base alloy with a composition 75Ni10Al15V (in at.%)+50 wt.% Ta by three substitution methods for Ni, Al and V. Alloy button ingots prepared by arc-melting were solution-treated at 1553 K for 5 h in a vacuum, followed by furnace cooling at a rate of 10 K/min. Microstructure observation was carried out by scanning electron microscopy (SEM) and electron probe micro analyzer (EPMA). Lattice parameters of the constituent phases were calculated from X-ray diffraction (XRD). Mechanical properties were evaluated by Vickers hardness test at room temperature.

The dual two-phase microstructure was especially fine in the 2Ta(Al) alloy among three substitution methods where the alphabet between the parentheses indicates the constituent element substituted by Ta. The hardness was observed to be ranked in order, the Base < 2Ta(V) < 2Ta(Ni) < 2Ta(Al) alloys. The solid solution hardening predicted from the unit cell volume increment rate |dV/dC|, where V is unit cell volume and C is Ta content dissolving in the
constituent phases, is ranked in order, \( \text{TaAl} \) – \( \text{TaV} \) < \( \text{TaNi} \). Based on the observed results of microstructure and hardness, and the calculation on lattice expansion in the constituent phases, it is suggested that the additional hardening operating on the \( \text{TaV} \) and \( \text{TaNi} \) alloys is dominated by the solid solution hardening while that operating on the \( \text{TaAl} \) alloy is dominated by the hardening due to fine microstructure in addition to the solid solution hardening, consequently resulting in the largest hardness.

A New Ni-Based Superalloy for Parts of Advanced Engineering Plastics Injection Molding Machines

Takahiro Nakano, Hiroshi Nakamoto and Nobuyuki Funahira, Nachi-Fujikoshi Corp., Toyama-shi, Japan.

Use of engineering plastics has been steadily increasing in advanced industry hardware; automobiles, trains, aerospace, electronic parts, and electricity production/storage, where always demand materials with lighter, stronger, and more heat resistant properties, which has been persistent to attain their better performances, as called “high performance plastics”. A recent example is a group of fluorocarbon polymers (PFA) gradually replacing currently popular engineering thermoplastics or metals. PFA, however, stays elastic at low temperatures and shows its plasticity only above a transition temperature (~400 °C).

Engineering plastics have been made into many product shapes of complex geometries through injection molding machines with critical parts made of many conventional tool (high strength, high carbon) steels. However, for advanced engineering plastics, like PFA, we need wrought metals with more heat resistant strength. Another inevitable property required for those parts is resistance against hot corrosion, as those parts' surfaces are continuously exposed to high temperature corrosive gas during the PFA plasticization process. In this study we developed a new Ni-based wrought superalloy, (hereinafter called “F-alloy”) to be used for critical parts of advanced engineering plastics injection molding machines.

F-alloy has a characteristic as follows: the composition of this alloy was determined according to the L18 table of the design of experiment (DOE), which commonly practiced by a quality engineering method and enabled us not only reduce a number of experiments for new alloy developments but grasp quantitatively influence of each elements to the target properties; hardness and corrosion-resistance to PFA.

Experiment procedure is as follows; 18 melts of ingots, 10kg each, with 18 different composition were made by a laboratory induction melting furnace. The major alloy elements and composition were selected according to the L18 table of "DOE". The mechanical and metallurgical test samples were machined out from bars and plates made through press forging the 18 ingots, followed by heat treatments (solution and aging) at the temperatures predetermined by thermal and metallurgical analyses.

Hardness of F-alloy was measured at room temperature up to at 900 °C and the results were compared to the data of a conventional corrosion-resistant alloy (UNS N10276), a tool steel (UNS T30402), which has been commonly used for the parts of present injection molding machines. Hot corrosion tests were performed for F-alloy and two reference materials, the said corrosion-resistant alloy, and the said tool steel, being exposed composed with PFA at 400 °C.

The results of those experiments show that this alloy has both hardness (HV600 at 400 °C) and good hot corrosion-resistance to PFA at 400 °C, which is an outstanding characteristic compared to conventional materials for the parts of PFA injection molding machines.

Crystallographic Anisotropy of FeCr Sigma Phase (τP30) Caused from Site Occupation Behaviors in Fe-Cr-M Ternary Systems

Sota Maruyama, Satoru Kobayashi and Masao Takeyama; Materials Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan.

To clarify the nature of FeCr-\( \sigma \) phase (τP30), the structural features of \( \sigma \) phase in Fe-Cr-binary and Fe-Cr-M ternary systems were investigated in this study. All of the alloys have a composition of \((Fe_{50})(Cr_{50-X}, MX), (Fe_{50-X}, MX)(Cr_{50})\) or \((Fe_{50-X}, MX)(Cr_{50-X}, MX)\), and were produced in arc melting furnace. The as-cast alloys were cold rolled by the height reduction of 50 % and equilibrated at 973 K and 1073 K for up to 1000 h to obtain \( \sigma \) single phase structure, with and without prior homogenization treatment at from 1273 K to 1523 K. Phase compositions analysis and identifications in annealed alloys were conducted by EPMA and powder XRD technique respectively. Obtained XRD profiles were further analyzed by means of Rietveld method. During the analysis, crystallographic parameters of lattice constants and site occupancies in non-equivalent five sub-lattice sites \((M1, M2, M3, M4 \text{ and } M5)\) were refined. It was found that lattice expansion and shrinkage of \( \sigma \) phase with changing composition were reasonably explained only by considering relative size difference between constituting and solute elements. i.e. larger elements like Mo expand lattice uniformly and smaller elements like Co or Ni do in opposite manner. On the other hand, when the specific type of the elements such as Fe or Si coming into the \( \sigma \) phase, lattice parameter ration \( c/a \) shows increase with increasing \( c \) axis and decreasing \( a \) axis. The nonuniformity cannot be explained only by consideration of atomic size, and other factors such as magnetic or interatomic interaction could be involved. Combined with \( X \)-ray profile analysis, it implied that the origin of crystallographic anisotropy is a characteristic site occupation behavior of the specific elements. The relations between preferential site occupation and its crystallographic features will be discussed in detail.

Refinement of Crystal Structure of Highly Ordered \( \eta^* \)-derivative Phase

Ryutaro Sakai1, Masaya Higashi2, Kodai Nishii1,2 and Haruyuki Inui1,2; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Strategic Materials (ESISM), Kyoto University, Kyoto, Japan.

Hot dip aluminized steels are practically used as automotive exhaust system parts because of their good heat resistance, corrosion resistance and designability. The coating layers have been believed to mainly consist of a thick \( \eta^* \)-FeAl phase and a thin \( \eta \)-FeAl13 phase. The orthorhombic \( \eta^* \)-FeAl13 (space group \( Cnmm \)) comprises chains of atoms with partial occupancies along the \( c \)-axis. Recent studies report that these sites are ordered in a different manner in relation to compositions, and that there are variations of ordered phases such as the \( \eta \) and \( \eta^* \) phases, which possess the framework structure of the \( \eta \) phase. Furthermore, another derivative of the \( \eta \) phase (the \( \eta^* \) phase) is suggested to exist by means of powder X-ray diffraction (XRD) analysis. However, the reported structure does not seem to be consistent in terms of the hierarchical ordering of the \( \eta \) phase. In this study, crystal structure of the \( \eta^* \) phase is assessed by means of transmission electron microscopy (TEM), scanning transmission electron microscopy (STEM), and XRD analysis. Ingot with Al-rich composition Fe-73.7 at.%Al was prepared by arc-melting method. After solution treatment at 1073 K for 8 hours, the ingot was encapsulated in vacuum-sealed quartz ampoules and heat-treated at 523 K for 60 days followed by water quenching. Thin foils for TEM and STEM observations were prepared by electro-polishing.

In the selected-area electron diffraction (SAED) patterns obtained from various incidence azimuth, there are superlattice diffraction spots in addition to fundamental ones of the \( \eta \) structure. For example, the superlattice diffraction spots are located at the positions that divide the distance between the 000 and 1-1-11 fundamental spots by two. From STEM observations, it is clarified that the \( \eta^* \) phase accompanies orderings of the atom sites with partial occupancies as those of the \( \eta \) and \( \eta^* \) phases. Furthermore, the \( \eta^* \) phase contains periodic anti-phase boundaries (APBs) normal to the \( c \) axis. According to the analysis of XRD pattern, APBs are presumably introduced to compensate for the \( c \)-axis lattice incompatibility among adjacent \( \eta \), \( \eta^* \) and/or \( \eta \) phases.
PM06.05.18
Plastic Deformation Behavior of Single-Crystalline Micropillars of the Fe-Cr Sigma Phase Masaoiti Kudaka1, Nobuyuki Kadota1, Kyoink Ishida1-2 and Haruyuki Inui1-2; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Structural Materials (ESISM), Kyoto University, Kyoto, Japan.

The so-called sigma phase has long been considered to cause detrimental influences on the mechanical properties of stainless and heat-resistant steels mainly because of its high hardness and brittleness at room temperature that stem from its complex crystal structure (D8, structure, fP30, space group: P4/mnm, c/a ~ 0.52). Recently, it has been reported that the creep strength, ductility, yield strength and tensile strength of stainless steels can be improved if the distribution and morphology of the sigma phase are properly controlled. These results have caused a growing demand for fundamental understanding of plastic deformation behavior of the sigma phase itself. However, the deformation behavior of the sigma phase is largely unknown because of its brittleness at room temperature. Recently, micropillar compression tests of single crystals have been proved to be useful for studying fundamental deformation behavior of hard and brittle materials such as high temperature intermetallics, semiconductors and ceramics. In the present study, we have prepared single crystalline micropillars of the Fe-Cr sigma phase and compression-tested at room temperature as a function of loading axis orientation and specimen size. Plastic flow was observed at room temperature for all tested micropillars mostly exhibiting a smooth transition from elastic to plastic deformation similar to those observed for ductile materials. Four different slip systems were identified to be operative depending on the loading axis orientations. The values of critical resolved shear stress (CRSS) for the four slip systems identified are extremely high about 1.2 – 2.5 GPa. However, it should be noted that very good ductility more than 5% compressive strain was achieved for most loading axis orientations tested, which clearly indicates that the Fe-Cr sigma phase is not inherently brittle at least under compressive loading.

PM06.05.19
Structural Control of Porous Nickel Aluminides Fabricated by Reactive Synthesis with Space Holder Powder Ayaka Suzuki, Yumiao Shu, Naoki Takada and Makoto Kobashi; Nagaoka University of Technology, Nagaoka, Japan.

Porous metals have unique properties like ultra-low density, energy absorption, thermal insulation, sound absorption, fluid permeability, and so on. For example, the thermal conductivity of the porous metals with 80% porosity is about one tenth of the bulk metals. Transition metal aluminides, which have all of these properties, are expected as a high-strength energy absorber and a heat-resistant thermal insulator, and so on. Our group has developed a powder metallurgical process to synthesize porous titanium aluminides such as TiAl, Ti3Al, and Ti5Al by combining reactive synthesis and a spacer method, and revealed the high strength of porous TiAl. In the present study, we attempted to synthesize porous nickel aluminides like NiAl and Ni3Al through the reactive process and control their porous structure. Al powder with 2 μm in size and 99.99% in purity, Ni powder with 1 μm in size and 99% in purity, and sodium chloride (NaCl) particles with 30-50 μm in size and 99.99% in purity were used as starting powders. These powders were blended with various molar ratio of Al/Ni (3, 1, and 1/3). The volume fraction of NaCl was varied within the range of 0-80%. The blended powder was cold compacted at 25 MPa to obtain cylindrical precursors with 10 mm in diameter and height. An electric current sintering was performed under applying a pressure of 5 MPa. Temperature was raised in a rate of 0.5 K/s and held at 923 K for 10.8 ks. The sintered samples were soaked in water for 86.4 ks to leach out NaCl completely. For comparison, porous Al specimens were also fabricated by powder sintering and spacer method. X-ray diffraction measurements were performed operating at 40 kV and 20 mA with a Cu-Kα radiation in order to confirm the constituent phase. The porous structures of fabricated samples were observed with a scanning electron microscopy. Synthesized porous nickel aluminides had bi-modal pore size distribution. Large pore replicated the shape of NaCl particles. Small pore (0.5~4.0 μm in diameter) derived from reactive synthesis are formed where Al particles existed before the reaction. As the size of Al particles was larger, the size of small pores increased. Porosity of small pores increased with increasing the Al/Ni molar ratio. The porous structure can be controlled by the size and the composition of the starting powders.

PM06.05.20
Micropillar Compression Deformation of Single-Crystals of Cementite Fe3C Nobuyuki Kadota1, Kyoink Ishida1-2 and Wei Chen1-2; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Structural Materials (ESISM), Kyoto University, Kyoto, Japan; 3School of Materials Science and Engineering, Xi’an Jiaotong University, Xi’an, China.

Pearlitic steels with a lamellar structure composed of alternating ferrite and cementite (Fe3C) layers are widely used as high-strength steel wires and rails because of their high strength. The strength of pearlitic steel wires has been known to be improved further by drawing, which makes their lamellar structure much finer. These attractive mechanical properties related to their microstructure evolution during drawing have been considered to be strongly influenced by the mechanical properties of cementite. Cementite has the orthorhombic D012 structure (oP16, space group: Pnma, a = 5.08, b = 6.73, c = 4.52A), which is composed of corner- and edge-sharing carbon-centered trigonal prisms. Cementite has been considered to be brittle mainly because of its complex crystal structure with low symmetry. However, inherent deformation mechanisms of the cementite Fe3C are still largely unknown, except for some implications of plastic deformation observed as slip band propagation across very thin Fe3C lamella in pearlite grains and the thickness reduction of Fe3C lamella during the drawing process of pearlitic steel wires. This is mostly because of the lack of systematical studies using single crystals. Recently, micropillar compression tests have been proved to be useful in studying deformation behavior of various crystalline materials including those with serious difficulty in preparing bulk single crystals. In this study, single crystalline micropillars of cementite were fabricated by focused ion beam technique, and tested in compression at room temperature as a function of loading axis orientation and specimen size. Plastic deformation was observed at room temperature for all tested specimens. Five different slip systems were identified experimentally for the first time. The values of critical resolved shear stress for the five slip systems were confirmed to be very high about 1.0 ~ 2.0 GPa. Characteristics of identified slip systems such as actual glide plane and dislocation dissociation scheme were investigated by both experimentally through TEM analysis and theoretically by first-principles DFT calculations of generalized stacking fault energy.

PM06.05.21
Intermetallic Formation at Deeply Supercooled Ni/Al Multilayer Interfaces—A Molecular Dynamics Study Peng Yi, Michael L. Falk and Timothy P. Weihs; Johns Hopkins University, Baltimore, Maryland, United States.

Reactions at interfaces between different solid phases are critical processing steps for a variety of applications including microelectronics, superconducting magnet wires, coatings on turbine blades, and reactive materials. Due to the highly non-equilibrium nature of interfaces between metastable solid phases, phase formation at these interfaces is complicated and difficult to predict. It is well established experimentally that the first phase to form through an interfacial reaction need not be the most stable phase predicted by the phase diagram. As an example, DSC and TEM experiments in the Ni/Al multilayer system have suggested that the formation of intermetallic phases can be suppressed by a high heating rate, or by reducing the interspacing between the layers.1, 2 Two possible mechanisms were proposed to explain phase selection for interfacial reactions: a growth-controlled mechanism[3], and a nucleation-controlled mechanism[4].
Here we use molecular dynamics simulations to study the formation of the non-stoichiometric intermetallic compound, NiAl(B2), in the Ni-Al multilayer system, focusing on how composition gradients at the Ni/Al interfaces impact the intermetallic formation [5]. Simulations were designed to test the intermetallic formation under isothermal conditions within a constant composition gradient (10^{-7}-10^{-9} m⁻³) that mimics those found in nature, where Al and Ni layers inter-diffuse. Simulation temperatures of 800K and 650K were chosen so as to be above and below the compositionally-dependent melting point of Al-Ni solid solution. We observed melting or amorphization at the interface region due to intermixing at 800K or 650K, respectively. The intermetallic phase then forms at the interface from the melted or amorphous region through heterogeneous nucleation, followed by growth in both lateral and normal directions. Kinetics of the transformation follows the Johnson-Mehl-Avrami model and an Avrami exponent of 0.5 was extracted from the data obtained at 800K, and 0.1 for 650K. The NiAl formation is growth-controlled and the growth rate is found to increase with decreasing composition gradient. Our findings support a growth-competition mechanism of phase selection for interfacial reactions, which might be favored at high undercooling.

PM06.05.22

Atomistic Kinetic Monte Carlo Modeling of the Formation of G.P. Zone in Al-Cu Alloy

Hirosi Miyoshi1, Akio Ishii2, Hajime Kinizuka2 and Shigenobu Ogata3, 4; 1Graduate School of Engineering Science, Osaka University, Osaka, Japan; 2Kyoto University, Kyoto, Japan; 3Osaka University, Osaka, Japan.

Al alloys are widely used as key structural materials especially in aerospace and automobile industries owing to their high weight, high strength, and good workability. In Al alloys, nanosized clusters of solute atoms called Guinier-Preston (G.P.) zones play a significant role in the precipitation hardening effect, in which the Cu nanoclusters impede the movement of dislocations in the Al matrix while maintaining balanced strength and ductility. Thus, it is important to control the size, orientation, and shape of the nanoclusters for the adequate design of Al alloys. The observations with high-resolution transmission electron microscopy revealed that the structures of G.P. zones consist of disk-shaped, monoatomic layered precipitates of Cu atoms along the [100] planes. However, the detailed mechanism of the formation of the zones has not been clarified yet. Understanding of the atomistic mechanism may serve as relevant information for the design and exploitation of advanced Al alloys with excellent mechanical performance. In this study, to elucidate the atomistic behavior of solute atoms and vacancies in the process of the formation of G.P. zones, a framework of atomistic kinetic Monte Carlo modeling for Al-Cu alloys was developed based on density functional theory (DFT). An on-lattice potential model for a dilute Al-Cu-vacancy system was constructed using the DFT-calculated binding energies for the pairs and triplets of Cu atoms and a vacancy in the Al matrix, and then applied to atomistic kinetic Monte Carlo calculations. The DFT results revealed that the Cu-Cu pairs in the first-nearest neighbor (1NN) position and the Cu triplets with a 1NN bond angle of approximately 90 degree exhibit significant attractive interactions whereas a vacancy does not prefer to occupy sites neighboring to these Cu pairs and triplets. This suggested that a vacancy can diffuse rather randomly without strong bindings to Cu atoms and that Cu atoms gradually form clusters via a vacancy-assisted diffusion mechanism with a lowering of the energy of the system. Indeed, the results of atomistic kinetic Monte Carlo calculations supported this view and reproduced the planar segregation of Cu atoms along the [100] planes in a manner consistent with experimental measurements. Also, the effects of temperature and vacancy concentration on the formation of G.P. zone were investigated. The nucleation behavior of G.P. zone obtained from the kinetic Monte Carlo analysis was compared with the counterpart based on classical nucleation theory. The critical nucleus size for the formation of G.P. zone was estimated from the formation free energy of Cu clusters with considering a competition between the enthalpic and entropic contributions to the free energy at finite temperatures.
low microstructural stability of the Al alloys significantly reduces their strength at elevated temperatures. On the other hand, the commercial refractory metals and alloys (e.g. Ni-based superalloys) contain stable intermetallic phases with a high volume ratio of 50% or more as a strengthening phase, resulting in maintaining high strength even at high temperature. In this study, we designed two Al-based cast alloys strengthened by thermodynamically stable intermetallic phases with a high volume fraction.

We focused on eutectic reactions in order to have high volume fractions of intermetallic phases. We selected two commonly used metals, Zn and Mg, as alloying elements, and attempted to fabricate two types of α-Al (fct) matrix reinforced by η-ZnMg (hexagonal) and T-AlMgZn (cubic) intermetallic phases. Thermodynamic assessments revealed two alloy compositions of Al-36Zn-18Mg and Al-23.5Zn-22.5Mg (at%) with the α-Al (fct) phase reinforced with high fractions (>50%) of the η and T phases. The morphology of the α-Al phase in the eutectic colonies varied upon changing the neighboring intermetallic phase. The lamellar structure consisting of α-Al and η phases appeared in a large part of the cast Al-36Zn-18Mg alloy. In the cast Al-23.5Zn-22.5Mg (at%) alloy, rod-shaped α-Al phase was observed within T-phase matrix in the eutectic microstructure. These eutectic microstructures exhibit high stability at an elevated temperature of 300 °C. It was found that the solidification segregation of Zn component was observed around the eutectic cell boundaries in the Al-36Zn-18Mg alloy. The microstructural observation of the alloy exposed at 300 °C confirmed that the Zn-enriched regions would enhance the local microstructural change at elevated temperatures. This result demonstrates that the Al-23.5Zn-22.5Mg (at%) alloy is superior to the Al-36Zn-18Mg alloy in terms of microstructural stability at elevated temperatures. The fabricated alloys exhibited high hardness values exceeding 220 HV, which were much superior to those of conventional Al alloys. These alloys exhibited high hardness values exceeding 200 HV even after the exposure at 300 °C for 1000 h. In this presentation, crystallographic features of these eutectic microstructures will be presented in conjunction with transmission electron microscopy.

**Effect of Intermetallic Compound YAl2 Particles on the Corrosion Behavior of Mg-Li Matrix Composite**

Zihan Chen and Chonggao Bao; Xi'an Jiaotong University, Xi'an, China.

Mg-Li based alloys are currently the lightest among the metallic structural materials, and they have many excellent properties such as high values specific strength, mechanical casting properties, good damping capacity, good thermal conductivity and electromagnetic shielding performance. The strength of Mg-Li alloy is greatly improved by the composite strengthening of intermetallic compound YAl2 particles, but the low corrosion resistance of Mg-Li alloy is still the main factor that restricts the application of the alloy and its composites. The effect of intermetallic compounds YAl2 particles on corrosion behavior of Mg-Li matrix composite (YAl2/LA143) in 3.5 wt.% NaCl solution was systematically investigated. Microstructure was examined by Electron microscope, X-ray diffraction, and 3D laser scanning microscope. Corrosion performance was evaluated by immersion tests, electrochemical measurements, and direct visual observation. The results showed that the corrosion resistance of YAl2/LA143 composite improved significantly as the formation of a transitional interface layer by adding YAl2 particles. The diffusion of yttrium and aluminum atoms from YAl2 particles improved the stability of the surface film and enhanced the adhesion between the corrosion products and the substrate, which hindered the further expansion of pitting.

**PM06.05.26**

**Thermodynamics and Kinetics of Bimetalllic Nanoparticles from First Principles Calculations**

Shubham Pandey1, Robert Kochl1, Guangfang Li1, Hui Wang1, Scott Mixture2 and Simon R. Phillpot1, 1Department of Materials Science and Engineering, University of Florida, Gainesville, Florida, United States; 2Inamori School of Engineering, Alfred University, Alfred, New York, United States.

We use Density Functional Theory (DFT) to characterize the energetics of Cu-Au and Ni-Au ordered alloys and the effects of epitaxial strain on their relative stabilities. We find that epitaxy on a Au substrate tends to destabilize Cu-rich alloy structures, while having little effect on Au-rich alloys. Work of adhesion is used to characterize the interfacial stability and we find higher works of adhesion for alloys grown epitaxially on Au, than on Cu or Ni. Diffusion in bulk intermetallics, random alloys and at epitaxial interfaces is analysed. Diffusion across the Cu-Au [111] interface is modeled for Au substrate where we find that, there is a barrier for Cu diffusion while Au diffusion is barrierless. Random alloys give identical migration barriers for both Cu and Au, and follow a Gaussian distribution. The computational results are correlated with experimental analysis of phase stability and kinetics in the corresponding nanoparticles.

This work was supported by the Center for Hierarchical Waste Form Materials (CHWM), an Energy Frontier Research Center (EFRC) funded by the United States Department of Energy Office of Basic Energy Sciences through Award DESC0016574.

**PM06.05.27**

**Phase-Field Modeling of Evolution of Compact Ordered Precipitates in Ternary Alloy Systems**

Sandeep Sugathan and Saswata Bhattacharya; Department of Materials Science and Metallurgical Engineering, Indian Institute of Technology, Hyderabad, Hyderabad, India.

Several technologically important alloys exhibit compact precipitates in their microstructure. For example, tertiary Al-Sc-Li alloys form coherent L12 precipitates of Al-Li and Al(Sc,Li) during a two-step ageing process [Radmilovic et al., Nature Materials 10, 710 (2011)]. Al-Li phase envelopes the Al(Sc,Li) phase giving rise to a compact core-shell morphology with strong monodispersity. Modified Inconel 718 also exhibits a compact morphology where three orientational variants of γ envelop cuboidal γ′ precipitates [Cozar, R. and Pineau, A., Metall. Trans. 4, 47 (1973)]. Factors affecting the formation of such precipitates include alloy chemistry, relative interfacial energies between the coexisting phases, elastic misfit and solute diffusivities. We present a phase-field model in two dimensions to study the effects of alloy chemistry, interfacial energy and elastic stress (arising due to coherency) on the morphological evolution of compact precipitates. The model employs a modified regular solution description of the bulk free energy of the disordered matrix phase and ordered precipitates with coefficients obtained from the thermodynamic data for the relevant systems. Elastic strain energy of the three-phase system is described using Khachaturyan’s micromechanics theory. The temporal evolution of the spatially dependent field variables is determined by numerically solving coupled Cahn-Hilliard and Allen-Cahn equations for composition and order parameter fields, respectively. We use a semi-implicit Fourier spectral scheme to integrate the governing equations. We systematically vary the gradient energy coefficients and misfit strains to study their effect on the development of compact precipitates. Further, we vary the mobilities of diffusing species in order to understand their effect on the stability of compact morphology. The sign and degree of misfit as well as the relative interfacial energies between the phases affect solute partitioning, thereby influencing the formation of compact morphology. Our simulations show the development of stable core-shell morphology when the misfit between the ordered precipitate phases is lower than those with the matrix phase although the interfacial energies between the coexisting phases do not satisfy the criteria proposed by Cahn J. W. and Cahn, J. Chem. Phys. 65, 6245 (1976). Thus, the elastic interactions between the phases is a crucial factor affecting the stability of “monodisperse” core-shell microstructures. We further conclude from our simulations that low mobility of solute atoms forming the core lead to sluggish coarsening of compact core-shell structures.

**Superelasticity in Micro/Nano Pillars of Cu-Al-Be Shape Memory Alloys**

Valeria Fuster1, Jose F. Gómez-Cortés1, Maria L. No2 and Jose San Juan3; 1Fisica Materia Condensada, Universidad del País Vasco, Bilbao, Spain; 2Fisica Aplicada II, Universidad del País Vasco, Bilbao, Spain; 3Instituto de...
Shape memory alloys are functional intermetallics which undergo a reversible martensitic transformation responsible for the shape memory and superelastic effects. In addition, shape memory alloys offer the highest work output density, in comparison with other smart materials, and consequently are firm candidates to be incorporated as sensors and actuators into MEMS and NEMS because of their ability to undergo the thermal or stress-induced martensitic transformation (superelastic) with a high-displacement actuation. A good shape memory behaviour and superelasticity were recently reported in Cu-Al-Ni SMA [1, 2, 3]. However, among the different explored alloy families, up to now Cu-Al-Ni is the only SMA system exhibiting good properties at nano-scale.

The aim of the present work is to explore a novel Cu-Al-Ni SMA system and to this purpose [001] oriented D03 single-crystals grown from a Cu-12.0Al-0.47Be (wt.%) shape memory alloy were synthesized in our laboratory. This alloy has the martensitic transformation temperatures below room temperature, showing excellent superelastic properties at macroscopic scale. Then, in the present study we carried out a quantitative characterization and analysis of the superelastic behaviour at the micro and nano scale. A series of pillars covering a broad-range of size diameters, between 265 nm and 1.800 μm, were milled by Focused Ion Beam (FIB) from single crystal slides. These pillars were studied by hundreds of nano-compression cycles at room temperature using instrumented nanoindentation. Our results show that this alloy also exhibits an excellent superelastic behaviour at small scale, as well as a size effect on the critical stress to induce the transformation. In addition, the analysis of such size effect shows that the critical stress follows a power-law type as a function of the pillar diameter, in agreement with recent reports in the Cu-Al-Ni system [3]. These results seem to confirm the universality of the power law found in Cu-based SMA, and open the door for future small-scale applications.

PM06.05.29
Isomteric Martensitic Transformation Behavior of NiCoMnIn Metamagnetic Shape Memory Alloy Yosuke Yano1, Kodai Nishi2, Ryosuke Kainuma1 and Haruyuki Inui1; 1Department of Materials Science and Engineering, Kyoto University, Kyoto, Japan; 2Center for Elements Strategy Initiative for Structural Materials (ESISM), Kyotou University, Kyoto, Japan; 3Department of Metallurgy, Materials Science and Materials Processing, Tohoku University, Sendai, Japan.

Dynamics of thermo-elastic martensitic transformations (MTs) is described by the nucleation and growth processes, and in particular the former is associated with only the forward transformation. In relation to this, isothermal forward MT behavior with a C-shaped curve in TTT (Time-Temperature Transformation) diagram has been discussed in terms of the thermal activation process of nucleation, but not studied for the reverse MT. Considering the dominance of nucleation process is different with respect to the direction of MTs, isothermal dynamics of the reverse MT is expected not to be the same as that of the forward one.

In the present study, we investigated the isothermal and non-isothermal behaviors of magnetic-field-induced martensitic transformation in Ni$_{40}$Co$_{30}$Mn$_{2}$In$_{13.2}$ magnetic shape memory alloy. Non-isothermal MT was performed for various scanning routes of temperature and magnetic field to figure the phase diagram. Isothermal MT was examined by settling magnetic field and temperature at various stages of forwarding/reversing MTs. Isothermal holdings showed logarithmic evolutions of transforming fraction both in the forward/reverse MTs. However, its temperature and time dependences were in contrast with respect to transforming directions; while isothermal forward MT showed iso-fraction C-shaped curves in the TTT diagram as reported elsewhere, isothermal reverse MT showed only lower half of C-shaped curve that terminates at the reverse MT finishing temperature.

This alloy is shown to know an increasing MT hysteresis upon cooling due to the development of thermal activation nature of MT. By decomposing the hysteresis into thermal activation and non-thermal activation components, the origin of different isothermal MT behaviors between forward/reverse MTs was discussed. We propose a new formula that can describe the dynamics of forward/reverse isothermal MTs simultaneously by taking into account the thermal and non-thermal activation processes of nucleation and growth.

Influence of NiAl Precipitation on the Martensitic Transformation of Cu-Al-Ni Shape Memory Alloys Nora Egido1, Jose San Juan2, Isabel Ruiz-Larrea1, Mariano Barrado1, Tomasz Breziewski1 and Maria L. No1; 1Facultad de Ciencias, Universidad de Guadalajara, Guadalajara, Mexico; 2Física Aplicada II, Universidad del País Vasco (UPV/EHU), Bilbao, Spain.

Shape memory alloys (SMAs) exhibit a diffusionless martensitic transformation (MT) between the high-temperature phase (austenite) and the low temperature phase (martensite). SMAs have recently attracted renewed interest from the scientific community as a result of their behavior and properties at micro and nano scales [1,2]. At present the technological applications of SMA are based on superelastic, pseudoelastic and shape memory thermomechanical properties and in particular the CuAlNi SMAs with small amounts of Ni show their best properties as single crystals without α and γ1 precipitates. The CuAlNi is a disordered L21 phase that transform during cooling to an ordered β, monoclinic martensite or to an ordered γ',orthorhombic martensite or to both of them.

With the idea that NiAl B2 precipitates could improve the mechanical properties of the CuAlNi SMAs, by hardening the austenite phase, in the present research work the influence on the thermal martensitic transformation of larger amounts of Ni and their precipitation as NiAl, has been studied. The best temperature, thermal treatment and quenching process has been determined in order to avoid the precipitation of the other non desirable stable phases γ', α and α. Oriented [001] single crystals with 26.26Al-5.05Ni-68.69Cu (At.%) were used in the present work. Internal friction (IF) experiments were employed to optimize the thermal treatments and temperatures in order to obtain and control the NiAl precipitation. The microstructure of the as-quenched samples from 1173K, without precipitates, and the thermally treated samples, with precipitates, were determined by different techniques of scanning electron microscopy (SE, BSE, EBSD) focus ion beam (slice mode) and transmission electron microscopy (BF, DF, STEM-HAADF, EDX) with a philips CM-200 and a TitanCubed 80-300KV with the super-X detector ChemiSTEM. The results show us that it is possible to control the density and the size of NiAl precipitates avoiding the α and γ1 stable phases and preserving the martensitic transformation.

Mechanical Properties of Au–Cu–Al Biomedical Shape Memory Alloys Containing Ag Ayano Toriyabe1, Kenji Goto1, Akira Umise1, Hiroyasu Kanetaka4 and Hideki Hosoda2; 1Institute of Innovative Research (IIR), Tokyo Institute of Technology, Yokohama, Japan; 2Tanaka Kikinzoku Kogyo K.K.,
AuCuAl alloy is a promising shape memory alloy which is suitable to X-ray radiography and magnetic resonance imaging. In order to enhance biocompatibility and antibacterial activity of AuCuAl alloy, Ag addition to AuCuAl alloy was focused in this study. Because Ag ions released from material bring strong antibacterial effect in human body. However, the effect of Ag addition to AuCuAl of phase constitution, transformation behavior and mechanical properties has not been reported in the literature. Several AuCuAl alloys containing Ag in which Ag is expected to substitute for the Au sites and Cu sites were fabricated by Ar arc-melting method. They were hot-forged at 873K and solution-treated at 773K for 3.6ks followed by ice water quenching. Phase constitution, transformation temperatures, microstructure and chemical compositions were evaluated by θ-2θ X-ray diffractometry (XRD), differential scanning calorimetry (DSC) and scanning electron microscopy (SEM) equipped with energy dispersive X-ray spectroscopy, respectively. Mechanical properties were evaluated by micro Vickers hardness tests and tensile tests, compression tests at room temperature.

The phase constitution of 45Au-25Cu-25Al-5Ag and 50Au-25Cu-25Al-5Ag alloys was L21, parent single phase at RT by XRD. However, 45Au-25Cu-25Al-5Ag alloy contained small amount of second phase by SEM. Reverse martensitic transformation finish temperature by DSC was 240K in 45Au-25Cu-25Al-5Ag and 243K in 50Au-25Cu-25Al-5Ag, which were approximately 50K lower that of the stoichiometric AuCuAl. Then, martensitic transformation temperature was decreased by Ag addition but the substitution site seems little influence. Micro Vickers hardness of 50Au-25Cu-25Al-5Ag and 45Au-25Cu-25Al-5Ag alloys was HV272 and HV236, respectively. These values were higher than HV170 of AuCuAl. By tensile tests at RT, both Ag-added alloys exhibited no plastic deformation due to the intergranular fracture, similar to the AuCuAl. The ultimate tensile strength of both alloys was 182 and 177 MPa, which was higher than that of AuCuAl. Then, Ag addition is found to enhance hardness and fracture strength of Au-Cu-Al alloys. This work was supported by Grant-in-Aid for Scientific Research Kiban S 26220907 from Japan Society for the Promotion of Science (JSPS).

Ductility Enhancement of AuCuAl Biomedical Shape Memory Alloys by Introducing FCC α Phase
Akira Umise1,2, Koki Yamaji1, Hayato Gunji1, Kenji Goto1,3, Masaki Tahara1, Takao Hanawa2 and Hideki Hosoda1; 1Institute of Innovative Research, Tokyo Institute of Technology, Yokohama, Japan; 2Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Chiyoda, Japan; 3Tanaka Kikinzoku Kogyo K.K., Isehara, Japan.

Au-based shape memory alloys exhibiting good biocompatibility and excellent X-ray radiography have a large potential to exceed Ti-Ni SMAs in the field of biomedical implant devices. Especially AuCuAl alloys have attracted attention. However, on the present available data, ternary polycrystalline AuCuAl alloys which are often brittle due to intergranular fracture. In this study, we focused on introduction of second phase at grain boundaries that must enhance grain boundary cohesive strength, and mechanical properties were investigated. The second phase selected is α phase that is the fcc terminal solid solution of (AuCu) in the Au-Cu-Al system.

Au-37Cu-15Al (AuCuAl single phase) and Au-37Cu-15Al (AuCuAl+α two phases) alloys (hereafter, in at%) were prepared by Ar-arc melting method using a non-consumable W electrode. Both electrodes were expected to have a similar chemical composition of AuCuAl phase. The ingots were hot-pressed at 873K for 21.6ks and solution-treated at 773K for 3.6ks followed by water quenching. Microstructural observation and chemical analysis were done by scanning electron microscopy equipped with energy dispersive X-ray spectrometry (SEM-EDX). Phase constituent and phase transformation were characterized by θ-2θ X-ray diffractometry and differential scanning calorimetry, respectively. A cyclic loading-unloading tensile test with a constant strain increment of 1% was performed at RT.

SEM and XRD analysis revealed that Au-37Cu-15Al alloy contains α phase. The chemical composition of the matrix AuCuAl and fcc phase in Au-37Cu-15Al alloy were 48.3Au-35.3Cu-15.8Al and 45.6u-40.6Cu-13.8Al, respectively. Then, the chemical composition of matrix in Au-37Cu-15Al is close to that of Au-33Cu-Al. Then, the difference of phase is in comparison with Au-33Cu-15Al single-phase alloy. The tensile tests revealed that the elongation of Au-37Cu-15Al alloy containing α phase was much lower than that of Au-37Cu-15Al alloy.

Ductility Improvement of Ni-Mn-Sn Magnetic Shape Memory Alloys by Co and Cu Addition
Kun Zhang and Changlong Tong; Harbin University of Science and Technology, Harbin, China.
Compared to the traditional shape memory alloys (SMAs), ferromagnetic shape memory alloys (FSMAs) show a strong coupling between structure and magnetism. Except for thermal drive, FSMAs can produce force and deformations in response to a magnetic field. Recently, the applications of Ni-Mn-Sn FSMAs in actuator, sensor, and solid-state refrigerator can be expected due to their unique phase transition mechanism and rich physical properties. The low working temperature and the poor mechanical properties are the crucial problems limiting the application and development of Ni-Mn-Sn FSMAs. Moreover, to increase the working temperature, it is necessary to elevate the martensitic transformation temperature (Ms) while keeping the Curie temperature (Tc) unchanged. How to solve all the problems mentioned above at the same time is the key. In this paper, the new idea for increasing the working temperature and enhancing the mechanical properties is proposed by doping two elements simultaneously. Owing to the performance of different roles in Ni-Mn-Sn alloys, adding Co and Cu at the same time may elevate Tc while keeping the Ms high, and improve the mechanical properties of Ni-Mn-Sn alloys. The results of the DSC and TGA curves show that martensitic transformation is observed in Ni$_{53}$Co$_{12}$Mn$_{26}$Sn$_{11}$Cu$_{10}$ alloy.

Fabrication of Thermoelectric Power Generator Using Solely N-Type Mg$_2$Si for Automotive Application

Intermetallic silicide of magnesium silicide (Mg$_2$Si) is a promising candidate for practical thermoelectric (TE) power generation, because it has several promising features, such as the abundance of its constituent elements, its non-toxicity, and the facts that it is light weight and has the capability of generating power. For automotive applications, lighter and tougher thermoelectric power generators are advantageous; however, these applications are sometimes demanding on the devices. Mg$_2$Si has already achieved a ZT value greater than unity. In order to realize its practical use as a TE generator (TEG), both low fabrication cost and a significant lifetime at an elevated operating temperature are important. We have developed n-type Mg$_2$Si TE elements as parts of a feasible TE device. There are economic advantages to using Mg$_2$Si in thermoelectric devices. Basically, the p-type conductivity of Mg$_2$Si is possible but the thermoelectric properties of p-type material are not equivalent to those of n-type Mg$_2$Si one. Therefore, a so-called “unileg” device structure, incorporating only a n-type Mg$_2$Si TE leg, is one possible solution to realizing practical Mg$_2$Si TEGs. Compared with the conventional p-structure TE module, which comprises both p- and n-type TE elements, the uni-leg structure alleviates the problems associated with the difference in thermal expansion between p- and n-type TE elements at high temperature. To reduce the electrical and thermal contact resistance of the module, each part of the module was joined using new soldering intermetallic alloys. We are currently tuning the TE chip power generation ability by modifying the type of dopant and the contents of the matrix and the TE chip dimensions. The elemental n-type Mg$_2$Si TE chip, which is doped by donor impurities with dimension of 5x5x5 mm$^3$, exhibits power generation density of 4.1 W/cm$^2$ over a temperature difference between 737 K and 373 K (DT~ 500 K). Using this TE chip, a prospective unileg structure module TE device consisting of the arrangement of 6 TE chips in a line as a basic TEG structure. The thermal distribution and p-power generation characteristics for the fabricated unileg TEG was analyzed using finite element modeling using the ANSYS code, and the heat transfer analysis to understand the thermal impedance characteristics using the Flow Designer code. A making a consistency between the calculation parameters of the ANSYS and the Flow Designer and the fabricated TEG, precise measurements of the temperature, heat flow, and power generation at various probe points on the module were made. Fabricated TE module were examined for vibration test corresponding to automotive test procedures. Moreover, results obtained from automotive engine simulation using GT-POWER will be also discussed in terms of power generation ability and adaptability for attaching to automotive exhaust line.

Synthesis of N-Type Mg$_2$Si Using Conventional Vertical Bridgman Method for Thermoelectric Power Generation Application

Magnesium silicide (Mg$_2$Si) has been identified as a promising advanced thermoelectric (TE) material and it has some important attributes in that it is lightweight, there is a worldwide abundance of its constituent elements, and it is non-toxic. Moreover, since it has good power generation performance in the mid-temperature (~900K) range, it is expected that it can be applied in the automotive industry or in industrial furnaces. The current status for Mg$_2$Si is aimed toward TE module fabrication and appropriate system integration techniques for electric vehicle (EV) range-extender waste-heat recovery applications. For the industrialization, thermal stability under the practical operation temperatures is needed to ensure the power generation durability. Mg$_2$Si is its capability for being doped in order to modify its electrical conductivity, thermal conductivity and durability at elevated operating temperatures. Typically, impurity elements were introduced into a congruent melt of Mg$_2$Si using the “All Molten Synthesis” method. Then, the resultant polycrystalline Mg$_2$Si was pulverized and then sintered using a “Plasma Activated Sintering” (PAS) technique to form a TE power generation chip. However, we have been trying to establish a TE chip fabrication directly from melt synthesis Mg$_2$Si, so polycrystalline Mg$_2$Si by all-molten synthesis using Bridgman method is performed. For the industrialization of Mg$_2$Si TE chip for generator, thermal stability at the practical operation temperatures is predominant requirement, thus a synthesis possessing with a thermodynamically stable grain boundary were made with less process contaminant. Because the instrument of oxidation of residual Mg during synthesis process is seen to be closely associated with an onset of degradation. Typically, degradation of the Mg$_2$Si TE chip begins from MgO located at grain boundaries and proliferate to the periphery, when the TE chip is elevated up to mid-operation temperature. Thus, we are interested in an elimination of residual metallic Mg or MgO at grain boundary, namely, an obtaining thermally stable grain boundary of polycrystalline Mg$_2$Si by all-molten growth method. The examined Mg$_2$Si grown specimens were heavily doped with donor impurities of Sn and isoelectric impurity of Zn to enhance their power generation characteristics. In this report, we discuss about crystalline quality, doping behavior and corresponding TE properties (Seebeck coefficient, electrical conductivity, thermal conductivity, power factor and figure-of-merit), thermal durability of all-molten synthesized polycrystalline Mg$_2$Si.

Nanocrystallization and Recoilless Fraction Determination of Fe$_{68.5}$Co$_{10}$Nb$_{3}$Cu$_{1}$Si$_{15.5}$B$_{7}$ Ferromagnetic Alloy

Amorphous alloy Fe$_{68.5}$Co$_{10}$Nb$_{3}$Cu$_{1}$Si$_{15.5}$B$_{7}$ was obtained by melt spinning. Samples cut from the foil were annealed at 450, 550, 650 and 750 C in a vacuum furnace. 57Fe Mossbauer spectroscopy was used to identify the crystalline phases formed and the orientation of the magnetic moments based on the refined values of the hyperfine parameters. The as-quenched sample was analyzed with a hyperfine magnetic field distribution and corresponded to an in-plane orientation of the magnetic moment directions. Similar field orientation and orientation were obtained for the specimen annealed at 450 C, while for Fe$_{68.5}$Co$_{10}$Nb$_{3}$Cu$_{1}$Si$_{15.5}$B$_{7}$ system analyzed previously we obtained the onset of nanocrystallization at this annealing temperature.

Nanocrystallization and Recoilless Fraction Determination of Fe$_{68.5}$Co$_{10}$Nb$_{3}$Cu$_{1}$Si$_{15.5}$B$_{7}$ Ferromagnetic Alloy

Monica Soreasa and Kevin Byerly2, 1Duquesne University, Pittsburgh, Pennsylvania, United States; 2NETL, Pittsburgh, Pennsylvania, United States.
sample annealed at 550 C exhibited the nanocrystalline state formation due to the observation of the DO3 structure of the Fe-Si alloy with small amounts of Co replacing Fe in the composition. Five distinct sextets in the Mossbauer spectra could be assigned to $^{57}$Fe$^{57}$$\text{Ni}$-$\text{Al}$, $^{57}$Fe-$\text{Al}$, $^{57}$Fe-$\text{Al}$ and $^{57}$Fe-$\text{Al}$ and a metalloid enriched amorphous grain boundary phase. The relative line intensities showed that the magnetic moments were distributed at random. The spectra of the samples annealed at 650 and 750 C were also indicative of nanocrystallization, with the magnetic moments reoriented out-of-plane for the last sample. This behaviour is in contradistinction with that of the Co-rich system, which was totally crystallized at these annealing temperatures. Our results show that small Co additions can lead to the formation of nanostructures over a wide range of annealing temperatures. A new series of Mossbauer spectra was obtained by recording simultaneously the intensity transmitted by a superposition of the sample with the stainless steel etalon, based on the dual absorber method recently introduced by us. The values of the recoilless fraction could be derived from the relative spectral areas. The $f$ factor maintained values close to 0.7 for all samples measured, but dropped to 0.37 for the sample annealed at 750 C. This behavior could be related to the presence of elastic stresses in the system, which caused the out-of-plane reorientation of the magnetic moment directions.

Fabrication and Mechanical Thermoelectric Properties of Mg$_2$Si Reinforced with Intragranular SiC Nano Particles

Junko Nakano, Ryo Inoue, Tsutomu Iida and Yasuo Kogo; Tokyo University of Science, Tokyo, Japan.

Thermoelectric (TE) materials could play an important role in a global sustainable energy solution. Magnesium silicide (Mg$_2$Si) is a promising TE material because of light weight, high abundance of its constituent elements and high thermoelectric properties around 873 K (figure of merit, $ZT = 0.96$). For these reasons, Mg$_2$Si is expected to apply the component of automobile. However, Mg$_2$Si presents brittle failure behavior and its fracture toughness is quite low ($\sim 0.64$ MPa m$^{1/2}$, which is smaller than that of typical structural material). Therefore, it is necessary to improve fracture toughness. Particle dispersed strengthening is a prospective way to improve fracture toughness of brittle materials because the secondary phase dispersed intergranular or intergranular restrain crack propagation. However, the reinforcement dispersed matrix grain boundaries has negative influence on thermoelectric properties. In this study, intragranular-composites prepared by melting process to improve fracture toughness without reducing thermoelectric properties.

Pre-synthesized all-molten commercially available polycrystalline Mg$_2$Si-Sb 0.5 at. % - Zn 1.0 at. % was used as a starting material. Mg$_2$Si ingots were pulverized to powder with sizes of less than 25 μm. In addition, the powders were mixed with silicon carbide (SiC) nanoparticles. The volume fraction of SiC was set to be 1-10 vol%. The powder mixtures were pressed under uniaxial pressure and packed by Mo foil. Then, the pressed samples were sealed in a quartz tube which was filled with argon gas. In addition, the compacted samples were heated at 1358 K for 5 min. Melted samples were pulverized to powder with sizes of less than 25 μm. Then, the powders were sintered by plasma activated sintering (PAS). Young’s modulus and fracture toughness of the sintered pellets were measured by ultrasonic pulse method and indentation fracture (IF) method. Electrical conductivity, Seebeck coefficient and Thermal conductivity were also measured by four-terminal sensing, thermo-electromotive force method and laser flash method. Dimensionless figure of merit ($ZT$) was determined using those values. We successfully incorporate SiC nanoparticles within Mg$_2$Si grains through melting treatment. Fracture toughness of intragranular-composites increases about 80% compared with pure Mg$_2$Si-Sb 0.5 at. % - Zn 1.0 at. %. In contrast, TE properties are decreased with increasing volume fraction of SiC nanoparticles. However, we could confirm the effect of SiC nanoparticles dispersed within Mg$_2$Si grains, because electrical conductivity of intragranular-composites is higher than that of intergranular composites. In this presentation, the influence of SiC nanoparticles dispersed Mg$_2$Si grains on mechanical thermoelectric properties will be discussed.

PM06.05.39
The Effect of Vibration on Mechanical and Electrical Properties of Magnesium Silicide Based Thermoelectric Modules

Tetsuro Takagi, Keisuke Nagayoshi, Takashi Nakamura, Ryo Inoue, Tsutomu Iida and Yasuo Kogo; Tokyo University of Science, Tokyo, Japan.

Magnesium-based silicide (Mg$_2$Si) is one of the most attractive materials for application in thermoelectric generators (TEG) because this material has high power generation efficiency at 300-600 °C. TE modules are typically composed of n-type and p-type TE leg, however difference of thermal expansion between p-type and n-type TE leg becomes critical problem. For fabrication of the Uni-leg TE modules composed of Mg$_2$Si, silver-alloy braze was used for bonding between legs and the metal terminals. In this case, nucleation of crack owing to thermal expansion mismatch of constituent materials is inevitable. Recent studies used aluminum as a bonding layer instead of silver-alloy braze because of its low melting point. These TE modules are usually subjected to thermal cycling and continuous vibration during operation, however, effects of vibration on mechanical, and electrical properties of TE modules have not been sufficiently investigated. For designing reliable TE module, it is necessary to understand mechanical properties of the interface and degradation of interface properties by vibration. The objective of this study is to develop TE modules fabricated by Al foil. Furthermore, evaluation of interface properties was done before and after vibration tests.

Polycrystalline Mg$_2$Si-Sb 0.5 at. % - Zn 1.0 at. % with particle size 25-75 μm was used as raw material. The Mg$_2$Si powder was sintered by plasma activated sintering (PAS). The Ni foils and the Mg$_2$Si pellet were bonded by PAS at 923 K under a pressure of 10 MPa in Ar atmosphere for 10 min. The Ni/Mg$_2$Si TE leg and the Ni terminal were bonded by hot pressing using the aluminum foil. The microstructure and phase composition of the prepared samples were examined by scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS). The shear strength of the interface between Al/Ni before and after vibration test was measured by bonding tester PRT1101 with a displacement rate of 0.1 mm/min. The vibration test was also performed under the condition of 33, 200, 400 Hz frequency for 4 h by simple harmonic motion parallel to the interface using electrodynamic vibration test system al210/SA1M. Finite element (FE) analysis was also done to calculate natural frequencies and stress/strain distribution in TE modules during vibration.

Mg$_2$Si/Ni$_3$Al ($\eta$-phase) is formed between Ni electrode and Mg$_2$Si after hot pressing. Two phases were formed at the Ni/Al interface. Based on the results of microstructural analysis, evaluation of mechanical properties, and numerical simulation, the effect of simple harmonic motion parallel to the interface on performance of TE modules will be discussed.
We explore deformation structures arising from room temperature compressive deformation of polycrystalline Pt modified RuAl alloy. Intermetallics such as NiAl and CoTi that possess high melting points deform by \(< 100\) slip at room temperature while B2 phases such as CuZn and FeAl with relatively lower melting points or order-disorder temperatures deform by \(< 111\> slip. RuAl, although it has relatively high melting point, occupies a unique position in this hierarchy in that slip occurs by both \(< 100\> and \(< 111\> dislocations with debris of sessile \(< 110\> dislocations and complex dipole structures. \(< 100\> dislocations are cusped and cross slip frequently. \(< 111\> dislocations trail dipoles and also decompose into sessile configurations of \(< 110\> or \(< 100\> dislocations in near screw orientations. An analysis of gamma surfaces in RuAl and the energetics of dislocation dissociations provides insight into its deformation behaviour.

Diversity and Phase Equilibria in Highly-Ordered \(\eta\)-Fe\(_2\)Al\(_5\) Derivative Phases  
Kodai Niitsu\(^1\), Rytaro Sakai\(^2\), Masaya Higashi\(^1\) and Haruyuki Inui\(^1\); \(^1\)Kyoto University, Kyoto City, Japan; \(^2\)ESISM, Kyoto, Japan.

While being one of the most fundamental and practically important binary systems, Fe-Al binary system still has intriguing issues on its constituting phases and phase equilibria. The orthorhombic \(\eta\)-Fe\(_2\)Al\(_5\) (space group \textit{Cmcm}) is such an intermetallic compound, raising inconsistencies in its crystal structure and ordering tendency. To date, several derivatives with highly-ordered crystal structures such as \(\eta'\), \(\eta''\), \(\eta'''\) and \(\eta\)\(_m\) phases have been reported to exist with slightly deviated stoichiometry from that of the \(\eta\)-Fe\(_2\)Al\(_5\) phase. While various attempts have been demonstrated by means of transmission electron microscopy (TEM), X-ray diffraction (XRD) analysis and differential scanning calorimetry, some controversial remains on their crystal structures and the phase equilibria among these phases.

In this study, we fabricated various Fe-Al alloy ingots with Al content of \(68\%\)–\(74\%\) and homogenized at various temperatures. TEM and scanning transmission electron microscopy (STEM) observations were performed on the thin foils prepared by electro-polishing. To refine the crystal structures, XRD was alternatively performed on the single crystals of some homogenized alloys. As a result of systematic TEM and STEM observations, four kinds of highly-ordered intermetallic compounds (termed as \(\eta'\), \(\eta''\), \(\eta'''\) and \(\eta\)\(_m\) in line with previous reports) are observed in addition to the \(\eta\) phase. These compounds have different ordering tendencies with maintaining the framework of the \(\eta\) phase, thus that their stoichiometry is slightly different from each other. In addition, periodic anti-phase boundaries (APBs) are observed in some of the compounds, which are presumably introduced to compensate for the lattice mismatch among the adjacent compounds. In spite of strong similarity in crystal structures, their phase stabilities show a remarkable contrast; the \(\eta''\) and \(\eta'''\) phases seem to be stable up to \(\approx 1300\) K with the solubility range of \(\approx 1\) at.\% but the \(\eta'\) and \(\eta\)\(_m\) phases exist only below \(-650\) K with little solubility range. This contrast may be attributed to the hierarchical ordering among these structures. The conclusive phase diagram will be also shown in the presentation.

9:15 AM PM06.06.03  
Creep Mechanism of Lamellar Fe-Al Alloys  
Anke Schmitt\(^1\), Sharvan Kumar\(^2\), Alexander Kauffmann\(^3\) and Martin Heilmair\(^4\); \(^1\)Karlsruhe Institute of Technology, Karlsruhe, Germany; \(^2\)Brown University, Providence, Rhode Island, United States.

Iron aluminides are possible alternatives for steels in warm-temperature application due to their low-density and oxidation-resistance. However, their frequent use is limited mainly due to a low ductility at room temperature and rather poor creep resistance at elevated temperatures beyond \(600^\circ\)C. In order to improve the creep resistance of B2-ordered FeAl classical physical metallurgy approaches are used, such as solution strengthening, precipitation strengthening and dispersion strengthening. As previously demonstrated for TiAl, a lamellar microstructure can enhance the creep resistance as well. In the Fe-Al system, a lamellar microstructure can be obtained by an eutectoid transformation in the composition range of \(55\%\)–\(65\%\) Al. Particularly, the high-temperature \(\varepsilon\)-phase, Fe\(_2\)Al\(_5\) decomposes into B2-ordered FeAl and triclinic FeAl\(_2\). The creep resistance of such a lamellar alloy was previously studied in a constant true stress of 100 MPa and \(700^\circ\)C in compression. It exhibits a characteristic minimum after achieving a strain of roughly 0.5\%, which is followed by an increase of the creep rate with increasing time and strain. The absence of a pronounced steady-state regime is attributed to a deterioration of the lamellar structure in the vicinity of colony boundaries. The determined stress exponent indicates a creep based on dislocations motion. Nevertheless, the presence of the two phases combined with a high interphase density due to the lamellar morphology precluded final understanding of the individual contributions to the observed creep response -- both, in the early stages as well as at and just beyond the minimum creep rate. Thus, TEM investigations of creep eutectoid FeAl material were performed on samples that were isothermally creeping under above conditions and interrupted for microstructure analysis at characteristic strains. In this presentation we will discuss the following situations determining the strain rate response of the lamellar materials: a) Both phases contribute to the creep deformation from the beginning and the degradation of the lamellar morphology is responsible for the increase of the strain rate beyond the minimum. b) Only one of the two phases deforms and the second phase does not contribute directly to creep throughout the entire experiment, and the degradation of the lamellae causes the increase of the strain rate beyond the minimum. c) The second phase starts to creep-deform beyond the minimum causing the increase in the strain rate and subsequently, lamellae degradation enters the picture as well.

Understanding Structural Phase Transitions Between the Simpler Structures and Topologically Close-Packed Phases  
Anirudh Rau Natarajan and Anton Van der Ven; University of California, Santa Barbara, Santa Barbara, California, United States.

Structural phase transitions between vastly different crystal structures are often exploited to enhance the properties of structural and functional materials. Understanding the transformation mechanism in applications such as shape-memory, magnetocaloric, high-entropy and precipitation strengthened alloys is thus critical to developing better alloy chemistries. However, very few links between disparate structure classes are known. Further, such phase transitions typically involve several length-scales, making it difficult to develop rigorous ab-initio mesoscale models. In this talk, we will describe a new facile pathway connecting the simpler structures to a hierarchy of topological close-packed phases consisting of Kagomé nets and triangular layers. Several typical intermetallic compounds such as the Laves phases are specific members of this family of structures. First-principles calculations reveal that the pathway connecting the simpler structures to a hierarchy of topological close-packed phases consisting of Kagomé nets and triangular layers. While various attempts have been demonstrated by means of transmission electron microscopy (TEM), X-ray diffraction (XRD) analysis and differential scanning calorimetry, some controversial remains on their crystal structures and the phase equilibria among these phases.

In this study, we fabricated various Fe-Al alloy ingots with Al content of \(68\%\)–\(74\%\) and homogenized at various temperatures. TEM and scanning transmission electron microscopy (STEM) observations were performed on the thin foils prepared by electro-polishing. To refine the crystal structures, XRD was alternatively performed on the single crystals of some homogenized alloys. As a result of systematic TEM and STEM observations, four kinds of highly-ordered intermetallic compounds (termed as \(\eta'\), \(\eta''\), \(\eta'''\) and \(\eta\)\(_m\) in line with previous reports) are observed in addition to the \(\eta\) phase. These compounds have different ordering tendencies with maintaining the framework of the \(\eta\) phase, thus that their stoichiometry is slightly different from each other. In addition, periodic anti-phase boundaries (APBs) are observed in some of the compounds, which are presumably introduced to compensate for the lattice mismatch among the adjacent compounds. Ultrahigh Elastically Compressible Intermetallic Compound, CaKFe\(_{4}\)As\(_{4}\)  
Gyhuo Song\(^1\), Vladislav Borisov\(^2\), William Meier\(^1\), Keith Dusoe\(^1\), John T. Sypic\(^1\), Roser Valenti\(^2\), Paul Canfield\(^3\) and Seok-Woo Lee\(^1\); \(^1\)University of Connecticut, Storrs, Connecticut, United States; \(^2\)Theoretical Physics, Goethe University, Frankfurt am Main, Germany; \(^3\)Physics and Astronomy, Iowa State University, Ames, Iowa, United States.

Intermetallic compounds often exhibit superior physical and chemical properties due to their unique atomic arrangements and crystal structures, but their practical applications have been significantly limited because most intermetallic compounds are extremely brittle and are not able to absorb strain energy
high enough to sustain its structure. The nature of strong covalent bonds and complexity of crystal structures usually do not permit the plastic deformation, so brittle failure occurs at the elastic limit even less than 0.5% except a few limited materials such as shape memory intermetallic compounds. Therefore, it is extremely rare to obtain a large amount of elastic deformation over 10% in intermetallic compounds.

However, CaKFe₄As₄ recently began to receive great attention due to its superelasticity and potential usage of high temperature superconductivity. These two super-properties do not typically get along because superconductors, which are brittle oxides or intermetallic compounds in many cases, shatter easily particularly under non-hydrostatic stress state. Here, by synthesizing a single crystalline CaKFe₄As₄ through Sn-flux solution growth and performing in-situ micromechanical experiments, we report that the giant compressible strain, 13~17%, is possible under uni-axial compression along c-axis. Notably, this material is able to absorb the strain energy orders of magnitude higher than advanced engineering materials. The density functional theory shows that this unusually large elastic axial compressibility results from the half-collapsed tetragonal phase transition, which is induced by As-As atomic bond formation and magnetic moment collapse, and significant local compliance. All these processes are fully reversible upon unloading. Also, we performed in-situ cryogenic micromechanical test with liquid nitrogen cooling capability, and confirmed that superconductivity could be suppressed by inducing the half collapsed tetragonal around 1 GPa. This huge uni-axial reversible deformation mechanism is differentiated from the conventional shear mechanism, martensite-austenite phase transformation of shape memory intermetallic compounds and can be extended to over 1000 AX₂Y₂- and ABX₄Y₄-structured intermetallic compounds. Furthermore, this giant elastic strain could make strain engineering possible, leading to the development of mechanically-switchable functional materials, for instance, superconductivity switching even under uni-axial mechanical loading, which is significantly desirable for device applications.

10:30 AM PM06.06.06 Predicting Defect Behavior in Intermetallic Compounds by Merging Ab Initio Modeling and Machine Learning Mark Ates1,2, Bharat Medasani1, Hong Ding1, Wei Chen3, Kristin Persson1,2, Andrew Canning1, Maciej Hanaszczyl and Anthony Gamsu1, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 3Pacific Northwest National Laboratory, Richard, Washington, United States; 4Illinois Institute of Technology, Chicago, Illinois, United States; 5University of California, San Diego, California, United States.

We present a combination of machine learning and high throughput calculations to predict point defect behavior in binary intermetallic (A–B) compounds, using as an example systems with the cube B2 crystal structure (with equatomic AB stoichiometry). High throughput first principles density functional calculations have been employed to compute intrinsic point defect energies in 100 B2 intermetallic compounds. The systems are classified into two groups: (i) those for which the intrinsic defects are antisites for both A and B rich compositions, and (ii) those for which vacancies are the dominant defect for either or both composition ranges. The data was analyzed by machine learning-techniques using decision tree, and full and reduced multiple additive regression tree (MART) models. Among these three schemes, a reduced MART (r-MART) model using six descriptors presents the highest fit and predictive accuracy. This model is used to predict the defect behavior of other B2 compounds, and we find that 45 % of the compounds considered feature vacancies as dominant defects for either A or B rich compositions (or both). The ability to predict dominant defect types is important for the modeling of thermodynamic and kinetic properties of intermetallic compounds, and the present results illustrate how this information can be derived using modern tools combining high throughput calculations and data analytics. This work was supported by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division under Contract No. DE-AC02-05-CH11231: Materials Project program KC23MP.

11:00 AM PM06.06.07 Design of a Hardenable Cu-Cr-Nb Alloy by Laser Metal Deposition Amoon R. Kim1, Dora Maischner2, Andreas Weisheit2, Eric Jagle2 and Dierk R. Raabe1, Max-Planck-Institut für Eisenforschung GmbH, Düsseldorf, Germany; 2Fraunhofer Institute für Laserotechnik, Aachen, Germany.

Dilute copper alloys are of high interest, uniquely at the intersection of the property combination, specifically conductivity (thermal/electrical) and mechanical strength (hardness). We propose the design of a dilute Cu-Cr-Nb alloy focusing on achievement of greater hardening (146 VHN), compared to respective established ternary alloys. We achieve this goal, by processing the alloy by laser metal deposition (LMD). Importantly, we utilize a lower alloying solute amount (4 at.%; lower by at least ~ 33%) compared to previous alloys. Careful alloy compositional choice results in introduction of novel hardening contribution in this ternary system, by coherence of precipitates enriched in chromium. The precipitate hardening, size and chemical composition has been investigated by transmission electron microscopy and atom probe tomography. The coherency hardening operates in conjunction with dispersed Laves phase particle hardening. Each of the contributions has been modelled, which adds up to match the measured hardness of 146 VHN. Spatial homogeneity of hardening has been established by means of nano-indentations across the alloy sample. The hardening attained is in the as-produced condition itself i.e. after LMD. This is because of favorable LMD processing conditions for in-situ precipitation (intrinsic heat treatment).

11:15 AM PM06.06.08 A New Ab Initio Modeling Scheme for Ion Self-Diffusion Coefficient Applied to ε-Cu₃Sn Phase of Cu-Sn Alloy Tom Ichihara1, Genki Prayogo2, Kenta Hongo3, 4 and Ryo Maezono3, 4, School of Information Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 3School of Materials Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 4Research Center for Advanced Computing Infrastructure, Japan Advanced Institute of Science and Technology, Nomi, Japan; 5PRESTO, Japan Science and Technology Agency (JST), Kawaguchi, Japan; 6Research and Services Division of Materials Data and Integrated System, National Institute for Materials Science, Tsukuba, Japan.

Ion diffusion via vacancy relates to various properties such as corrosion, monotectoid, fracture, and degradation in material solids. To reveal the microscopic processes of ion diffusion, ab initio simulations have been used commonly. On the other hand, when evaluating self-diffusion coefficient, its application has been limited in just simplest systems, because it is difficult to model diffusion coefficients based on predictable quantities especially for complicated structures such as long-range periodic crystals.

We tackled this issue with our own idea in order to simplify the complicated connection of ion sites based on the calculated barrier energies. We established a modeling scheme, introducing a couple of novel concepts, "domain division" and "coarse graining" of the diffusion network. The first concept is expected to be useful for long-lange periodic structures: We classify the diffusion routes into three groups 1–3, according to their barrier energies, $E_1 < E_2 < E_3$. The diffusion routes in group III can be excluded from the diffusion network, because an ion jump affects the diffusion coefficient by the Boltzmann factor of barrier energy. Then, if the diffusion network is (fortunately) separated into a few types of disjunct domains, the problem is reduced into multiple modelings for each domain. These modeling are further simplified with the second concept. Since vacancies can move along the diffusion routes in group 1 more frequently than those in group 2, ion sites connected by these routes can be replaced with just a single site. Then, the diffusion networks of each domain are course-grained with the representative sites to be simplified.
We applied the modeling scheme to evaluate the diffusion coefficient of Cu ion in ε-Cu5Sn alloy, which is a typical system having long-range periodicity. The predicted diffusion coefficients agree with experimental values, and it is better than those reported by a classical molecular dynamics by a digit. Furthermore, we justified the constructed model by comparing the correlation factor with that of two-dimensional hexagonal lattice at high temperature limit.

Solidification Microstructure of Ti-Ag and Ti-Ag-Nb Immiscible Alloys Focusing on the Formation of Intermetallic Compounds Takeshi Nagase; Osaka University, Ibaraki, Japan.

Ti-Ag alloy system is characterized by a flat liquidus line and the existence of two intermetallic compounds (TiAg and Ti2Ag) in the binary phase diagram. The solidification microstructure of binary Ti-Ag alloys and ternary Ti-Ag-Nb alloys were investigated focusing on the formation of intermetallic compounds. In binary Ti66.7Ag33.3 alloy, the conventionally cast ingots obtained by arc melting technique showed a dendritic structure that included Ti-Ag-based intermetallic compounds; on the other hand, the rapidly solidified melt-spun ribbons showed a particulate microstructure comprising Ag-rich globules and a Ti-rich matrix phase without Ti-Ag-based intermetallic compounds. The formation of emulsion-like structures in the rapidly solidified specimens can be explained in terms of liquid phase separation [1]. The occurrence of the liquid phase separation also can be seen in Ti-Nb-Ag alloy [2].

Microstructure-Corrosion Property Correlation in Graphene Oxide Containing SnZn and SnNi Composite Coatings Rekha Mahendrakar; Indian Institute of Science, Bangalore, India.

Coatings have been traditionally used for protecting the underlying substrate against corrosion. Recently, it has been demonstrated that chemical inertness and impermeability of graphene/graphene oxide (GO) makes them excellent coating material for corrosion protection. Use of only graphene/GO as coating material is however impractical due to challenges associated with large scale production of graphene/GO sheet with minimal defects at low cost. One other way to employ these materials for corrosion protection is by incorporating them into the matrix of conventional coatings. Researchers have shown that composite metallic coatings containing graphene/GO exhibit higher corrosion resistant than corresponding pristine metallic coatings. This work explores the correlation between microstructure and electrochemical behaviour of SnZn-GO and SnNi-GO composite coatings electrodeposited on mild steel substrate. Amount of GO in the composite coatings was varied by changing the concentration of the chemically synthesized GO in the electrolyte bath. Corrosion behaviour of the SnZn and SnNi coatings were examined through potentiodynamic polarization and electrochemical impedance spectroscopy methods. Transmission electron microscopy technique was used to investigate the coating microstructure. In the case of SnZn-GO composite coating, relative compactness of the coatings increased with increase in the concentration of GO. Texture and the crystallite size, however, did not show any significant variation with the concentration of GO in the coatings. Microstructural investigation of the coating cross-section revealed large scale segregation of Zn-rich and Sn-rich phases in pure SnZn coating. However, in the case of SnZn-GO composite coatings uniform distribution of Zn phase in Sn-rich matrix was observed. This distribution caused early and uniform formation of ZnO, which is the corrosion product, yielding better corrosion resistance for the SnZn-GO composite coatings as compared to pure SnZn coating. In the case of SnNi-GO composite coating, morphological characterization revealed the presence of rod shaped features in a flat matrix. Structural characterization showed presence of Sn-rich phase along with Ni3Sn4, Ni3S2 and Ni5Sn intermetallics. Crystallite size of the Sn-rich phase decreased significantly due to the addition of GO. Microstructural investigation revealed that the SnNi coating without GO contained Sn and Sn-Ni solid solution grains. Whereas, SnNi coatings with GO contained Sn grains with Ni present at the grain boundaries. With increase in the GO content in the SnNi-GO composite coatings, size of the Sn sub-grains within the larger Sn grains reduced. Smaller Sn sub-grains and presence of Ni at the grain boundaries facilitated formation of the oxide corrosion products which provided protective cover and enhanced the corrosion resistance behaviour for the composite coating.

SESSION PM06.07: Intermetallic Precipitates
Session Chairs: Anne Denquin and Dierk Raabe
Wednesday Afternoon, November 28, 2018
Hynes, Level 1, Room 104

1:30 PM *PM06.07.01

We report about recent findings which reveal the close connection and interdependence among Fowler-Guggenheim-type equilibrium segregation, local spinodal decomposition and phase transformation phenomena at lattice defects. We show that several types of phase formation effects at grain boundaries and dislocations can be jointly understood in terms of preceding equilibrium segregation and decomposition precursor states. Random high angle grain boundary structure features seem to be of secondary relevance for these phenomena owing to prevalence of the local chemical driving forces. Corresponding examples which have been documented by applying site-specific correlating atom probe tomography and electron microscopy probing are given for Fe-Mn model steels [1-3], superalloys and high entropy alloys [4].

Effects of Si on Phase Stability and Precipitation Behavior of C14 Laves Phase (Fe, Cr)\(_2\) (Nb, Mo) in High Cr αFe-base Alloys Yoshisato Kimura, Ko Kato and Yaw Wang Chai; Tokyo Institute of Technology, Yokohama, Japan.

Ferritic stainless steels with high Cr contents around 20 at% can be used not only for heat resistant alloys such as exhaust manifolds of automobile engines but also for functional alloys such as separator or/and interconnector of fuel cells. It is important to control microstructure of ferritic stainless steels focusing on morphology of C14 Laves phase precipitates depending on applications. Structural applications tend to require fine and homogeneous distribution of C14 Laves phase, while gradient distribution with rather large volume fraction would be desirable for functional applications mentioned above. The objectives of the present work are to understand effects of the Si addition on phase stability and precipitation behavior of C14 Laves phase (Fe,Cr stoichiometric ratio) in the Fe-Cr-Nb-Mo quaternary αFe-base model alloys, and to determine the growth mechanism of C14 Laves phase in the bcc αFe matrix.

It is interesting that the addition of Si remarkably enhances the precipitation of C14 Laves phase cooperatively with Mo. For instance, the volume fraction of C14 Laves phase increases about twice as large in an Fe-20Cr-0.5Nb-2Mo alloy (in at%) by the addition of 2 at% Si compared with Si-free counterpart under the same aging condition at 1073 K for 24 hours. Contrary to this, the addition of Si is not effective to increase the volume fraction of C14 Laves phase on a Mo-free Fe-20Cr-0.5Nb alloy. It is suggested that the addition of Si improves the phase stability of C14 Laves phase while the partitioning of Mo into C14 Laves phase would be promoted due to the attractive interaction between Mo and Si. It is noteworthy that the site preference of Si in binary C14 Laves phase, Fe\(_2\) Nb and Fe\(_2\) Mo, was examined using the electron probe microanalysis. It was found that Si substitutes for the both-site in Fe\(_2\) Nb, and for the Fe-site in Fe\(_2\) Mo. The lattice mismatch between the bcc αFe matrix and C14 Laves phase decreases as the Mo content increases, which may lead to the uniform distribution of fine Laves phase precipitates. We have also determined that the growth mechanism of C14 Laves phase in the bcc αFe matrix is the ledge mechanism in an Fe-20Cr-0.5Nb-1Mo alloy annealed at 1073 K for 24 hours, using the transmission electron microscopy. The terrace is formed on the close-packed basal plane of hcp C14 structure as we predicted. Precipitation particles tend to grow in a needle-like shape depending on the anisotropic difference of lattice mismatch. The addition of Si up to 2 at% on Fe-20Cr-0.5Nb-1Mo alloys seems not to have appreciable effect on the ledge mechanism of C14 Laves phase precipitates.

Role of Cr-rich Carbide Precipitates in the Intergranular Oxidation of Ni-Cr Alloys Maria Sushko, Daniel Schreiber, Kevin Rosso and Stephen Bruemmer; Pacific Northwest National Laboratory, Richland, Washington, United States.

The influence of grain boundary Cr carbides on the intergranular (IG) oxidation behavior of a Ni-16Cr alloy is considered using a novel atomistic-to-mesoscale model and three-dimensional atom probe tomography (APT). The results show that Cr carbide strongly perturbs the collective reactive dynamics of oxidizing species and alloy elements in the IG region. Strong attractive interactions between oxygen and carbide create a driving force for Cr and Ni accumulation in the grain boundary adjacent to the carbide, and for the depletion of Cr and Ni ahead of the oxidation front beyond the carbide. High local Cr chemical potentials from Cr carbide and Cr in the alloy dictate preferential oxidation of Cr and the formation of Cr\(_2\)O\(_3\) in the region adjacent to the carbide 1-2 nm away from the carbide surface. APT observations also reveal Ni accumulation at the interphase between the carbide and Cr\(_2\)O\(_3\), possibly indicating emergence of a distinct interfacial phase. The results inform a mechanistic model underlying the thermodynamics of IG oxidation of a Ni-Cr alloy in the presence of Cr carbide, and shed light on the mechanism of carbide-assisted protection of the alloy against grain boundary corrosion/oxidation. Our findings can be used for the development of new alloys that are more stable under extreme conditions.

Microstructure and Strength of Heat-Resistant Aluminum Alloy Strengthened by T-Al\(_6\)Mg\(_{11}\)Zn\(_{11}\) Intermetallic Phase Naoki Takata, Masato Ishihara, Satoshi Nakatsuka, Asuka Suzuki and Makoto Kobashi; Nagoya University, Nagoya, Japan.

Wrought aluminum (Al) alloys with relatively high specific strength are widely used for radial compressor impellers in vehicle turbochargers. The limited high-temperature strength determines the service temperature of compressor impellers for turbochargers. One of the common wrought Al alloys used for radial compressors is alloy 2618. However, its strength is significantly reduced at temperatures above 200°C. Thus, further improving the combustion efficiency at elevated temperatures is necessary to increase the service temperature of the Al alloys applied for the radial compressor impellers. In the present study, we designed an aluminum (Al)-based alloy with α-Al (fcc) matrix strengthened by T-Al\(_6\)Mg\(_{11}\)Zn\(_{11}\) (cubic) intermetallic phases using a large two-phase region of α and T phases in the Al-Mg-Zn ternary system for the possible application of the radial compressor impellers operating at elevated temperatures above 200°C. Thermodynamic assessments revealed a composition of Al-5Mg-3.5Zn (at%) with the α-Al phase reinforced with high fractions (approximately 10%) of T phase. We attempted to control microstructure of the Al-5Mg-3.5Zn alloy by the solution treatment and subsequent aging. T phase preferentially precipitates on grain boundaries in the α-Al matrix, which increases the area fraction of T phase on grain boundaries during the aging. The granular precipitates of T phase were dispersed rather homogeneously in the α-Al matrix with a particular orientation relationship of (1-11), (1-21) and [011], // [111] at elevated temperatures above 300°C. During the aging at 200°C there were numerous fine precipitates with a mean size of approximately 20 nm in grain interior, which is likely the metastable phase associated with T phase. The present alloy aged at 200°C for 1 h exhibits high yield strength of approximately 260 MPa at 200°C, which is much superior to those of the conventional Al alloys at an
Elevated temperature corresponding to possible service temperatures for the compressor impellers in turbochargers.

4:15 PM PM106.07.06
The Role of Intermetallic Particles on the Bendability of AA6xxx Alloys  Sin Ting Cynthia Chang1, Miroslav Smid1, Samy Hocine1,2 and Helena Van Swygenhoven-Moens1,2; 1Photons for Engineering and Manufacturing Group, Paul Scherrer Institut, Villigen, Switzerland; 2Neutrons and X-rays for Mechanics of Materials, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

The role of intermetallic particles on the bendability of Al 6xxx alloys is investigated during in-situ bending tests in a scanning electron microscope (SEM). High resolution digital image correlation (HR-DIC) analysis is undertaken to investigate the role of microstructural features on the strain partitioning and the role of pre-existing voids and precipitates on early stages of the crack initiation and fracture. Aluminum alloys AA6014 and AA6016 after T4 temper, i.e. after solution heat treatment and quenching are investigated in as-received and pre-strained (10% strain) conditions. The in-situ bending setup was developed in-house and is based on a Kammrath & Weiss tensile module suitable for a scanning electron microscope (SEM) chamber. The experiments are performed with constant displacement rate and with several interruptions for SEM imaging at selected displacement values. DIC with high spatial resolution is performed using colloidal silica (OPS) particles. Full-field strain maps are complemented with Electron Backscatter Diffraction (EBSD) maps before and after the bending. The crystal orientation data enables the identification of activated slip planes observed by HR-DIC. Furthermore, EBSD data document the different texture evolution in the compression and tension parts of the specimen.

It is observed that the pre-existing voids and cracks along the intermetallics play an important role in the strain localization. At small bending, intermetallics can deform and become elongated in the tension direction. With further bending, strain localization is observed around intermetallics leading to cracking of intermetallics and producing additional voids in-between the intermetallics. Failure mechanisms are often related to the presence of fine precipitates along grain boundaries. The final crack leading to sample failure propagates along the cracked intermetallics. The results are discussed in terms of the different type of intermetallics present in AA6014 and AA6016.

4:30 PM PM106.07.07
Superior Mechanical Properties Induced by Extrusion in Mg-Based Long-Period Stacking Ordered (LPSO) Phase Alloys Koji Hagiwara1, Zixuan Li1, Michiaki Yamasaki2, Yoshito Kawamura2 and Takayoshi Nakano3; 1Osaka University, Osaka, Japan; 2Kumamoto University, Kumamoto, Japan.

The recent hot topic found in Mg-alloys containing large amount of long-period stacking ordered (LPSO) phase is the unusual increase in the strength by the extrusion. In this study, the detailed mechanisms which induce the drastic strengthening of the LPSO-phase alloys by extrusion was first elucidated on the basis of the quantitative analysis. To achieve this, the temperature and loading orientation dependence of the deformation behavior of the Mg0.9Zn0.1 extruded alloy which contains a ~86 vol.% of LPSO-phase were examined. Using several extruded alloys with different extrusion ratio, the influence of extrusion ratio to the microstructure formation and the following mechanical properties were examined. Rectangular specimens were cut by electro-discharge machining from the as-cast ingot and extruded alloys, and the mechanical properties of them were examined by compression tests. The tests were conducted in a temperature range between the room temperature and 400 degree C in a vacuum. Two loading orientations were selected for the compression test; one is parallel to the extrusion direction (0 orientation), and the other is inclined at an angle of 45 degree from the extrusion direction (45 orientation), to clarify the anisotropic mechanical properties of the extruded alloys. As a result, the yield stress of the LPSO phase alloy was found to exhibit a strong orientation dependence varied with the extrusion ratio. Especially, the yield stress of the extruded alloy with the reduction ratio of 10 showed an extremely high value more than 450MPa when loaded at 0 orientation, while it was largely reduced when loading at 45 orientation. This strong anisotropy of the plastic deformation behavior was considered to be derived from the variation in the deformation mechanisms depending on the loading orientation because of the development of strong (10-10) fiber texture along the extrusion direction. Basal slip was found to govern the deformation behavior at 45 orientation, while the predominant deformation mechanism varied from basal slip to the formation of deformation kink band at 0 orientation, as increasing in the extrusion ratio. In addition, it was found that the introduction the deformation kink band boundary during the extrusion process effectively act as strong obstacles against the motion of basal slip. This contributes to the drastic increase in the yield stress and work-hardening rate of the LPSO-phase alloys in the wide temperature range investigated.

4:45 PM PM106.07.08
Atomistic Simulation and Modeling of γ-Precipitate Nucleation in Mg-Al Alloys Peng Yi and Michael L. Falk; Johns Hopkins University, Baltimore, Maryland, United States.

Magnesium alloys have drawn increasing interest as a lightweight material for applications in transportation and aerospace industries. Some Mg-Rare earth alloys have shown significant precipitation hardening properties. These hardening properties are determined by the morphology and distribution of the precipitate particles, which strongly depend on the processing conditions during aging treatment, for example, temperature, applied strain, and the presence of defects like dislocations. It is important to understand how these processing conditions affect the precipitation process, particularly during the initial nucleation stage. This understanding is crucial for processing condition optimization, property prediction, and materials design for performance improvement and cost reduction.

We studied the nucleation of γ-Mg17Al12 precipitates in Mg-Al alloys with various solute Al concentrations, using atomistic simulation and modeling methods. The critical nucleus size at 277°C (550K) was determined using molecular dynamics simulations with a survival probability method. The critical nucleus size is very sensitive to the solute concentration; and is compared with calculations based on the chemical driving force and interfacial energy. The external pressure plays an important role in affecting the critical nucleus size as well. The external pressure not only changes the misfit strain energy, but also significantly changes the interfacial energy. As a result, although γ precipitate is denser than the a matrix, counter-intuitively nucleation is favored under tension conditions rather than compression conditions.

We also calculated the effect of dislocations on the nucleation of γ precipitate. The theoretical framework detailed in a number of [1, 2] and first-principle calculation database were used for our thermodynamic modeling in calculating the nucleation rate of dislocation facilitated precipitation. The calculation results were used to compare with recent equal channel angular extrusion (ECAE) experiments of γ precipitation at 150°C (423K), where the dislocations are found to be preferable forming sites for the precipitates.

NiTi shape memory alloys (SMA) are used in the medical device industry for fabricating self-expandable stents, stent grafts and heart valve frames that can be implanted with minimally invasive techniques. This material experiences a reversible stress-induced martensitic phase transformation from its parent austenite form (B2 austenite ↔ B19’ martensite) that is accompanied by 6-8% recoverable strain. The stress for the reverse transformation (martensite to austenite) is lower than that for the forward transformation, resulting in a stress-strain hysteresis. The combination of device geometry, deployment practice and conditions that prevail in service makes evaluating and isolating factors that control the cyclic deformation response and fatigue failure as well as predicting high cycle fatigue life of these biomedical implants particularly challenging. In uniaxial tension, the austenite-to-martensite transformation progresses heterogeneously, leading to a complex distribution of strain whose local magnitudes differ from what is globally imposed. Thus, mechanistically interpreting the cyclic response of ultrafine ligaments that compose the stent construct in bending poses a significant scientific challenge. To address some of these issues, we have used a mildly center-tapered flat dog-bone specimen geometry that has been subjected to uniaxial tensile cyclic loading from the lower stress plateau where the material is in a mixed-phase state to mimic device service conditions. We apply controlled displacement amplitudes and obtain local strains experienced by the co-existing phases in the specimen gauge section using digital image correlation; we use a high-speed camera to monitor the specimen surface to track phase transformation and fracture initiation and propagation. We have examined the consequence of imposed cyclic frequency and testing medium on cyclic response. Additional experiments have been conducted to obtain fatigue life as a function of imposed displacement amplitude. The results from these experiments will be presented and their implications will be discussed.
Deformation Behavior of Stoichiometric Au2CuAl resonance imaging are drawbacks. Then, in order to overcome these problems, we have proposed AuCuAl shape memory alloy especially for endovascular application. The high ductility and the excellent SE in the CAM SMA is reviewed and the microstructural control to obtain the ultra-large single crystal is introduced. New route to obtain an extremely large single crystal using abnormal grain growth only by cyclic heat treatment was examined. In this presentation, the alloy design for obtaining high interfacial energy is preferentially formed in the initial stage of martensitic transformation. Group A and C show relatively low interfacial energy. This is one of the reasons that group C is preferentially formed in the initial stage of martensitic transformation.

CuAlMn (CAM) alloy is one of the attractive shape memory alloys for practical applications because of high superelastic (SE) performance, high cold-workability and low cost. The SE properties of CAM alloy are known to be affected by relative grain size and the single-crystalline specimens show excellent properties [1]. Recently, our group has established the method for obtaining extremely large single-crystals in this alloy by cyclic heat treatment (CHT) without deformation process [2], and to achieve fabricated ultra-large single-crystalline rods of about 700 mm in length [3]. On the other hand, the most critical drawback for the practical use in this alloy is the low cyclic properties. Actually, in Cu17Al11.4Mn (at.%) alloy, the residual strain suddenly increases at about 100th cycle [4], while keeping a low value until 10^5 cycles in NiTi [5]. In this work, for the CuAlMnNi (CAMN) alloys, in which precipitation hardening by NiAl B2 phase is expected, the microstructures and the cyclic SE properties were examined. CAMN single-crystalline sheets with dimension of 1×5×60 mm^3 were obtained by the CHT process as well as in the CAM alloys. In the CAMN sheet, excellent cyclic properties in SE with the residual strain smaller than 0.5% at 2000th cycle for applied strain of about 5% were obtained. This dramatic improvement in cyclic properties is due to coherent precipitation of the NiAl phase.

Ultra-Large Single Crystals by Abnormal Grain Growth in Cu-Al-Mn Heusler-Type Shape Memory Alloy

Intermetallic compounds are generally brittle, which is one of the main reasons to impede practical use. In 1996, we reported Cu-Al-Mn (CAM) shape memory alloy (SMA) with high ductility by decrease of degree of order in the parent phase with L21 ordered structure [1]. The superelastic (SE) property in SMA is affected by grain size [2] and single-crystalline sample is known to show SE property better than polycrystalline one. Recently, we discovered a new route to obtain an extremely large single crystal using abnormal grain growth only by cyclic heat treatment [3]. In this presentation, the alloy design for the high ductility and the excellent SE in the CAM SMA is reviewed and the microstructural control to obtain the ultra-large single crystal is introduced.

Deformation Behavior of Stoichiometric AuCuAl

Although TiNi becomes widely applied for biomedical applications, the possibility of Ni-hypersensitivity, weak X-ray radiography and artifact in magnetic resonance imaging are drawbacks. Then, in order to overcome these problems, we have proposed AuCuAl shape memory alloy especially for endovascular intervention. In the present study, the deformation behavior of the stoichiometric Au25Cu25Al (at.%) alloy is comprehensively summarized in addition to recent achievements by micro compression tests. It should be noted that the stoichiometric composition of B2 AuCuAl (Spangold) is recognized to be Au2CuAl, but in this study, we regard the stoichiometry as AuCuAl due to L21 Heusler of the parent phase. Mechanical tests used were indentation test, tensile test, compression test for polycrystal material as well as micro compression test for micro pillars. Micro Vickers hardness of AuCuAl is around 170HV. By tensile tests at room temperature, the polycrystalline alloy specimens generally exhibit intergranular failure during elastic deformation. This brittleness is partially due to large grain size. The ultimate tensile strength is less than 100MPa. On the other hand by compression tests, the specimens show relatively good plastic deformation around 10% and the maximum stress is around 700MPa. By the micro compression tests, the single crystal specimens show clear shape memory and superelastic behavior. The stress for inducing martensite linearly increases with increasing test temperature and obeys the Clausius-Clapeyron type relationship. By taking into account of the observed slip planes during plastic deformation and the deformability of polycrystal, the dislocation slip is judged to be <111> type, instead of <100> and <101> types. This implies the polycrystalline materials must exhibit room temperature tensile deformability when the intergranular failure is suppressed, similar to B-added Ni3Al. This work is supported by Grant-in-Aid for Scientific Research Kiban S 25220907 from Japan Society for the Promotion of Science.
11:15 AM *PM06.08.08
The Effects of Defects and Microstructure on the Superelasticity of 1:2:2 Ternary Intermetallic Compounds Jan N. Baker1, Keith Duseo2, John Sypek3, Seok-Woo Lee4 and Christopher Weinerberger1; 1Colorado State University, Fort Collins, Colorado, United States; 2University of Connecticut, Storrs, Connecticut, United States.

1:2:2-intermetallic compounds with the ThCr2Si2-type crystal structure have recently been shown to exhibit superelastic responses to hydrostatic, and ε-axial uniaxial compression. It has been shown that the nature of this response can be altered through processing which is associated with the formation of point defects. In this talk, we combine materials theory and DFT to examine the role defects have on the mechanical response and phase stability of two compounds: CaFe2As2 and LaRu2P2. First, we explore the nature of isolated point defects in these materials. Then, we investigate the stability of high densities of these defects. We further investigate the responses of these defected structures using DFT, as well as how these structures, when combined with the pure compounds, alter the responses of these composites. These results are then compared against recent experiments, explaining the processing-microstructure-property relations of differently-fabricated samples. We are able to gain insight into the similarities and differences between two specific 1:2:2-intermetallics.

Utilizing Shape Memory Alloys for Novel, Non-Pneumatic Tire Design Santo Padula and Colin Creager; NASA Glenn Research Center, Cleveland, Ohio, United States.

Conventional mobility elements, such as pneumatic tires, suffer from a number of issues related to reliability. Two of the more prevalent problems are the high likelihood of single point failure owing to puncture (i.e. flat tire), and loss of efficiency due to reduction in tire pressure over time. In order to overcome these limitations, alternative compliant tire designs not requiring pneumatics are being widely investigated. Although current designs have addressed some of the aforementioned issues, many of the designs tend to have their own set of limitations. First, most of the non-pneumatic tires designed for high load applications often have restricted envelopment capability, making their performance less than optimal, especially on uneven terrain. Second, many of the designs that can achieve larger envelopment capability tend to still suffer from large amounts of plasticity (permanent deformation) or failure (rupture). Both of these limitations are the direct result of the choice of material being used for the design; conventional metals undergo plastic deformation at low strain while elastomer-based designs are often too rigid for the localized deformations needed for high envelopment.

Recent advancements at the NASA Glenn research center in a unique class of metals know as shape memory alloys (SMAs) has opened the design space for non-pneumatic compliant tire technologies allowing designs to incorporate orders of magnitude more deformation without damage. The work presented herein highlights the advantages of using SMAs as compared to conventional metals. Additionally, the development of a unique SMA compliant tire design capable of carrying up to 13.2 kN (3000 lbf) with reversible, local deformations on the order of the side wall height will be presented.

SESSION PM06.09: Other Functional Intermetallics
Session Chairs: Yoshisato Kimura and Matthew Willard

1:30 PM *PM06.09.01
Microstructure and Magnetic Properties of τ – MnAl Jan Baker; Dartmouth College, Hanover, New Hampshire, United States.

τ–MnAl adopts an ordered tetragonal L12 crystal structure with two atoms per unit cell. It has a theoretical maximum energy product, (BH)max, of ~100 kJ/m3, which is twice that of AlNiCo magnets, and a density-compensated (BH)max that is almost two-thirds the value for SmCo magnets. It has a magnetocrystalline anisotropy constant, K1, of ~2 MJ/m3, and thus it is of great interest as a permanent magnet. Fortuitously, it is composed of relatively inexpensive elements. It can be made by heating to above 870°C to produce the high-temperature hexagonal ε-phase and then either quenching to room temperature and re-annealing at temperatures up to ~500°C or by simply slow cooling. The transformation introduces anti-phase boundaries, microtwins, stacking faults and dislocations. During the transformation to τ – MnAl it is difficult to avoid some conversion to the equilibrium trigonal γ2 (Al8Mn5) and complex cubic β-Mn phases.

In this presentation, we will outline a variety of MnAl processing routes including gas atomization, rapid solidification processing using the Pratt and Whitney RSR process, and casting followed by pulverization to produce MnAl powders. The resulting particulates were mechanically milled to produce MnAl powders. The results will be compared with the magnetic properties obtained after various bulk and powder processing techniques.

2:00 PM *PM06.09.02
First-Principles Assessment of Nd-Fe-B Thermodynamic Properties for Application in CALPHAD Adrie Tri Hanindrino1, Soumya Sridar2, K.C. Hari Kumar2, Kenta Hongo3 and Ryo Maazono2; 1Graduate School of Advanced Science and Technology, Japan Advanced Institute of Science and Technology, Nomi, Japan; 2School of Information Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 3Research Center for Advanced Computing Infrastructure, Japan Advanced Institute of Science and Technology, Nomi, Japan; 4Department of Metallurgical and Materials Engineering, Indian Institute of Technology Madras, Chennai, India.

The Nd-Fe-B system is of great interest in the field of magnetic materials. Currently commercially available, powerful permanent magnets use the ternary phase Nd2Fe14B as a base due to its high degree of magnetisation and relatively robust coercivity. The knowledge of phase equilibria and thermochemical properties of Nd-Fe-B system is therefore of great value in the context of optimization of alloy chemistry, manufacturing and application of magnetic materials based on this system.

The CALPHAD method of computational thermodynamics provides a framework to obtain phase equilibria information and thermochemical properties of materials in a cost-effective and efficient manner. The method relies on Gibbs energy functions of constituent phases, which are generated using thermodynamic modeling. Here first-principles calculations of thermodynamic properties can play an important role by means of providing crucial input data required for thermodynamic modeling. These data include formation enthalpy and heat capacity at constant pressure (Cv) for selected phases.
Contribution of localized 3d/4f orbitals, which is very important for the system in question, presents a challenge for the \textit{ab initio} framework stemming from exchange-correlation approximation. Mott insulators are also a well-known example of this issue, of the ‘strongly correlated’ class of materials. To address this challenge, we implement a simplified Hubbard correction under the Density Functional Theory (DFT) framework. We show that this DFT+U method results in relatively reliable values of formation enthalpy, certainly more so than classical exchange-correlation approximation (non-corrected). In order to obtain the phonon frequencies, the forces acting on the atoms in the perturbed supercell are calculated using DFT. \( C_\text{p} \) is then evaluated under the quasi-harmonic approximation (QHA) to account for volume dependence of phonon frequencies. In contrast to the available data, we find that the computed values deviate considerably from Neumann-Kopp rule. These computational results are expected to improve the reliability of Gibbs energy functions obtained by CALPHAD approach.

2:15 PM PM06.09.03
Influence of Thermo-Mechanical History on Disorder \textendash Order Transformation in 18 Carat Red Gold Alloys Marina Garcia Gonzalez1, 2, Nadine Baluc1, Steven Van Petegem1 and Helena Van Swygenhoven-Moens1, 2; 1Paul Scherrer Institute, VILLIGEN, Switzerland; 2IMX - NXMM, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland; 3SPH-ENS, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

Residual stress management is a major concern during the processing of 18 carat Au-Cu-Ag red gold alloys. Depending on the thermo-mechanical history and chemical composition of these precious alloys, residual stresses cause reduced workability, shape distortions and eventually fracture. The solid state disorder/order phase transformation forming \( \text{Au}_2\text{Cu}_3\text{Sn}_5 \) nano-precipitates lies at the origin of the problems.

18 carat red gold is an age-hardenable alloy which hardens via chemical ordering. Above the critical temperature (~350°C) the alloy shows a chemically disordered FCC structure. However, below this temperature, chemical ordering takes place and a dispersion of harder nano-precipitates of \( \text{Au}_2\text{Cu}_3\text{Sn}_5 \) phase starts to form. This causes a tetragonal distortion of the initial cubic lattice and induces strong misfit strains. Order/disorder phase transformations are diffusional; therefore, any industrial process that affects the vacancy density and its distribution (such as thermal treatments and plastic deformation) may influence the kinetics of precipitation. This implies that the final microstructure and volume fraction of the ordered precipitates will depend on the history of thermo-mechanical operations.

Our study investigates how thermal parameters and plastic deformation affect the ordering kinetics and the microstructure of the precipitates, with the aim of understanding the link between precipitation and residual stress. \textit{In-situ} x-ray diffraction experiments during cooling are performed at the P07 beam line in PETRA III (DESY, Germany). Diffraction patterns were recorded during cooling, using cooling rates between 100 and 800 K/min. Subsequently, the samples were isothermally aged with and without prior plastic deformation. Rietveld refinement is performed to derive the volume fraction of precipitates. By applying the isothermal JMAEK model, the reaction rates and activation energies are obtained. The results are discussed in terms of the thermo-mechanical history.

2:30 PM PM06.09.04
Microstructure Characterisation of Ni-75 at.% Al Raney Type Alloy as a Result of Cooling Rate and Chromium Doping Naveed Hussain1 and Andrew M. Nullis; University of Leeds, Leeds, United Kingdom.

The effect of cooling rate on the phase composition of gas atomized Raney type catalysts was studied using the Ni-75 at.% Al composition. The resulting particles were sieved into 3 standard size fractions and analysed using XRD with Rietveld refinement: as expected the three phases, \( \text{Al}_2\text{Ni}, \text{Al}_3\text{Ni}, \) and \( \text{Al}-\text{Al}_3\text{Ni} \) eutectic were identified. Differing phase compositions in the 3 size ranges were identified which offer a possible explanation for varying catalytic activity with cooling rate. With increasing particle size, there is more \( \text{Al}_3\text{Ni} \) and less \( \text{Al}_2\text{Ni} \). The amount of \( \text{Al} \) eutectic also decreases as the particle size increases. This agrees with the expectation that the higher cooling rates experienced by the smaller droplets allow less time for the peritectic conversion of \( \text{Al}_2\text{Ni} \) to \( \text{Al}_3\text{Ni} \) to proceed. This in turn results in a more \( \text{Al} \)-rich residual liquid, increasing the volume fraction of eutectic. This was further confirmed when analysing the microstructure using SEM backscatter imaging. \( \text{Al}_2\text{Ni} \) was found to be encased in a shell of \( \text{Al}_3\text{Ni} \) characteristic of peritectic reactions. The remainder of the alloy was found to consist of \( \text{Al}_3\text{Ni} \) eutectic. The SEM backscatter imaging also indicated that the larger particles, experiencing slower cooling rate, had a less dendritic and a more globular structure than the smaller particles. Similar Raney type Ni-75 at.% Al doped with 1.5 at.% Cr were synthesised using the same method and sieved into the three standard size fractions. It was found that the Cr doped alloys exhibited a more dendritic character than the undoped samples in the corresponding size fraction, although the material still displayed an increasingly dendritic character with increasing cooling rate. The phase composition found by Rietveld refinement also followed a similar trend to the undoped samples with decreasing amounts of \( \text{Al}_2\text{Ni} \) formed at the higher cooling rates. However, significant amounts of an additional phase, \( \text{Al}_3\text{Cr}_2 \), were also observed. Rietveld refinement found that a larger amount of \( \text{Al}_3\text{Cr}_2 \) was present than could be accounted for by the addition of 1.5 at.% Cr. This can be explained by the substitution of Ni onto the Cr lattice, as confirmed by Rietveld refinement. \( \text{Al}_3\text{Cr}_2 \) was found to be located mostly at the boundary of the \( \text{Al}_3\text{Ni} \) and \( \text{Al}-\text{Al}_3\text{Ni} \) eutectic phases during elemental mapping and quantitative image analysis of backscattered electron micrographs. This indicates that precipitation of \( \text{Al}_3\text{Cr}_2 \) is towards the end of the solidification process. The relatively large amounts of the \( \text{Al} \)-rich \( \text{Al}_3\text{Cr}_2 \) may explain the enhanced catalytic activity observed following leaching of Cr-doped Raney catalysts.

2:45 PM PM06.09.05
Nb/Sn Coatings for Next Generation Particle Accelerators Michael J. Kelley1, Uttar Pudasaini1, James Tuggle2, Grigory Eremeev3 and Charles Reece4; 1College of William & Mary, Williamsburg, Virginia, United States; 2Virginia Tech, Blacksburg, Virginia, United States; 3Thomas Jefferson Laboratory, Newport News, Virginia, United States.

Nb/Sn has the potential to achieve superior performance in terms of quality factor, accelerating gradient and operating temperature (4.2 K vs 2 K) resulting in significant reduction in both capital and operating costs compared to traditional niobium SRF accelerator cavities. Tin vapor diffusion coating of Nb/Sn on niobium appears to be a simple, yet most efficient technique so far to fabricate such cavities. Here, cavity interior surface coatings are obtained by a process of nucleation followed by deposition. The first step is normally accomplished with Sn/SnCl4 at a constant low temperature (~500 °C) for several hours. To elucidate the role of this step, we systematically studied the niobium surface nucleated under varying process conditions. The surfaces obtained in typical tin/tin chloride processes were characterized using SEM/EDS, AFM, XPS, SAM and TEM. Examination of the surfaces nucleated under the standard conditions revealed not only tin particles, but also tin film on the surfaces All the nucleation attempted with SnCl2 yielded better uniformity of Nb/Sn coating compared to coating obtained without nucleation, which often included random patchy regions with irregular grain structure. Even though the variation of nucleation parameters was able to produce different surfaces following nucleation, no evidence was found for any significant impact on the final coating. Coatings cross-sectioned by FIB and examined by EBSD showed columnar structure. Composition measurement by XPS sputter profile showed constant Nb/Sn composition except adjacent to the interface. Examination of overcoated samples by FIB/EBSD showed growth by formation of new grains at the interface.

3:00 PM BREAK
Phase Evolution of Nanostructured Fe-Si-Al-Based Intermetallic Phases in Soft Magnetic Alloys Matthew A. Willard, Maria Danil, Rajesh Jha, David Grimmer, Aaron Stehner and Cristian Ciobanu; Case Western Reserve University, Cleveland, Ohio, United States; 2Colorado School of Mines, Golden, Colorado, United States; 3Bard High School Early College, Cleveland, Ohio, United States.

Nano crystalline soft magnetic materials are the latest and most promising of the soft magnetic materials that were developed at the end of the 20th century. They have since been studied extensively, and various alloy compositions have been developed and optimized for ambient and extreme (cryogenic and elevated temperature) applications. Their advantage lies in the unique combination of fine microstructure, crystal structure and composition, which can be achieved by rapid solidification and subsequent controlled annealing. In this article, we discuss the requirements and the characteristics of the designing these alloys and how it affects the crystal structure, microstructure and eventually the magnetic performance of new alloys designed for use at temperatures below 150K in applications such as cryo-power electronics and magnetic shielding. Efforts to use computational materials science to accelerate the alloy design process will be discussed.

Composition Dependency of Thermoelectric Properties in Ca-Mg-Si System Using Thin Films Prepared by RF Magnetron Sputtering Method Hiroshi Funakubo, Mutsuo Uehara, Mao Kurokawa, Atsuo Katagiri, Kensuke Akiyama, Takao Shimizu, Masaaki Matsuume, Hiroshi Uchiwa and Yoshisato Kimura; 1Tokyo Institute of Technology, Yokohama, Japan; 2Kanagawa Institute of Industrial Science and Technology, Ebina, Japan; 3Sophia University, Tokyo, Japan.

Ca-Mg-Si ternary system consists of abundant and non-toxic elements. This system includes MgSi that reported to show good thermoelectric properties and realize both p- and n-type conduction. CaMgSi is expected to show good thermoelectric properties. However, the investigation of the thermoelectric property in Ca-Mg-Si system is limited to the narrow composition region. Investigation for wide composition region, possibility of the composition dependency in the sinterability remains a problem to evaluate the thermoelectric property in case of the sintered body. To overcome this problem, we selected thin films that can make dense samples for wide range of composition. In the present study, films of Ca-Mg-Si system were prepared by RF magnetron sputtering system and thermoelectric properties were investigated for wide composition region. Films with wide composition range were successfully obtained on (001)Al2O3 substrates at the deposition temperature of 260-340 °C using Mg target with various numbers of Ca and Si chips. Obtained films were post heat treated at 500-700 °C under the 5% hydrogen included argon atmosphere. Conductivity type of the films mainly changed by the Ca/(Ca+Mg+Si) ratio of the films and p-type and n-type conduction were observed below 0.6 and above 0.7, respectively. Single phases of CaMgSi and CaMg22Si were successfully obtained and showed p-type. Maximum power factor of 0.15 mW/(mk2) at 400 °C was obtained for the films with Ca:Mg:Si = 0.2:0.2:0.6. In our presentation, we show the systematic data of the crystal structure and thermoelectric properties as a function of film composition.

Enhancing Thermoelectric Properties through Control of Nickel Interstitials and Phase Separation in Heusler/Half-Heusler TiNi1.1Sn Composites Emily E. Levin, Francesca Long, Jason Douglas, Malinda Buffon, Leo Lamontagne, Tresa Pollock and Ram Seshadri; University of California, Santa Barbara, California, United States.

Heusler intermetallics, including compounds crystallizing in the F–43m half-Heusler and Fm–3m full-Heusler crystal structures, are known for their diverse functional properties, a consequence of their wide chemical tunability. At intermediate compositions between the half-Heusler and full-Heusler, some systems appear to phase separate while others form complete solid solutions. This differing behavior constitutes an additional tuning parameter in the development of these compounds as functional materials. Here we discuss the half-Heusler/Heusler system Ti(1−x)NiSn (0 ≤ x ≤ 1) where a driving force for phase separation exists. However, we have found that appropriate heat treatment can trap Ni interstitials by design, in order to strongly accentuate the thermoelectric properties.[1] Rietveld analysis of synchrotron X-ray diffraction confirms the incorporation of Ni interstitials into the half-Heusler, and electron microscopy illustrates the evolution of microstructure with heat treatments. Half-Heusler samples with Ni interstitials display an enhanced Seebeck coefficient due to potential in-gap states and modification of the carrier concentration,[2] leading to an improved power factor. Furthermore, Ni interstitials act as point defects, scattering phonons and reducing thermal conductivity, leading to over fivefold increase in room temperature figure of merit compared to homogenized TiNi1Sn. Further annealing at low temperature allows the excess Ni to diffuse, forming full-Heusler nanocrystallites which also act to scatter phonons and lead to over 2× increase in the figure of merit as compared to homogenized TiNi1Sn.

Kinetic Analysis of Crystallization Reaction Within Co-Sn Alloy Muna S. Khushaim, Fatimah Alahmary, Ahmad Al-Joraid and Torben Boll; 1Taihahu University, Ahmedabad, India; 2King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 3Karlsruhe Institute of Technology–Institute for Applied Materials, Karlsruhe, Germany.

Co-Sn alloy is an important system for Sn-based anode materials of lithium ions batteries due to the different interesting intermetallic compounds nucleate and grow during crystallization reaction. These compounds are: CoSn, CoSn2 and CoSn3. These intermetallic compounds, which are containing Sn, are important as anode materials in order to provide a means for efficient Li storage. Co–Sn alloys are applied in specific high-tech applications; and hence study the kinetics of the crystallization reaction of this system and the dependency of the activation energy for crystallization of different intermetallic phases on the temperature might provide a method to control the reaction and the synthesized products. Moreover, a critical knowledge about the growth mechanism will assist in the understanding of the of the melting – solidification region within Co-Sn system. In this study, Co–Sn alloy with ratio of approximately 1:3 were prepared by using metal flux method using arc-melter technique. Microstructure characterizations of the samples have been done by using x-ray diffraction (XRD) and scanning electron microscopy (SEM). The alloy was heated under a non-isothermal condition by using differential scanning calorimetry (DSC) at different heating rates. After observing the exothermic changes which indicate to the crystallization of different intermetallic phases during the DCS scanning, different isoconversional methods were applied in order to determine the variation of the activation energy of crystallization with temperature. In order to shed light on a segregation of atoms at the interface between the metal flux and different intermetallic phases, and hence understanding the growth mechanism of the observed intermetallic phases, atom probe tomography (APT) is used. Using APT as a sophisticated tool allowed us to obtain a critical knowledge of nano scale evolution of the microstructure and investigate the intermediate steps in the mechanism of flux-grown intermetallic phases. The results obtain from APT analysis in combination with the calculation of the variation of activation energies of different
intermetallic phases with the temperature provide new combined methods to investigate the kinetic of crystallization reaction within Co-Sn alloy.

4:45 PM PM06.09.10
Room Temperature High Pressure Hydrogen Storage in Mg2Ni Nanoparticles Decorated Frustule-Nitrogen Doped Graphene
S. Ramaprabhu and Sai Smruti Samantaray; Indian Institute of Technology Madras, Chennai, India.

Hydrogen as an alternative energy carrier is a promising solution for reducing CO2 emissions and its related adverse effects on the environment. However, lack of an economically viable, safe and efficient storage method is a significant barrier between its production and use. This problem arises mainly due to the low energy per unit volume of hydrogen under ambient conditions. Hydrogen storage in metal hydrides is a better option in comparison to the conventional hydrogen storage methods in terms of safety, but the requirement of high temperatures for the dissolution of the adsorbed hydrogen is disadvantageous. Magnesium based materials have the potential as good hydrogen storage materials and have been widely investigated. But, their practical utilization is hindered by poor thermodynamics and sluggish dehydrogenation kinetics. With the aim of overcoming this barrier, we have synthesized low cost Mg based alloy nanoparticles decorated frustule –nitrogen doped graphene (Mg2Ni-N-D-G) and investigated its hydrogen storage properties. The underlying hydrogen storage mechanism in the synthesized nanocomposite is the spillover effect. Mg2Ni decorated nitrogen doped graphene (Mg2Ni-N-G) systems have been previously studied in our laboratory and a hydrogen storage capacity of ~4 wt% at room temperature and moderate hydrogen equilibrium pressures has been obtained. Combining this with the unique physical and chemical properties of diatom frustules such as large surface area, chemical inertness and good porosity has proved to be fruitful for hydrogen storage. Hence, the synthesized nanocomposite Mg2Ni-N-D-G is explored as a potential hydrogen storage material to obtain a gravimetric density of ~ 5wt% at room temperature and moderate hydrogen pressure.

SYMPOSIUM PM07

Plasma-Based Synthesis, Processing and Characterization of Novel Materials for Advanced Applications
November 26 - November 28, 2018

8:30 AM *PM07.01.01
Mass-Production of CNT Materials from Gas Phase Chemical Vapour Deposition and Microwave Plasma
Brian Graves, Fiona Smail and Adam Boies; Engineering, University of Cambridge, Cambridge, United Kingdom.

The exceptional mechanical, thermal, and electrical performance of carbon nanotubes (CNTs) makes them ideal for a wide range of applications, however they are costly to produce and difficult to integrate effectively with other materials. We have developed several continuous gas phase CVD processes that can synthesize novel CNT bulk-produced materials at high mass-throughput.

The presentation will demonstrate how CNTs can be grown and synthesized into macroscopic materials using continuous gas phase processes. In a tube furnace, CNTs are grown with gas phase CVD from catalyst particles comprised of a transition metal and sulphur. As the CNTs increase in length and number concentration, they agglomerate to form an aerogel which can be extracted continuously from the reactor. The self-assembled CNT structure can be wound to form fibres and mats which can be easily integrated into composites, wires, and heat pipes, among many other applications. New developments of this process will be discussed along with the properties and applications of the resulting CNT materials.

We are also currently working towards replicating this aerogelation process with a microwave plasma reactor, in which we have previously synthesized a metal oxide – CNT composite material for the anodes of lithium ion batteries. This plasma-based process exhibits several key advantages over other techniques. The extremely high temperature of the plasma permits vaporization of a wide range of precursor materials, including those in powdered, elemental form which are ideal for an industrial process since they are cheap and readily available. The plasma also has a high energy density, meaning that a large mass throughput can be achieved with a small system. Large-scale production of these materials with this method could contribute to significant advances in materials for an array of engineering fields.

9:00 AM PM07.01.02
Plasma Activation of Carbon Fiber Reinforced Thermoplastics
Trey Oldham1, Daniel R. Ferriell2, Marcus A. (Tony) Belcher2, Alexander Rubin2 and Elijah Thimsen1; 1Washington University in St. Louis, Saint Louis, Missouri, United States; 2The Boeing Company, St. Louis, Mississippi, United States.
Carbon fiber reinforced thermoplastic (CFRTP) composites are a platform material for structural applications due to their high fracture toughness, lightweight, and chemical resistance. However, the chemical inertness of the thermoplastic hinders the material’s ability to robustly bond to form structural assemblies. Non-thermal plasma treatments of CFRTP composites have been shown to overcome this limitation by producing an activated surface. The highly reactive surface comprised of ions and radicals is intrinsically unstable, resulting in the deterioration of the activation state over time. The ability to characterize the activation state is of significant importance in terms of quality control of bonded structural assemblies. In this work, a novel, non-destructive method of determining the activation state of plasma-treated surfaces was discovered using Kelvin probe force microscopy (KPFM) surface potential measurements. Activated surfaces are characterized by a sharp, well-defined surface potential distribution. The sharp peak is hypothesized to be due to the presence of quasi-stable radical-ion complexes. Plasma-treated CFRTP surfaces being uniformly comprised of anionic and radicalic species is supported by KPFM, contact angle, magnetic force microscopy (MFM), and radical scavenger experiments. Radical-anion complexes are only stabilized when both species are present (i.e., radicals readily react in the absence of anions and vice versa). Evidence in support of radical-anion stabilized complexes was observed by a decrease in radical scavenging activity of a plasma-treated sample which had been charge-neutralized compared to non-neutralized plasma-treated sample. MFM measurements provide an independent verification of this result.

9:15 AM OPEN DISCUSSION

9:30 AM PM07.01.04
Effect of Airborne Contaminants on Plasma-Induced N-Doping of Graphene Films Germain Robert Bigras, Xavier Glad, Richard Martel and Luc Stafford; Université de Montréal, Montréal, Quebec, Canada.

Graphene has been extensively studied thanks to its promises for the next generation of electronic and optoelectronic devices [1]. The availability of versatile post-processing techniques of graphene is mandatory for applications in which properties of pristine graphene are insufficient. In recent years, various methods, including plasma-based approaches, have been explored to tune the doping with nitrogen atoms of graphene films as a means of either increasing the electron density or inducing a band gap [2]. An ideal and efficient nitrogen doping would precisely tune the N-doping and keep a minimal defect density. Studies often blindly aim at increasing the nitrogen content while minimizing defect generation. In addition, very few measures are taken into account to control the gas phase impurities. Even for freshly grown graphene, Li et al. [3] showed that the graphene receive a strong variation of its hydrophobicity within days due to the deposition of hydrocarbons on the surface. Analysis of the N-doping dynamics must therefore discriminate if N- incorporation occurs in the airborne contaminants or in the graphene lattice itself.

In this work, we explore the potential of the late afterglow of a microwave N₂ plasma at reduced pressure (6 Torr) for post-growth tuning of CVD-grown graphene films on copper foils. The low ion density (< 10⁴ cm⁻³) and the high density of reactive neutrals (> 10¹⁴ cm⁻³) and metastable species (> 10¹⁰ cm⁻³) of the nitrogen late-afterglow [4] are believed to enhance chemically driven surface reactions over purely physical ion bombardment. Therefore, enhanced functionalization at the surface is expected due to interactions between nitrogen and the hydrocarbons. In addition, the tunable nature of the nitrogen afterglow allows the exposition of the sample to a continuum of environments; from damaging conditions (Early afterglow - EA) to a milder region (Late Afterglow - LA).

A single graphene sample received five subsequent 30-second plasma treatments between which X-Ray photoelectron spectroscopy (XPS) and Raman spectroscopy (RS) were carried out. XPS measurements confirmed a strong N-incorporation increasing with the plasma treatment time (up to N/(N+C+O) = 19% for LA and 49% for EA) while RS assessed an uncommonly low damage generation (D:G ≈ 0.4 for LA and D:G ≈ 1.3 for EA) for such incorporation. Transfer towards SiO₂ substrate reveals the loss of a strong proportion (80%) of weakly bonded nitrogen moieties for LA-treated graphene. This can be explained by a significant incorporation of N atoms within the hydrocarbon layer.

9:45 AM PM07.01.05
Roll-to-Roll Vacuum Deposition of Polymers with In-Line Curing—A Comparison of Two Curing Sources (Plasma and Electron Beam) Carmen Alonso Herr and Hazel Assender; 1University of Oxford, Oxford, United Kingdom.

The high-speed roll-to-roll deposition of smooth, thin layers of polymer in vacuum, by flash evaporation of the monomer followed by radiation curing, is useful for smoothing and topcoat layers (e.g. for high performance gas barrier films) as well as dielectric for capacitors and OTFTs. The properties of a diacrylate (TPGDA), deposited using different curing sources (plasma and electron beam, both which are used commercially for in-vacuum polymer layer deposition) have been studied, both with the layer attached to the polymer substrate, and by removing the thin film from the substrate to study the properties of free-standing films. The degree of cure, which determines mechanical, adhesion and stability properties for example, has been measured by FTIR-ATR and by Soxhlet extraction to reveal the relative contributions of free monomer and ‘dangling ends’ in the network. This degree of cure, and the film thickness (by ellipsometry), mechanical properties (by dynamic mechanical thermal analysis) and surface topography (by AFM) have been characterized as a function of process parameters, and a comparison has been made between the two curing sources. A model is proposed to describe the differences: for plasma curing density of reactive species created is independent of the layer thickness, and hence the degree of cure depends primarily upon the flux of radiation. In contrast for E-Beam cured samples, the number of reaction centres created depends primarily on the thickness of the coating. Such an understanding of the curing leads us to link the process parameters with other polymer’s properties, which is relevant especially when creating multilayers such as barrier coatings or devices for organic electronics.

10:00 AM BREAK
The ever-increasing demand for high-quality nanosized materials coming from many industrial and research fields has spurred the research on viable methods for their synthesis. In the first part of the talk, RF inductively coupled plasmas for nanoparticle synthesis will be introduced as an effective tool for the continuous production of nanoparticles at high throughput. This technology has encountered the interest of many industrial nanoparticle producers thanks to its distinctive features such as high energy density, high chemical reactivity, high process purity, large plasma volume and long residence time; also, RF synthesis of nanoparticles benefits from the large number of available process variables (e.g. power, frequency, process gases, phase of the precursor and system geometry) that ensure the versatility of the process and from the high cooling rate ($10^{-3}$--$10^{-5}$ K/s) in the tail of the plasma, that allows to produce tailored nanoparticles with a narrow particle size distribution (PSD). During the talk, advantages and disadvantages of the technology will be introduced, focusing, in particular, on the challenges posed by up-scaling. The use of modeling instruments as supporting tools for the design and engineering of industrial-scale high-throughput thermal plasma systems for nanoparticle synthesis will be discussed [1, 2]. The second part of the talk will deal with Cold Atmospheric Plasmas (CAPs) as the centerpiece of a family of simple and environmentally friendly methods for the synthesis and modification of nanostructures in liquid environments [3]. Results highlighting the role of the chemical composition of the liquid environment (either NaCl + NaOH or NaCl only, dissolved in distilled water) on the characteristics of the produced nanoparticles will be presented. Furthermore, the possibility of synthesizing nanoparticles from a nebulized solution containing metallic salts will be discussed; an applicable example, where this process is employed to produce an antibacterial coating composed of a layer of antibacterial silver nanoparticles embedded within two polymeric thin films, will also be provided. A similar approach, simultaneously depositing silver nanoparticles and a polymeric matrix, will be presented as well [4].

Ultra-Small Metallic Nanocrystals Synthesis from Solid Wire Precursors via an Atmospheric Pressure Microplasma Bruno Alessi, Atta ul Haq, Dilli Babu Padmanaban, Paul Maguire and Davide Mariotti; University of Ulster, Newtownabbey, United Kingdom.

Metal nanoparticles are interesting for a wide range of scientific fields. Particles with diameters ranging from 10 nm up to hundreds of nanometers exhibit attractive properties for various applications (e.g. catalysis, chemical sensors etc.). Some of the most studied characteristics are for instance related to the possibility of tuning localized surface plasmon resonance, which depends on the nanoparticle size, shape and surrounding environment. Meanwhile, particles with diameters below 10 nm down to and below 1 nm, approach a new regime and can in some cases associated to large molecular clusters, with properties of interest to electronics and semiconductor science. Model calculations for such metallic quantum dots predict, depending on the composition, the opening of the energy bandgap and the consequent appearance of photoluminescence effects. However, most of the synthesis methods that yield narrow size distributions employ high vacuum methods or use surfactants to sterically control particle size during their synthesis. Atmospheric pressure microplasmas recently revealed their value for nanomaterial synthesis. Microplasmas simultaneously offer a cheap alternative to low pressure plasmas and some unique peculiarities. For example, the high ratio of energetic electrons allows activating chemical reactions which are otherwise hard to achieve. These plasmas at atmospheric pressure typically show also high electron densities and enhanced rate of ion-neutral interactions, which are mainly responsible for charging and selective heating of particles inside a plasma. The former preventing agglomeration of particles and the latter allowing to achieve higher particle temperatures compared to the gas background. A clear advantage of microplasmas for nanomaterial synthesis is the small residence time of nucleating particles inside the active plasma region, which can be reached with a flow-through type reactor. Moreover, samples can be easily prepared either as evenly dispersed colloids or as solid films of stacked particles.

In the current work, ultra-small metallic nanocrystals, or quantum dots (below 5 nm) of different elements such as tin, copper, bismuth and others have been produced with a gas phase atmospheric pressure microplasma using the corresponding solid bulk form as precursor; we discuss material characterization as well as the potential underlying mechanism of formation supported by a few different experimental plasma diagnostics.

Low Temperature Plasma Synthesis of III-V Stibnide and Nitride Nanocrystals from Bulk Metals Necip B. Uner and Elijah Thimsen; Washington University in St. Louis, Saint Louis, Missouri, United States.

Low temperature plasma (LTP) is a unique gas-phase synthesis tool for various forms of nanomaterials. The nonequilibrium environment in the LTPs has been utilized to synthesize many semiconductor nanocrystals in tubular flow-through reactors by using suitable vapor precursors. These materials mostly comprise Si, Ge, various sulfides and oxides. III-V semiconductors, which constitute an important family of materials for optoelectronic applications, haven’t been explored as well. Although reports on the synthesis of InP and GaN have been reported, stibnides and nitrides currently don’t have an established method of synthesis that yields high quality nanocrystals. In this work, we present a general plasma synthesis route for bare nanocrystals of GaSb and GaN. The method diverges from the previously reported syntheses of semiconductor nanocrystals, since use of vapor precursors is avoided. Instead, aerosols of constituent metals are generated in evaporation and condensation sources. These aerosols of Ga, Sb and gaseous nitrogen bearing species were used as precursors. Produced aerosols are mixed and then sent into a flow-through Ar LTP reactor. Aerosols vaporize inside the LTP and the generated vapor re-forms the compound semiconductor by way of nucleation and condensation [1]. Since particles obtain unipolar negative charge inside the LTP, Coulombic repulsion prevented the formation of agglomerates. Synthesized particles were verified to be free-standing and crystalline via transmission electron microscopy. Furthermore, particles were mixed on atomic scale. Stoichiometry was found to be adjustable by manipulating the input aerosol concentrations and input plasma power. In addition to results on reactor operation and on extensive ex-situ characterization of materials by means of electron microscopy and x-ray diffraction, functionalization of the produced nanocrystals by surfactants and the resulting photoluminescent properties of the materials will be presented.

References
At the present stage of nanotechnology development nanoparticles are considered as important building blocks for the construction of nanodevices with working parameters exceeding those of the bulk analogs. Therefore, to reach the distinctive properties of nanoparticles the development of the controlled synthesis procedures that enable tuning the particles parameters during the preparation is now considered to be crucial. Among the nanoparticles fabrication methods plasma-assisted techniques that imply the combination of top-down and bottom-up approaches, are considered to be promising for controlled fabrication and targeted modification of nanoparticles parameters such as size distribution, phase composition, inner structure and surface chemistry. The present paper summarizes the developed plasma and laser-assisted approaches focusing on the controlled fabrication and modification of nanoparticles of different composition and morphology.

Several plasma-assisted techniques were used in the experiments: electrical discharge in liquids, plasma generated in contact with liquid, laser ablation in liquid and laser irradiation of colloidal solutions. Studying the influence of liquid composition on the particles properties it has been found that electrical discharge and laser ablation in non-reactive liquids can be used for effective fabrication of metallic and semiconductor (Si, Ge) nanoparticles. In contrast, plasma generation in reactive liquids by electrical discharge or laser ablation can be simple but effective route for binary nanoparticles synthesis.

For the effective fabrication of composite nanoparticles the combined laser-plasma approaches have been developed. One of them is based on the sequential laser ablation of targets in liquids that can be used as a tool to prepare binary or ternary nanocomposites as well as for the doping of nanocrystals. Another route of the compound nanoparticles preparation is based on the laser treatment of the nanoparticles mixtures. Special attention has been paid to the production of metastable alloys as their formation is favorable under the conditions of dense plasma with high temperature and pressure.

For this, the combined plasma-laser approach based on electrical discharge treatment of the micropowders suspension in liquids with subsequent laser irradiation of the formed colloids has been developed that has been shown to be suitable for fabrication of Cu-Zn, Ag-Cu, Ge-Sn and Si-Sn alloys as well as binary and ternary compounds, such as GdSi2, GdSi2Ge and CuInSe2. The surface chemistry of the prepared nanoparticles can be additionally adjusted by treatment of the prepared colloid by plasma in contact with liquid. This method was demonstrated to be effective for the improvement of the luminescent efficiency of the carbon and silicon quantum dots promising for photovoltaic and biomedical applications.
number of 4-fold coordinated dopant atoms are located within the core of the nanoparticle to explain their plasmonic resonance. Furthermore, we find that low-temperature annealing of these nanocrystals produces an apparent increase in the concentrations of dopant atoms within the nanocrystal core. K. Synthesis of Silicon Nanoparticles in a Low Pressure Microwave Plasma Reactor on a Pilot Plant Scale—Characterization of Particle Growth and Influence of Different Process Conditions on Particle Characteristics

Fredrik Künze, Stefan Kuns, Mathias Spree, Tim Huesler, Hartmut Wiggers and Sophie M. Schnurri, IUTA, Institut für Energie- und Umwelttechnik e.V., Duisburg, Germany; JIV, Institute for Combustion and Gas Dynamics – Reactive Fluids, University of Duisburg-Essen, Duisburg, Germany; CENIDE, Center for Nanointegration Duisburg-Essen, University of Duisburg-Essen, Duisburg, Germany.

Within the last years, numerous research results have indicated that nano-sized silicon can be used for a multitude of different applications. Especially its size-dependent properties such as limited phonon transport (in thermoelectric devices), structural flexibility (for battery applications) or quantum-confined optical properties (for optical applications) are of high interest. Gas-phase synthesis is a suitable method for the continuous production of high amounts of specific nanoparticles, which enables applications based on highly-pure nanostructured materials. Up to now, microwave plasma reactor processes have mainly been investigated on the laboratory scale and only a few very approaches were dealing with scaling to higher production rates. Therefore, microwave supported plasma reactors are not yet regarded as a competitive manufacturing method to produce high amounts of nanoparticles with consistent high quality.

In this work, a microwave plasma reactor is used for the generation of silicon nanoparticles from gaseous monosilane (SiH4) at the pilot scale. The reactor uses a microwave frequency of 915 MHz and a microwave power up to 50 kW in contrast to 2.45 GHz and 6 kW on the laboratory scale. It will be shown that this reactor enables the formation of highly crystalline and either soft-agglomerated or hard-agglomerated silicon nanoparticles depending on the process conditions. In order to characterize the growth process of the particles within the plasma reactor, samples of particles were extracted directly from the gas phase at different distances from the plasma utilizing high-speed thermophoretic sampling. Furthermore, the systematic investigation of process conditions reveals that the particle size and aggregation can be independently controlled by a selective adjustment of the process conditions. It was identified that a higher gas outlet velocity of the nozzle results in a reduced residence time, thus leading to shorter growth time and smaller particles. In contrast, an increase in SiH4 concentration up to 48 vol.% does not lead to further growth of isolated primary particles but promotes aggregate formation from smaller primary particles. In addition, it is shown that we are able to run a production process with consistently good quality of the silicon nanoparticles at high production rates of up to 200 g/h. Therefore, a full-day synthesis of silicon nanoparticles was performed. Nanoparticles were collected at fixed time intervals during the synthesis period and characterized via BET measurements and TEM images. This continuous sampling allows to detect unwanted changes of the particle characteristics during the synthesis and gives an indication of the long-term stability of the plasma process. The results indicate a stable process for many hours.

The authors gratefully acknowledge the support by the German research foundation (DFG) in scope of the research group 2284 “Model-based scalable gas-phase synthesis of complex nanoparticles”.

Boron and Phosphorus Co-Doped Colloidal Silicon Quantum Dots

Minoru Fujii, Hiroshi Sugimoto and Shinya Kano, Kobe University, Kobe, Japan.

A colloidal solution of Si quantum dots (QDs) is a versatile material for electronics, optoelectronics and biophotonics. Recently, we have developed a new type of all-inorganic Si QDs that can be dispersed in alcohol and water almost perfectly without organic ligands, and exhibit size-dependent luminescence in the near-infrared range in water. The unique property of the QDs arises from the unique structure. The QD has a core-shell structure; the core is heavily B and P codoped crystalline Si and the shell is an amorphous layer composed of B, Si and P. The shell induces negative potential on the surface and prevents agglomeration of Si QDs in polar solvents. Furthermore, isolation of an exciton in a crystalline core from environment by the shell makes the luminescence insensitive to the change of the environment and robust for chemical treatments. To the liquid-free surface of codoped Si QDs, molecules in a solution can access easily, and thus a variety of charge-transfer-induced processes such as a photocatalytic effect and chemical doping are expected. In this presentation, we first discuss the structure of codoped Si QDs based on the data obtained by atom probe tomography and transmission electron microscopy. We then discuss the size dependence of the energy state structure, especially that of the donor and acceptor levels, based on the data obtained by scanning tunneling spectroscopy, photoemission yield spectroscopy and photoluminescence spectroscopy. We then discuss charge transfer interaction between Si QDs and adsorbed molecules, including the photocatalytic activity and chemical doping. We show the formation of a variety of nanocomposites composed of codoped Si QDs and noble metal nanostructures, and discuss the enhanced optical responses due to the coupling with the localized surface plasmon resonances of metal nanostructures. Finally, we discuss the electrical transport property of a Si QDs film produced from the colloidal solution and demonstrate the possible application as electronic devices.

Low Resistivity HfN Layers by Plasma-Assisted ALD with External rf Substrate Biasing

Mariadriana Creatore; Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands.

In this contribution I will discuss the deposition of HfN by means of plasma-assisted ALD. The process adopts tris(dimethylamino)cyclopentadienylhafnium [CpHf[NMe2]3] as Hf precursor and H2 or Ar/H2 plasmas as reducing co-reactant. Films are found to exhibit...
an electrical resistivity of 9.0 × 10³ Ω cm, in the absence of external substrate biasing [1]. The latter is attributed to the presence of oxygen in the film up to 20 at%, which is responsible for a limited Hf²⁺ fraction of 0.65. First-principles DFT calculations are adopted to explore the underlying mechanisms of O incorporation: chemisorption of H₂O from the reactor background on the bare HfN surface is kinetically and thermodynamically highly feasible, and leads to Hf-OH surface groups. A steady decrease in electrical resistivity down to 3.3 × 10³ Ω cm is observed upon increasing the substrate potential up to -130 V by externally biasing the substrate [2]. The variations in electrical resistivity with the potential correlate with the extent of grain boundary scattering in the films, which significantly decreased upon increasing the potential up to -130 V. The latter is primarily due to major changes in the film chemical composition, namely the decrease in O content to less than 2 at% for a potential of -130 V and an associated increase in the Hf³⁺ fraction up to 0.82. In parallel, DFT calculations reveal that cationic species present in Hf plasma are highly reactive towards the surface – OH groups. An increase in the energy of bombarding cations promotes the dissociation of Hf-OH surface bonds, followed by H₂O formation and desorption. When heavier and more energetic ion bombardment (as generated in an Ar/H₂ plasma) is applied, the electrical resistivity goes down to 4.1 × 10³ Ω cm. It is worth noting that such low resistivity is achieved for films as thin as ~35 nm. Next to a high Hf(III) oxidation state fraction of 0.86±0.02, the key towards the very low resistivity is the suppression of in-grain defect density and nano-porosity in HIN films. Overall, the application of a substrate potential is shown to highly affect the chemical composition, microstructure and the associated electrical properties of the HIN layers.

Synthesis of Layered Sulfide Heterostructures via RF Sputtering
Dennise M. Roberto1,2, Sage Bayers2 and Andriy Zakutayev2; University of Colorado-Boulder, Boulder, Colorado, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Deposition of layered chalcogenide materials allows for generation of novel material systems with tunable optical and electronic properties sensitive to changes in both dimensionality and the stacking sequence of constituent compounds. Synthesis of kinetically-controlled products can be achieved by the deposition of an amorphous “initial state” in which thickness and composition are precisely controlled, thus enabling rational study of structure-property relationships as a given material progresses from a monolayer to a more bulk-like state. To date, only selenide and telluride thin films have been demonstrated in this vein. We show the first synthesis of sulfide materials assembled under this framework and generate heterostructures comprised of alternating layers of crystalline MoS₂ and SnS. RF sputtering is utilized to generate thin films of amorphous material in which layer-by-layer control of phase relationships is a given material progressively from a monolayer to a more bulk-like state.

AIN Etching Under ICP Cl/BCl3/Ar Plasma Mixture—Experimental Characterization and Plasma Kinetic Modeling
Mohammad Rammal1,2, Ahmed Rifaihi1, Delphine Néel1, Dahlia Make1, Alexandre Shen3 and Abdou Djouadi1,2; 1Institut des Materiaux Jean Rouxel, Nantes, France; 2University of Nantes, Nantes, France; 3III-V Lab, Palaiseau, France.

AlN is one of the III-V materials used in a new generation of electronic and optoelectronic devices especially in high power devices. Indeed, thanks to its good conductivity, it is well qualified to evacuate heat from the devices and thus improves their performance and reliability. One of the challenges is to succeed in the pattern transferring from the mask to AlN material using plasma etching process. Chlorinated plasmas are well tested to etch AlN material. Some studies show that chlorinated plasmas containing only molecular chlorine or with argon is not efficient to properly succeed the etching step in terms of selectivity, anisotropy and surface roughness. The addition of BCl₃ seems to improve the performance of the AlN etching. However, it remains difficult to find the optimal operating conditions that improve the morphological properties of etched AlN structures. In this context, we present experimental results of AlN etching using ICP BCl₃/Cl₂/Ar plasma mixture. The AIN is deposited on Si and InP substrate using DC magnetron sputtering. Then, a SiO₂ patterned hard mask is used to have a selective etching. The etch rate reached is 200 nm/min; with a small problem of microtrenching and a sidewall angle of 75°. This problem can be overcome using simulation in which the optimum etching conditions can be found. In parallel, plasma kinetic model of BCl₃/Cl₂/Ar is developed to study the effects of the reactor parameters such as RF power, pressure and gas flow rates on the neutral and charged species evolution as well as the electron temperature and density. The model is based on the 0D global kinetic model. Mass balance equations of 34 neutrals, negative and positive ions coupled to the charge neutrality equation and power balance equation are established to quantify the species densities and their fluxes onto the substrate surface. Particular attention is given to the analysis of the percentage of BCl₃ gas effect on the reactive species densities involved in the etching processes such as the positive ion and atomic chlorine densities.

Surface Reactions During Plasma-Assisted Atomic Layer Deposition of SiN₃
Sumit Agarwal; Colorado School of Mines, Golden, Colorado, United States.

The shrinking device dimensions in integrated circuits combined with the introduction of 3-D device architectures has created a need for novel atomic layer deposition (ALD) processes for a variety of materials including Si-based dielectrics such as SiN₃. Development of new ALD techniques that can meet the demands for semiconductor manufacturing requires an atomic level understanding of the surface reaction processes. In our lab, we use in situ optical diagnostic techniques including highly surface sensitive attenuated total reflection Fourier transform infrared spectroscopy and multi-wavelength ellipsometry to study the surface processes that occur during ALD.

In this presentation, I will discuss the low-temperature plasma-assisted ALD of SiN₃ films where one of the key challenges has been to grow conformal films in high-aspect-ratio nanostructures such that the sidewall structure and composition is the same as the top surface. I will discuss the surface reactions that occur during ALD of SiN₃ using chlorosilanes and aminosilanes as the Si precursors with an NH₃ and N₂ plasma, respectively, as the nitrogen source. The NH₃ plasma based processes show >95% conformity, but the wet-etch rate in dilute HF is much higher for the sidewalls compared to the planar surface. While N₂ plasma based processes show a low wet-etch rate for both the sidewalls and the planar surface, the conformity is ~50%. Based on these observations, we have developed a new three-step ALD process for SiN₃ growth using Si₂Cl₆ followed by CH₃CN, and then an N₂ plasma. I will show that in this three-step ALD process because nitrogen is supplied to the surface partially in a thermal step followed by an N₂ plasma, the films are more conformal with a sidewall wet etch rate that is intermediate between NH₃ and N₂ plasma based ALD processes.
Graphene nanoribbons (GNRs) combine the unique electronic and spin properties of graphene with a transport gap that arises from quantum confinement and edge effects. This makes them an attractive candidate material for the channels of next-generation transistors. However, the reliable site and alignment control of nanoribbons with high on/off current ratios remains a challenge. We have developed a new, simple, scalable method based on novel plasma catalytic reaction [1-4] for directly fabricating narrow GNR arrays with a clear transport gap [5]. Since the establishment of our novel GNR fabrication method, direct conversion of a Ni nanobar to a suspended GNR is now possible. Indeed, GNRs can be grown at any desired position on an insulating substrate without any post-growth treatment, and the wafer-scale synthesis of suspended GNR arrays with a very high yield (over 98%) is realized [6]. The growth dynamics of suspended GNR is also investigated through the systematic experimental study combined with molecular dynamics simulation and theoretical calculations for phase diagram analysis. The improvement of thermal stability of Ni nanobar can be a key to realize the GNR nucleation in our method, which can be given by supplying higher density of carbon plasma to liquid-phase Ni nanobar. The wettability of liquid-phase Ni nanobar against to the SiO2 substrate is also found to be an important factor forming the suspended structure of GNR. It is also revealed that the minimum length of GNR can be decided by the wavelength of Plateau-Rayleigh instability known as a traditional instability of fluid flow. Furthermore, unique optoelectrical property, known as persistent photoconductivity (PPC), is also observed in our suspended GNR devices. By using the PPC, GNR-based non-volatile memory operation is demonstrated. We believe that our results can contribute to pushing the study of atomically thin layered materials from basic science into a new stage related to the optoelectrical applications [7-9] in industrial scale.

Optical-Erasable TiO2 Non-Volatile Memory Using Deep Trap Charges Taewoon Kim1,2, Jung Wook Lim1,3, Seong Hyun Lee1, Jeho Na1, Jiwoon Jeong1, Kwang Hoon Jung1,2, Gayoung Kim1,2 and Sun Jin Yai1,2. 1ICT Materials Research Group, Materials & Components Basic Research Division, Electronics and Telecommunications Research Institute, Daejeon, Korea (the Republic of); 2Advanced Device Engineering, University of Science and Technology, Daejeon, Korea; 3Company of Korea.

Recently, oxide-based metal-oxide-semiconductor field-effect transistors (MOSFETs) have been actively studied for the applications of non-volatile memory devices in transparent and flexible electronic products. Oxide-MOSFETs have much lower off-state leakage current than Si-MOSFETs, allowing low-power memory operation, and further advantages such as good uniformity, low process temperature, and high transmittance in the visible wavelength range. Conventional oxide-based non-volatile memory generally uses positive and negative gate voltage (Vg) pulses to achieve the program and erase states, respectively. However, the n-type nature of most oxide semiconductors makes it difficult to conduct sufficient amounts of holes in the channel oxides, leading to a high power consumption and long erase times; thus input power sources (e.g. light) in addition to voltage are required. In a memory device, the difference between the programming and erasing voltages is known as the “memory window”. In a non-volatile memory, the memory window should be set to secure a sufficient margin of read voltage (V(read)) for stable device operation; wider memory windows can be achieved with more defect sites trapping more charges. However, shallow traps among the defect sites adversely affect device stability. Therefore, it is necessary to selectively exclude shallow trap sites to satisfy both a wide memory window and high device stability.

In this work, we propose TiO2 MOSFET-based non-volatile memory device, employing the deep trap interface (DI) sites as a simple floating gate without tunneling oxide. For the fabrication of TiO2 MOSFET, 80 nm-thick Al2O3 gate dielectric layer on 30 nm-thick TiO2 films were deposited by plasma enhanced atomic layer deposition on a n+ Si wafer which plays a role of back gate. In order to demonstrate performance of TiO2 MOSFET, we measured electrical characteristics of the fabricated devices in the dark and violet light (VL)-irradiated conditions at 25 ºC. For VL irradiation, we used standard LEDs (center wavelength of 400 nm) as a light source with an incident power of 0.13 W/cm². This device demonstrated a high on/off ratio of 103 and a sizable memory window due to deep traps at the interface between Al2O3 and TiO2. Interestingly, irradiation with 400 nm VL could completely restore the program state to the initial state (performing an erasing process) owing to the visible light-sensitive TiO2 channel. Device reproducibility was greatly enhanced by selectively passivating shallow traps using an in-situ H2-plasma treatment. The passivated memory device showed a highly reproducible memory window and on-state current even during a retention bake test at 85 ºC. We expect that our simple-structured TiO2-based non-volatile memory device, which is completely erasable only by light irradiation and shows reproducible and stable operation, will usefully employed in a wide range of future electronic devices.

9:15 AM PM07.05.03
Impact of CMOS TiN Metal Gate Process on Microstructure and Its Correlation with Electrical Properties Pushpendra Kumar1,2,3, Florian Domenge1, Charles Leroux2, Patrice Gergaud2 and Gerard Ghibaudo3; 1STMicroelectronics, Crolles, France; 2CEA-LETI, Grenoble, France; 3Université Grenoble Alpes, Grenoble, France.

TiN metal gate has been introduced in advanced CMOS devices for its advantages such as eliminating Fermi level pinning and phonon scattering, but it also introduces the metal gate granularity due to multiple crystal orientations. This may impact device electrical and physical properties, such as effective
workfunction WF_eff, threshold voltage local variability σV_TH, mechanical stress and sheet resistance. σV_TH might be reduced by reducing the TiN grain size or by obtaining a unique crystal orientation and so we have focused on identifying TiN metal gate process conditions that can achieve this goal. Hence, the impact of RF Physical Vapor Deposition (RF-PVD) parameters, Ar pressure and RF power, on the preferred orientations and size of the TiN crystallites is investigated.

28nm CMOS FDSOI HKMG stack was deposited, consisting of 1 nm SiO2 interfacial layer, 1.8 nm HfSiON High-k layer and 5 nm TiN gate deposited by RF-PVD with combined DC and RF generators. TiN is formed by reactive sputtering of a pure Ti target in a nitrogen-containing ambient of Ar:N2. Ar pressure and RF power were varied over a wide range. The preferred orientations and grain size are determined by X-Ray Diffraction (XRD), in out of plane (0-20) and in-plane configurations respectively. Sheet resistance is measured by 4 probe method and thickness by X-ray-reflectometry (XRR) to calculate TiN deposition rates. Mechanical stress was calculated by applying Stoney’s equation and Ti/N ratio is measured by X-ray fluorescence (XRF).

It is observed that as Ar pressure decreases and RF power increases, average grain size, σTiN <200/>TiN <111>, deposition rate and film mechanical stress increases. For 3 conditions a unique TiN grain orientation is obtained. As the RF power increase and pressure decrease, the number of Ar+ ions and number and energy of sputtered Ti atoms increase. Increased Ti atoms energy enhances crystal growth and favors the preferred orientation <200>, having the lowest energy. Increased Ar+ ions, due to channeling effect, enhances crystal orientation and will re-sputter TiN <111> crystals more than <200>. Increase in Ar+ and Ti number and energy will result in denser films due to peening effect, thus increasing the stress. TiN sheet resistance follows an inverse power law as the grain size is decreased due to an increase in grain boundaries.

EOT and WF_eff were extracted by fitting CV measurements with Poisson Schrödinger simulations for devices with varying EOT. Extrapolation of WF_eff to EOT=0 gives intrinsic TiN workfunction (WF_m) + dipole at SiO2/high-k interface (δ). WF_m change is expected to depend on the % of <200>/(WF_m=4.6eV) or <111> (WF_m=4.4eV). The electrical extraction of WF_m = δ evidences an opposite trend. Our results strongly suggest that WF_m expected shift is hidden by an opposite effect at the SiO2/high-k interface due to the sensitivity of its dipole to TiN process. The Ti/N ratio is playing a major role with a suppression of dipole δ for Ti rich gates.

9:30 AM PM07.05.04

Advanced packaging requires ever-increasing I/O counts which calls for shrinkage in the Cu interconnect dimension while meeting device performance and reliability. In Applied Materials, we are enabling fine line/spacing (L/S) Cu redistribution line (RDL) by scaling the barrier thickness, controlling amount of wet etch critical dimension (CD) loss and controlling undercut, developing plasma surface treatment to meet electrical performance specs, and exploring new material with better barrier property. We demonstrated end-pointed Ti etch process with 10nm Ti barrier thickness to reduce undercut from >300nm to <20nm and extend RDL scaling to sub-2um regime. Step coverage is not compromised with such thin barrier as demonstrated by successful plating on topography features. With end-pointed Cu etch process, we were also able to reduce Cu CD loss from >0.3um to <0.1um and reduce line resistance non-uniformity from >1mOhm to <0.5mOhm. We established the importance of plasma treatment to lower RDL electrical leakage from >1mA to <1nA. Low leakage is critical to minimize device power dissipation.

9:45 AM PM07.05.05

The fabrication of hybridised silicon nanospheres by simplified plasma-enhanced chemical vapour deposition (PECVD) without the need for seed particle injection or microwave plasma has been improved upon by applying a modified multi-layer deposition technique (ML-PECVD). In this, we have incorporated our method for fabricating the hybridised nanospheres with the topical advantage presented by the ML-PECVD method for active functionalisation of the particles within the plasma itself. Additionally, we have improved the active control of nanospheres during plasma formation utilising our proprietary spectroscopic imaging system.

As the physiochemical properties of nanoparticles depend on their size and shape, isolation within a suitable matrix permits single-particle analysis and experimentation, overcoming averaging effects. Following suspension in ethyl acetate, analysis of the multiasblattice ordering was observed by SEM, µRAMAN and plasmonic nanospectroscopy on both crystalline silicon (c-Si) and semiconductor polymer substrates. While c-Si acts as a suitable measurement surface, our interest is aimed at the inclusion of the hybridised nanospheres to flexible opto-electronic devices. To this extent, suitable pairing between the nanosphere and polymer functionalisation states are desired. Typically, this must be done ex-situ of the deposition process, however, our method utilised exchange bias effects with suitable semiconductor polymer substrates within the deposition chamber during deposition. This presents a promising methodology for the rapid fabrication of active opto-electronic materials while removing extensive chemical processing between fabrication layers.

Gas-Surface Reactivity of Vibrationally Excited Molecules—Energetics, Dynamics, and Their Significance in Interfacial Reactivity Arthur Utz;
Tufts University, Medford, Massachusetts, United States.

Vibrationally excited molecules exhibit enhanced reactivity in the gas phase and on surfaces. In high temperature or plasma processing environments where they are abundant, they are potentially important, or even dominant contributors to chemical reactivity. This talk will highlight state-resolved gas-surface scattering experiments that use infrared laser excitation of molecules in a supersonic molecular beam to quantify a molecule's reaction probability as a function of its incident kinetic, vibrational and rotational energy and quantum state. The experiments quantify how effectively vibrational energy promotes a molecule's dissociative chemisorption probability on the surface, and how that efficacy varies with the energy and the character (e.g. bend vs. stretch) of the molecule's vibrational motion. We find that the reactivity of individual molecules is strongly influenced by the dynamics of the molecule-surface collision. Vibrationally mode-selective chemistry, in which reaction probability, S0, depends on the molecule's vibrational motion, and not just its energy, and bond selective reactivity, in which a localized vibrational excitation dictates which bond breaks, are the rule, rather than the exception in our studies of
methylene dissociation on Ni and Ir surfaces. These markedly non-statistical reactivity patterns result from the limited duration of the methane molecule-surface collision, and the resulting constraint on the time available for significant energy redistribution within the reaction complex. A consideration of the rates and pathways for vibrational energy flow within the reaction complex provides a qualitative picture for predicting the extent of non-statistical behavior that might be expected in more complex reactive systems.

The ability to control precisely and independently how energy is partitioned among translational, rotational, and vibrational motion of the gas-phase molecule and surface atom excitation allows to explore chemical reactivity over a wide range of strongly non-thermal conditions. These measurements have proven to be invaluable benchmarks for testing and validating the absolute accuracy of DFT-based electronic structure calculations. Varying surface temperature for a fixed energetic configuration of the gas-phase reagent reveals a dramatic surface temperature enhancement that is most pronounced near the energy threshold for reaction. Coverage-dependent measurements of reactivity show how the surface-bound carbon products of methane's dissociation can initially enhance, and then inhibit further methane activation on Ni(111).

Nonthermal plasma-assisted reaction enhancement mechanism in porous Ni/Al2O3 catalysts (3-mm spherical pellets) in CH4/CO2 conversion was investigated. Dielectric Barrier Discharge (DBD) was employed for this purpose. In the plasma catalysis, carbon filaments were deposited only on the external surface of catalyst pellets, providing the clear evidence that the DBD and catalyst interaction is possible only in the external surface of the pellets: neither generation of DBD nor the diffusion of excited species in the internal micropores is possible. Meanwhile, coke distribution over the pellet cross-section revealed the coke formation in the internal micropores was diminished dramatically by DBD, although plasma and catalyst interaction is limited only in the external surface. We also found that the external surface of catalyst pellets was oxidized exclusively by DBD, forming NiO shell with thickness of ca. 20 micrometers. Ni catalyst was not oxidized in the thermal catalysis regime. Such unique reaction behavior was explained by the catalyst effectiveness factor. The reactivity of plasma generated species is so high that the surface reaction of those species completed at the external surface of pellets: Carbon deposition and oxidation cycle is accelerated by the plasma generated reactive species at the external surface of pellets, while those species do not diffuse towards internal micropores.

According to the molecular beam experiments, vibrationally excited CH4 is known to promote dissociative chemisorption over the metal surface. Although vibrationally excited species have yet to be identified experimentally in the high-pressure nonthermal plasma system, the numerical simulation of one-dimensional streamer type discharge plasma (typical in DBD) predicted that the vibrationally excited CH4 is the most abundant and long-lived species produced by low energy electron impact. Likewise, vibrationally excited CO2 and H2O are expected to promote catalytic surface reactions; nonthermal plasma is the viable and economical approach to generate copious amount of vibrational species at low temperature. Based on these ideas, nonthermal plasma enabled greenhouse gas conversion was diagnosed by temperature programmed reaction spectrometry as well as materials characterization by XRD and Raman spectroscopy. Moreover, carbon deposition and Ni catalyst oxidation behavior was correlated in the plasma- and thermal-catalysis regime, enabling clear insight into the reaction enhancement mechanism induced by nonthermal plasma. The reaction enhancement mechanism were further discussed in relation to vibrationally excited species.

Due to their higher specific surface area, nanoscale structured materials possess excellent optoelectronic properties [De Mello Donegá C, 2014]. Here in our work, we demonstrate the synthesis of nanoscale zinc oxide tetrapods (ZnO-TPs) from zinc metal wire in ambient air using an atmospheric pressure microplasma technique. The ZnO-TPs were characterised for crystal structure (scanning electron microscopy, transmission electron microscopy and x-ray diffraction), chemical composition (x-ray photoelectron spectroscopy) and optical properties (ultraviolet-visible spectroscopy, photoluminescence). The ZnO-TPs consist of tetragonally placed arms each of about 65 nm length and 11 nm diameter; these particles are further classified as wurtzite phase with each arm particularly grown along the (0002) plane containing polar surfaces. The lattice parameters of the crystals were evaluated using Rietveld refinement procedure [Luca Lutterotti, 1999]. The analysis of optical properties shows that the ZnO-TPs exhibit sharp absorption near the ultraviolet region of the electromagnetic spectrum due to direct band electronic transition. Photoluminescence shows a strong ultraviolet emission due to band to band transition and with a weak visible-violet emission due to interface traps or interstitial Zn metals. Phase purity is confirmed by XPS and x-ray crystal diffraction measurements. Overall, the characterization shows that ZnO-TPs crystals are free from its oxygen vacancies. The formation mechanism of ZnO-TPs in the plasma is initially characterized by sputtering of metal atoms from the Zn solid wire precursor. The interaction of the plasma afterglow with the surrounding air contributes to reacting of the plasma product with air oxygen and fast quenching. While nitrogen does not contribute to the chemistry of the ZnO-TPs, there is evidence that it plays a crucial role in determining the quality of nanocrystals produced. We finally demonstrate the applicability of the plasma process in the fabrication of solar cells, where ZnO-TPs were used as the electron transport layer for devices with methyl ammonium lead iodide perovskite as the absorber.

Reference

Plasma chemistry has been the subject of considerable studies due to the intrinsic characteristics brought by highly non-equilibrium state and high reactivity of chemical species. These characteristic properties include ultra-fast reaction time (~10^-4 s), mild reaction condition (ambient pressure and temperature), and rapid start-up/ shutoff. Plasma-catalysis, which combines nonthermal plasma with various catalysts, is based on the bilateral interaction. The potential applications of plasma-catalysis include hazardous VOCs removal, NOx removal, ammonia synthesis, CO2 conversion, and fuel reforming. Many of synergistic effects have been reported by many researcher groups in the past 10 years. However, the degree of enhancements seems to be dependent on the type of combinations (i.e. reactor configuration, power supply, type of catalysts, and operating conditions). In this regard, fundamental studies are necessary to accelerate the broad use of plasma-catalysis in many industrial fields. Our recent study on the time-resolved ICCD imaging of surface streamer provided different nature of streamer depending on the polarity of applied voltage. Especially, a counter-propagating cathode-directed streamer initiated from ground electrode (anode) was appeared. This presentation will cover from the current understanding the interaction of plasma and catalyst to the possible applications in various chemical reactions.

metal-free substrates which eliminates the need for transfer. Additionally, the approach is additive, producing materials wastage and producing materials at the point-of-need including patterned structures.

Two examples of thin film materials will be presented that demonstrate the capabilities of this synthesis approach: hexagonal boron nitride (h-BN) and molybdenum disulfide (MoS2), both of which are layered materials and can be produced atomically thin. To synthesize h-BN, a single-molecular precursor, ammonia borane, is initially prepared as a thin film by spray deposition, spin coating, or ink-jet printing, and subsequently converted in a cold-wall reactor with a planar, atmospheric-pressure dielectric barrier discharge. We performed a systematic study of h-BN growth with plasma-assisted heating and heating alone. Micro Raman spectroscopy shows that the minimum nucleation temperature is lowered from 800 to 500 °C by the addition of a plasma. From the full-width-half-maximum (FWHM) of the E2g Raman scattering peak characteristic of h-BN, we also find that the crystal domain size is larger with a plasma. From capacitor devices, the dielectric properties of the synthesized h-BN are found to be improved with a plasma from a relative permittivity of 2.8 to the near-maximum value of 3.7. To synthesize MoS2, a similar approach of converting its corresponding single-molecule precursor, ammonium tetrathiomolybdate with a plasma has been studied. In this case, a single-step conversion leads to a rough, nanostructured film. Adding a second thermal annealing produces a very smooth (RMS < 0.5 nm) and continuous film. We will discuss potential superior properties of these films over exfoliated and CVD-grown films, as well as preliminary studies of their applications as electrocatalysts and transistor elements.

3:00 PM *PM07.08.01
Microplasma Jet Spray Deposition of Nanostructured Materials for Energy Applications Michael Gordon; Chemical Engineering, University of California, Santa Barbara, Santa Barbara, California, United States.

The ability to synthesize a wide range of nanostructured materials, as well as integrate them into larger systems, is fundamental to the development of next-generation micro- and optoelectronic devices, sensors, and energy harvesting and storage technologies. Toward this goal, we have developed a versatile, plasma spray-like deposition technique, based on flow-through hollow cathode discharges at 10-100 Torr (microplasma jets), that can deposit nanoparticles, dense layers, and structured thin films of crystalline materials on virtually any surface (e.g., conductors, insulators, polymers, fibers, and lithographic patterns). A superionic microplasma jet is seeded with organometallic precursors under reducing or oxidizing conditions to create a directed flux of growth species (e.g., atoms, ions, clusters, and/or nanoparticles) that are subsequently 'spray-deposited' onto the surface of interest at room temperature. A diverse range of nanostructured materials, e.g., metals (Cu, Ni, Pd), oxides (CuO, ZnO, MnOx, RuOx, NiOx, FeOx, CoOx), doped oxides (Fe3Ni, Ni3), and spinels (NiFe2O4), with different morphologies (nanoparticles, dense columnar films, or hierarchical nanostructures, etc.) can be realized with the technique. Applications to be discussed include Fe-doped NiO and Fe3Ni2O for electrocatalysis (OER); NiO and CoOx for supercapacitors; and combining microplasma spray deposition with photolithography and lift-off to create MnOx and RuOx-based microsupercapacitors for on-chip energy storage.

One-Pot Synthesis of Boron Nitride Nanotube/Metal-Ceramic Hybrids by Thermal Plasma Keun Su Kim1, 2, Homin Shin1, Martin Couillard3, Mark Plunkett1, Dean Ruth1, Christopher Kingston1 and Benoit Simard2; 1 National Research Council Canada, Ottawa, Ontario, Canada; 2Mechanical and Industrial Engineering, University of Toronto, Toronto, Ontario, Canada.

Boron nitride nanotubes (BNNTs) are nano-sized rolled-up cylinders of single- or few-layered hexagonal BN sheets. Thanks to their ultra-strong impact resistance and lightweight, BNNT-metal or ceramic nanocomposites are highly promising in the development of advanced hard armours such as anti-ballistic body armours or armoured vehicles1; however, developments of such composites have been significantly hampered by the low reactivity of pristine BNNTs towards metal or ceramic matrices, as well as by the complexity and inefficiency of BNNT functionalization via multistep post-processing. To address this issue, we have developed a new plasma process in which growth of BNNTs and their subsequent surface modification (e.g., doping or decoration) with metal or ceramic nanoparticles occur in a same reactor. The density functional theory (DFT) study was performed first to gain insights into stable structures of BNNT-metal/ceramic hybrids and their reaction stoichiometry. Based on the theoretical predictions, synthesis experiments were conducted with different additive materials such as AlN, TiN, and Cu in order to provide different reactivity to BNNTs. The morphological properties and chemical compositions of the products were assessed by various characterization techniques including SEM, TEM, TGA, FT-IR, UV-Vis, and XRD. The results of optical emission spectroscopy (OES) and 2D thermo-fluid modelling studies will be also presented to discuss the growth mechanism of those hybrid materials in this plasma process.

Growth and Characterization of Nano-Platelet IrOx Films Milena B. Graziano1, Brendan Hanrahan1, Thomas C. Parker2, David Baker1, Bradley Sanchez1, 3; Manuel Rivas1, 3 and Paul Sunal1; 1University of Maryland, College Park, Maryland, United States; 2Aberdeen Proving Ground, Aberdeen, Maryland, United States; 3U.S. Army Research Laboratory, Adelphi, Maryland, United States; 4University of Connecticut, Storrs, Connecticut, United States; 5General Technical Services, LLC, Wall, New Jersey, United States.

Iridium oxide (IrOx) is a well investigated compound with superb physical and electrical properties that have proven advantageous to numerous medical, electrochemical, and microelectronic systems. Its vast applicability is attributed to its electrical and ease of fabrication using common deposition
Cold plasma consists of electrons, ions, excited atoms and molecules, neutral gas species, and UV radiation that occur at low temperatures and can be used to initiate chemical reactions. Often plasma treatment is carried out in high vacuum, low-pressure devices. Vacuum plasma treatment allows plasma particles to achieve large mean free paths and results in very energetic ions and electrons capable of rapid and extreme surface modification and highly successful chemical grafting. However, low-pressure devices are most suitable for batch processing of substrates. They require long pump down times and have a limited volume per batch. Therefore, the integration of these devices into a continuous industrial manufacturing process is not readily achievable. Atmospheric-pressure plasma, as used in this research, allows for the continuous treatment and curing of substrates and transforms an otherwise costly and small-batch technology into a commercially viable approach for high-volume processing. Despite the lower mean free paths of atmospheric plasma systems, proper selection of processing parameters and working gas can be used to successfully induce chemical reactions. These chemical reactions include the polymerization of monomers and their attachment to material substrates. The use of cold atmospheric-pressure plasma to induce chemical reactions eliminates the need for heat, allowing for heat-sensitive materials to be processed and coated with desired functional finishes. These high-performance coatings can add attributes to the finished goods such as high levels of water and oil repellency, photoresistive, and antireflective properties. As such, the use of plasma treatments in various industries, including automotive, electronics, and building materials, is growing rapidly. Efficient plasma polymerization systems are designed to provide a versatile, environmentally friendly, and cost-effective method of surface modification.

**Surface Treatment Against Process Oxidation of Ultra-Thin Silver Films**  
Soroush Hafezian1, Rodolphe Béain1, Ludvik Martinu2 and Stéphane Kéna-Cohen1,  
1École Polytechnique de Montréal, Montréal, Quebec, Canada.

Metallic transparent conductors play an important role in modern optoelectronic devices and as heat-reflectors in energy saving applications. Their high conductivity and high transparency for thicknesses below a few nanometers are crucial for device functionality. In particular, silver thin films demonstrate high sheet conductivity shortly after percolating as well as a neutral transmitted color. Moreover, silver can easily be scaled to coat large surfaces with the help of physical vapour deposition techniques such as magnetron sputtering, providing nanoscale uniformity over a few square meters. Silver, however, is extremely sensitive to reactive oxygen and requires special precautions in reactive plasma-based processes. One strategy for protecting silver thin films is to have a thinner (~3 nm) metallic film (here Ti) as protective layer. As the silver/barrier double-layer is exposed to the O2 plasma, reactive species diffuse through the Ti barrier layer which gradually transforms into a film of TiOx. This metal-oxide layer eventually self-passivates and blocks oxygen diffusion. However, in the presence of oxygen and ultraviolet radiation, if the barrier thickness is not adequate or if the oxidation process is too severe, reactive species can diffuse through the barrier and lead to film failure.

In this work, we characterize the degradation mechanism of silver at the interface with the barrier and present a solution to reduce and prevent the process oxidation of silver in a reactive environment. We first compare the growth of silver films deposited by magnetron sputtering on glass, ZnO and (3-Mercaptopropyl)trimethoxysilane (MPTMS) treated glass. The bare glass and ZnO film represent a case of physisorption with low and high surface energy, respectively. Higher surface energies tend to reduce the mobility of sputtered silver atoms and lead to early coalescence. The MPTMS-treated glass, thanks to the thiol bond formation, represents a case of chemisorption process where the incoming silver atoms are attached to the sulfur available on the surface. Samples are covered with a 2-nm barrier titanium film and exposed to reactive O2 plasma. XPS and TOF-SIMS analysis on the samples reveal that the degradation process starts with the migration of silver through the top titanium barrier. We quantify the degradation by comparing the atomic content of silver present at the very top of the degraded samples. We find that in the case of the ZnO and glass substrates there is a much higher amount of silver migrating through the top barrier to the surface compared to the MPTMS-treated glass. We attribute this difference of migration to the sulfur-silver bonds provided by the MPTMS monolayer.

**Universal High-Resolution Surface-Structuring Technique for Fabricating Complex 3D Nanopatterns by Plasma Process and Its Application in Display Devices**  
Hwan-Jin Jeon1, Department of Chemical Engineering and Biotechnology, Korea Polytechnic University, Siheung-si, Korea (the Republic of).

High-resolution, high-aspect-ratio nanostructure patterning technology has the potential to be of significant value in various fields such as nanoelectronics, optics, biosensors, energy devices, and display devices owing to the optical and electric peculiarities of nanostructured materials. Lots of approaches, which include nanosprint, photo-, interference-soft-edge, colloidal lithography and electron-beam assisted deposition, have been studied to achieve 3D 10-nm-scale features.

Recently, we introduced a new surface nanostructuring technique termed “secondary sputtering lithography (SSL)”, which enables the fabrication of 10 nm-scale ultrahigh-resolution 3D patterned structures of substrate surface with high aspect ratios over large areas by utilizing secondary sputtering phenomena during plasma ion etching process. This new technique utilizes the secondary sputtering phenomenon, wherein target material particles are emitted by accelerated Ar+ ions over a large angular distribution, leading to the fabrication of 10nm scale high-resolution patterns without complicated equipment. We have successfully created various nanostructures on a 10 nm-scale, including ultrathin lines, hole-cylinders, and honeycomb structure. We have also applied ~10nm-scale line patterns with a high aspect ratio to align liquid crystal molecules. High-resolution patterning (~20 nm) of indium-tin-oxide (ITO) surface layers with a high aspect ratio (~10) was successfully carried out without damage to the electrical/optical properties of the ITO, and the patterned ITO could function as a bifunctional conductive alignment layer for liquid crystal devices without a conventional polymer alignment layer fabrication process.

**PM07.09.03**

**VHF Plasma CVD Synthesis of Photochromic ZnO Nanocrystal**  
Hiroshi Kaijyama1, Shin Kuboyama2, Hiroki Uyama3, Atsushi Otomo4, Shuhei Inoue5, Yukihiko Matsusaka1, Keiji Takata2 and Kichiho Uchinoto2, 1Tokushima Bunri University, Sanuki-shi, Japan; 2Tokushima Bunri University, Sanuki-shi, Japan; 3Kyushu University, Kasuga-shi, Japan; 4Hiroshima University, Higashi-Hiroshima-shi, Japan; 5Kansai University, Suita-shi, Japan.

Zinc oxide (ZnO) is a promising material for ultraviolet optical devices, especially in light emitting diodes and lasers. In this study, it is shown that ZnO nanocrystal synthesized by a VHF plasma CVD process is a photochromic material. The structural and electronic properties of PC states are investigated.

We developed a VHF (80MHz) plasma CVD apparatus, which could hold stable plasma with a high electron density and low electron energy at the pressures up to 100 Pa. Because of this, the growth of nanocrystals in a vapor phase is greatly promoted. For the ZnO synthesis, a vapor of Zn(C2H5)2 was introduced to a VHF plasma of a gas mixture of argon (Ar) and oxygen (O2). The ZnO film was formed on an unheated substrate. The film was exposed to UV lights and annealed at various temperatures. An x-ray absorption fine structure (XAFS) measurement was done to analyze the changes of local structures.

The as grown films were transparent. An AFM observation showed that the films consisted of ball-like nanocrystal with a diameter of 60-120 nm. The gas pressure during the plasma synthesis was a few hundred Pa. A substrate was not heated. Therefore, it is plausible to consider that crystal growth completed in a vapor phase.

The transparent film (as grown) changed to dark color by UV (254 nm) irradiation in an ambient air at 300 K. This is the PC transition of ZnO nanocrystal. The PC states were quite stable at the temperatures up to 500 K. At 550 K, however, the color gradually changed back to transparent like as grown films. The transparent film once experienced PC transition again changed to PC states by UV irradiation. However, the PC films annealed at 600 K never
Here we present a facile synthesis of Au@Ag bimetallic nanoparticles using a novel atmospheric-pressure microplasma-assisted electrochemistry. Most widely used method. However, this conventional approach is usually time-consuming and laborious. In our experiments, microplasmas are defined as gaseous discharges formed in electrode geometries where at least one dimension is less than 1mm. Due to surface volume ratio of the core and the shell can produce strong excitation and scattering spectra than pure Ag and Au nanoparticles. Therefore, Au@Ag have attracted considerable attention because of the embedded Ge nanocrystals that results from RF-PECVD growth. In the context of these findings the produced “virtual” Ge substrates for mitigating the problem of polar/nonpolar low-mismatch GaAs–Ge interface, Ge surface baking at 400 C and 700 C for 5min and 10min, respectively has been carried out. The growth of GaAs is based on two-step method. The structural properties of the GaAs layer are studied using HRSEM with EDX and cross sectional TEM. High-Resolution TEM images show high-quality Ge/GaAs interface where no anti domain interfaces are seen. This might be attributed to the embedded Ge nanocrystals that results from RF-PECVD growth. In the context of these findings the produced “virtual” Ge substrates for GaAs growth can provide a robust method for scaleable integration of high performance III-V photovoltaics devices with large area Si wafers.

PM07.09.05
Plasma Enhanced Processing of Ge Films on Silicon as a Virtual Substrate for Lattice Matched GaAs Growth
Ghada H. Dushaq, Ammar Navafleh and Mahmoud Rasras; 1Engineering, New York University, Abu Dhabi, Abu Dhabi, United Arab Emirates; 2Electrical Engineering and Computer Science, Khalifa University of Science, Technology and Research, Abu Dhabi, United Arab Emirates.

Direct growth of germanium (Ge) on silicon (Si) substrate is a key approach for the development of future high-speed photonics and electronic devices. Germanium is an ideal template for growing GaAs due to the lattice mismatch. This will enable the fabrication of tandem solar cell and GaAs based photodetectors on low cost Si platform. While the lattice mismatch between GaAs material and Ge is significantly low compared to GaAs directly on Si, the considerable lattice mismatch of ~4.2% between Si and Ge must be considered to grow high quality Ge layers on Si and enable its use for high quality GaAs growth. Several research groups have reported high quality Ge layers on Si, however, temperatures as high as 650 C were used in performing the epitaxial deposition, also post annealing process is required. Radio Frequency Plasma Enhanced Chemical Vapor Deposition (RF-PECVD) has an advantage of depositing Ge at 400 C. The plasma power in RF-PECVD system acts as another energy source that stimulates energetic ions and free radicals to be deposited on the surface of the wafer at lower temperature. In this work, we present a direct growth mechanism of thin Ge-on-Si films at low temperature using RF-PECVD. These films will be used as a template to initiate GaAs growth for heterojunction solar cells. A two-step temperature technique and different GeH4 flow rates have been employed during the deposition process as the following: step one (low temperature (LT), high rate (HR)) the deposition was performed at 350 °C with 3 sccm flow of GeH4. In step two (high temperature (HT), low rate (LR)) of the Ge deposition the growth is carried out at 500 °C with 1 sccm of GeH4. The results show that this optimized growth limits the defect nucleation or dislocation misfit to 50 nm at the Si/Ge interface. Moreover, the measured threading dislocation density (TDD) of 700 nm thick Ge films is ~1x10^6 cm^-2 which paves the way to achieve high quality growth of GaAs for solar cells. After this, the RF-PECVD grown Ge film on Si is used as a virtual substrate to initiate GaAs growth.

PM07.09.06
Microplasma-Assisted Synthesis of Core-Shell Au@Ag Bimetallic Nanoparticles for SERS Applications
Guan-Jun Chen and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taipei, Taiwan.

Surface enhanced Raman scattering (SERS) is a promising technology for various applications including plasmonic devices. Photo energy generation and conversion, biomedicinal detection and chemical sensing. Gold-Silver core-shell bimetallic nanoparticles are extensively used in SERS, due to the unique localized surface plasmon resonance (LSPR) property [1]. Au@Ag allow tuning the physical and chemical properties through the composition and radius ratio of the core and the shell can produce strong excitation and scattering spectra than pure Ag and Au nanoparticles. Therefore, Au@Ag have attracted great attention in material science, surface science, and biological analysis by SERS. To synthesize this attracted material, seed-mediated growth is the most widely used method. However, this conventional approach is usually time-consuming and laborious. Here we present a facile synthesis of Au@Ag bimetallic nanoparticles using a novel atmospheric-pressure microplasma-assisted electrochemistry. Microplasmas are defined as gaseous discharges formed in electrode geometries where at least one dimension is less than 1mm. Due to surface volume change, microplasmas can be operated stably with an aqueous solution as an electrode at atmospheric pressure. Energetic species formed in the microplasma is capable of initiating electrochemical reactions and nucleating particles in solution without chemical reducing agents [2]. In our experiments
result, we found Au@Ag bimetallic NPs can be a synthesis in a minute time scale. The as-produced samples were extensively characterized by TEM, XRD, Raman, XPS and UV-Vis spectroscopy. We further systematically studied the Raman and XPS spectra to verify the molar ratio of the Au-Ag bimetallic nanoparticle using Rhodamine 6G (R6G) as the Raman probe molecules. The result indicates that the special ratio of Au@Ag bimetallic nanostructure gives significant enhancement of SERS signal than pure Au, Ag nanoparticle in similar size and verify ratio of Au/Ag will induce different SERS performance.

PM07.09.07 Effects of Nitrogen Impurity on Sputtering Growth of ZnO Films on Si(111) Substrates Soichiro Muraoka, Jiahao Lyu, Daisuke Yamashita, Kunihiro Kamatoki, Kazunori Koga, Masaharu Shiratani and Naho Itagaki; Kyushu University, Fukuoka-shi, Japan.

ZnO is a multi-functional material with a distinctive property set and a wide range of existing and emerging applications. We have recently developed a fabrication method of high-quality ZnO films employing magnetron sputtering, “nitrogen-mediated crystallization (NMC)”, where crystal nucleation and the growth are controlled via absorption-desorption behavior of nitrogen “impurities” [1-4]. By utilizing the films grown via NMC as buffer layers, single crystalline ZnO films with atomically flat surface have been successfully fabricated on 18%-lattice mismatched sapphire substrates. Here, we employ 15% lattice mismatched Si(111) substrates, which offer significant advantages in terms of cost, wafer size, and electrical and thermal conductivity, for NMC growth of ZnO and see what happens if nitrogen impurity is added into the growth atmosphere. First, 10-nm-thick NMC buffer layers were deposited on Si(111) substrates by RF magnetron sputtering in Ar/N2 atmosphere. The substrate temperature was 750°C, and the total gas pressure was 0.35 Pa. Next, 1-um-thick ZnO films were fabricated on NMC buffer layers by RF magnetron sputtering in Ar/O2 atmosphere. The substrate temperature was 700°C, and the total gas pressure was 0.70 Pa. We observed NMC method leads to significant change in the grain size of buffer layers. The average grain size derived from AFM images jumps from 9.2 to 24 nm by adding N2 gas into sputtering atmosphere. The analysis on height-height correlation function (HHCF) indicates that N2 addition causes an increase in the lateral correlation length \(\xi\), a measure of migration length of adatoms, from 15 to 29 nm. Such enhanced migration allows adatoms to reach the thermodynamically favored lattice positions, and thus leads to the large grain size as well as to high crystal quality of the films deposited on them. In fact, we observed high quality of ZnO film on NMC-ZnO buffer layer, where the full width at half maximum (FWHM) of (002) rocking curve is 0.67°, one-fourth of that for the films fabricated without buffer layers. The crystal quality has been further improved by introducing 1-nm-thick AlN layers prior to NMC-buffer layer deposition. The FWHM of ZnO film on AlN/NMC-ZnO double-layer is significantly small of 0.50°, attributed to AlN layer protecting Si surface against oxidation and thus promoting epitaxial growth of ZnO on the surface. We believe that the high-quality ZnO films obtained in this study will open up a new avenue for ZnO-based devices on Si substrates that would have a great impact on Si integrated circuit technology.

PM07.09.08 Electrical Property Change of Transparent Doped ZnO by Zn Addition and Desorption Yasuyuki Yamada1, Shuhei Funaki1, Orkut Sancakoglu1,2 and Rei Sugihara1; Shimane University, Matsue, Japan; 1Dokuz Eylul University, Izmir, Turkey.

Doped ZnO films show low electrical resistivity comparable to indium-tin oxide films and is suitable for transparent electrodes. To obtain a high performance in opto-electrical properties, many deposition studies have been conducted. However, optimum conditions have not been revealed because electrical properties vary with deposition method, equipment and even position in a deposited film. This is because crystalline defects that deteriorate electrical properties are not revealed and controlled completely. In a planner magnetron sputtering method, suppression of electrical conductivity happens to the deposition position facing the erosion area on the target. This suppression is caused by the positional distribution of crystalline defects induced by the incidence of high-energy particles coming from the erosion area.

To reveal the critical defect types to affect electrical properties of doped ZnO film, we have studied the property change of the films with different structures that provide different state and amount of Zn vacancy in the crystal after high temperature annealing. Three types of film structures of Ga-doped ZnO (GZO) were prepared by RF magnetron sputtering method at room temperature. One of the types is a simple monolayer of GZO on a glass substrate. Second one is SiO2/GZO layered structure. Third one is a zinc inserted GZO film, SiO2/GZO/Zn/GZO. For the GZO layer deposition, the substrates were placed on a substrate holder parallel to the target. Typical GZO thickness was 200 nm. SiO2 capping layers were deposited also by RF magnetron sputtering with the thickness of 70 nm. Zn metal layers were deposited 6 nm in thickness between two 100 nm-thick GZO layers. GZO monolayer films showed resistivity about 1X104 Ωcm after deposition. As the films annealed at 500°C for 30 min in vacuum, the resistivity decreased due to the improvement of crystalline perfection. However, annealing for longer times and at higher temperatures caused apparent increase of resistivity and decrease of carrier density. On the other hand, SiO2 capped GZO films showed no significant increase in carrier density after long and high temperature annealing. These behaviors indicate that Zn desorption from GZO lattice creates defects that reduce carrier density. Zn inserted GZO films showed slightly decreased resistivity after the deposition and as they were annealed resistivity was further reduced to 3X102 Ωcm. In addition, Zn inserted films exhibited no difference in resistivity between films deposited at center and erosion positions. Increase in carrier density and homogenization in resistivity by the enrichment of Zn atoms in GZO lattice can be explained by Zn vacancy. Inhomogeneous distribution of Zn vacancies existed in the as-deposited films trap electron carriers and decrease of Zn vacancies improves electrical properties. The results obtained in this study contain revealing information on crystalline defects that control properties of doped ZnO films.

PM07.09.09 Catalyst-Free Growth of C-Axis Aligned (ZnO)x(InN)1-x Nanorods by RF Magnetron Sputtering Nanoka Miyahara, Daisuke Yamashita, Daisuke Nakamura, Kazunori Koga, Masaharu Shiratani and Naho Itagaki; Kyushu University, Fukuoka, Japan.

We present catalyst-free growth of (ZnO)x(InN)1-x nanorods on c-plane sapphire substrate by RF magnetron sputtering. (ZnO)x(InN)1-x (called ZION hereafter) is a new semiconducting material, a pseudo-binary alloy of wurtzite ZnO and wurtzite InN [1-3]. This ZION has a tunable band gap over the entire visible spectrum and a high optical absorption coefficient of 105 cm-1, making ZION a promising material for solar cells and light emitting devices. Here, we report for the first time c-axis aligned ZION nanorods where the one-dimensional structures should bring about superior electronic/photonic properties.

ZION films were deposited at 450°C by RF magnetron sputtering on c-plane sapphire substrates. O2, N2 and Ar gases were used and the total pressure was
than 6% O₂ in sputtering atmosphere display resistivity of (7-13) × 10⁻⁴ Ω-cm, carrier concentration of (7.1-11.5) × 10²⁰ cm⁻³ and Hall mobility of (5.5-8.7) cm²V⁻¹s⁻¹, and show marginally superior electrical parameters, just below the critical threshold value of 6% O₂ in sputtering atmosphere. With increase of substrate temperatures display a minimum in reflectance in the range of (1250–1800) nm due to plasma resonance, depends on the carrier concentration. Investigation on Photovoltaic Properties of Nb-Doped MoS₂ Thin Films Grown by Magnetron Sputtering Seyed A. Shahahmadi1,2, Siti Z. Othman2, Puvaneswaran Chevathanth1, Halina Misran1, Md. Akhtaranuzaman1 and Noowish Amji3,2; 1Institute of Sustainable Energy, Universiti Tenaga Nasional, Kajang, Malaysia; 2Electrical Electronic and Systems Engineering, Universiti Kebangsaan Malaysia, Bangi, Malaysia; 3Solar Energy Research Institute, Universiti Kebangsaan Malaysia, Bangi, Malaysia.

In this study, the effect of niobium (Nb) on properties of molybdenum disulfide (MoS₂) thin film absorber layer is investigated. So far, MoS₂ (0.6-20 nm) monolayers have got the most interest for nanoscale electronic devices. However, properties of MoS₂ thin films (> 50 nm) have not been explored in details for photovoltaic (PV) applications. Hence, various films (up to 150 nm) such as undoped MoS₂, MoS₂:Nb (0.05%), and MoS₂:Nb (0.5%) are deposited by radio frequency magnetron sputtering to investigate the usage as PV materials. These films are also subjected to dynamic sulfurization process at 550°C for 90 min to improve the crystallinity and optical properties. Results from field emission scanning electron microscope (FESEM) show similar surface morphology in all samples and the tendency for vertical lamellae growth that represents type-I layered structure. Moreover, it is found that the thickness of the as-deposited samples increased about 50 nm after sulfurization probably due to the volumetric expansion. Structural properties are characterized by grazing incidence X-ray diffraction and it is found that the films exhibit dominant diffraction peak corresponding to (101) plane at 2θ = 33.7 degree, which also points to the lamellae structure as observed earlier in FESEM images. Transmittance and absorbance are obtained by UV-VIS-IR spectrometer in the range of 300–2500 nm. It is found that sulfurization leads to the emergence of a peak at 1062 nm in the transmittance spectra, besides the increase of average transmittance (300-1300 nm) from 30% to 44% for as-deposited MoS₂. The peak position shifts to higher energies (up to 794 nm) as the Nb increases, which is correlated to the changes in band structure. Carrier concentration, mobility, and resistivity are obtained from Hall measurement and n-type semiconducting properties are detected in all samples. Hole concentration drops from 10¹⁴ cm⁻³ to 10¹⁵ cm⁻³ after sulfurization while mobility increases from 0.035 to 22.6 cm²/Vs for as-deposited MoS₂. The increase of Nb reduces the resistivity of the as-grown films from 6.78 to 4.9 Ω.cm and similar trend is also attained for sulfurized MoS₂ films.

Electrical and Optical Studies of Ga-Doped ZnO Films Grown by Reactive Co-Sputtering of Zn and GaAs Shrvan Kumar Appani, Samanth V Rayapati and S.S. Major, Indian Institute of Technology Bombay, Mumbai, India.

Ga-doped ZnO (GZO) films were deposited by reactive co-magnetron co-sputtering of zinc and GaAs (~ 3% of the area of erosion track) in Ar-O₂ mixture. This work focuses on the role of oxygen percentage (4–10%) in sputtering atmosphere and substrate temperature (350 °C to 500 °C) in controlling the electrical and optical properties and investigating free carrier effects in heavily doped GZO films. XRD studies show in all the films display single wurtzite phase of ZnO with nearly complete c-axis orientation and practically negligible strain. The conducting GZO films deposited at 375 °C with less mono-layers have got the most interest for nanoscale electronic devices. However, properties of MoS₂ thin films (> 50 nm) have not been explored in details for photovoltaic (PV) applications. Hence, various films (up to 150 nm) such as undoped MoS₂, MoS₂:Nb (0.05%), and MoS₂:Nb (0.5%) are deposited by radio frequency magnetron sputtering to investigate the usage as PV materials. These films are also subjected to dynamic sulfurization process at 550°C for 90 min to improve the crystallinity and optical properties. Results from field emission scanning electron microscope (FESEM) show similar surface morphology in all samples and the tendency for vertical lamellae growth that represents type-I layered structure. Moreover, it is found that the thickness of the as-deposited samples increased about 50 nm after sulfurization probably due to the volumetric expansion. Structural properties are characterized by grazing incidence X-ray diffraction and it is found that the films exhibit dominant diffraction peak corresponding to (101) plane at 2θ = 33.7 degree, which also points to the lamellae structure as observed earlier in FESEM images. Transmittance and absorbance are obtained by UV-VIS-IR spectrometer in the range of 300–2500 nm. It is found that sulfurization leads to the emergence of a peak at 1062 nm in the transmittance spectra, besides the increase of average transmittance (300-1300 nm) from 30% to 44% for as-deposited MoS₂. Influence of Flash Lamp Annealing on Ga-Doped ZnO Films Reis Susiriya, Yasuji Yamada, Arisa Sakaguchi and Shuei Funki; Shimane University, Matsue, Japan.

Zinc oxide (ZnO) attracts many attentions to be studied as an oxide semiconductor. Resistivity of ZnO semiconductor added with Ga or Al is almost equal to Sn doped In₂O₃ (ITO). Recently, we have been studying electrical properties of Ga doped ZnO (GZO) films deposited by radio frequency (RF) magnetron sputtering at room temperature and revealed that annealing at high temperatures for 30 min improves electrical properties. As annealing temperature increases, mobility of GZO films were increases gradually. Carrier concentration increases as annealing temperature increases up to 350°C,
however, it decreases at higher temperatures than 400°C. While longer annealing time reduces carrier density, shortening the annealing time in the order of a minute at a high temperature increases carrier density, resulting in electrical resistivity lower than the 350°C annealing for 30 min. From these behaviors of carrier density, we have concluded that the reduction of carrier density is caused due to zinc atom desorption from the GZO lattice. Therefore, it is very curious to know the effect of extremely short time annealing on carrier density and resistivity. Flash lamp annealing technique is used for very short time of annealing, as short as milliseconds, often used in Si semiconductor industry. We applied this technique to the annealing of transparent GZO films as a post-annealing. GZO films with thickness of 200 nm were deposited on quartz glass substrates at room temperature by RF magnetron sputtering. These films were annealed by using a xenon lamp with the pulse width from 1 to 5 milliseconds in the ambient atmosphere. Electrical properties and crystallinity were measured by van-der-Pauw method and XRD measurement. By the flash lamp annealing in appropriate pulse width and power, carrier density of the films increased and mobility was unchanged, resulting in decrease of resistivity. The change of properties of the GZO film by flash lamp annealing is different from conventional furnace annealing. The carrier density of GZO film decreases at higher temperatures than 400°C by a conventional furnace. On the other hand, it does not decrease by the flash lamp annealing as the power increases until the films are caused fatal damage. In conclusion, short time is slightly higher than those annealed for typical annealing time using conventional heating equipment.

Structural and Mechanical Characterization of Amorphous Carbon-Silica Thin Films Deposited on Stainless Steel Substrates by PECVD Neithoth J. Stand Figueurete1, Erika Abigail Ochoa Becerra1, Leonardo Mathias Leidens2, Carlos Alejandro Figuereot2, Fernando Lazaro Freire J3 and Marcelo Eduardo Huguenin Maia da Costa41; 1Physics, Pontifícia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil; 2Universidade de Caxias do Sul, Caxias do sul, Brazil.

Nowadays, various materials are being studied, for instance, diamond like carbon (DLC) which has properties such as low friction coefficient, high hardness, mechanical wear resistance, optical transparency and high electrical resistivity, these properties can be modified used other elements such as Si, N, O, etc. The DLC thin film is very useful as a protective coating on metallic pieces such as stainless steel, but there is an issue: the low adhesion of the DLC on this type of substrate, caused by its high internal stress and low thermal stability.

Our work is about the study an amorphous carbon-silica thin films used an organosilicon, this precursor was deposited using a rf-PECVD (radio frequency plasma enhanced chemical vapor deposition) on steel surface (ISO316L). The precursor was hexamethyldisiloxane (HMDSO) in its liquid state at room temperature and atmospheric pressure.

Those films were deposited in several self-bias and two different substrate temperatures (200°C, 300°C, at room temperature there was no deposition). The deposition pressure was 2.6 Pa and they were characterized by Raman spectroscopy, X-ray photoelectron spectroscopy, Fourier transform infrared spectrometry, profilometer measurements and nanoindentation.

Our results indicate that the temperature plays an important role in the adhesion of the amorphous carbon-silica thin film with the steel surface, although at temperatures lower than 150°C the adhesion is poor. The films deposited at 200°C and 300°C with different self-bias had an excellent adhesion, the spectra Raman showed that this films are amorphous and with X-ray photoelectron spectroscopy we noticed, that the percentage of Si-C and C-C binding increase as the self-bias. The hardness of these films were of the order of 20GPa.

PM07.09.14

Role of Organosilicon Films Deposited by PECVD Protecting Polypropylene Against Photodegradation Walter R. Waldman1, Amanda d. de Freitas7, Felipe Fernandes8, Elidiane C. Rangel9, Nilson C. Cruz10, Adriana O. Silva11 and Joyce Araujo12; 1Federal University of São Carlos, Sorocaba, Brazil; 2University of São Paulo State—UNESP, Sorocaba, Brazil; 3Materials Metrology Division, National Institute of Metrology, Quality and Technology, Duque de Caxias, Brazil.

The sensitivity of polymers to photodegradation when exposed to the weather limits their options for outdoor use and reduces their shelf life. The deposition of thin films of organosilicon by plasma on polymers can influence its resistance to photodegradation without interfering in aspects such as color or brightness in bulk properties due to the transparency and nanometric dimension of these films. Polypropylene samples were coated with organosilicon films by plasma-enhanced chemical vapor deposition (PECVD). First, a five-minute pre-treatment with oxygen gas, pressure 9 Pa, radiofrequency 13.56 MHz and power of 50 W. Subsequently the organosilicon films were deposited for 30 or 60 minutes at a pressure of 6 Pa, an atmosphere of 50 % of O2 and 50% of HMDSO, radio frequency 13.56 MHz and power 80W. We exposed the samples to a UV-C light of fluorescent, germicidal, 15W power, maximum emission at 254 nm wavelengths, at 48, 96, 144 and 192 hours. We characterized the samples by MEV, FTIR, UV-Vis, XPS, profilometry and contact angle goniometry.

FILMS were homogeneous and continuous with a thickness between 300 and 550 nm and roughness between 20 and 30 nm. FTIR and XPS measurements after degradation showed that there was no difference between pure polypropylene and polypropylene coated with organosilicon films in the formation of indicators for polypropylene photodegradation, such as hydroxyls and carbonyls. It is clear that the organosilicon film did not offer photoprotection against the auto-oxidation cycle, so we expected the decrease of molar mass by the chain scission, consequent increase of the surface crystalline domains and formation of cracks, which compromise the mechanical properties making the material fragile. However, Scanning Electron Microscopy (SEM) results show that while fissures of virgin polypropylene have a width of 3.5 to 5 micrometers and a length of several millimeters, the polypropylene coated with organosilicon films had cracks with a width of 0.5 to 1 micrometer and length of 2 to 5 micrometers. Along to the fact that the organosilicon film keeps adhered to polypropylene during the photodegradation period, we conclude that the organosilicon film mechanically held the surface cohesion of the polymer material, limiting the crack propagation, despite the oxidation reactions of the polymer. This is, to our knowledge, the first observation of mechanical stabilization of polymers by thin films deposited in plasma. This role of the organosilicon thin film deposited on polypropylene can allow the development of protections for polymers exposed to the weather with benefits as the increase of the useful life and a smaller detachment of photodegraded layers, diminishing the environmental impact by the minor production of secondary microplastics.

PM07.09.16

Plasma Surface Treatment as an Important Tool for Polymer Applications Pericles L. Santana, José Roberto R. Bortoleto, Elidiane C. Rangel, Nilson C. Cruz and Steven F. Durrant; State University of Sao Paulo, Sorocaba, Brazil.

We demonstrated in this work, the use of plasma immersion techniques as an important tool for polymer surface modification. The treated polymers found out a lot of applications, one it is possible to change a thin layer of its surface keeping the bulk properties. Among the properties changed by plasma immersion techniques, it was analyzed the surface topography by contact angle measurements, surface morphology evaluated by Atomic Force Microscopy, the transparency at visible range using a UV-Visible-nxt Infrared Spectrometry and the barrier properties against water vapor measured by gravimetric method. The major results shows a selective surface physico-chemical properties being possible to obtain, hydrophobic or hydrophilic behavior, appearing smooth or rough surfaces, increase or loss of transmitted light, presenting an increase of barrier properties, depending on the plasma composition and technique used, when the temperature can be controlled during the processes. The quantitative measurements exhibit low or high values of contact angle, (Wettability), Surface roughness (Morphology), and Optical transmittance (Transparency) in the visible range. In most cases, the increase of barrier properties measured by gravimetric method is important for food packaging applications and optical devices, for example. Other applications can be
considered for the treated polymers such as: biocompatibility, adhesion and medical applications.

PM07.09.17
Ammonia (NH₃) Gas Detection Based on Tin-Nitride Chemi-Resistive Sensor Teena Jangid and G. M. Rao; Indian Institute of Science, Bangalore, India.

Tin-nitride has not received the experimental attention given to similar IV-Nitrides such as Si₃N₄ and Ge₃N₄. Although Sn nitride has semiconducting properties, suitable for micro-electronic and optoelectronic devices, large disparity in the atomic radii of N and Sn poses a challenge in obtaining good quality tin-nitride films. In this study tin-nitride thin films were prepared on glass and Si substrates, by reactive radio frequency magnetron sputtering of metallic tin target (3" diameter and 3 mm thick) in nitrogen gas ambient. Process parameters such as substrate temperature, target-substrate distance, N₂ gas pressure and RF power were varied in a systematic way, to find-out best suitable combination of these parameters for growth of pure poly-crystalline tin-nitride films. Deposited films were characterized for their crystalline structure and surface morphology by X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM) and results revealed that pure tin-nitride films can be grown at 600°C substrate temperature, 15 W RF power in pure nitrogen gas ambient, if target-substrate distance is fixed at 10 Cm.

To date, no work has been carried out on gas sensors, using tin-nitride as the sensing material for NH₃ gas. Chemi-resistive gas sensing characteristics of tin-nitride film (~60 nm thickness) deposited at optimized process parameters, were investigated for NH₃ in air at room temperature, as a function of gas concentration (10–70 ppm). Upon exposure to NH₃, the electrical resistance of the tin-nitride film was found to decrease. The sensor exhibited low base line drift and high sensitivity to NH₃ gas at concentrations as low as 10 ppm with fast response and recovery time at lower concentrations. The sensor exhibited a sensitivity of 0.065 (at 10 ppm) to 0.3 (at 70 ppm), recovery of 4 sec (at 10 ppm) to 23 sec (at 70 ppm), and recovery of 6 sec (at 10 ppm) to 23 sec (at 70 ppm) for NH₃. The NH₃ sensing mechanism can be explained on the basis of the depletion of chemisorbed oxygen at the film surface.

PM07.09.18
Dielectric and Ferroelectric Behaviors of Modified PZT Thin Films Synthesized by Pulse Laser Deposition Mohan K. Bhattacharji¹, Alvaro Instan¹, Sita Dugù¹, Pawan Kumar² and Ram Katiyar¹; ¹Physics, University of Puerto Rico, Rio Piedras, San Juan, Puerto Rico, United States; ²Physics, Gurukula Kangri University, Haridwar, India.

We synthesized highly oriented 0.90[Pt(Zr₀.₅₃Ti₀.₄₇)₀.₁₀LaₓSc₁₋ₓ]O₃-δ, where 0 ≤ x ≤ 0.6 thin films on La₀.₆₇Sr₀.₃₃MnO₃ (LSMO) coated MgO (100) substrates utilizing laser ablation process in oxygen atmosphere. We optimized thin films deposited at a substrate temperature of 650°C using KrF excimer laser of wavelength, λ = 248 nm, f = 5 Hz and energy/pulse 270 mJ, and annealed at 700°C for half an hour in an oxygen atmosphere. The orientation of the thin films was examined by x-ray diffractometry. We carried out elemental analysis of thin films by high resolution X-ray photoemission spectroscopy (XPS). The morphology and surface roughness of thin films were analyzed by Atomic force microscopy (AFM). The dielectric measurements were conducted on LSMO/PLZTS/Pt metal-ferroelectric-metal capacitors using impedance analyzer as a function of temperature (100-600 K) and frequency (10-10³ Hz). The ferroelectricity of thin films was probed by hysteresis measurements. High dielectric constant, low losses and high remnant polarization of thin film capacitors are suitable characteristics for applications in electronic devices.

In Situ Stress Measurements of W and Nanocrystalline Nanotwinned Cu Deposited by HiPIMS Alison Foregall, Swannee J. Shin and Yinnmin Wang; Lawrence Livermore National Laboratory, Livermore, California, United States.

High power impulse magnetron sputtering (HiPIMS) is an emerging method for the deposition of thin films. Pulsed power applied to a sputtering target at a low duty cycle and high power density generates a dense plasma with a high percentage of sputtered ions. The resulting films have improved properties of adhesion, hardness, density, and uniformity compared to films deposited with traditional magnetron sputtering. The technique also shows potential in synthesizing advanced microstructures such as nanocrystalline nanotwinned films. In-situ stress measurements have been performed on HiPIMS W and nanocrystalline nanotwinned Cu and contrasted with DC sputtered films under similar processing conditions, followed by characterization and microstructure analysis of the resulting films.

LLNL-ABS-753116. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. The authors acknowledge the support of LDRD program (17-ERD-048) at LLNL.

Laser Ablation of Molybdenum foil Immersed in Precursor Solution Mostafa Mozael, Bernard Kear and Stephen D. Tse; Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Titanium dioxide belongs to the transition-metal oxide family and forms several polymorphs, including anatase (tetragonal), brookite (orthorhombic) and rutile (tetragonal). In comparison with other polymorphs, anatase-TiO₂ is preferable for solar cell applications because of its high electron mobility, low dielectric constant, and low density. The main drawback is that it does not absorb well visible light. In this work, a novel method is used to synthesize amorphous molybdenum-doped-TiO₂ nanoparticles, which upon subsequent post-annealing, transform into nanocrystalline structures. The resulting nanoparticles display photocatalytic activity, which is improved after doping, in comparison to that for undoped nanoparticles. Amorphous Mo-doped-TiO₂ nanoparticles are synthesized using pulsed-laser decomposition of a molybdenum foil immersed in liquid titanium tetraisopropoxide (TTIP). Interaction between the focused laser beam and the Mo substrate generates a submerged-plasma, where vaporization of the Mo substrate along with decomposition of the liquid precursor combine to produce Mo-doped TiO₂ nanoparticles upon quenching by the surrounding unreacted liquid precursor. The as-synthesized nanoparticles have non-crystalline or amorphous structures, primarily because of rapid condensation and quenching of vaporized species from the plasma-reaction zone. Interestingly, upon subsequent heat treatment in air or oxygen, starting at ~400°C, transformation to the more stable anatase-TiO₂ phase occurs, but doped with molybdenum. Initial results show that Mo-doped anatase TiO₂ exhibits a higher UV and visible photochemical activity than that for undoped anatase-TiO₂. Heat treating the nanopowders were investigated in this work to study the effect on crystal structure of TiO₂ after doping with molybdenum ions. It is notable that the phase transformation from anatase to rutile of Mo-doped TiO₂ samples is delayed a certain temperatures, implying that the molybdenum may help to stabilize the anatase phase.

PM07.09.21
Micro-Plasma Based Enhancement in Dielectric and Piezoelectric Properties of ZrO₂ and BaTiO₃ Based Multifunctional Composite Thin Films by Surface Modification—Comparison of Plasma Regimes and Materials Characterization Using Corona Discharge Harlavnreet Brar¹, Walker Tuff², Saquib Ahmed³, Edbertho Leal-Quiroz³ and Sankha Banerjee¹; ¹California State University, Fresno, Fresno, California, United States; ²Mechanical Engineering, Buffalo State College, Buffalo, New York, United States; ³Mechanical Engineering, University of California, Merced, Merced, California,
Atmospheric pressure and ambient temperature based micro-plasmas have been used in polarization and alignment of dipoles in ferroelectrics. The same phenomenon can be used to enhance the surface energy and surface characteristics of composite multifunctional thin films by means of surface modification. The current work involves the use of dielectric barrier and corona discharge based atmospheric micro-plasmas to treat ZnO-Epoxy-BaTiO3 nano-composite flexible thin films towards enhancement in electrical, dielectric and piezoelectric properties of these composites. The ZnO volume fraction is varied from 1-10%, while the BaTiO3 volume fraction is held constant at 40%. Both voltage driven (stable) and current driven (pulsed) corona discharge regimes are identified and used to process the thin films. The voltages in the stable regimes are varied from 8 – 11 kV, while the current is held constant around 0.01 mA. The current in the pulsed regime is varied from 0.05 – 0.1 mA and the voltage is held constant around 9 kV. The surface properties are characterized by multi-point probe measurements to map and analyze the effect of the different plasma regimes. The composite thin films are also tested for their bulk dielectric, impedance, electrical and piezoelectric properties. The effects of the different plasma regimes on the surface micro-structure are analyzed using a scanning electron micrographs and energy-dispersive x-ray spectroscopy.

PM07.09.22
Synthesis of Nanoscale Optical Multilayer Coatings via Reactive Magnetron Sputtering Chelsea D. Appleget and Andrea Hodge; Aerospace and Mechanical Engineering Department, University of Southern California, Los Angeles, California, United States.

Optical multilayers are comprised of nanoscale layers, where the layers are arranged to alter the way the material reflects and transmits light. The interplay of these nanolayers increases the potential for novel combinations of properties, including transparency and strength. These characteristics are important for applications that require light penetration for function but a robust barrier for protection. For these reasons, optically transparent multilayers are promising materials because they offer extraordinary strength, hardness, heat resistance, and most importantly, transparency in both the UV/Vis/NIR wavelengths.

A series of optical nanomultilayers were synthesized using sequential DC and RF reactive magnetron sputtering. The nanomultilayers were designed using predictive methods for maximized optical transmittance, and the experimental results were compared with calculated transmittance values. The effects of deposition parameters were examined in order to understand their influence on the interface, microstructure, mechanical deformation and light propagation of the films. As-sputtered layer roughness, interfaces, and texture were characterized using SEM, TEM, and XRD. Overall, this work focuses on reactive magnetron sputtering of multifunctional nanoscale multilayers, and the effect of the as-deposited microstructure on resulting mechanical and optical properties is discussed.

PM07.09.23
Iron Oxide-Hydroxide Photovoltaic Nanomaterials Synthesized by Atmospheric Micro-Plasma Ayasha Shanmuki, Marieme Ndaw, Sz-Chian Liou, Sabir Pokharel, Mobolaji Zondode, Saroj Pramanik, Jiang Li, Abdellah Lisfi, Yongle Pan and Yucheng Lan; 1Department of Physics and Engineering Physics, Morgan State University, Baltimore, Maryland, United States; 2Department of Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; 3Department of Biology, Morgan State University, Baltimore, Maryland, United States; 4Department of Civil Engineering, Morgan State University, Baltimore, Maryland, United States; 5\( ^{\oplus} \) U.S. Army Research Laboratory, Adelphia, Maryland, United States.

With the increasing global energy demand and diminishing fossil fuel reservation, renewable and environmental-friendly sustainable energy is interested in the past years. Solar photovoltaic technology is a promising way to collect solar energy into electricity directly. Iron oxides and hydroxides are one kind of candidate materials for photovoltaic materials because of their abundance on earth and chemical stability in aqueous media. Here, iron oxide-hydroxide was synthesized in aqueous solutions by the atmospheric micro-plasma. The hydroxide powders were characterized by X-ray powder diffraction, transmission electron microscopy, Raman scattering, and UV-vis spectroscopy. The effects of pH values, electric fields, and synthesis temperatures etc were systematically studied to understand the morphology, crystallinity, magnetic property, band-gap, and UV-visible light absorptions. The plasma reaction mechanism was discussed. The as-synthesized nanomaterials were further fabricated into dye-sensitized solar cells and their photovoltaic properties were investigated.

PM07.09.24
Controllable Plasma Based Synthesis of MoS2 for Optoelectronic Applications Dipanjan Nandi, Dhvanini Gudi, Xinsong Lin, Andrea Sedgwick, Manisha Gupta and Jianin Fan; 1Electrical and Computer Engineering, University of Alberta, Edmonton, Alberta, Canada; 2Centre for Oil Sands Sustainability, Northern Alberta Institute of Technology, Edmonton, Alberta, Canada; 3Department of Electrical and Computer Engineering, University of Alberta, Edmonton, Alberta, Canada.

Recent advancement of two dimensional (2D) materials paves new avenues for potential optoelectronic and nanotechnology applications. Advancement in molecular biology, atomic and molecular physics demands new techniques to explore the atomic level features of different 2D materials as these materials have exciting optoelectronic properties [1, 2]. Mechanical exfoliation and chemical vapor deposition (CVD) are two well-known techniques for MoS2 synthesis. Monolayers of MoS2 are attached with van der Walls forces and can hence be exfoliated easily. However, it is difficult to control the structural parameters such as size, shape, and thickness of the exfoliated MoS2 flakes. CVD technique used for synthesis of good quality MoS2 crystals lacks in in-situ thickness control. Pulsed laser deposition (PLD) is a well-established laser plasma based material growth technique to maintain good stoichiometry for complex compound materials with good control in thickness and repeatability.

In this work, PLD technique is used for growing large area homogeneous MoS2 thin films for nanoscale optoelectronic applications. This study focuses on the optimization of the PLD growth parameters for obtaining high-quality uniform large area MoS2 thin films on quartz, sapphire and SiO2/Si substrates and characterizing the physical properties. In this work, a pulsed KrF (248 nm, 15 ns, 10 Hz) laser is used for ablation of the 99.9% pure MoS2 target. Major parameters influencing the quality of MoS2 thin film like the laser fluence, target-substrate distance, substrate material and temperature along with the ambient gas pressure will be optimized to obtain thin films with high crystallinity and mobility.

Initial growths at different temperatures (room temperature to 850°C) indicate higher crystallinity at higher temperatures like 700°C to 850°C. Also, we have been able to control the growth time to obtain 2-3 monolayer MoS2 thin films, which have been confirmed by the Raman peaks at 382.1 cm\(^{-1}\) and 404.9 cm\(^{-1}\). Initial measurement at room temperature shows electron mobility of 0.19 cm\(^2\) V\(^{-1}\) s\(^{-1}\) for ~30 monolayers. Metal-oxide-semiconductor capacitor will be fabricated to calculate the doping concentrations and Hall measurements will be performed to calculate the carrier mobility. Material, optical and electrical characterization of the optimized MoS2 thin films grown using PLD will be presented. Future prospects of this work is to fabricate nanoscale field effect transistors on flexible substrates for flexible electronic applications.

Methods are widely used to synthesize ATO nanocrystals. However, to meet the electronic conductivity requirements, post-synthesis anneal treatments are required to activate the electron donors and increase the conductivity of ATO nanocrystal assemblies prepared using liquid-phase techniques, which may adversely affect the surface area and size distribution of the material. In this work, we report on our efforts to synthesize monodispersed, conductive ATO powders with respect to size and core-shell structure formation will be discussed in details in conjunction with TEM, S/TEM, VSM and XRD results.

Non-equilibrium atmospheric pressure plasma has emerged as a new platform technology for the synthesis/surface engineering of various nanomaterials. When interacting with water, a high density of gas phase plasma electrons become solvated in the liquid, creating a rapid cascade of transient non-linear chemical reactions and highly reactive radicals. As plasma induced species and reactions propagate through the liquid, they are interrupted at solid surfaces, leading to energetic final reactions. In this work, we deployed a direct current (DC) room temperature atmospheric pressure plasma (APP) for the in situ synthesis of gold nanoparticle/nanocarbon (AuNP/NC) hybrid structures in aqueous solutions. More specifically, carboxyl functionalized multi-wall carbon nanotubes and graphene oxide nanosheets have been decorated with different sized AuNPs through manipulating the gold salt (HAuCl4) precursor concentration in the aqueous mixture. UV-vis spectroscopy and zeta potential analysis suggested that the bonding between the [AuCl4] complex and nanocarbons carboxyl functional group took place prior to the APP processing. These binding sites facilitated the preferential nucleation and growth of AuNPs through the APP induced liquid chemistry. The AuNP/nanocarbon hybrids also demonstrate enhanced Raman scattering and greater photothermal conversion efficiency under the irradiation of NIR laser, hence may hold great potential in future multi-modal cancer treatment involving bio-imaging and hyperthermia therapy.

For electrochemical applications, metal-oxide materials have attracted research interest as alternative electrode materials for reactions occurring at positive potentials in the presence of water. Often, these metal-oxide materials function as an electrically-conductive support for a noble metal catalyst, and therefore must have very high specific surface area and uniform distribution of the particles. Among thermodynamically stable metal-oxide materials, antimony-doped tin oxide (ATO) stands out with its combination of: 1) high electrical conductivity by incorporation of suitable Sb doping, 2) high chemical stability over a wide range of pH values and reduction potentials, and 3) abundant constituent elements. In liquid phase, sol-gel and colloidal methods are widely used to synthesize ATO nanocrystals. However, to meet the electronic conductivity requirements, post-synthesis anneal treatments are required to activate the electron donors and increase the conductivity of ATO nanocrystal assemblies prepared using liquid-phase techniques, which may adversely affect the surface area and size distribution of the material. In this work, we report on our efforts to synthesize monodispersed, conductive ATO nanocrystals through a single-step low temperature plasma growth method without any post treatments. Precursor vapors of tin and antimony were fed into a radiofrequency, flow-through low temperature plasma reactor. ATO nanocrystals were formed in plasma by reacted precursor vapors. Thin films comprised of ATO nanocrystals were then immediately deposited by inertial impact deposition of the aerosol resulting from plasma synthesis. A variety of methods were utilized to characterize the resulting materials, and determine properties such as film thickness, porosity, nanocrystal size, and elemental composition. Local electron concentration and mobility within the nanocrystals were investigated by Fourier-transform infrared (FTIR) absorption spectroscopy. Hall effect was used to characterize longitudinal electrical transport in the thin film. The nanocrystal growth mechanism in the plasma will be discussed with a focus on antimony dopant incorporation, and the effects of nanocrystal size on the transport properties of ATO thin films will be presented in this work.

For electrochemical applications, metal-oxide materials have attracted research interest as alternative electrode materials for reactions occurring at positive potentials in the presence of water. Often, these metal-oxide materials function as an electrically-conductive support for a noble metal catalyst, and therefore must have very high specific surface area and uniform distribution of the particles. Among thermodynamically stable metal-oxide materials, antimony-doped tin oxide (ATO) stands out with its combination of: 1) high electrical conductivity by incorporation of suitable Sb doping, 2) high chemical stability over a wide range of pH values and reduction potentials, and 3) abundant constituent elements. In liquid phase, sol-gel and colloidal methods are widely used to synthesize ATO nanocrystals. However, to meet the electronic conductivity requirements, post-synthesis anneal treatments are required to activate the electron donors and increase the conductivity of ATO nanocrystal assemblies prepared using liquid-phase techniques, which may adversely affect the surface area and size distribution of the material. In this work, we report on our efforts to synthesize monodispersed, conductive ATO nanocrystals through a single-step low temperature plasma growth method without any post treatments. Precursor vapors of tin and antimony were fed into a radiofrequency, flow-through low temperature plasma reactor. ATO nanocrystals were formed in plasma by reacted precursor vapors. Thin films comprised of ATO nanocrystals were then immediately deposited by inertial impact deposition of the aerosol resulting from plasma synthesis. A variety of methods were utilized to characterize the resulting materials, and determine properties such as film thickness, porosity, nanocrystal size, and elemental composition. Local electron concentration and mobility within the nanocrystals were investigated by Fourier-transform infrared (FTIR) absorption spectroscopy. Hall effect was used to characterize longitudinal electrical transport in the thin film. The nanocrystal growth mechanism in the plasma will be discussed with a focus on antimony dopant incorporation, and the effects of nanocrystal size on the transport properties of ATO thin films will be presented in this work.

Directed Plasma Synthesis of TiO2 Nanopatterning for Templated Growth and Alignment of Au and Alloyed Nanoparticles Ming Kit Cheng, Brandon J. Holybee, Akshath R. Shetty and Jean Paul Allain; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.
TiO₂ has been an important semiconductor for optical applications including: photovoltaics and photocatalysis, due to favorable properties such as wide band gap, chemical stability and low cost. Recently the incorporation of photonic crystal (PC) structures and noble metal nanoparticles (NPs) on the free surfaces have been carried out to exploit the photonic and plasmonic resonance in enhancing absorption of a broader sunlight spectrum. The optical performance can be further improved if they can be coupled. A versatile processing synthesis approach that can control the shape, size and alignment of NPs to scale is needed to maximize the coupling. Directed low-energy plasma and ion-beam synthesis is a promising technique to induce complex nanopatterns such as ripples on various material surfaces. These nanopatterns can then act as a template for the growth and alignment of NPs with high areal density at nanometer scales. Ions extracted from plasma can also modify the surface chemistry and wettability, which mediates NP growth kinetics and adhesion onto the surface. However, few research focuses on plasma-based nanosynthesis on TiO₂ despite its wide usage, unlike other widely-used materials such as Si. Therefore, it is necessary to first examine the parameters necessary to nanopattern TiO₂ via plasma nanosynthesis. Moreover, when dealing with a non-flat surface with PC structures, additional factors such as non-uniform sputtering rate across the surface and shadowing effects by the structures have to be examined.

We were able to induce periodic ripples with wavelengths and amplitude varying between 14-57 nm and 0.9-3.0 nm respectively on a 100 nm thick TiO₂ film coated on a polymer substrate with 1D diffraction gratings via Ar⁺ and O₂⁺ irradiation at an oblique angle and varying fluence. The photonic resonance peak of the substrate was blue-shifted from 860 nm to as low as 838 nm. In a particular case in which the beam orientation is oblique relative to the gratings, an additional peak about 40 nm higher than the primary one appeared. Moreover, while both Ar⁺ and O₂⁺ can nanopattern TiO₂, Ar⁺ created oxygen vacancies and reduced the oxide while O₂⁺ suppressed its formation. Ordered ripples also appeared at a lower fluence with less defects when using O₂⁺. Our goal is to utilize these ripples for a templated NP growth by glancing angle PVD, by exploiting the shadowing effect by the ripples to facilitate nucleation and NP alignment. We will investigate the ability to tune the NP size, shape and spacing and its plasmonic properties by varying the ripple dimensions and deposition parameters, in order to achieve broadband absorption and coupling with photonic resonance. We will also examine whether creating or suppressing oxygen vacancies is more beneficial to NP growth. For the composition of the NPs, we will not only examine conventional Au NPs, but also novel metallic alloy NPs that is cheaper, more sustainable and absorbs light more efficiently.

Nanocomposite Thin Films Obtained with Cold Atmospheric Pressure Plasma Processes
Jacopo Profili and Luc Stafford; Université de Montréal, Montreal, Quebec, Canada.

In the last decade, many efforts have been made for the understanding and the analysis of nanocomposite thin films. The new properties created by these materials open a wide range of possibilities for new industrial applications. Different physical and chemical advanced processes are used to develop these products. Among them, low plasma pressure processes have been studied since Philips’s work in 1982. Today, the desire to reduce production costs and environmental impacts of the manufacturing process allowed the study of new plasma approaches at atmospheric pressure. These systems offer the possibility to reduce the amount of precursor and favor the process scale-up in a production line. Recently, some researchers have demonstrated the possibility to use colloidal suspensions as precursors for the synthesis of nanocomposite thin films in atmospheric pressure dielectric barrier discharge (DBD). This approach broadens the chemical range of obtainable nanocomposites because of the large variety of commercially available suspensions. Through this work, we aim to highlight the current understanding of the process and the remaining scientific challenges for the synthesis of a homogeneous distribution of chemical phases with plasma treatment. The DBD is obtained between two parallel alumina plates separated with 1 mm gas gap. An AC high voltage in the kV frequency range is used to sustain a homogeneous Townsend discharge in N2-N2O gas mixtures. Titanium dioxide nanoparticles (TiO₂ NPs, anatase phase, 20 nm in diameter) are functionalized and mixed with Hexamethyldisiloxane (HMDSO) to get a stable colloidal solution. This suspension is injected in the gas mixture using a pneumatic injector coupled to a nebulizer. The obtained colloidal aerosol is then evaporated before reaching the discharge chamber. Plasma-deposited coatings were then characterized by SEM, FTIR and XPS. The hydrodynamic radius of particles (and agglomerates) in the colloidal solution was determined using Dynamic Light Scattering analysis (DLS). The electrical analysis of the process shows that the discharge remains stable and homogeneous during the injection of the suspension, indicating that nanoparticles do not affect the physical regime of the discharge. The SEM analysis indicates that spherical agglomerates remain included in a dense matrix or stuck on the surface. The size distribution of these structures can be larger than 1 micrometer, i.e. bigger than the coating thickness. The Raman peak at 143 cm⁻¹, associated with the anatase structure, shows no structural change of NPs during their interaction with the discharge. Our results show that the observed agglomeration can take place at different steps of the process, including in the initial suspension, during the atomization process and as a result of plasma interactions. Finally, our results reveal that the transport dynamics of NPs can judiciously be controlled using custom-designed voltage waveform.

Additive Manufacturing of Nanomaterials Using Plasmas
Kyle O’Shea, Alexander Ha and Rebecca J. Anthony; Michigan State University, East Lansing, Michigan, United States.

Plasma reactors have been used for synthesis of many types of nanomaterials with great success, from a range of materials including semiconductors and metals. These reactors feature versatile operation across pressure, power, and size regimes. While low-pressure plasmas typically lead to nanoparticle ensembles with the narrowest size distributions, atmospheric pressure plasmas can produce high-quality and tunable nanocrystals particularly when the reactor size is miniaturized. Both the small reactor size and atmospheric pressure operation contribute to the potential to use these reactors in roll-to-roll manufacturing and other large-scale deposition schemes, removing batch post-processing steps and enhancing the ability to incorporate the nanoparticles into the manufacturing stream.

Here we present our work on additive manufacturing of silicon nanoparticles using an atmospheric pressure glow discharge. The reactor consists of a quartz tube encircled by a powered coil electrode (one end floating) supplied with RF power at 13.56 MHz, together with a coaxial central ground electrode. We supply silane and argon gas (total gas flowrate ~ 200 sccm) for silicon nanoparticle production. Silicon nanoparticles are produced in the plasma and spray out of the tube onto the substrate beneath. The nanoparticles are crystalline with a relatively wide size distribution (5-40nm) as verified using transmission electron microscopy and the ensembles exhibit photoluminescence near 600 nm. The reaction is performed in air, and the nanoparticle surfaces are coated in an oxynitride layer as determined using Fourier-transform infrared spectroscopy. The reactor is mounted to a computer-controlled 3D manipulator which allows the nanoparticles to be deposited in pre-programmed patterns in all three coordinates directly out of the reactor. Our current work focuses on characterizing the deposition properties including porosity, mechanical properties, and yield while simultaneously engineering the reactor to enable narrower linewidth and a smaller size distribution of nanoparticles, along with controlled shell composition and thickness using additional gas flows. This work could lead to directly printable nanocrystal layers and coatings for in-situ fabrication of devices and other technologies.

Effect of Zr Target Power on Structure Property Relations of Ni-Zr Alloy Thin Films Processed by DC Magnetron Co-Sputtering

The application of strong electric fields in water and organic liquids has been studied for many years, because of its importance in electrical transmission processes and its practical applications in biology, chemistry, and electrochemistry. More recently, liquid-phase electrical discharges have been investigated, and are being developed. Recent advances in pulsed power technology permitted application of much faster voltage rise times (including the subnanosecond range) and revealed that plasma-like phenomena can, in fact, occur in fluid phase quasi-homogeneously without any bubbles and voids. Very sharp rise times leads to overvoltage and development of a non-thermal discharge (direct ionization of liquid phase) before fluid moves forming bubbles or gas voids. Here we present the first results on characterization and diagnostics of nanosecond-pulsed discharge in liquid nitrogen and characterization of produced materials.

Synthesis, Processing, and Characterization of Materials Processed by Spark Plasma Sintering

Spark Plasma Sintering (SPS) has been employed as a very effective method for consolidation of powders into dense polycrystalline materials. We have employed SPS as a unique approach for material synthesis, including crystal growth. Moreover, due to the internal localized heating during SPS processing, the rapid, low temperature densification of fine-grain powders can be realized. Since only the surface temperature of the sample powders rises rapidly by self-heating, grain growth is minimized, thus high density, bulk polycrystalline semiconductors with nano-scale grains can be achieved. This technique is important in obtaining thermoelastic materials whereby grain-boundary scattering is realized thus allowing for materials with enhanced thermoelectric performance, as compared to the same polycrystalline material with micro-scale grains. A variety of examples, including synthesis and, in particular, the crystal growth of materials with complex crystal structures that have not been previously synthesized even in microcrystalline form, will be presented. In addition, our consolidation technique for nanostructured materials will be discussed, with specific emphasis on an understanding of specific processing conditions and their effect on the morphology of different semiconductors and the resulting grain size and product density.

11:15 AM PM07.11.03
Effect of Zr Target Power on Structure Property Relations of Ni-Zr Alloy Thin Films Processed by DC Magnetron Co-Sputtering

A comparative study has been carried out on microstructural evolution, surface roughness, nanoindentation and scratch behavior, electrical resistivity, and corrosion resistance of Ni1-xZrx (0.13≤x≤0.40) thin films deposited on Si-(100) substrate by DC magnetron co-sputtering of high purity elemental targets in argon atmosphere. The Zr target power has been changed from 75 watt to 175 watt by keeping the Ni power constant at 200 watt. The film compositions have been examined by energy dispersive X-ray. Grazing incidence X-ray diffraction (GIXRD) studies have shown presence of Ni-rich solid solution, Ni3Zr and amorphous phase in all the films, with Ni3Zr being additionally observed in the Ni5Zr13 film. Analysis of GIXRD data along with transmission electron microscopic studies have shown that volume fractions of both amorphous phase and Ni3Zr are increased, whereas the average crystallite size is decreased with increase in Zr concentration. Nanoindentation hardness and Young’s modulus as well as electrical resistivity measured by Van-der Pauw four-probe method are influenced by volume fractions of both Ni3Zr and amorphous phase. Surface roughness and coefficient of friction obtained from atomic force microscopy and nano-scratch experiments, respectively decrease, whereas corrosion resistance in 3.5 wt% NaCl solution increase with Zr concentration primarily due to increase in amorphous phase content. Resistance to pitting corrosion is facilitated by formation of ZrO2-rich passive film, as confirmed by X-ray photoelectron spectroscopy.

11:30 AM PM07.11.04
Atmospheric Pressure High Power Impulse Plasma Source (HiPIPS) for Deposition of Metallic Coatings

Southwest Research Institute (swRI) is developing a novel atmospheric pressure, non-thermal High Power Impulse Plasma Source (HiPIPS) technique for field applicable deposition of metallic protective coatings. The HiPIPS technology is an advanced variation of atmospheric pressure plasma process that uses high power pulsed DC generators. Power is applied in microsecond pulses at low duty factor (< 10%) and low frequency (< 1 kHz) leading to high peak power densities (tens of kWatts) and high peak currents (hundreds of Amps) while keeping low overall power (< 50 W) and low processing temperatures (< 50 °C). These conditions result in the generation of a highly dense plasma discharge, with increased ionization for surface modification and deposition of coatings. SwRI has conducted a systematic experimental study on the HiPIPS process parameters and resultant coating properties towards proof-of-concept development of HiPIPS deposition of CoCr, Ti-6Al-4V and TiN coatings. Plasma properties were characterized using current-voltage probes and optical emission spectroscopy (OES). The microstructure and elemental composition of resulting deposited were examined using scanning electron microscopy (SEM), energy-dispersive X-ray (EDX) spectroscopy and X-ray diffraction (XRD).
Tailoring the Magnetocaloric Potential of AlFe₂B₂ Using Conventional and Additive Manufacturing Processing Schemes 

Radhika Barua¹, Brian Lejune², Brandt Jensen³, Ryan Ott⁴, Matthew J. Kramer⁴; ¹Department of Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, Virginia, United States; ²Department of Chemical Engineering, Northeastern University, Boston, Massachusetts, United States; ³Division of Materials Science & Engineering, Ames Laboratory, Ames, Iowa, United States; ⁴Department of Mechanical Engineering, Northeastern University, Boston, Massachusetts, United States.

Material processing schemes play a critical role in guiding the development of emerging magnetocaloric materials for energy-related applications such as magnetic refrigeration and thermomagnetic energy conversion. To this end, the intermetallic boride AlFe₂B₂ has attracted considerable attention due to its low cost, promising thermal properties that promote effective heat transfer (specific heat capacity \( C_p = 120 \text{ J mole}^{-1} \text{K}^{-1} \)), thermal conductivity \( \kappa = 5.6 \text{ W m}^{-1} \text{K}^{-1} \), and moderate magnetocaloric response near room temperature (adiabatic temperature change \( \Delta T_{\text{ad}} = 1 \text{ K} \) and magnetic entropy change \( \Delta S = 2.6 \text{ J kg}^{-1} \text{K}^{-1} \) at \( \mu_0 H = 2 \text{ T} \)). In this work, a number of synthesis methods to form single-phase AlFe₂B₂ alloys were investigated. Further, the feasibility of 3D-printing honeycomb shaped samples was explored. It is surmised that AlFe₂B₂ is amenable for construction of magnetocaloric heat exchangers where the working material may be shaped as channel structures to facilitate efficient heat transfer between the solid refrigerant and the heat exchange fluid. Overall, this study provides strategies for maximizing the magnetofunctional potential of AlFe₂B₂.

Exploiting First and Second Order Phase Transitions in Magnetocaloric NiMn-Based Heusler Compounds Francisco Alberini¹, Cecilia Bennati², Simone Fabbrici², Riccardo Cabussi¹, Francesco Cugini¹, Nicola Sarzi Annadi², Massimo Solzi², Antonio Pepicelli² and Ciro Visone²; ¹IMEM-CNR, Parma, Italy; ²Università di Parma, Parma, Italy; ³Università del Sannio, Benevento, Italy.

Room temperature magnetic refrigeration requires materials with large isothermal entropy and adiabatic temperature changes at around 293 K and negligible thermo-magnetic hysteresis, when cycled in magnetic fields below 2T. Ferromagnetic shape memory Heusler compounds with metamagnetic martensitic transformations are among the most studied materials for magnetocaloric applications thanks to their high adiabatic temperature changes \( \Delta T_{\text{ad}} \) related to their inverse magnetocaloric effect [1]. These materials are rare earth free, easy-to-prepare and offer large tailoring possibilities. Remarkably, thanks to the strong discontinuities of the physical properties at the martensitic transformation (e.g. magnetization, volume), caloric effects can be obtained not only by applying magnetic fields but also stress and pressure, enabling multicaloric applications [2,3]. Although very high values of adiabatic temperature change have been reported, metamagnetic Heuslers show poor reversibility due to hysteresis and spreading of the transition. By taking advantage of suitable substitutions, in NiMn-based Heusler alloys it is possible to tune the order and the number of transitions that can be exploited for magnetocaloric applications. In the present talk we will report some particular cases in the phase diagram of NiMnGa and NiMnIn compounds and discuss the reversible and irreversible contributions to the magnetocaloric effects, based on in-field calorimetry and direct \( \Delta T_{\text{ad}} \) measurements. Interesting effects occurs when the first order magnetostructural and second order Curie transition are almost coincident. In In-based compounds, for example, the coexistence of direct and inverse magneto calorific effects can be obtained [4]. The possible exploitation of direct and inverse MCEs in alternative refrigeration cycles will be discussed.

Tailoring the Magnetocaloric Potential of AlFe₂B₂ Using Conventional and Additive Manufacturing Processing Schemes Radhika Barua¹, Brian Lejune², Brandt Jensen³, Ryan Ott⁴, Matthew J. Kramer⁴; ¹Department of Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, Virginia, United States; ²Department of Chemical Engineering, Northeastern University, Boston, Massachusetts, United States; ³Division of Materials Science & Engineering, Ames Laboratory, Ames, Iowa, United States; ⁴Department of Mechanical Engineering, Northeastern University, Boston, Massachusetts, United States.

Suction-casting allows fabrication of samples of various composition, including Al₁₋ₓMₓFe₂B₂ (M=Ga and/or Ge, x<0.1). Experimental data obtained using structural and magnetic probes indicate that the unit cell volume, saturation magnetization (Mₛ), Curie temperature (Tₘ) and specific heat capacity (Cₚ) of the samples increase with increased Ga and Ge content (x). Relative to the unmodified parent AlFe₂B₂ sample, a larger than two-fold improvement in the magnetocaloric effect (MCE) was observed in the Al₁₋ₓGaₓFe₂B₂ specimen (\( \Delta S = 6.5 \text{ J kg}^{-1} \text{K}^{-1} \), \( \Delta T_{\text{ad}} = 2.2 \text{ K} \) at \( \mu_0 H = 2 \text{ T} \)). Intriguingly, the solid solubility of Ga and Ge in AlFe₂B₂ was determined to be negligible and it is deduced from calorimetric data that additions of these substituent elements alter the solidification route for formation of the AlFe₂B₂ phase. The enhanced MCE of the Al₁₋ₓ(Ga/Ge)ₓFe₂B₂ samples is ascribed to a combination of chemical bonding and electronic effects arising from a hypothesized enrichment of Fe atoms on the Al sites within the (ac) plane of the AlFe₂B₂ lattice. These results provide fundamental insights regarding the phase stability of the Al-Fe-B ternary system, and guide development of AlFe₂B₂ samples of complex geometries using laser engineered net shaping (LENS). The MCE of cylindrical LENS samples (5 mm dia; 30 mm length) was found to be comparable to that of corresponding undoped suction-cast samples (\( \Delta S_{\text{LENS}} = 2.8 \text{ J kg}^{-1} \text{K}^{-1} \), \( \Delta T_{\text{ad,LENS}} = 1.1 \text{ K} \) at \( \mu_0 H = 2 \text{ T} \)). Further, the feasibility of 3D-printing honeycomb shaped samples was explored. It is surmised that AlFe₂B₂ is amenable for construction of magnetocaloric heat exchangers where the working material may be shaped as channel structures to facilitate efficient heat transfer between the solid refrigerant and the heat exchange fluid. Overall, this study provides strategies for maximizing the magnetofunctional potential of AlFe₂B₂.

**Disorder and Electron Correlation Effects in the Ground State of Ni-Co-Mn-Sn Alloys with Heusler Structures**

Bernardo G. Barbiellini, 1, 4, Aki Pulkkinen, 2, Johannes Nokelainen, 1, Vladimir Sokolovskiy, 3, Vasiliy Buchelnikov, 3, Mikhail Zagrebin, 3, Katariina Pussi, 3, Erkki Lähderanta, 2 and Alexander Granovsky, 3

1Physics, LUT, Lappeenranta, Finland; 2Chelyabinsk State University, Chelyabinsk, Russian Federation; 3Physics, Moscow State University, Moscow, Russian Federation; 4Department of Physics, Northeastern University, Boston, Massachusetts, United States.

We consider ab-initio calculations of Co-doped Ni-Mn-Sn shape memory alloy. The Co doping leads to a decrease in both the martensitic transformation temperature and the Curie temperature of martensite and to an increase in the Curie temperature of austenite. Besides, large magnetisation changes occur in the vicinity of structural transformation. As a result, the tuning of Co and Mn contents can lead to favorable magnetocaloric properties [1]. In this work, we focus on the effect of atomic disorder and electron correlation on the structural, magnetic and electronic properties of Ni-Co-Mn-Sn systems by using the Density Functional Theory (DFT) implemented in the VASP and SPR-KKR packages [2, 3] within a 32-atom supercell and the coherent potential approximation, respectively. The optimized atomic positions for compositions studied are obtained by the USPEX package [4]. To study the effect of exchange-correlation, a series of ground state calculations were performed using both the GGA-PBE functional and Meta-GGA with SCAN functional of DFT [5].

**Magnetic and MagnetoCaloric Properties of Fe-(W)Ta Thin Films**

Surabhi Shaji, Nikhil R. Mucha, Prakash Giri and Dhananjay Kumar

1 North Carolina A&T State University, Greensboro, North Carolina, United States; 2University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

A first hand magnetocaloric effect (MCE) in rare-earth free Fe-W (Ta) thin film systems, induced by simultaneous transformation in structural and ordered magnetic phases, is reported. The MCE has been realized by varying the levels and types of dopants in the Fe-host. These materials systems in thin film form have shown a crystallographic phase transition from a regular body center cubic (BCC) crystal structure to a distorted BCC. Applying the Maxwell relation to the magnetization (M) versus magnetic field (H) curves at various temperatures, we have calculated dM/dT vs H the integration of which provides a quantitative information about isothermal entropy change. We have observed positive a MCE with a maximum entropy value of 6.9 J/K-m³ for the magnetic field changing from 0.05 – 0.5 T. The mass specific entropy changes are small in comparison with existing magnetocaloric material. A peak in dM/dT versus H has shown that maximum entropy change takes place around 0.15 T, which is more than an order of magnitude lower than the magnetic fields generally used to realize a large MCE effect.

9:45 AM **TP01.01.05**

**Thickness Dependent Size Effects on Hysteresis in Electrochemically Deposited Thick Film NiMnSn Heusler Alloys**

Yijia Zhang, Julia Billman and Patrick Shamberger

Texas A&M University, College Station, Texas, United States.

Characteristic length scales of Heusler alloy films, including film thickness and grain size, affect the transformation hysteresis by altering internal energy barriers to interphase boundary motion. Previous studies have illustrated strong film thickness effects on transformation temperatures of nanoscale TiNiCu thin film with film thickness < 100 nm, and that stress hysteresis and temperature hysteresis of CuAlNi microwires increased with decreasing wire diameter with diameter < 100 μm. However, length-scale dependent hysteresis has yet to be determined for other classes of caloric materials, including Heusler alloys. Understanding such transformation behavior at small length scales is critical for microelectronic and micromechanical applications, for promoting rapid heat transfer through caloric alloy thin films and thin wires, in strain-coupled magnetoelectric composites, and in microstructured multifunctional composites and foams.

By annealing electrochemically deposited multi-layer monatomic (Ni, Mn, Sn) films, Ni0.5Mn0.386Sn0.114 Heusler alloy films with decreasing thicknesses, 14.5, 8.7, and 2.9 μm, were synthesized. Phase transformation temperatures and sizes of nearly four hundred grains on each film were collected optically while the samples were heated or cooled. These data showed that the average grain areas/volumes decrease with decreasing film thicknesses. For grains within a single film (constant thickness), there is no statistically significant correlation between grain area or volume and hysteresis width. At the same time, film hysteresis increases with decreasing film thicknesses (from 4.9°C at 14.5 μm to 15.7°C at 2.9 μm). Previously, Chen and Schuh (2011) attributed the size effect in the hysteresis of small CuAlNi alloy microwires to the enhanced internal frictional work during transformation, associated with an increase in surface area and volume ratio. Our thickness dependent size effects could be similarly explained by internal friction-induced energy dissipation, whereby the thinner the film is, the stronger the interactions between interphase boundaries and the film-substrate interface, and the more energy is dissipated by frictional work. A power law model is fit to hysteresis width-film thickness data, and is used to elucidate scaling relationships which govern size dependence of hysteresis in Heusler alloy thin films, which are compared against previously observed size-dependent hysteresis in other thermoelastic martensitic transformations.

**Orientation Relationships and Lattice Matching Effects on Hysteresis in (Mn,Fe)2(P,Si) Phase Transitions**

Timothy D. Brown and Patrick Shamberger

Texas A&M University, College Station, Texas, United States.

Hysteresis associated with the non-diffusive phase transformation in magnetocaloric (Mn,Fe)2(P,Si) alloys creates substantial energy dissipation.
undesirable for cooling applications. Although reduced hysteresis has been achieved in this system through tuning of Mn/Fe and P/Si site occupancies, a deeper understanding of the underlying mechanisms necessary for designing low-hysteresis materials across a wide range of critical temperatures has proved elusive. A successful and general mechanistic theory relating hysteresis to lattice matching has been developed for similar transformations in thermoelastic martensites, dependent on both the change in lattice parameters and the orientation relationships between the parent and daughter crystal lattices. Despite the theory’s success and generality, the parent-daughter orientation relationships in (Mn,Fe)(P,Si) have not yet been established, and the lattice matching theory has not yet been tested against hysteresis in this system. In this work, we establish the orientation relationships for basal and prismatic planes in hexagonal (Mn,Fe)(P,Si) alloys through two independent experiments: (1) comparison of temperature-dependent x-ray diffraction pole figures below and above the phase transition and (2) electron backscatter diffraction orientation mapping of adjacent grains of coexisting magnetic parent and non-magnetic daughter phases. Afterwards, we combine these orientation relationships with experimental measurements of lattice parameter discontinuities in order to calculate the lattice mismatch parameter \( \lambda_2 \) for several representative alloys in the (Mn,Fe)(P,Si) system. Finally, the calculated mismatch is correlated with the samples’ hysteresis as measured from calorimetry experiments and compared with the predictions of the theory, thereby establishing whether lattice matching effects may also be used to control hysteresis in (Mn,Fe)(P,Si) alloys’ phase transitions.

11:15 AM TP01.01.08
Effect of Phase Segregation on Phase Transformation Behavior in (Mn,Fe)(P,Si) Alloys

Timothy D. Brown, Jonathan S. Van Buskirk, Daniel Galvan and Patrick Shamberger; Texas A&M University, College Station, Texas, United States.

Alloying in quaternary (Mn,Fe)(P,Si) allows for highly tunable phase transformation temperatures and hystereses, potentially enabling high-efficiency magnetocaloric cooling over a wide range of temperatures. However, compositional control of the alloy is also subject to complex thermodynamic constraints, as evidenced by segregation of multiple transforming hexagonal phases, as well as precipitation of a non-transforming cubic P-poor (Mn,Fe)Si phase. In either case, the composition, and therefore hysteresis and transformation temperature, of the transforming phases are modified significantly from the nominal bulk composition, thereby obscuring direct causal relationships between composition and transformation behavior. Thus, in order to recover these relationships, as well as to control the expression of transforming phases of interest for cooling applications, it is critical to map out the thermodynamic phase coexistence of the alloy system. In this work, we investigate thermodynamically driven phase segregation behavior in (Mn,Fe)(P,Si) by measuring the compositions and mass fractions of coexistent transforming and non-transforming phases for a range of nominal alloy compositions \((1.20 < \text{Mn} < 1.25; 0.35 < \text{P} < 0.50)\) through quantitative wavelength dispersive spectroscopy and backscatter electron imaging. It is found that oxygen preferentially segregates to the cubic phase over the hexagonal phase (5 at. % vs. <1 at. %), suggesting oxygen plays some role in mediating the stabilization of the cubic phase. Measured compositions of the expressed transforming hexagonal phases are then combined with critical transformation temperatures and thermal hystereses from calorimetry experiments to map out the underlying dependence of the transformation behavior on the phase compositions. The analysis suggests Mn/Fe site occupancy plays a much larger role than P/Si in controlling hysteresis of the phase transition, providing insight into the nature of the energy barriers that fundamentally control hysteresis in this alloy system.

11:30 AM TP01.01.09
Spatially and Temporally Resolved Temperature Measurements of Magnetocaloric Materials Under Varying Applied Magnetic Field

We present an experiment where magnetocaloric samples are spatially and temporally resolved using infra-red (IR) thermography. The spatial resolution is approximately 10x10 microns, while the temporal resolution is 170 Hz. The magnetic field applied to the sample is varied in a controlled way and thus the dynamics of the first order phase transition are observed on the sample surface. We also present complimentary differential scanning calorimetric (DSC) measurements and are therefore able to relate the specific heat peaks of a single sample with the temperature distribution as observed by IR. This work presents our preliminary results for the first order phase transition of La(Fe,Si,Mn)13Hz compounds and describes the challenges of bringing the device into operation. Moreover, an outlook for comparing the results with a time-dependent numerical model, which can predict the material behaviour by finding its internal magnetic field and including finite heat transfer calculations, is given.

11:45 AM OPEN DISCUSSION

1:30 PM TP01.02.01
Optimizing the Electrocaloric Effect by Molecular Dynamics Simulations

Anna Grünebohm; University of Duisburg Essen, Duisburg, Germany.

In this talk I will discuss the benefits of ab initio based molecular dynamics simulations [1] for the optimization of the electrocaloric effect (ECE). The basic principles of the ECE are now well understood [2]. A further optimization asks for a detailed understanding of the impact of phase transitions as well as atomic, defect and domain structures on the ECE and its reversibility. Simulations allow to isolate these factors and predict design rules for ferroelectric materials and composites with superior cooling responses.

I will focus on the factors giving rise to a large inverse caloric response [3], in particular phase transitions [4] and internal bias fields [5].

[3] A. Grünebohm et al., Energy Technol. 10.1002ente.201800166, ‘18,

Electrocaloric Studies on Epitaxial BaTiO3-Based Thin Films

Stefan Engelhardt1,2, Pengfei Song1,2, Christian Molin2, Sylvia Gebhardt3, Sebastian Faehler4, Kornelius Nielsch4, and Ruben Huehne1; IFW Dresden, Dresden, Germany; 2TU Dresden, Dresden, Germany; 3Fraunhofer IRTS, Dresden, Germany.

Electrocaloric (EC) materials show reversible thermal changes in response to the variation of an applied electric field. This EC effect got a renewed interest within the last decade due to the quest for energy-efficient cooling technologies and recent discoveries of large adiabatic temperature changes \( \Delta T \) in various ferroelectric thin films during the application or removal of an electric field. Among them, lead-containing oxides exhibit strong caloric effects but contain hazardous elements. BaTiO3 (BT) based materials might be a more environment-friendly alternative to these compounds. Therefore, we have chosen BaZr0.1Ti1-xO3 (BZT) and BaHf0.1Ti1-xO3 (BHT) as model systems for our studies in order to investigate the correlation between the composition dependent phase transitions, the dielectric and ferroelectric properties as well as the EC effect of such BT based thin films. Moreover, we use epitaxial films, which additionally enable a detailed microstructural analysis as well as a study of orientation dependent properties.

Accordingly, epitaxial BZT and BHT films were grown by pulsed laser deposition on single crystalline substrates utilizing a conducting oxide buffer layer and additional top electrodes to obtain capacitor like structures. The grown films were studied by X-ray diffraction as well as scanning electron and atomic force microscopy. Depending on the specific growth parameters, a twin-free epitaxial growth and a smooth surface morphology is observed. Temperature dependent measurements of the relative permittivity suggest diffuse phase transitions, where the transition temperature clearly varies with the film composition. The EC properties of the thin films were determined by an indirect method from temperature dependent polarization measurements showing values of up to 0.3 K for a \( \Delta E \) of 170 kV/cm. We assume that the clamping of the thin films to the rigid substrate reduces the magnitude of the EC effect significantly compared to the respective bulk materials. Finally, we will present our approaches for the direct measurement of the EC effect in our epitaxial thin films.

Epitaxial Na0.5Bi0.5TiO3 Based Thin Films for Electrocaloric Studies

Bruno M. Magalhães1, Stefan Engelhardt1, Sebastian Faehler4, Christian Molin2, Sylvia Gebhardt3, Kornelius Nielsch4, and Ruben Huehne1; IFW Dresden, Dresden, Germany; 2Fraunhofer Institute for Ceramic Technologies and Systems, Dresden, Germany; 3Technische Universität Dresden, Dresden, Germany.

Substantial efforts are being employed to the search and development of efficient and environmentally friendly materials with potential for solid state cooling. Motivated by recent discoveries, electrocaloric cooling might be a promising solution as an innovative refrigeration technique, as it shows a significant variation in temperature by adiabatically switching an applied electric field. Among them, lead-free thin films have raised an increased interest in research as they avoid the harmful effects of lead-containing materials. The purpose of our study is to investigate the electrocaloric effect in such lead-free epitaxial thin films. In particular, we are focusing on microstructural changes close to the phase transition of Na0.5Bi0.5TiO3 (NBT) in order to understand the basic mechanisms of the caloric effects, which might enable a further optimization of the electrocaloric properties for specific applications. Accordingly, the growth of NBT thin films with BaTiO3 and SrTiO3 additions is targeted to study the influence of the deposition parameters on the microstructural and the electrocaloric properties in this material system.

Therefore, NBT-based epitaxial thin films were grown by pulsed laser deposition on a variety of single crystalline substrates using LaSr1-xCoO3 as a bottom electrode for a subsequent ferroelectric characterization. The structural characterization displays an epitaxial growth of NBT on the different substrates. Temperature and frequency dependence of the dielectric properties were assessed to measure the temperature of maximum permittivity \( T_m \). Simultaneously, the electrocaloric temperature change was determined indirectly by the dependence of polarization on temperature and electric field strength. Finally, we will discuss the impact of the deposition parameters on the structural and functional properties of the grown films.

This work is supported by the DFG priority program 1599 “Ferroic cooling”.

Large Electrocaloric Effects in PST Multilayer Capacitors Over a Wide Range of Useful Temperatures

Bhavi Nair1, Tomoyasu Usui1, Sam Crossley1, Xavier Moya1, Sakyo Hirose1 and Neil D. Mathur2; 1Murata Manufacturing Co., Ltd., Nagaokakyo-shi, Japan; 2Applied Physics, Stanford University, Palo Alto, California, United States; 3Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom.

Using both thermocouples and infrared imaging, we report large electrocaloric effects in PbSc0.5Ta0.5O3 multilayer capacitors near room temperature. For field changes of 29.0 V \( \mu \text{m}^{-1} \), we find changes of temperature that peak at 5.5 K, and exceed 3 K for starting temperatures that span 176 K. This directly measured performance in a macroscopic body improves upon the magnetocaloric response of gadolinium when driven by expensive permanent magnets, suggesting the possibility of a straight swap in prototype cooling devices.

A New Class of Electrocaloric Materials—Exhibiting Large Electrocaloric Response at Low Electric Field

Xin Chen, Wenhan Xu, Biao Lu, Tian Zhang, Qing Wang and Qiming Zhang; The Pennsylvania State University, University Park, Pennsylvania, United States.

Electrocaloric effect (EC) is the temperature and change in a dielectric material as the applied field changes. ECE occurs due to electrical field induced dipole-entropy change in dielectrics, which is an extremely efficient form of energy conversion exhibiting minimum losses, e.g., polarization-electric field coupling approaching 100% efficiency. The past decade has witnessed the discovery and advancement in electrocaloric polymers, which display large electric field induced temperature and entropy changes.

In contrast with a burgeoning literature on large ECE in various ferroelectric materials, there are no EC devices employing these materials, demonstrating a meaningful cooling power. The critical barrier for the transition from high performance EC materials to practical EC devices is the dielectric breakdown. Hence, EC devices have to work under electric fields far below their dielectric breakdown. On the other hand, EC devices to achieve sufficient cooling power require large size EC films, which can further reduce their dielectric breakdown. To address these issues, high performance EC materials should possess a large EC response at large fields far below dielectric breakdown. However, the EC response of the state-of-art EC polymer P(VDF-TrFE-CFE) at these practical field range is not high even though it possesses a large ECE at high electric fields (\( > 100 \text{MV/m} \)).

In this work, inspired by the materials concept of high entropy alloys, in which the presence of a large number of elements increases the entropy of the alloys, we developed a new class of EC polymer, tetrapolymer, which possesses a large dipolar entropy. Moreover, the tetrapolymer exhibits a critical end point behavior at low electric fields, thus leading to a giant EC response at low electric fields, which have the promise for high performance and highly reliable EC coolers.
Elastocaloric cooling is currently under extensive study owing to its great potential to replace the conventional vapor-compression technique. In the first part, I will present a Ni$_{50}$Fe$_{19.0}$Ga$_{27.1}$Co$_{3.9}$ ferromagnetic shape memory single crystal, which exhibits giant elastocaloric effect of 11 K and ultralow fatigue behavior during above 12,000 mechanical cycles. The numerical simulation shows that this unique alloy offers 18% energy saving potential and 70% cooling capacity enhancement potential than the conventional shape memory nitinol alloy in a single-stage elastocaloric cooling system, making it as a great candidate for the energy-efficient air conditioner application. Second, I will introduce a Ni$_{50}$Mn$_{11.1}$In$_{16}$Cu$_{2.5}$ metamagnetic shape memory alloy exhibiting giant adiabatic temperature changes of 13 K upon loading. Simultaneously, a small thermal hysteresis of 3 K and an exceptional phase transformation stability over 10$^7$ magnetic field cycles have been achieved by ensuring the compatible kinematic conditions of specific lattice interface. Moreover, we proposed an approach to reduce hysteretic losses and improve the reversibility of magnetoelastic effect by manipulating transformation paths evoked by magnetic field and stress, and therefore such a multicaloric approach is attractively beneficial for reaching high energetic utilization efficiency.

Stability of Additive Manufactured NiTi for Compressive Elastocaloric Properties Beyond One Million Cycles
Huilioug Hou$^1$, Emrah Simsek$^2$, Tao Ma$^2$, Suxin Qian$^3$, Drew Stasak$^1$, Naila Al Hasan$^1$, Lin Zhou$^2$, Yunho Hwang$^1$, Reinhard Radermacher$^1$, Matthew J. Kramer$^2$, Ryan Ott$^2$, Jun Stasak$^1$, Ji Hidaka$^1$ and Ichiro Takeuchi$^1$; $^1$University of Maryland, College Park, College Park, Maryland, United States; $^2$Aerospace Engineering and Mechanics, University of Minnesota, Minneapolis, Minnesota, United States; $^3$Iowa State University of Science and Technology, Ames, Iowa, United States.

We report on properties of additive manufactured Ni–Ti alloys in the geometries of solid rods and hollow tubes. We have characterized their room-temperature superelastic and elastocaloric properties after one million cycles. Alloy compositions are flexibly and quickly adjusted by controlling the flow rate of elemental powders during synthesis. Unique microstructure in the material results from rapid solidification and thermomechanical processing with the phase transformation occurring near room temperature. A quasi-linear superelasticity and elastocaloric cooling temperature changes up to 4.1 K are observed in the additive-manufactured alloys under uniaxial compressions at room temperature. We perform extended cycling tests of the alloys while in-situ monitoring their stress-strain properties. Elastocaloric properties are monitored after every 200,000 cycles. After 1,000,000 cycles, the alloys exhibit superelasticity and the stability of alloys after a large number of cycles.

4:15 PM TP01.03.03
Fatigue Influencing Factors in NiTi Based Shape Memory Alloys for Elastocaloric Cooling
Lars Bunke$^1$, Hanlin Gu$^2$, Florian Bruederlin$^2$, Christoph Chluba$^1$, Manfred Kohl$^1$, Richard James$^2$ and Eckhard Quandt$^1$; $^1$Institute for Materials Science, Kiel University, Kiel, Germany; $^2$Aerospace Engineering and Mechanics, University of Minnesota, Minneapolis, Minnesota, United States; $^3$Istitute of Microstructure Technology, Karlsruhe Institute of Technology, Karlsruhe, Germany.

Caloric cooling is an emerging technology with the potential to replace traditional technologies like environmentally harmful vapor compression systems, which already operate close to their theoretical efficiency limit or rather inefficient thermoelectric devices. Within the field of caloric, elastocaloric materials show high latent heats larger than 20 J g$^{-1}$. The elastocaloric effect in shape memory alloys (SMAs) is based on the reversible stress induced martensitic phase transformation. Binary NiTi is a benchmark material for elastocaloric materials, since it shows a high effect size > 15 K and is widely accessible. On the other hand NiTi shows a poor fatigue life resulting in an early breakdown of the device. It is assumed that the material has to withstand at least 10$^7$ cycles. Recently it was demonstrated that magnetron sputtered TiNiCu based SMAs show negligible fatigue for 10 million cycles, an effect size > 10 K and tuneable transformation temperatures below RT [1,2]. These materials possess a unique microstructure with coherent precipitates, acting as nucleation centres for the phase transformation and a grain size in the sub µm range. In addition they show a nearly perfect compatibility of the austenite and martensite phase, which can be expressed by the cofactor conditions [3]. If fulfilled an unstressed transition layer between the corresponding phases is created, leading to a phase transformation without slip, reduced hysteresis and an increased fatigue life. First demonstrators using a solid to solid heat transfer show a maximum temperature span of 14 K [4]. Within this talk several NiTi based shape memory alloys will be discussed in terms of microstructure, compatibility and fatigue life to determine critical parameters for the design of SMAs with a sufficient fatigue life.

materials, several demonstrators of cooling systems have been developed and characterized by various groups. In general, for an energy- and cost-efficient system, the heat transfer between elastocaloric material and heat sink and source is essential. While most published systems use either thermal conduction or forced convection, here an elastocaloric system using latent heat transfer in combination with thermal diodes is presented. Similar to gravity-assisted heatpipes, thermal energy is efficiently transported by condensation and evaporation processes leading to heat transfer rates which are several orders of magnitude larger than in conventional systems. Furthermore, no additional pumps are required for transporting the heat exchange fluids, enabling systems with large temperature spans and competitive COPs at the same time.

In this work, an experimental setup based on this system approach is shown, using an extender wheel for providing compressive force on Nitinol tubes and showing the proof of concept of heat transfer in combination with elastocaloric materials.

Mechanochemical Synthesis and Magnetocaloric Properties of Nanostructured Equi-Atomic FeRh with the Ordered B2 Structure Shalabh Gupta1, Yaroslav Mudryk1, Biswas Anis1, Jacob Rabe1 and Vitalij Pecharsky1, 2; 1Ames Laboratory, Ames, Iowa, United States; 2Material Science and Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

The equiaxed, sub-micron sized particles of Fe50Rh50 were synthesized by solvent-free mechanochemical co-reduction (MCR) of iron chloride (FeCl3) and rhodium chloride (RhCl3) followed by annealing between 600–1000 °C under argon. Typically, nearly equiatomic, ordered FeRh alloys exhibiting first-order transition are synthesized from the elements by arc-melting and annealing. The resulting large grains are difficult to scale-down because of the high ductility of the alloy. The bottom-up syntheses, such as MCR, inherently produce materials with grain-size in sub-micron to nano regime, allowing greater flexibility in tailoring the properties. In a typical MCR synthesis, the chloride (or fluoride) metal precursors are mixed in a 1:1 molar ratio in an agate mortar followed by high-energy milling along with a stoichiometric amount of Li-metal under argon. After about 2 h of milling, the reaction product contains no trace of halide salts. Prior to annealing, the LiCl (LiF) by-product is washed out with water-ethanol mixture. The cleaned sample is then heated under Ar at 600°C for 24 h and quenched in ice-cold water at which point the ordered B2 structure is obtained in high-purity. The temperature dependence of magnetization, M(T), was measured in field cooled protocol between 5 K and 400 K at different magnetic fields, and the magnetic entropy change, DSM, was calculated from the M(T) curves using Maxwell’s equation. In contrast to regular magnetocaloric effect (MCE), in case of inverse MCE (I-MCE), magnetic field induced enhancement in magnetic configuration entropy is observed. The as-synthesized particles of Fe50Rh50 alloy exhibit maximum I-MCE around ~340 K, which is attributed to a first-order antiferromagnetic to ferromagnetic transition. The maximum value of DSM near the transition is ~9 J Kg⁻¹K⁻¹ at 2 T, which is about 25 % smaller than that of bulk Fe50Rh50 but is larger than that of Gd, the benchmark material for the room-temperature magnetocaloric applications. In a fine particle system, grain boundaries play a vital role in determining magnetic and magnetocaloric properties. Grain boundaries are sources of crystalline disorder, which can affect the magnetic correlations. In some cases, disorder effects can suppress the first order transition. It is noteworthy that fine particles of Fe50Rh50 (average size <1 μm) retain a first order transition with large DSM despite the large concentration of disordered grain boundaries.

This work is performed under auspices of the caloric materials consortium, CaloriCool®, which is a member of the Energy Materials Network and is supported by the Advanced Manufacturing Office of the Office of Energy Efficiency & Renewable Energy and managed jointly through the Advanced Manufacturing and Building Technologies Office of the U.S. Department of Energy. Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University of Science and Technology under Contract No. DE-AC02-07CH11358.

X-Ray Magnetic Circular Dichroism Study on Ni Based Thermoseeds for Self-Controlled Hyperthermia Applications Sudin Pandey1, Alpha T. N'Diaye2, Igor Dubenko1, Anil Aryal1, Dipanjan Mazumdar1, Shane Stadler1 and Naushad Ali1; 1Department of Physics, Southern Illinois University Carbondale, Carbondale, Illinois, United States; 2Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Department of Physics & Astronomy, Louisiana State University, Baton Rouge, Louisiana, United States.

Ni-Cu alloys are potential magnetocaloric thermoseeded materials for application in self-controlled magnetic hyperthermia methods. The magnetic ordering temperatures and magnetic properties of Ni-Cu alloys can be tailored to fit within a range suitable for hyperthermia applications. To understand the details of the electronic and magnetic structures of these alloys, X-ray absorption spectroscopy (XAS) and X-ray magnetic circular dichroism (XMCD) measurements were done at the L2,3 absorption edges of Ni in ferromagnetic Ni-Cu. In this case, the XMCD technique has provided valuable information on how doping affects the relative magnetic moment on the Ni site. XMCD measurements employing the total electron yield method (i.e., surface sensitive to the depth of few nm) show that the collective of surface Ni atoms has a lower Curie temperature than that of the bulk. The influences of small compositional changes through the substitution of Cu for Ni on the electronic and crystal structures and thermomagnetic properties was studied to determine the optimized composition suitable for functional magnetic hyperthermia applications.

Effect of Al and Fe Solubility on Magnetostructural Properties of AlFe₂B₂
Brian Lejeune¹, Deborah Schlage², Brandt Jensen¹, Thomas Lograsso², Matthew J. Kramer¹ and Laura Lewis¹; ¹Northeastern University, Boston, Massachusetts, United States; ²Materials Science and Engineering, The Ames Laboratory, Ames, Iowa, United States.

One of the main design criteria for caloric materials is the ferroic phase transition temperature, magnetism, and antislattice occupancy in the magnetostructural AlFe₂B₂ system. This orthorhombic system is comprised of abundant elements, possesses a near-room-temperature magnetostructural phase transition temperature Tt and exhibits good magnetic cooling potential (ΔS = 4.4 J/kg-K @ μB/M = 2 T) [1,2]. Preliminary results suggest that the magnetic phase transition temperature is highly sensitive to Fe and Al solubility within the AlFe₂B₂ phase, allowing for tuning of the transition temperature through control of processing conditions.

A drop-cast ingot of composition Al₂Fe₂B₂ was used as the initial charge for Bridgman single crystal growth of the AlFe₂B₂ phase, allowing for Al-Fe composition regulation down the pathway of solidification. The influence of Al and Fe antisite defects within the AlFe₂B₂ crystal structure was assessed with X-ray diffraction, temperature-dependent magnetometry and compositional assessment from energy dispersive spectroscopy. Clear trends in composition are confirmed as a function of the Fe:Al at% ratios (1.94-2.06). In particular an Fe-rich AlFe₂B₂ phase due to Fe residing on the Al site results in an enhanced Tt relative to the stoichiometric composition. These findings quantify the sensitivity of the magnetic transition temperature in AlFe₂B₂ to antisite defects, where a 2 at% difference in Fe and Al content leads to a large change in Tt spanning 280-315 K. The interplay between Al and Fe site occupancy and the resultant structural and magnetic responses provides flexibility to tailor the magnetic phase transition temperature of the AlFe₂B₂ system.

Magnetocaloric Properties of the Magnetically Frustrated Mineral, Gaudefroyite
Colin Greaves¹, Rukang Li² and Guangjing Li¹; ¹University of Birmingham, Birmingham, United Kingdom; ²Beijing Center for Crystal Research & Development, Beijing, China.

New materials for refrigeration devices are needed for efficient, clean operation at a variety of temperatures. In adiabatic magnetic refrigeration using the magnetocaloric (MC) effect, cooling is related to the entropy change that occurs when a magnetic field is removed from a magnetic material. Efficient MC refrigeration requires stable materials that give a large change in magnetic entropy and has traditionally been achieved using expensive rare earth cations with large moments. In this presentation we will describe how mineral structures can point the way to new types of magnetic materials with excellent MC properties in the absence of rare earth cations. The mineral schafarzikite, Fe₁₉₁₉₂O₉₂, has a tetragonal structure comprising chains of edge-linked FeO₆ octahedra running along [001]. Following our studies of how the magnetic order of this structural family can be controlled, we then sought new materials with similar chains of linked octahedra, but frustrated interchain interactions, since enhanced MC behaviour has been predicted for frustrated magnetic materials. The mineral gaudefroyite, Ca₆Mn₆O₆(BO₃)₃CO₃, was particularly attractive because its chains of edge-linked Mn₆⁺ octahedra are located on a Kagome lattice perpendicular to the chains, and introduce inherent magnetic frustration between the chains. The low temperature magnetic properties of gaudefroyite were therefore investigated: extremely high MC effects were observed at temperatures suitable for liquefying hydrogen, ca. 20 K. The properties, which will be summarized, are better than those of existing optimized oxide materials at this temperature, but no rare earth element is present; the temperature changes are also exceptionally rapid because of the magnetic frustration. We now have low temperature neutron powder diffraction data collected in fields of 0-3 T within the temperature range 0.1-15 K, and the presentation will focus on these results. We will report an ordered antiferromagnetic structure (q=0, 120⁰ alignment) below 11 K, which transforms to a ferromagnetic ground state in fields greater than 1.5 T; ferromagnetism was also found at these fields for temperatures above 15 K. The results will be discussed in relation to the observed MC properties. The concept demonstrated could be of value for sustainable materials for liquefying hydrogen for transport/storage in a future hydrogen energy economy and could possibly be extended to materials operating at other temperatures.

9:30 AM TP01.05.04

XAS and XMCD Studies of Ni-Mn-In-B Thin Films
Sudip Pandey¹, Alpha T. V'Diaye², Anil Aryal³, Igor Dubenko³, Sujey Roy⁴, Shane Stadler⁵ and Nahed Alfi⁶; ¹Department of Physics, Southern Illinois University Carbondale, Carbondale, Illinois, United States; ²Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; ³Department of Physics & Astronomy, Louisiana State University, Baton Rouge, Louisiana, United States.

Ni-Mn-In-B thin films were synthesized on Si substrate using ultra high vacuum magnetron sputtering. Metamagnetic transition with thermal hysteresis has been observed on 30 nm Ni₈₆Mn₂₅In₈₂-₉₂H₃₅ thin film from the magnetization measurements. The temperature dependences of magnetization curves are found to be similar with those of bulk counterpart with the shift in transition temperatures. Electronic and magnetic properties of Ni₈₆Mn₂₅In₈₂-₉₂H₃₅ thin
The thermomagnetic generator (TMG) is a promising device to convert low temperature heat to electricity by using the change in magnetization with temperature of a ferromagnetic material placed in a magnetic circuit. Thus the magnetic flux, provided by permanent magnets, also changes and induces a voltage in a pick-up coil according to Faraday’s law of induction. This principle of energy harvesting is known for more than a century but no prototypes and only few proof of concepts have been realized. However theoretical consideration predicted the efficiency of such a device approach the thermodynamic limit. Here we present a TMG with a new topology of the magnetic circuit. This topology allows the magnetic flux to change its direction, resulting in a doubled magnetic flux amplitude. Thus the electrical power of the generator is increased by a factor of four. The topology of the magnetic circuit within the generator is optimized with FEM simulations. An additional advance of the realized topology is avoiding hysteresis as well as magnetic stray fields, which results in further improvement in electrical power output. A La-Fe-Co-Si alloy, developed for magnetocaloric refrigeration, is used as thermomagnetic material, since it exhibits a large and sharp change of magnetization in a small temperature range. Thereby low temperature heat can be thermally switched the thermomagnetic material, are experimental parameters as well. With these measurements and with the electrical power output, the efficiency of the energy conversion is determined. In the experiments the parameters are adjusted for an optimum in electrical power output and efficiency. These values of this TMG are significant higher in comparison to previously published proof of concepts. The experimental evaluation of this prototype allows to suggest further improvements of TMGs and paves the way for these devises to become competitive with thermoelectric generators for low temperature waste heat recovery.

10:45 AM *TP01.06.01
Phase Transitions in Elastic Media and the Enhancement of Caloric Effects Peter B Littlewood1, Gian Guzman-Verri2 and Xavier Moya3; 1James Franck Institute, University of Chicago, Chicago, Illinois, United States; 2Materials Research Science and Engineering Center (CICIMA), University of Costa Rica, San José, Costa Rica; 3University of Cambridge, Cambridge, United Kingdom.

The metal-insulator transition driven by strong electronic correlations – generically called the “Mott” transition – is usually described entirely by electronic Hamiltonians, with models designed to exhibit emergent phenomena such as magnetism and superconductivity. In real solids, the electronic localization also couples to the crystal lattice, and it turns out that these elastic degrees of freedom insert important new entropic phenomena more familiar in soft matter physics.

The coupling to the lattice induces elastic strain fields, which have intrinsic long-range interactions that cannot be screened. When strain fields are produced as a secondary order parameter in phase transitions - as for example in ferroelectrics - this produces unexpected consequences for the dynamics of order parameter fluctuations, including the generation of a gap in what would otherwise have been expected to be Goldstone modes. A very important class of transition metal oxides – the perovskites – can be thought of as an array of tethered octahedra where the Mott transition produces a shape-change in the unit cell. Coupling of the fundamental order parameter to octahedral rotations gives rise to large entropic effects that can shift the transition temperature by hundreds of degrees K,[1], essentially by exploiting the physics of jammed solids. The insight might offer ways to make better refrigerators by enhancing electro-caloric and magneto-electric effects.[2]

11:15 AM TP01.06.02
A Regenerative Electrocaloric Cooling Device—Numerical Modelling and Experimental Validation Uros Plaznik1, Marko Vrablj2, Zdravko Kutnjak1, Barbara Malic2, Brígida Rozic2, Jaka Tusek1, Alojz Poredos1 and Andrej Kitanovski1; 1Faculty of Mechanical Engineering, University of Ljubljana, Ljubljana, Slovenia; 2Jozef Stefan Institute, Ljubljana, Slovenia.

A research and development on a cooling device based on an active electrocaloric regenerator (AER) made of bulk ceramic material (1-x)Pb(Mg1/3Nb2/3)O3-xPbTiO3 (PMN-100xPT) will be presented. For that purpose, a new, 2D transient numerical model of the AER based on the energy equation for the solid electrocaloric material and the heat transfer fluid was developed and implemented in Matlab software. The model allows to investigate the cooling characteristics (temperature span, cooling power and efficiency) of an AER at different operating conditions (mass-flow rate, operating frequency, applied electric field change, etc). In addition, the model includes the impacts of the electrocaloric material’s hysteresis and the...
electric-energy recovery released during the depolarization (discharging) of the electrocaloric material on the AER performance. The results of the numerical analysis show that the degree of electric energy recovery has a crucial impact on the efficiency of the electrocaloric device. By comparing an idealized electric-energy recovery system, the energy efficiency (expressed by the coefficient of performance - COP) of the device could be increased by up to ten times compared to the case of without the energy recovery. A validation of the numerical model was performed through the design, construction and experiments on a new AER cooling device (without electric-energy recovery system). The experimental results revealed a maximum specific cooling power of 16 W kg⁻¹ and a maximum temperature span of 3.1 K. A comparison between the numerical and experimental results shows that model can correctly predicts the trends of cooling characteristics with respect to various operating parameters. On the other hand, there is some deviation between the absolute values of the cooling characteristics calculated with the numerical model and the experimental results. These deviations are mainly due to some effects not included in the numerical model, for example flow maldistribution.

11:30 AM *TP01.06.03

It has been more than two decades since electrocaloric-based temperature lifts on the order of 20°C were first reported in the ceramic materials and more than a decade since equivalent lifts were observed in polymeric thin films. Yet, since that time, the demonstration of even a single high performance electrocaloric-based cooling module has not been realized. Indeed, only modest performance (<5°C total lift) has been achieved when such modules have been challenged against a temperature incline. Coefficients of performance (COP) have been either unreported or inconsequential. Conversely, theoretical models predict the potential for regenerative cooling with lifts in excess of 10°C at COPs of ~6. In this talk we examine the cause of the shortfall in module performance from a material perspective. We discuss: (1) The impact of performance parasitics. (2) Active area loss due to dielectric breakdown and local arcing. (3) Degraded performance due to stress concentration, clamping from the electrode metallization and cyclic fatigue. Solutions to film and electrode failures can potentially be found by using material engineering to improve electrical, mechanical, and thermal-caloric properties.

SESSION TP01.07: Mechanocaloric Materials and Systems II
Session Chairs: Kilian Bartholome and Jian Liu
Tuesday Afternoon, November 27, 2018
Sheraton, 3rd Floor, Berkeley AB

1:30 PM *TP01.07.01
Active Elastocaloric Regenerators—Tension vs Compression Loading Jaka Tusek; Faculty of Mechanical Engineering, University of Ljubljana, Ljubljana, Slovenia.

The elastocaloric effect (eCE) associated with a stress-induced martensitic transformation in shape memory alloys (SMA) has recently shown a promising route for high-efficiency, solid-stated cooling and heat-pumping applications. It was already demonstrated that the most effective way of utilizing the caloric effects (magnetocaloric, electrocaloric, elastocaloric) in a practical cooling device is so-called active caloric regenerator, which is a porous structure made of caloric material. It has a double function in a caloric cooling device; it works as a refrigerant as it contains active caloric material as well as a regenerator and enables an enhancement of the temperature span between heat sink and heat source.

In this talk different possibilities of active elastocaloric regenerator geometries to be loaded in tension and compression will be reviewed and discussed. Both tension and compression loading has some important pros and cons for elastocaloric cooling. The main advantage of tension loading is the ability to apply thin elements and small channels for the fluid-flow that allows for fast and efficient heat transfer, while its main disadvantage is reduced fatigue life when compared to compression loading. However, thin elements which would enhance heat transfer characteristics are difficult to compress without buckling. It is therefore a big challenge to design an active elastocaloric regenerator that is geometrically stable during compression loading, while maintaining high eCE and highly efficient heat transfer.

The fatigue strain limits and the associated eCE for durable operation (~10⁶ cycles) of Ni-Ti plates to be applied in efficient active elastocaloric regenerator loaded in tension will be presented. In addition, different potential geometries of an active elastocaloric regenerator to be loaded in compression, such as block with holes, set of tubes in a holder, shell-and-tube-like regenerator, etc., will be discussed together with the main challenges associated with those geometries.

2:00 PM TP01.07.02
Comparison of Electrocaloric Materials on Basis of Material Related Cooling Power Florian Weyland¹ and Nikola Novak²; ¹TU Darmstadt, Darmstadt, Germany; ²Institute Jozef Stefan, Ljubljana, Slovenia.

The centerpiece of solid state coolers using caloric effects, i.e. electrocaloric, magnetocaloric or mechanocaloric, is the caloric material. In the search of a refrigerant for electrocaloric cooling devices a large number of ferroelectric materials, with their respective adiabatic temperature change, have been identified. To find the most suitable material not solely the electrocaloric but also the thermophysical properties need to be accounted for. To compare materials with each other a useful figure of merit is the material related cooling power, as it considers the material properties, i.e. electrocaloric effect and thermophysical behavior, without including device specifications. The performance characteristics of ferroelectric materials are determined to a large degree by the nature of the paraelectric to ferroelectric phase change. Here, the electrocaloric and thermophysical properties of BaTiO₃ (BT) and 0.72PbMg₁/₃Nb₂/₃O₃-0.28PbTiO₃ (PMN-28PT) single crystals and polycrystalline BaZr₀.₃Ti₀.₇O₃ (BZ₃T) ceramics are compared. BT and PMN-28PT are typical representatives of first order and relaxor-like ferroelectrics, respectively. Furthermore, they both show a dielectric permittivity peak around ~400 K. The BZ₃T ceramics are BT derived compositions with Zr-ions substituted on the Ti-ion site. By the amount of Zr-ion substitution the phase change characteristic and transition temperature is modified. The dependence of the material related cooling power of those materials on the dimensionless temperature, characteristic distance and holding time for heat transfer is determined on the basis of directly measured electrocaloric temperature changes, thermophysical properties and a simple model based on Newtonian cooling of a thin plate. It is shown, that a decrease in the holding time for heat transfer increases the cooling power. It is found that the higher thermal conductivity of BT contributes significantly to its large cooling power. At temperatures near the Curie point the electrocaloric temperature change of BT is large and hence, the cooling power is large. In contrast, the relaxor-like PMN-28PT exhibits a much broader range of peak cooling power, which can be useful for widening the temperature range of operation. The BZ₃T displays a broad peak of maximum cooling power near room-temperature. Although device-level factors, such as thermal resistances at electrode interfaces are ignored, the results suggest a simple basis of comparison for ferroelectric materials. In addition, the derived equation for the material related cooling power is used to compare the different caloric effects with each other.
Low Temperature Magnetocaloric Materials for Cryogenic Gas Liquefaction by Magnetic Cooling Technique

In this work we report on the results of investigation of low temperature magnetocaloric materials based on ReTm2 compounds (Re- rare earth's, Tm – transition metals) for magnetic refrigeration in cryogenic application. Special accent made for investigation an influence of severe plastic deformation on magnetocaloric properties of such alloys.

Copper Based Elastocaloric Materials

Elastocaloric cooling has high Coefficient of Performance and minimum environmental impact. In 2014, U.S. Department of Energy ranked it as the most promising new HVAC technology to replace vapor compression. While many alloys exhibit elastocaloric effect, few can simultaneously meet the criteria on delta T, biasing stress, and cost. To date, NiTi remains as the best material for elastocaloric cooling application. While NiTi alloy has high latent heat and long fatigue life under compression, it requires large stress (>600 MPa) and it is prohibitively expensive, which makes it difficult for wide spread industrial and consumer applications. This talk reviews the concept of elastocaloric cooling, the challenges and the progress of developing copper based elastocaloric materials using combinatorial materials development approach.

SESSION TP01.08: Magnetocaloric Materials and Systems III

Tuesday Afternoon, November 27, 2018

N'Diaye2, Amil Aryan1, Pinaki Das1, Igor Dubenko1, Susjoy Roy1, Dipanjan Mazumdar1, Helmut Kaiser1, Shane Stadler1 and Naushad Ali1; 1Department of Physics, Southern Illinois University, Carbondale, Illinois, United States; 2Department of Physics & Astronomy, Iowa State University, Ames, Iowa, United States; 3University of Missouri Research Reactor, University of Missouri-Columbia, Columbia, Missouri, United States; 4Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 5Department of Physics & Astronomy, Louisiana State University, Baton Rouge, Louisiana, United States.

Natural gases are one of the main sources of energy nowadays and will be of increasing importance in the near future. Currently, there is an upward trend of the production and consumption of this type of energy including methane, hydrogen, oxygen etc. For its storage, liquefaction is needed, which requires complex energy-intensive compressor devices operating at cryogenic temperatures. The efficiency of traditional liquefaction methods is quite low at temperatures below 150 K. We propose here a fundamentally different approach to liquefy gases - the emerging magnetic cooling technology. With the recent progress in superconducting magnets with static magnetic fields of up to 15 – 22 T, cooling at cryogenic temperatures can enable a revolution in the technology of gas liquefaction. A review on recent scientific publications reveals the large variety of different magnetic materials showing a significant magnetocaloric effect in the relevant temperature region of 15 to 150 K [1]. Thus, the efficient liquefaction of almost any natural gas in the same type of magnetic cooling machine would be possible [2-5].

3:20 PM TP01.08.02
Low Temperature Magnetocaloric Materials for Cryogenic Gas Liquefaction by Magnetic Cooling Technique

Natural gases are one of the main sources of energy nowadays and will be of increasing importance in the near future. With the recent progress in superconducting magnets with static magnetic fields of up to 15 – 22 T, cooling at cryogenic temperatures can enable a revolution in the technology of gas liquefaction. A review on recent scientific publications reveals the large variety of different magnetic materials showing a significant magnetocaloric effect in the relevant temperature region of 15 to 150 K [1]. Thus, the efficient liquefaction of almost any natural gas in the same type of magnetic cooling machine would be possible [2-5].

In this work we report on the results of investigation of low temperature magnetocaloric materials based on ReTm2 compounds (Re- rare earth’s, Tm – transition metals) for magnetic refrigeration in cryogenic application. Special accent made for investigation an influence of severe plastic deformation on magnetocaloric properties of such alloys.

Getting the Most Out of Your Magnetocaloric Heat Pump

A magnetocaloric heat pump, dimensioned to the requirements of a domestic house in Northern Europe, has been designed, constructed and tested. The design has been optimised towards a heating power of 1500 W and a temperature span of about 20 K. The regenerator beds are packed with 10 layers of spherical La(Fe,Mn,Si)13H particles. The use of such magnetocaloric materials with a first order magnetic phase transition imposes constraints on how the temperature span of a magnetocaloric device may be controlled, which again imposes constraints
on the type of heating system the heat pump can be connected to. Different ways of dealing with this issue will be presented and discussed.

Part load conditions where less than the maximum heating power is required can be achieved by varying the flow rate or the frequency. However, by combining the control of the two parameters it is demonstrated how it is possible to increase the coefficient of performance (COP) for part load conditions. Finally, the experimental and modelling performance of the heat pump will be considered in the context of connection to a ground source and an underfloor heating system, for the heating of a model house.

4:30 PM TP01.08.04
Stability of Magnetocaloric La(Fe\textsubscript{x}Co\textsubscript{y}Si\textsubscript{1-x-y})\textsubscript{13} in Water and Air
Khushar Javed\textsuperscript{1}, Ravi L. Hadimani\textsuperscript{1}, Brent Williams\textsuperscript{1}, Shane Harstad\textsuperscript{1}, Vitalij Pecharsky\textsuperscript{2,3} and Shahab Abdolvand\textsuperscript{2,3}
\textsuperscript{1}Department of Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, Virginia, United States; \textsuperscript{2}Division of Materials Science and Engineering, Ames Laboratory, US Dept. of Energy, Ames, Iowa, United States; \textsuperscript{3}Department of Materials Science and Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

Lanthanum Iron Silicide with Cobalt substitution, LaFe\textsubscript{x}Co\textsubscript{y}Si\textsubscript{1-x-y}\textsubscript{13}, is a room temp magnetocaloric material and these particles exhibit different magnetic properties when stored in air and compared to the same stored in the sample. With the sample with a nominal composition of LaFe\textsubscript{x}Co\textsubscript{y}Si\textsubscript{1-x-y}\textsubscript{13}, was prepared by arc-melting and these Ingot pieces were annealed at 1050°C for 7 days followed by quenching in ice-cold water. The annealed pieces were crushed to particle size of 100μ and then ball-milled using a SPEX8000 mill for 10 min. PANalytical X'Pert Pro diffractometer shows that powder stored in water for 14 days appear to be missing some of the Bragg peaks and develop low-Bragg angle halos typical of non-crystalline components. It concludes that both types of powders; milled and course crushed samples react with water.

The course crushed powder stored in air and water show sharp transition at the Curie temp Tc = 300K without large magnetization above the Tc. The milled fine-particle sample stored in air shows significantly broadened transition at Tc, and that stored in deionized water for 14 days shows no obvious magnetic transition; both show large magnetizations above 300K. This is indicative of relatively fast hydrolysis and removal of some or all La, likely as hydroxide, from fine powders, leaving behind La-poor and, potentially, La-free Fe-Co-Si containing ferromagnetic residue with much higher Curie temp.

The milled sample stored in water also shows the highest saturation magnetization followed by both sample stored in air. The course crushed sample stored in water shows the maximum MCE of AS = 11 J Kg\textsuperscript{-1}K\textsuperscript{-1} near 300K with the change of 3T magnetic field and highest relative permeability while the milled sample stored in water has the lowest entropy change. The milling process has induced broadening of the transition. Course crushed sample stored in water and in air have similar magnetocaloric effect. It can be concluded that the course crushed samples contain larger particles and smaller surface area as compared to milled samples which have less than micron size particles. Water added to the milled sample leads to hydrolysis and removal of some of the La as hydroxide from fine powders, leaving behind La-poor Fe-Co-Si containing ferromagnetic residue of possibly Fe\textsubscript{3}O\textsubscript{4} or Co\textsubscript{3}O\textsubscript{4} with much higher Curie temp as follows from the absence of the obvious magnetic transition(s) and large magnetization beyond 300K. The course crushed samples show much greater stability and sharper magnetic transition when stored both in air and water. The course crushed sample stored in water has sharper magnetic transition and course crushed magnetization hence it shows the highest entropy change among all 4 types of samples.

\textsuperscript{1}Department of Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, Virginia, United States; \textsuperscript{2}Division of Materials Science and Engineering, Ames Laboratory, US Dept. of Energy, Ames, Iowa, United States; \textsuperscript{3}Department of Materials Science and Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States.

Fully hydrogenated LaFe\textsubscript{13-Si\textsubscript{13}} is one of the most interesting candidates for room temperature magnetic refrigeration. The first order nature of the magnetic transition is connected to its itinerant electron magnetism, which gives rise to a peculiar coupling between all microscopic degrees of freedom. By combining first principles calculations in the framework of density functional theory (DFT) and nuclear resonant inelastic X-ray scattering (NRIXS) we investigate the interplay of electronic structure, magnetism and vibrational degrees of freedom in fully hydrogenated LaFe\textsubscript{13-Si\textsubscript{13}}. In the past, we could show that for the non-hydrogenated ternary compound, the itinerant nature of the Fe moments, which is responsible for the large volume change, gives rise to the adiabatic electron-phonon coupling [1,2]. This leads to a cooperative contribution of magnetic, electronic and vibrational degrees of freedom to the entropy change, which results in the excellent caloric properties [1,3]. By hydrogenation it is possible to shift the operating range to ambient conditions, which is required for mass market application. A common strategy is to fully load the material with hydrogen and fine-tune the transition temperature by adding other components, such as Mn.

In this contribution, we demonstrate that the same mechanism acting in LaFe\textsubscript{13-Si\textsubscript{13}} is also responsible for the superior magnetocaloric properties of the hydrogenated compound LaFe\textsubscript{13-Si\textsubscript{13}}H\textsubscript{13}. Again, the cooperative nature of the vibrational contribution to the entropy change is essentially determined by an anomalous softening of vibrational modes arising from the itinerant nature of the Fe moments, which is not destroyed by the hydrogenation. We find that hydrogen dominates the vibrational density of states at low energies, which one rather expects for heavy elements. Despite this, its contribution to the change in vibrational entropy remains rather small. Since full loading with hydrogen involves the occupation of only a part of the available (24d) lattice sites, we also discuss the site-occupation of hydrogen based on total energy calculations and by comparing vibrational density of states from DFT involving different distributions of hydrogen with the NRIXS measurements. Finally, we will give an outlook on the impact of a partial substitution of Fe with Mn on the vibrational properties and the coupling mechanism.

A new test system, CaloriSMART (Small-scale Modular Advanced Research Test station), is being developed to support new caloric materials
development efforts. This system is intended for rapid evaluation of performance of caloric materials in small quantities, 5-50 grams, over a wide range of
operating conditions (frequencies from 0.1 to 5 Hz, utilization from 0.2 to 1, and environment temperatures from -10 to 50 C) using magnetic, stress, and
electric fields, and combinations thereof as the driving fields. CaloriSMART is capable of measuring temperature spans at known cooling loads, zero span
cooling power, and passive heat transfer characteristics of regenerator beds.

The magnetocaloric system module can apply magnetic fields of 1.1 T or 1.4 T and exhibits very precise control over the flow profile and rotational speed.
Thorough characterization of the system using Gd as a baseline material demonstrated operation over the full range of operating conditions. It was found
that the no-load temperature span could be increased by as much as 10% using precise control and timing of the flow profile with respect to the field
application. Testing also revealed the importance of equal dwell time inside and outside the magnetic field in obtaining maximum performance. Test results
from several magnetocaloric materials will be presented.

The elastocaloric module design goals were to minimize forces needed to actuate materials while having the capability of testing samples in both tension
and compression. Unique regenerator designs based on composite structures of passive materials and active sections have been developed for both tension
and compression. While the compression arrangement limits access for heat transfer, it also allows for compression of a large sample without buckling. The
presentation includes initial test results based on these regenerator configurations using readily-available NiTi materials.

Future plans for module designs and regenerator testing will be discussed with particular focus on electrocaloric and multi-caloric capabilities. Initial ideas
for incorporating materials of different forms into useful and robust regenerator geometries are also presented.

This work has been carried out under the auspices of CaloriCool® – the caloric materials consortium – which is a part of the Energy Materials Network.
The consortium is funded by the Advanced Manufacturing Office and is managed jointly by the Advanced Manufacturing Office and Building
Technologies Office of the Office of Energy Efficiency and Renewable Energy of the United States Department of Energy. The research was performed at
the Ames Laboratory. Ames Laboratory is operated for the U.S. Department of Energy by Iowa State University under contract No. DE-AC02-
07CH11358.

9:00 AM *TP01.09.02
Heat Conductivity and Energy Efficiency of Electrocaloric Materials Emmanuel Defay, Luxembourg Institute of Science and Technology, Belvaux,
Luxembourg.

The specificity of electrocaloric (EC) materials among the other caloric materials is that electric field is the stimulus required to trigger the EC effect. The
advantage is that it is rather straightforward to apply an electric field on an EC capacitor. The main drawback is that electrodes and electric threads have to
be systematically associated to EC materials. These specificities induce two dedicated answers to two recurrent questions posed by all caloric principles,
namely energy efficiency and effective thermal conductivity.

Regarding energy efficiency, one can address the challenge through intrinsic means, meaning finding the best materials able to provide the largest variation
of entropy for the lowest input electric energy. Thanks to the electric nature of the stimulus, one can also think of extrinsic means to enhance substantially
the overall effective efficiency of given EC heat exchangers, typically by recycling the electric energy used to trigger the EC effect.

Besides, the necessity of using electrodes to trigger the EC effect infers extra complications when it comes to exchange heat. Indeed, using electrically
insulating caloric fluids limits their nature to poorly thermally conductive ones. On the other hand, figuring out EC prototypes without fluid infers
complex engineering and raises specific issues about solid-solid heat exchange. Besides, EC materials are generally weak thermal conductors. This
nowadays stands probably for the main hurdle to make convincing heat exchanger prototypes.

In this talk, we will address efficiency and thermal exchange of EC materials by drawing first the state of the art and then by giving potential solutions to
envision future EC heat exchangers.

9:30 AM TP01.09.03
Predictive Modeling of Electrocaloric Heat Exchangers Alvar Torello Massana1, Romain Faye1, Tomoyasu Usui2, Sakyo Hirose2 and Emmanuel
Defay1, 1Luxembourg Institute of Science and Technology, Luxembourg, Luxembourg; 2Murata Manufacturing Co., Ltd., Nagaokakyo, Japan.

In recent years, several Electrocaloric (EC) heat exchangers have been proposed, covering different kinds of mechanisms and working principles. Despite
this fact, little has been told about the numerical modeling of these devices.

In this work, finite elements simulations carried out with COMSOL Multiphysics software are presented. These simulations consist of 2D-representations
of the lead scandium tantalate multilayers capacitors (PST MLC) 22mm x 10.4mm x 1mm parallel-plates based active regenerator that is currently being
developed in LIST, where a maximum temperature difference of 1K in the device has recently been measured. In the model, the EC effect is triggered by
applying equivalent heat power square pulses synchronically with the induced bidirectional laminar flow of a dielectric fluid. The model is proved to match
the experiment for the first two minutes of performance before experimental intrinsic losses make the data moderately diverge.

Within this transient regime, the model is able to predict the performance of our heat exchanger for new sets of parameters. The results obtained showed
that by enlarging the length of the parallel plates by a factor of three or by decreasing their thickness by a factor of two, the temperature difference in the
device could increase already up to 7 degrees. The performance of other working fluids, which at the moment are not experimentally feasible to implement,
was also attempted. In the case of water, with better thermal properties, the frequency of the cycle was increased up to three times, displaying very
encouraging results. In conclusion, the modeling investigated indicates plenty of scope for ongoing improvement, reporting more than 10 K when the
simulation parameters were optimized.

Solid-State Electrocaloric Heat Pump David E. Schwartz, Yunda Wang, Michael Benedict, Jamie Kalb, Joseph Lee and Ziyang Zhang; PARC, Palo
Alto, California, United States.

Electrocaloric materials have the potential to enable compact, high-efficiency cooling devices. One advantage of electrocaloric heat pumps is the capability
for fully solid-state designs that do not rely on pumped fluid to transfer heat to and from the cooling elements. The core of an electrocaloric heat pump is a set of capacitors based on a dielectric material with a large electrocaloric effect (ECE). ECE can be characterized by adiabatic temperature change with applied electric field. Both polymer and ceramic materials with large ECE have been developed. However, realizing multilayer capacitors with large heat capacity has remained elusive. To date, the demonstration of electrocaloric heat pump demonstrations have utilized commercially available capacitors based on barium titanate (BTO), which have a small ECE <1K at maximum field, or capacitors with only one or two layers of polymer materials. This talk will describe PARC’s approach to solid-state electrocaloric heat pump design capable of high temperature span with limited parasitic thermal mass. Recent results of a demonstration system utilizing high performance bulk ceramic multilayer capacitors will be presented.

SESSION TP01.10: Multicaloric Materials
Session Chair: Lluis Manosa
Wednesday Morning, November 28, 2018
Sheraton, 3rd Floor, Berkeley AB

10:45 AM *TP01.10.01
Multi-Field Modulated Hysteresis Loss and Multicaloric Effect Feng-Xia Hu1,2, Qing-zen Huang3, Ji-rong Sun4,5 and Bao-gen Shen1,2; 1Beijing National Laboratory for Condensed Matter Physics and State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing, China; 2School of Physical Sciences, University of Chinese Academy of Sciences, Beijing, China; 3NIST Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Solid state refrigeration based on magnetocaloric, electrocaloric, mechanocaloric effect (multicaloric effect) has attracted world-wide attention for its environmental-friendly and energy-saving superiority over the conventional vapor compression technique. Here, we report our recent progress on multi-field modulated hysteresis loss and multicaloric effect for the well-known La(Fe,Co,Si)13[1], FeRh [2], and NiIn-type MM’X [3] materials. For a room temperature La(Fe,Co,Si)13, magnetocaloric material, enhanced magnetocaloric effect (MCE) by hydrostatic pressure has been demonstrated as magnetic measurements under pressure. To understand the origin, we performed neutron powder diffraction studies on the crystal and magnetic structures as a function of temperature under different pressures [4]. The change of atomic local environments and 5 kinds of Fe-Fe bonds (B1-B5) with pressure were illustrated. Detailed analysis indicated that the sensitivity of intra-icosahedron Fe-Fe bonds (B1, B2, B3) to hydrostatic pressure is mainly responsible for the change of magnetic properties. Moreover, we found that the change of lattice volume AV/V across Curie temperature TC becomes significantly larger with increasing pressure. Accordingly, lattice entropy change was estimated by Debye approximate. The results indicate that the contribution of entropy change from lattice increases by ~40% as the pressure increases to 11.3 kbar. This result indicates that hydrostatic pressure is an effective way to dig the lattice contribution. Multicaloric effect and the contribution from interplay between spin and lattice are also discussed. On the other hand, hysteresis loss is a longstanding problem harming refrigeration efficiency, which exists in most of giant magnetocaloric materials. Here we report a new way to reduce hysteresis loss in the model FeRh materials. Utilizing strain memory effect to engineer the magnetization process of FeRh film, a large reduction of hysteresis loss was achieved, consequently effective refrigeration capacity and COP (coefficient-of-performance) remarkably increases in a designed refrigeration cycle [5]. We also studied the impact of film strain on the magnetostructural coupling of NiIn-type Mn-Co-Ge-In films grown on different substrates. Strain modulated phase transition and MCE has been demonstrated [6].

This work was supported by the National Key Research and Development Program of China (2017YFB0702702, 2014CB643700), and the National Natural Sciences Foundation of China (51531008, 51771223, 51590880).

11:15 AM TP01.10.02
Ultra-Low-Field Magneto-Elastocaloric Cooling in a Multiferroic Composite Device Huilong Houl, Peter Finkel2, Margo L. Starch2; Jan Cun3,4 and Ichiro Takenchi2; 1University of Maryland, College Park, College Park, Maryland, United States; 2U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 3Ames Laboratory, Ames, Iowa, United States; 4Iowa State University of Science and Technology, Ames, Iowa, United States.

Given that caloric materials are ferroic materials which undergo first (or second) order transitions near room temperature, they open up intriguing possibilities for novel multiferroic devices with hitherto unexplored functionalities coupling their thermal properties with different fields (magnetic, electric, and stress) through composite configurations. Here, we demonstrate a composite magneto-elastocaloric effect with ultra-low magnetic field (0.16 T) in a compact geometry to generate a cooling temperature change as large as 4 K using a magnetostiction/superelastic alloy composite. Such composite systems can be used to circumvent shortcomings of existing technologies such as the need for high-stress actuation mechanism for elastocaloric materials and the high magnetic-field requirement of magnetocaloric materials, while enabling new applications such as compact remote cooling devices.

11:30 AM *TP01.10.03
Multicaloric Effects—Materials and Modeling Antonio Planes1, Teresa Castan1, Lluis Manosa1 and Avadh Saxena2; 1Física de la Matèria Condensada, Universitat de Barcelona, Barcelona, Spain; 2Los Álamos National Lab, Los Alamos, New Mexico, United States.

Multicaloric materials thermally respond to changes in their properties induced by the application or removal of multiple external fields. Particularly interesting are a class of multiferroic materials which are characterized by a strong interplay between different ferroic properties in the region where these properties emerge via a phase transition. In this talk, we will discuss a general thermodynamic framework to describe multicaloric effects in this class of materials. We will show that multicaloric effects comprise the contributions from caloric effects associated with each ferroic property and the cross-contribution arising from their interplay. In these materials, the use of more than one driving field can induce larger thermal changes, with smaller field magnitudes, over wider ranges of operating temperature. In addition, this permits to reduce hysteresis in one driving field in a controlled manner by transferring it to another field. These results will be illustrated with available experimental data.
1:30 PM TP01.11.01
Giant Barocaloric Effects at Low Pressure in Organic Salts Xavier Moya; Department of Materials Science, University of Cambridge, Cambridge, United Kingdom.

Barocaloric materials driven by hydrostatic pressure are currently being considered for cooling applications, following the observation of giant barocaloric effects in a small number of magnetic materials and ferroelectric materials. Here I will present pressure-dependent calorimetry data to demonstrate giant barocaloric effects in two organic salts that are made of cheap abundant elements, and that operate under low pressure.

2:00 PM TP01.11.02
Design and Operation of a 100 W Elastocaloric Compression-Based Active Regenerator David Catalini1, Nehemiah Emaikwu1, Jan Muehlbauer1, Suxin Qian2, Yunho Hwang1, Reinhard Rademacher1 and Ichiro Takeuchi1; 1University of Maryland, College Park, Maryland, United States; 2Xi’an Jiaotong University, Xi’an, China.

We have constructed and operated a 100W single-stage elastocaloric active regenerator based on compression of a bundle of NiTi tubes. Commercially available NiTi tubes placed inside a metallic sleeve undergo stress-induced martensitic transformation via compression. We use water as the heat transfer fluid which flows through the tubes. A numerical model of the system was developed in the Matlab/Simulink environment to solve the dynamic heat transfer and accounting for the thermodynamics-based phase transformation kinetics model of NiTi. The numerical tool was used to evaluate the influence of the operating parameters in the system’s performance and to find the optimal conditions for maximum temperature lift across the active regenerator. For compressive stress of 4%, where materials DT is 8K, an initial run has given the temperature lift of 13.5K under no cooling load conditions. The design can be scalable by adding parallel beds to increase cooling capacity and to add a work recovery mechanism to increase efficiency.

SYMPOSIUM TP02

TUTORIAL: Thermal Characterization of Materials and Devices
November 25 - November 25, 2018

1:30 PM Thermal Characterization of Wide Bandgap Semiconductor Materials and Device Samuel Graham; Georgia Institute of Technology

The development of wide bandgap semiconductors have enabled new optoelectronic, RF, and power electronic devices and their performance and reliability are strongly coupled to their thermal behavior. In this tutorial, a number of optical and electrical methods will be reviewed which allow for the characterization of the thermal properties of wide bandgap materials including thermal conductivity and thermal interface resistance at contacts. In addition, metrology methods for mapping temperature under steady-state and high speed thermal transients relevant to RF operation will be discussed along with their limitations and areas which remain a challenge to researchers.

3:00 PM BREAK

3:30 PM Challenges in Measuring Nano- to Micro-gram Samples: Scanning Calorimetry and Thermoviscoelasticity Gregory B. McKenna; Texas Tech University
Novel developments in making ultra-stable glasses lead to measurement challenges because extremely small amounts (nano- to micro-grams) of material are produced. We will describe work using chip calorimetry to determine the thermal properties and the cooling rate dependence of the Tg. In addition, nano-scale rheology on these materials can be carried out to determine material dynamics using a novel bubble inflation measurement method developed in our labs.

8:00 AM *TP02.01.01
Heat Capacity Determination—Tricks of the Trade Mary Anne White; Dalhousie University, Halifax, Nova Scotia, Canada.

Sometimes very accurate heat capacity data are required; an example would be for the calculation of a thermodynamic cycle that involves small differences between large numbers. Sometimes less accurate data would still be useful, especially if they can be acquired quickly. In this talk, some instances of each situation will be presented, along with tips to attain high-accuracy data using relaxation calorimetry, moderate accuracy with using DSC, and quantitative estimates using other means.

8:30 AM *TP02.01.02
The Boiling Temperature of Ionic Liquids—An Experimental Approach Amir Abdelaziz1, Sergey P. Verevkin3 and Christoph Schick1,2; 1Institute of Physics & Competence Centre “CALOR, University of Rostock, Rostock, Germany; 2A. Butlerov Institute of Chemistry, Kazan Federal University, Kazan, Russian Federation; 3Institute of Chemistry & Competence Centre “CALOR, University of Rostock, Rostock, Germany.

The very low vapor pressure of ionic liquids is challenging to measure. At elevated temperatures the liquids might start to decompose, at relatively low temperatures the vapor pressure becomes extremely low to be measured by conventional methods. We developed a highly sensitive method for mass loss determination at temperatures starting from 350 K up to 800 K. The technique is based on fast scanning (10 000 K s⁻¹) and an alternating current (AC) calorimeter equipped with a chip sensor, that consists of a free-standing SiN₅ membrane (thickness < 1 μm) and a measuring area with lateral dimensions of the order of 100 μm. A small droplet (diameter ca. 300 μm) of an ionic liquid is vaporized isothermally from the chip sensor in a vacuum-chamber. The surface-to-volume-ratio of such a droplet is large and the relative mass loss due to evaporation is therefore easy to be monitored by the changing heat capacity (J K⁻¹) of the remaining liquid. The vapor pressure is determined from the measured mass loss rates using the Langmuir equation. The method was successfully tested with determination of vapor pressures and the vaporization enthalpy of the archetypical ionic liquid 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIm][NTf₂]). The created in this way data set in the extremely broad temperature range 358 K to 780 K has allowed estimation of the boiling temperature of [EMIm][NTf₂]. The value (1120 ± 50) K should be considered as the first reliable boiling point of this ionic liquid obtained from experimental vapor pressures measured in the most possible close proximity to the normal boiling temperature.

Liquid to Glass/Crystal Transitions in Ionic Liquids Studied by Fast Thermal Conductivity Measurements

Carlos López-Bueno, David Bugallo Ferrón, Victor Leborán, M.C. Giménez-López and Francisco Rivadulla, Centro de Investigación en Química Biolóxica e Materiais Moleculares (CIQUS), Santiago de Compostela, Spain.

We have developed an experimental setup for the simultaneous measurement of the thermal conductivity and heat capacity of liquids. This system is an extension of the 3ω method [1] capable to measure a sample volume of the order of ~500 nL, which is an important advantage for the characterization of nanofluids, in which having a large amount of sample is sometimes difficult to achieve [2]. The setup is designed for fast measurements during a thermal ramp, which along with the extremely small volume required allows the possibility of using it in a cryostat for analysing the temperature dependence of the thermal conductivity in a variety of fluids, across phase transitions, kinetic studies, etc.

Particularly, in this work we will present the study of the low temperature thermal and electrical conductivity of different ionic liquids around their liquid-to-solid transition. Using these methods we are able to identify a spinodal decomposition temperature in in 1-Ethyl-3-methylimidazolium trifluoromethanesulfonate (EMIM TFSI) around 150K. Below this temperature, the glassy phase is unstable against the formation of a crystalline phase in the whole system. This produces a 30% variation of the thermal conductivity of the system, depending on the thermal history. We discuss the possibility of using ionic liquids as configurable models to study the low temperature thermal conductivity of ionic solids.

Abrupt Size Effect Observed in Layered Materials Below Critical Size—Linking Thermal Analysis with Local Structural Analysis

Zichao Ye1, Lito De la Rama1, Mikhail Efremov2, Andre Sutrisno3 and Leslie Allen1; 1Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Material Measurement Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Materials often exhibit exotic properties because of “discrete regions”, regions that have different chemical environment from the remaining part of the system. Material at the first level is treated as a uniform “bulk” with single sets of intrinsic and extrinsic characteristics; the next level incorporates finer details of the system by segmenting it with discrete regions, including interfaces (e.g., lamella mating boundaries), surfaces (e.g. nanoparticle spheres) and defects (e.g., gauche kinks). The effect of these discrete regions is highlighted by material miniaturization. At extremely small scale lengths (<10 nm), properties of the “whole” object (e.g., melting, lattice structure, bandgap, conductivity, optical) are dominated by the nature of “local” discrete regions.

Regular thermal analysis using calorimetry has no depth perception – it only yields average thermodynamic values, whereas NMR has the unique capability to probe the local structure of each individual atom. Here we link calorimetry (NanodSC or DSC) thermal analysis with 31C NMR structural analysis to report an abrupt bulk-to-discrete transition in 2D layered silver alkanethiolate (AgSCn, n=1-16) with a critical chain length of ~7. None of the carbon group share identical chemical environment below the critical length, making AgSCn (n=2-6) uniquely different materials, even though the crystal structures of all AgSCn are preserved throughout. Extraordinary changes of thermodynamic properties, including ~500% increase of melting enthalpy and ~50°C increase of melting point, are also observed at the bulk-to-discrete transition. This transition is universal for aliphatic layers, including n-alkanes with a critical chain length of n=11. A new 3D spatial model is constructed to divide the aliphatic chains of AgSCn into three bulk or discrete segments: (a) tail segment that forms interlayer interfaces, which are never planar structures but have 3D depth; (b) head segment that is strongly affected by the metallic core; (c) bulk mid-chain segment which shows similar properties to the hydrocarbon chains in polyethylene. The presence (multilayer) or absence (1-layer) of odd/even effect is exclusively attributed to the nature of the localized tail segment. Bulk-to-discrete transition occurs when material properties are dominated by the discrete head and tail segments over the bulk segment at/below critical length. This work is seminal to the design of novel aliphatic lamellae with tailorable properties and has applications in molecular electronics and biophysics.

Phase Transformations in CuZr-Based Shape Memory Thin Films Analyzed by Combinatorial Nanocalorimetry

Koost J. Vlaskak and Mark Miao; Harvard University, Cambridge, Massachusetts, United States.

We have investigated the phase transformations in sputtered CuZr-based shape memory thin films using a combinatorial nanocalorimetry technique that is capable of making differential calorimetric measurement on thin-film samples with a sensitivity as small as 12 pJ/K. We first investigate the crystallization kinetics of amorphous as-deposited equiatomic CuZr samples and demonstrate non-Arrhenius diffusion kinetics that is well described using a phenomenological model based on the fragility of super-cooled liquids. We then explore the conditions for the formation of the martensitic phase.
responsible for the shape memory properties of this alloy. We will show that fast, low-temperature cycling through the martensitic transformation increases the hysteresis, which we attribute to the accumulation of defects during the martensitic transformation. If, however, the austenitic phase is given sufficient time at elevated temperature to annihilate these defects, the transformation is stable under thermal cycling conditions. The addition of Ni to the CuZr alloy raises the martensite transformation temperature making it a potential high-temperature shape memory alloy. The microstructures of select CuZrNi samples have been analyzed using XRD and cross-sectional TEM. We will present the effects of composition, heat treatment, and grain size on the transformation temperature, hysteresis, and functional stability of the samples. We will also demonstrate that under certain conditions the martensitic transformation proceeds in an explosive fashion. The transformation behavior of these alloys will be discussed in light of ab initio simulations of the materials system.

Physical Limits of Laser Gold Nanowarming

Kanav Khosla1, Li Zhan1, Aditya Bhati1, Aiden Carley-Clopton1, Mary Hagedorn2, and John Bischof1,2; 1Department of Mechanical Engineering, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; 2Smithsonian Conservation Biology Institute, Smithsonian National Zoological Park, Washington, District of Columbia, United States.

In this work we explore the physical limits of a new technique to rewarm vitrified droplets and zebrafish embryos impregnated with 1064 nm resonant gold nanorods that are irradiated by a Nd:YAG ms pulsed laser. Importantly, the droplets and the embryos loaded with 2 M PG are first cooled by a modified cryostop at rates estimated to be 90,000 °C/min to a visually transparent state in liquid nitrogen. Numerical modeling demonstrates possible differences in warming depending on full mixing (droplets) vs. micro-injection into the yolk of the zebrafish. Experimental measurements based on optical transparency vs. cloudy behavior are then used to judge the physical success of the procedure. From this we present a map of the successful laser power, pulse length, CPA concentrations and gold concentrations that can yield physical success for laser gold nanowarming.

11:30 AM - TP02.01.08
Non-Contact Thermal Analysis with Fast and Micro-Scale Thermographical Imaging

Junko Morikawa; Tokyo Institute of Technology, Tokyo, Japan.

Non-contact quantitative thermal imaging in micro-scale is attractive to realize the non-contact thermal analysis. It visualizes not only the typical thermal analysis on phase transitions and thermal degradation, but also the heat transfer. We propose a system of infrared camera equipped with an original optics and temperature calibration algorithm, which enables to achieve the high-quality and fast-speed thermal imaging. The Infrared (IR) optical lens design has been optimized to each wavelength band of the photon type and the thermal type detectors of IR FPA. Typical applications to observe the freezing biological cells and the crystallization of organic molecular crystals are reviewed. Combined with the techniques of microscale flying spot laser and the superimpose processor, the method is applied to determine the heat transport properties. The recent instrumentation of thermospectroscopy and the high temperature imaging systems are also introduced.

11:45 AM - TP02.01.09
Time-Domain Transient Fluorescence Spectroscopy for Thermal Characterization of Polymers

Hao Wu1, Yanan Yu2, Yangheng Xiong2 and Xin Zhang2; 1School of Power and Mechanical Engineering, Wuhan University, Wuhan, China; 2Department of Mechanical Engineering, Boston University, Boston, Massachusetts, United States.

In this work, a time-domain fluorescence spectroscopy technique is developed to characterize thermophysical properties of polymers. The method is based on fluorescence thermometry of materials under periodic pulse heating. In the characterization, a continuous laser (405 nm) is modulated with adjustable periodic heating and fluorescence excitation. The temperature rise at sample surface due to laser heating is probed from simultaneous fluorescence spectrum. Thermal diffusivity can be determined from the relationship between normalized temperature rise and the duration of laser heating. To verify this technique, thermal diffusivity of a polymer material (PVC) is characterized as 1.031×10^-7 m^2/s, agreeing well with reference data. Meanwhile, thermal conductivity can be obtained by the hot plate method. Then, both steady and unsteady thermophysical properties are available. Quenching effect of fluorescence signal in our measurement can be ignored, as validated by longtime laser heating experiments. The uncertainty induced by uniformity of laser heating is negligible as analyzed through numerical simulations. This non-destructive fluorescence-based technique does not require exact value about laser absorption and calibration experiment for temperature coefficient of fluorescence signals. Considering that most polymers can excite sound fluorescence signal, this method can be well applied to thermal characterization of polymer-based film or bulk materials.

SESSION TP02.02: Thermal Properties of Polymers and Biomaterials

Session Chairs: John Bischof and Christoph Schick

Sheraton, 3rd Floor, Fairfax AB

1:30 PM - TP02.02.01
Fast Scanning Calorimetry of Silk Protein

Peggy Cebe; Physics and Astronomy, Tufts University, Medford, Massachusetts, United States.

Silk is a naturally occurring biopolymer used in textiles for over 5000 years. The properties of the B. mori silk protein, fibroin, are related to its secondary structures, such as helices, random coils, turns, and beta pleated sheet crystals. We have prepared fibroin by extracting it from the native cocoons and use this as a starting material for our investigations into the polymorphic structure of the protein. Using infrared spectroscopy and heat capacity measurements, we quantify the amounts of the different secondary structures. By varying processing treatments, two crystalline polymorphs, Silk I and Silk II, can be formed and their structure and properties studied using X-ray diffraction and fast scanning calorimetry (FSC). Silk degrades before melting when heated at slow rates. With FSC, we heat silk at 2000 K/s, thereby minimizing effects of thermal degradation. We show that beta pleated sheet crystals melt to form unstructured non-crystalline fibroin protein, upon the input of heat energy alone. We show that Silk I crystals melt at (565 ± 14) K, while Silk II crystals melt at (624 ± 11) K. A general method for using FSC to estimate the thermodynamic heat of fusion is presented, and demonstrated for the beta pleated sheet crystals. The FSC methods developed here for the study of silk are readily transferable to studies of other crystalline materials, such as synthetic polymers, amino acids, and proteins.

2:00 PM - TP02.02.02
Thermal Transport and Flow in Polymeric Materials

David Venerus1,2, David Nieto Simavilla3, Andy Kiessling2 and Jay D. Schieber2; 1NJIT, Newark,

Minneapolis, Minnesota, United States; 2Conservation Biology Institute, Smithsonian National Zoological Park, Washington, District of Columbia, United States; 3Hawaii Institute of Marine Biology, University of Hawaii, Kaneohe, Hawaii, United States; 4Department of Biomedical Engineering, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.
The strong coupling of mechanical and thermal effects in polymer processing flows has profound implications on both the processability and final properties of the material. Simple molecular arguments suggest that Fourier’s law must be generalized to allow for anisotropic thermal conductivity in deforming polymeric materials. In addition, theoretical results suggest a linear relationship between the thermal conductivity tensor and the stress tensor, or a stress-thermal rule. Using a novel optical method based on Forced Rayleigh Scattering (FRS) developed in our laboratory, we obtain quantitative measurements of all components of the thermal diffusivity tensor in polymers subjected to deformation. These data have been used to carry out the first (and only) tests of the stress-thermal rule, which we have found to be valid for several polymer chemistries in both shear and elongational deformations. More recently, we have developed a novel technique based on Infrared Thermography (IRT) that complements FRS and allows for the study of a wider range of polymeric materials. The IRT technique also allows us to investigate the dependence of heat capacity on deformation. These experiments are used to develop an understanding of the molecular mechanisms of thermal transport in polymers that are essential for the development of advanced materials.

2:15 PM *TP02.02.04 Utilizing Fast-Scan Calorimetry on Polymer Crystallization and Melting with Gibbs-Thomson, Hoffman-Weeks and Thermal Gibbs-Thomson Plots Akhiko Toda; Hiroshima University, Hiroshige-Hiroshima, Japan.

Crystallization and melting behaviors of chain-folded polymer crystals are examined by fast-scan calorimetry (FSC) combined with other various methods including small angle X-ray scattering (SAXS) with Gibbs-Thomson, Hoffman-Weeks, and thermal Gibbs-Thomson plots, which offer new insights on polymer crystallization mechanism. The melting point of lamellar crystals formed isothermally at \( T_M \) was measured by FSC and calibrated in terms of the heating rate dependence on the basis of the modeling of melting kinetics for the determination of the melting point at zero heating rate \( T_M^0 \). By combining \( T_M \) with the crystalline lamellar thickness \( d_c \) determined by SAXS, the Gibbs-Thomson (G-T) plots of \( T_M \) and \( T_M^0 \) are utilized for the determination of the equilibrium melting point of chain-extended infinite-size crystal \( T_M^L \). The Hoffman-Weeks (H-W) plot of \( T_M^0 \) against \( T_M \) is an alternative method of \( T_M^L \) determination. For many polymers, both of the plots, especially the G-T plots, are curved. In order to understand the meaning of the curved G-T and H-W plots, we propose a thermal Gibbs-Thomson plot in terms of the melting point \( T_M \) and the total heat of fusion \( \Delta H_f \) in the secondary stage of isothermal crystallization, during which thickening and perfecting of lamellar crystals undergo and bring the shift in both of \( T_M \) and \( \Delta H_f \) with longer annealing time.

2:45 PM OPEN DISCUSSION

3:00 PM BREAK

3:30 PM TP02.02.05 Thermal Properties and Structure of Electrospun Blends of PVDF and Fluorinated Copolymers Nelaka Govinna, Ilin Sadeghi, Ayse Asatekin and Peggy Cebe; Tufts University, Medford, Massachusetts, United States.

We report a study of the structure and thermal properties of blends comprising poly(vinylidene fluoride), PVDF, and a random copolymer of poly(methyl methacrylate) and 1H,1H,2H,2H-perfluorodecyl methacrylate, which are candidates for applications as superoleophobic membranes for oil-water separation. Blend composition was systematically varied by controlling the PVDF-to-copolymer ratio. The role of processing method and copolymer content on structure and properties was investigated for both fibers and films. Non-woven fibrous membranes were obtained by electrospinning (ES) solutions of PVDF and copolymer, at 20% w/v in a mixed solvent, N,N-dimethylacetamide/acetone (1/1 v/v). Scanning electron microscopy showed that bead-free fibers were obtained at all compositions. Fiber diameter ranged from 0.4 μm – 1.9 μm, and thinner fibers were obtained for PVDF content above 80 wt.%. As the copolymer content in the blends increased, the degree of crystallinity and the onset of degradation for each blend decreased while the glass transition fibers were obtained at all compositions. Fiber diameter ranged from 0.4 μm – 1.9 μm, and thinner fibers were obtained for PVDF content above 80 wt.%. Processing conditions had a greater impact on the crystallographic phase of PVDF than the copolymer content. For crystalline ES fibers, the blend composition was systematically varied by controlling the PVDF-to-copolymer ratio. The role of processing method and copolymer content on structure and properties was investigated for both fibers and films. Non-woven fibrous membranes were obtained by electrospinning (ES) solutions of PVDF and copolymer, at 20% w/v in a mixed solvent, N,N-dimethylacetamide/acetone (1/1 v/v). Scanning electron microscopy showed that bead-free fibers were obtained at all compositions. Fiber diameter ranged from 0.4 μm – 1.9 μm, and thinner fibers were obtained for PVDF content above 80 wt.%. As the copolymer content in the blends increased, the degree of crystallinity and the onset of degradation for each blend decreased while the glass transition temperature \( T_g \) increased, as evidenced by differential scanning calorimetry (DSC), Wide-angle X Ray Scattering (WAXS) and thermogravimetry (TG) experiments. The variation of \( T_g \) followed the Kwei model of \( T_g \) mixing in polymer blends and suggest strong intermolecular interactions between the PVDF and copolymer molecules when the copolymer is present in large quantities, and relatively weaker interaction when the copolymer fraction is smaller than 0.15. Processing conditions had a greater impact on the crystallographic phase of PVDF than the copolymer content. For crystalline ES fibers, WAXS and infrared spectroscopy indicated only polar phases were present, and beta was dominant over gamma phase at all compositions. In comparison, solution cast films also contained polar phases, with an increase of gamma phase PVDF. Melt crystallized films formed non-polar alpha phase exclusively.

3:45 PM *TP02.02.06 The Unfolding and Refolding Properties of Proteins—A Case Study on Lysozyme Zhiwu Yu; Department of Chemistry, Tsinghua University, Beijing, China.

Proteins, serving as the principal structural and functional units in living organisms, have highly ordered structures and conformations folded from peptide chains. When subjected to stress such as heat or chemicals, proteins may unfold. The unfolded peptide chains have the potential to refold when the stress factors are completely/partially removed. In this presentation, the unfolding/refolding behaviors of a model protein, lysozyme, are discussed in detail.

First, a method to differentiate the two-state and non-two-state unfolding of proteins is discussed. It is called an interruption-incubation protocol: protein solutions are incubated at different interrupting temperatures to allow the partial unfolding of the macro-molecules. Then the thermal behaviors of the proteins upon reheating are examined. Comparisons between lysozyme and a few other proteins including bovine serum albumin will be presented.

Second, the folding/unfolding behavior of lysozyme in the presence of micelles composed of the unstructured b-casein proteins will be presented. Depending on the b-casein/lysozyme molar ratio, the partially unfolded structure of lysozyme can occur. This partially unfolded state of lysozyme loses most of its tertiary structure and, after heating, the denatured lysozyme molecules are trapped in the charged coatings of b-casein micelles and cannot refold upon cooling. The thus obtained protein complex can be viewed as a kind of special polyelectrolyte complex micelle.

Third, the unfolding/refolding behavior of lysozyme in the presence of a negatively charged polyelectrolyte sodium poly(styrenesulfonate) or PSS will be presented. With elevated PSS concentration, a new state (state I) is first formed via a “two-state” conversion process and this state can further convert to a completely unfolded state (state II) via a “non-two-state” conversion mechanism.

Finally, the mutual influence of lysozyme and lipid liposomes consisting of neutral and negatively charged phospholipids on their thermal behaviors will be presented. Interestingly, the enrichment of the negatively charged lipids cannot be induced by the native and ex situ unfolded (unfolded in the absence of liposomes) lysozyme, but requires that lysozyme undergo an in situ unfolding process (unfolding in the presence of liposomes).

4:15 PM TP02.02.07
A Novel Approach to Evaluate Microorganism Viability and Microbial Growth Using the Highly Versatile Heat-Transfer Method (HTM) Kai Betlem, Mikhaljo Zubko, David Sawtell, Bart van Grinsven, Thomas Cleij, Peter Kelly and Marloes Peeters; 1Manchester Metropolitan University, Manchester, United Kingdom; 2Maastricht University, Maastricht, Netherlands.

The Heat Transfer Method (HTM) is a novel, versatile and low-cost thermal technique that has already shown its use in the analysis of (biological) targets ranging from small molecules, to DNA, to whole cells and bacteria. The surface can be functionalized with specific receptors (DNA, polymers) for measurements and is the central element through which the heat flux will pass. The internal temperature of the heat sink, $T_s$, is measured by a thermocouple and steered via a controller, which is connected to a power resistor. The front side of the chip is exposed to the liquid, where $T_2$ is measured at the solid–liquid interface. To extract the heat-transfer resistance $R_\text{HT} (\text{°C/W})$ quantitatively, the ratio of the temperature difference $\Delta T = T_1 - T_2$ and the input power $P$ according to $R_\text{HT} = \Delta T/P$, is analysed. Changes at the interface will reflect in a difference in the overall thermal resistance $R_\text{HT}$.

Here, we report a novel application for the HTM with the real-time viability study of microbes, using yeast (Saccharomyces cerevisiae) as a model organism. To accompany this study, the existing flow cell was redesigned, preventing the build-up of gases produced in the metabolic cycle yeasts, leading to an increase of the $R_\text{HT}$ signal corresponding with the increasing concentration of cells in the flow chamber. Therefore, it was possible to discriminate between a wild type strain (DLY640) and a temperature sensitive mutation (cdc13-1) based on the growth kinetics. At temperatures higher than 30 °C the mutant strain stops growing. This corresponds to a decrease in temperature of the optimal growth rate of the cells compared to wild type yeast cells.

The influence of factors inhibiting the replication process of yeast cells can be followed in real-time using this technique. Here, the signal increase in the thermal resistance under normal growth conditions ceased when changing to a growth medium depleted of nutrients, the introduction of a toxic component (CuSO4) or application of a thermal shock treatment. Upon restoring the normal conditions, only the nutrient depleted condition remained viable, in all other situations the yeast cells were permanently eliminated. These results were confirmed by classical plating experiments of yeasts that were exposed to the same conditions as during the HTM measurement.

Having the advantages of simplicity, signal processing and portability, the setup can be used on site without requiring a lab environment. The described methodology is versatile and can be adapted to study different antimicrobial properties, such as the response to antibiotics on a wide range of different microbes.

4:30 PM TP02.02.08 Determination of the Thermophysical Properties of Nucleobases with Fast Scanning Calorimetry Amir Abdelaziz, Dmitry Zaitsau, Sergey P. Verelkin and Christoph Schick; 1, 2, 3 ‘Competence Center ‘CALOR, Rostock University, Rostock, Germany; 2’Institute of Physics, Rostock University, Rostock, Germany; 3’Institute of Chemistry, Rostock University, Rostock, Germany; 4’Kazan Federal University, Kazan, Russian Federation.

The determination of the thermophysical properties, e.g. fusion temperature, fusion enthalpy, sublimation enthalpy and vapour pressure lay within focus of many scientific fields and industrial applications. These values are directly connected to the intermolecular forces in crystal state, provides the lattice energy, change in ordering by going from crystal to gas phase and the solubility properties of organic molecules.

In many cases investigation of thermally labile systems e.g. biomolecules at slow heating rates are accomplished with low thermal stability of them. The application of classic techniques to measure their thermophysical properties often fails, making the estimation of the corresponding thermodynamic parameters, like melting temperature, enthalpy of fusion, vapor pressure highly inaccurate or even impossible.

In the present study, fast scanning calorimetry was successfully applied for determination of the sublimation vapour pressure, enthalpies of sublimation and melting behaviour of the nucleobases cytosine, thymine, adenine, uracil and guanine, the building blocks of DNA and RNA, which are known to decompose at high temperature.
Electrospinning is a process used to create polymer fibers with diameters on the order of nanometers to microns. Blending polymers with nanomaterials, such as carbon nanotubes or graphene, to create nanocomposites can improve the thermal, mechanical and electrical properties of the host polymer. In this study, we investigate the effects of blending carbon-based fillers on the structural and thermal properties of electrospun fibers of poly(ethylene terephthalate). PET fiber solutions containing 1.0 wt.% multi-walled carbon nanotubes (MWCNTs) or graphene flakes were electrospun from hexafluoroisopropanol. The fibers were characterized structurally using wide angle X-ray scattering, infrared spectroscopy, and scanning electron microscopy. Thermal properties were studied using thermogravimetry and temperature modulated differential scanning calorimetry (TMDSC). Fiber diameters ranged from 670 to 900 nm. WAXS revealed that the as spun homopolymer as well as the composites containing 1.0 wt% of MWCNTs or graphene were amorphous. Prior to thermal analysis the fiber mats were dried at 85 °C for 20 minutes to evacuate any solvent, as well as minimize effects due to fiber shrinkage. Addition of the MWCNTs or graphene resulted in a modest decrease of the glass transition and cold crystallization temperatures. Quasi-isothermal TMDSC of the dried fiber mats reveals less mobile amorphous fraction in the blends. MWCNT-based composites had mobile amorphous fraction of 0.83 while graphene-based composites and neat PET fibers had 0.89 and 0.91, respectively. Cold crystallization during QI-TMDSC increased the solid fractions of the MWCNT composite, graphene composite and neat fibers to 0.53, 0.50 and 0.43 respectively. Future work will include investigation of the fiber composites using broadband dielectric spectroscopy.

Properties of Poly(Ethylene Terephthalate) Electrospun Fibers Containing Carbon Nanotubes or Graphene 
Andrew G. Clark and Peggy Cebe; Physics, Tufts University, Medford, Massachusetts, United States.

Shape memory polymers (SMPs) are materials considered to be intelligent due to the ability to be programmed to fix a temporary shape and subsequently regain their original shape after the application of an appropriate stimulus. They have been studied by researchers in different fields such as chemistry, materials engineering, mechanics, biomedical sciences, and microelectronics engineering. In addition to the benefits cited, they are low cost, easy to process and can have their properties easily modified through the combination with other chemical compounds, in order to expand the field of application, taking into account the needs of the market and favoring the technological advances. In this work, we analyze and compare the thermally induced shape-memory effect (SME) of two different polymer systems, one being a thermoplastic formed by a semi-interpenetrating network of poly (methyl methacrylate) and poly (ethylene glycol) (PMMA / PEG), and the other thermosetting based of the DGEBA epoxy resin (DER 331) using the aliphatic amine Jefamine D230 (DGEBA / D230). Each material was characterized according to its ability to deform, fix a temporary shape and recover, as well as response time and life cycle, which corresponds to the number of consecutive cycles that can be performed without failure. PMMA / PEG exhibited higher deformation rate and shape fixation, but DGEBA/D230 showed higher recovery rate and shorter response time. The differentiated behavior in the analyzed systems is directly associated to the molecular structure. The higher DGEBA / D230 cross-linking density allows for faster and more efficient response, but PMMA / PEG thermoplasticity is vulnerable to long-range molecular chain slippage.

**TP02.03.04**

Cyclic Phase Transformation Behavior in Shape Memory Zirconia—Single Crystals vs Polycrystals 
Isabel Crystal, Alan Lai and Christopher A. Schuh; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

In shape memory materials, cyclic martensitic phase transformation can accumulate damage over many cycles due to the mismatch stresses developed amongst the phases and grains. Reducing such mismatches improves the cyclic performance, as known in brittle Cu-based shape memory alloys, where structures with relatively fewer grains (i.e. oligocrystalline or single crystalline specimens) exhibit better cycling properties than conventional polycrystals. The purpose of the present work is to assess this approach in zirconia-based ceramic systems, which are attractive for their high temperature capabilities and higher transformation stresses than shape memory metals, yet are also known to be brittle and experience fracture during the martensitic transformation. Specifically, this work compares tetragonal-to-monoclinic transformation behavior of polycrystalline and single crystalline samples of yttria-doped zirconia compositions. The evolution of transformation enthalpies and strains as well as sample mass and integrity are measured to characterize thermal cyclic performance. Microscopic examination also provides insight into microstructural changes after repeated transformation.

**TP02.03.05**

The Shape Memory Effect in Polymer Systems Based on PMMA/PEG and Epoxy DGEBA / D230 
Katia Furlani and Ruben Rodriguez; State University of Northern Fluminense, Campos dos Goytacazes, Brazil.

Shape memory polymers (SMPs) are materials considered to be intelligent due to the ability to be programmed to fix a temporary shape and subsequently regain their original shape after the application of an appropriate stimulus. They have been studied by researchers in different fields such as chemistry, materials engineering, mechanics, biomedical sciences, and microelectronics engineering. In addition to the benefits cited, they are low cost, easy to process and can have their properties easily modified through the combination with other chemical compounds, in order to expand the field of application, taking into account the needs of the market and favoring the technological advances. In this work, we analyze and compare the thermally induced shape-memory effect (SME) of two different polymer systems, one being a thermoplastic formed by a semi-interpenetrating network of poly (methyl methacrylate) and poly (ethylene glycol) (PMMA / PEG), and the other thermosetting based of the DGEBA epoxy resin (DER 331) using the aliphatic amine Jefamine D230 (DGEBA / D230). Each material was characterized according to its ability to deform, fix a temporary shape and recover, as well as response time and life cycle, which corresponds to the number of consecutive cycles that can be performed without failure. PMMA / PEG exhibited higher deformation rate and shape fixation, but DGEBA/D230 showed higher recovery rate and shorter response time. The differentiated behavior in the analyzed systems is directly associated to the molecular structure. The higher DGEBA / D230 cross-linking density allows for faster and more efficient response, but PMMA / PEG thermoplasticity is vulnerable to long-range molecular chain slippage.
Iron oxide (Fe$_2$O$_3$) is one of the most abundant compounds in nature. This material has four well-known crystalline polymorphs, which exhibit different structural arrangements and physicochemical properties. These particular features have driven the use of this oxide for technological applications in water splitting, gas sensors, lithium-ion batteries, and magnetic storage devices. A fundamental concept is that controlling the thermal stability as well as final microstructure of Fe$_2$O$_3$ at nanoscale is possible to tailor its electric and magnetic properties. Hence, the aim of our study was focused on the thermal behavior of Fe$_2$O$_3$ nanoparticles previously grown via hydrothermal reactions at 160°C for 8 h. These nanoparticles were pressed and conformed as pellets (green compact), which were sintered in a dilatometer (DIL) by using a temperature range from 30 °C to 1300 °C under argon atmosphere. This analysis revealed a size-dependent sintering mechanism, since these nanoparticles presented a lower densification capability of a gel at a temperature gradient of 20 to 60 °C over 10 cm is raised up to 205% for 20 kbp DNA fragments. The enhanced separation is due to larger pore size of the gel at higher temperature, which will reduce diffusion resistance and increase migration rate. Theoretical analysis confirms that diffusion rate is proportional to temperature to the third power. Given the easiness and spatial flexibility of light modulation, the photothermally generated temperature gradient can be a powerful way to enhance separation capability of a given gel in electrophoresis.

Thermal Stability and Microstructural Behavior of Sintered Iron Oxide Nanoparticles
Josiane C. Souza, Edson R. Leite and Júlio César Szczancoski; Federal University of São Carlos, São Carlos, Brazil.

Iron oxide (Fe$_2$O$_3$) is one of the most abundant compounds in nature. This material has four well-known crystalline polymorphs, which exhibit different structural arrangements and physicochemical properties. These particular features have driven the use of this oxide for technological applications in water splitting, gas sensors, lithium-ion batteries, and magnetic storage devices. A fundamental concept is that controlling the thermal stability as well as final microstructure of Fe$_2$O$_3$ at nanoscale is possible to tailor its electric and magnetic properties. Hence, the aim of our study was focused on the thermal behavior of Fe$_2$O$_3$ nanoparticles previously grown via hydrothermal reactions at 160°C for 8 h. These nanoparticles were pressed and conformed as pellets (green compact), which were sintered in a dilatometer (DIL) by using a temperature range from 30 °C to 1300 °C under argon atmosphere. This analysis revealed a size-dependent sintering mechanism, since these nanoparticles presented a lower densification temperature (~750 °C) than Fe$_2$O$_3$ microparticles synthesized by other conventional routes (~1300 °C). In order to monitor the strengthening of the microstructure (neck growth between particles), densification (removal of porosity accompanied by shrinkage), and coarsening (grain growth and/or pore growth), other Fe$_2$O$_3$ pellets were sintered in a dilatometer (DIL) by using a temperature range from 30 °C to 1300 °C under argon atmosphere. This analysis revealed a size-dependent sintering mechanism, since these nanoparticles presented a lower densification temperature (~750 °C) than Fe$_2$O$_3$ microparticles synthesized by other conventional routes (~1300 °C). In order to monitor the strengthening of the microstructure (neck growth between particles), densification (removal of porosity accompanied by shrinkage), and coarsening (grain growth and/or pore growth), other Fe$_2$O$_3$ pellets were sintered in the DIL at 750 °C for 12 h and 900 °C for 1 min, respectively. In this case, both presented relative densities ranging from 50% to 80%. On the other hand, scanning electron microscopy (SEM) images indicated the presence of several grain grown containing interconnected porous. For pellets sintered at 900 °C for 1 min, X-ray diffraction patterns were indexed to α-Fe$_2$O$_3$ phase, while at 750 °C for 12 h was identified a mixture of α-Fe$_2$O$_3$ and Fe$_3$O$_4$. Magnetically cubic structure and hematite - rhombohedral structure. The existence of adsorbed water and organic compounds were detected by means of differential thermal analysis and thermogravimetry. These substances were able to affect the mass transport and densification process in Fe$_2$O$_3$ pellets.
obtaining an insulating oxide film from metal-ethylenediaminetetraacetic acid (EDTA) complex. We synthesized thick Er₂O₃ and Y₂O₃ films on aluminum alloy (A5052) from two types of metal-EDTA complexes (EDTA-Er-H and EDTA-Y-H) using a flame sprayer. The deposition of metal oxide in the proposed synthesis involves two mechanisms, namely, chemical reaction and physical collision. It begins with a chemical reaction in which metal-EDTA complex is decomposed and oxidized to form metal-oxide particles. Therefore, the properties of the deposited film depend on the temperature and velocity of the moving particles. It is the physical collision of the metal-oxide particles with the substrate happens, and forms a film as the accumulated layer of incident particles solidify. First, in order to optimize the fabrication conditions for TBCs, the adhesion between the A5052 and the oxide film was evaluated, and the splat morphology was investigated. Next, thick oxide films were synthesized on A5052 based on optimized synthesise conditions. Although the Y₂O₃ film synthesized on A5052 was annealed close to the melting point of the A5052 substrate, it showed strong adhesion without delaminations. As results, the obtained Er₂O₃ having porosities of 3.8 to 23.3% film with thickness of 105-125 μm, and the Y₂O₃ film having porosities of 8.1 to 21.8% with thickness of 85-163 μm were fabricated on A5052 substrate. These results indicated that thick metal oxide films with various microstructures were fabricated by chelate flame method.

TP02.03.12
Thermal and Spectral Analysis of Microencapsulated Leuco Dyes
Donovan R. Bassett, Danielle Hall, Alexis Corbett, Binit Shapati, Kannan Sivaprakasam and John E. Sinko; St. Cloud State University, Saint Cloud, Minnesota, United States.

Leuco dyes are phase-change materials that undergo characteristic thermal and spectral changes with temperature. These materials have the potential to contribute to energy savings by reducing the light absorption of structures at high temperatures. In this study, we characterized a set of microencapsulated leuco dyes with transitions at 20°C, 25°C, and 30°C. These materials were subjected to differential scanning calorimetry and thermogravimetric analysis to understand the thermodynamic behavior around the transition points. UV-Vis-NIR diffuse reflectance spectra were also collected under quasi-isothermal forced heating and cooling of coating samples. The thermal and spectrosopic results were compared as a function of temperature to establish the thermo-optical characteristics of the leuco dyes for application as energy capturing coating materials. Spectra of leuco dyes were also simulated and compared to the experimental data. The comparison of temperature-dependent optical and thermal data could provide the basis to diversify the use of leuco dyes as practical phase-change materials and in other applications.

Developing a Novel Platform for Characterizing Thermoelectric Materials for Uncooled Detectors for Land Imaging Applications
Riley A. Reid¹, Emily Barentz², Brendan Bramman¹, Ari D. Brown¹, Steven Cagiano², Nicholas P. Coster², Vilem Mikula¹ and Alicia T. Joseph¹; ¹North Carolina State University, Raleigh, North Carolina, United States; ²NASA-Goddard Space Flight Center, Greenbelt, Maryland, United States; ³University of Waterloo, Waterloo, Ontario, Canada.

Thermal land imaging (imaging at ~8-14 μm optical wavelength) is an essential tool for understanding and managing terrestrial freshwater resources. Current thermal imaging instruments employ low temperature detectors, which require cryocoolers. Consequently, cost-saving reductions in size, weight, and power can be achieved by employing uncooled detectors. One uncooled detector concept, which NASA is pursuing, is a thermopile detector with sub-micron thick doped-Si thermoelectric materials. In order to characterize the thermoelectric properties of the doped silicon, we designed and optimized a novel apparatus. This simple apparatus measures the Seebeck coefficient with thermally isolated stages and LABVIEW automation. We optimized thermal stability using PID tuning and optimized the thermal contact between the thin film samples and stages using electrically conductive springs. Utilizing our apparatus, we measured the Seebeck coefficient of 0.45 micron thick phosphorus-doped single crystal Si samples bonded to alumina substrates. Using these Seebeck coefficient measurements and four-wire electrical resistivity measurements, we determined the relationship between the thermoelectric figure of merit and dopant concentration. These characterization results for doped-Si will guide our thermopile detector design to provide an optimal and competitive detector alternative for future thermal imaging instruments.

Effect of Annealing Temperature and Oxygen Pressure on TiO₂ Films Grown on c-Cut Sapphire Substrates via Pulsed Laser Deposition
Alexandra Gordienko¹ and Anthony B. Kaye¹; ¹Texas Tech University, Lubbock, Texas, United States; ²United States Air Force Nuclear Weapons Center, Kirtland Air Force Base, New Mexico, United States.

Titanium dioxide (hereafter, titania or TiO₂) is a well-studied material, but despite of its 100 year history we still don't know everything about this material. It used to be thought that only one of the tetragonal phases of titania - rutile - can be grown on sapphire substrates. That is the reason why a comprehensive study of annealing effects on both phases of titania on c-cut sapphire doesn't exist. In previous works, we developed two pulsed-laser deposition protocols to grow both pure rutile and pure anatase films on this substrate, these protocols are used as the basis of this study. Titania has a number of properties that make it useful for a wide variety of applications; these include using titania as the basis for energy efficient solar cells, as photocatalytic materials to clean air and water, for self-cleaning coatings, as components of various sensor devices, and as a gate dielectric in MOSFET technologies. Further, because it is a wide bandgap semiconductor, titanium dioxide is becoming increasingly important for many next-generation optical and electronics applications, such as transparent electronics systems, transparent thin-film transistors, and see-through active matrix displays. The success of each of these applications depends critically upon the particular crystallographic state (anatase, rutile, or brookite) of the titania being utilized. This is why the annealing effects on the resulting phase of this material can be very important. Titania thin films were grown via pulsed-laser deposition technique on c-cut sapphire substrates using two pre-determined recipes: one leading to creating pure rutile, and one creating pure anatase films. Each of the resulting films was post-annealed in a vacuum furnace at different temperatures in 200 to 900 °C in 100 degree increments and at different oxygen pressures (5, 35 and 50 mTorr). The phase of the resulting films was later determined using x-ray diffractionmetry. Phase content of the films was later analyzed based on the fraction of each phase in overall peak intensity. The quality of each film was was studied using atomic force microscopy.

TP02.03.15
3D Printed Polypropylene Nanocomposites for Thermal and Electrical Conductivity Applications
Yuval Shmuely¹, Vedant Singh², Daniel Chao³, Ahmed Shata¹, Mustafa Zaidi¹ and Miriam Rafailovich¹; ¹Stony Brook University, Stony Brook, New York, United States; ²The Wheatley School, Westbury, New York, United States; ³Hunter College High School, New York, New York, United States.

Polypropylene (PP) is a common polymer being used in many products in all industrial fields. However, due to its relatively high crystallinity percentages it has difficulties in being produced in modern plastics production technology – 3D printing. In this work we show how crystallinity in the printed structure can be advantage due to its orientation that has great potential for conductance applications and also can increase the mechanical properties. We also show how incorporation of thermal conductive nano-fillers as Graphene nano platelets (GNPs) and hexagonal Boron Nitride (hBN) at 0, 5 and 10 wt% combined with the polymer orientation can lead to optimal thermal and electrical conductivity properties of the printed products. We modified the Gcode input to the printer and studied the printing process in order to study the printing conditions for optimal interfilaments fusion and printed product properties.
We used high resolution infra-red thermal camera to measure the thermal conductivity of the printed structure. We also used high voltage resistivity meter to measure the electrical properties. In addition, we used small angle X-ray scattering (SAXS) microbeam to study the macrostructure in the printed structure as function of the radial position from the filaments “skin” and interface to the “core” of the filaments. Our results show the significant improvement to the conductivity properties when the nano-fillers are being introduced to the matrix and in particular, the graphene nano platelets. We Acknowledge support from the National Science Foundation (Inspire Award No. 1344267) and The Morin Foundation Trust.

TP02.03.16
Evaluating the Coefficient of Thermal Expansion at Elevated Temperatures through Nanoindentation
Samuel Bacon, Kurt E. Johanss, Phil Webb, Rich Anthony and Warren Oliver; KLA-Tencor, Milpitas, California, United States.

The characteristics of thermal expansion for materials in low volumes is vital to effective manufacturing and service life. High temperature Nanoindentation is seen as a path to effectively evaluate the properties of the thermal expansion in significantly smaller volumes then what is conventionally measured by a thermomechanical analyzer. A series of experiments were run to explore the technique using coated and uncoated samples using molybdenum, aluminium and nickel plated copper to evaluate the potential for the technique to measure material expansion on the nanometer scale. A nanoindenter is found to be able to be replicate measurement on bulk materials and is found to be able to provide insight into underlying mechanisms in layered materials expansion.

TP02.03.17
High IR Transparency of Ultra-Thin Drawn UHMWPE/LDPE and UHMWPE/MDPE Blended Films via Solvent Casting
Yassine Ait-El-Aoud1, Seong Don Hong1, Richard Pang1, Svetlana V. Boriskina2, Michael Okamoto1, Alkim Akyurtlu3 and Richard M. Osgood1; 1Natick Soldier Research, Development and Engineering Ctr., Natick, Massachusetts, United States; 2Mechanical Engineering Department, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Electrical Engineering Department, University of Massachusetts Lowell, Lowell, Massachusetts, United States.

Polyethylene (PE) is well known polymer and has an extremely large spectrum of applications, depending on the particular molecular weight, chain length, and density. The micro and nano-structure polyethylene fibers in arrays have recently attracted great attention mainly in textile fiber industry for wearable personal thermal management. Lately, researchers have shown theoretically [1] and experimentally [2] that a particular type of polyethylene, UHMWPE [3] and Nanoporous [4] respectively, is transparent to long wave-infrared body radiation but opaque to visible light. This new passive generation of fabrics could lead to a possible wearable technologies that release heat in hot climates. UHMWPE is a type of polyethylene with extremely long molecular chains that are highly entangled and resulting in a high viscosity after melting. Therefore, UHMWPE raw materials need to be adjusted to meet the melt-spinning processing requirements. It has been shown that the processibilty and flowability of UHMWPE could be improved by 1) adding nanocomposites and/or 2) blending at certain mass ratio with low-density polyethylene (LDPE) or medium density polyethylene (MDPE). Yet, the melt-spinning of ultra-thin drawn UHMWPE/LDPE and UHMWPE/MDPE blended fibers which is our main focus aim remains a challenge whereas the blended films are feasible.

In this study, we have firstly investigated the optical properties of highly oriented ultra-thin drawn UHMWPE/LDPE and UHMWPE/MDPE blended films in the infrared wavelength range (7mm-14mm) via solvent casting. The blended films were drawn at various draw ratio from 5 times to 100 times at 130 °C. Preliminary results showed that highly transparent films with a total transmittance surpassing 95% were obtained by a mass ratio of 8:2 w/w % at draw ratio of 60 times with high crystallinity. The solvent-cast blend films were prepared by pre-mixing polymer powders then adding the mixed powders into decalin solvent in a silicone oil bath. Gradually, the temperature of the oil was increased to 150 °C in three stages within 3 hrs and was stable within ± 0.5°C precision. Secondly, we have been working on developing a thermal model of blended fibers that predict the heat transfer. This thermal model takes into consideration all possible modes of non-radiative heat transfer (convection + conduction) and radiative interaction (total reflection +total transmission +absorption) between skin-fabric and fabric-environment. The temperature cross the fabric is assumed to be uniform and the ambient temperature is approximated large relative to the fabric surface. The air gap between the skin and the fabric is taken sufficiently small.

TP02.03.18
Fabrication of Shape Memory Polymer Composites Using MWNT and Their Applications to Deployable Antennas
Yong-sun An1, 2, Young-min Kim1, 2, Yeontae Kim3, Jong Kyoo Park1 and Woong-Ryeol Yu1, 2; 1Seoul National University, Seoul, Korea (the Republic of); 2Agency for Defense Development, Daejeon, Korea (the Republic of).

Deployable antennas have an advantage of good transportability due to their small volume when folded. A space vehicle is launched with folded antenna, which will conduct assigned jobs after unfolded in space. Existing deployable antennas have some drawbacks such as heavy weight and small deformability. Shape memory polymer (SMP), a smart material which can recover the original shape from temporary deformation by external stimuli (e.g., temperature), can be used to overcome these disadvantages. Deployable antennas made up of SMPs have excellent properties such as lightweight, large deformability, good processability, and self-transformation capability without any power devices. However, they are not proper for aerospace application due to limited recovery force and speed caused by low stresses at rubbery states and low thermal conductivity. To enhance the mechanical and thermal properties of SMPs, the shape memory polymer composites (SMPCs) were prepared using surface-modified multi-walled carbon nanotubes (MWNTs) and an epoxy-type of SMP matrix. Raman spectroscopy was used to investigate the increased disorders in the surface of MWNTs after functionalization, which was verified by the XPS analysis. The thermal conductivity of the SMPC was measured by laser flash method. The functional groups in the surface of MWNTs formed covalent bonds with the polymer matrix so that the thermal interfacial resistance of SMPC was reduced, resulting in higher thermal conductivity. Then, the thermomechanical and the shape memory properties of SMPCs were characterized. Finally, a miniature of SMPC antenna (reflector) was fabricated and its deployment test was quantitatively characterized. Improved modulus at the rubbery state and increased thermal conductivity resulted in the high recovery force and speed.

SESSION TP02.04: Thermal Properties of Glasses I
Session Chairs: Leslie Allen and Gregory McKenna

Sheraton, 3rd Floor, Fairfax AB
Tailoring the Microstructure of Ce-Based Metallic Glass by Fast Scanning Calorimetry

Bingge Zhao, Manman Wu, Qiqie Zhai and Yalai Gao;
Shanghai University, Shanghai, China.

Differential fast scanning calorimetry (DFSC) is capable of heating and cooling a sample at ultrafast rates, allowing freezing the high-temperature structure down to ambient temperature. Additionally, the sensitivity of DFSC is in the order of nJ/K, making it possible to detect weak thermal signal and reveal phase transitions that are invisible by conventional differential scanning calorimetry (DSC). These two features permit the quantitative analysis on the formation of metallic glass. In this study, Ce$_{65}$Al$_{10}$Cu$_{20}$Co$_{5}$ (at. %) metallic glass was in situ prepared by DFSC, during which the nucleation and crystallization are quantitively determined. With the increase of cooling rate, the nucleation is suppressed, producing the amorphous structure free of nuclei. Based on that, an isothermal annealing was followed, which tailored the microstructure ranging from relaxed local configurations to nanocrystals. By the reheating after annealing, the role of structure tailoring on glass transition, crystallization is demonstrated according to the Johnson-Mehl-Avrami (JMA) equation.

Highly stable glasses prepared by vapour deposition at deposition temperatures around 0.85 of their glass transition temperature exhibit higher density, kinetic and thermodynamic stability with respect to their glassy counterparts obtained directly from the liquid [1]. In these vapor-deposited glasses molecular packing is so tight that the transformation into the supercooled liquid proceeds in time scales much longer than the alpha relaxation time and occurs, for sufficiently thin films, through an heterogenous mechanism starting at the free surface [2-4]. In-situ membrane-based nanocalorimetry is an ideal tool to explore the thermodynamic properties of the glass and its transformation into the supercooled liquid during temperature upscans [5]. By using appropriate capping layers the front mechanism can be suppressed and stable glasses without free surfaces transform through a ‘nucleation and growth’ like process. The transformed fraction follows a sigmoidal shape and can be explained using the KJMAE model, initially derived for crystallization studies. The isothermal kinetic stability increases by a factor of 50 with respect to the uncappped stable glass. We also identify, both in thin films and bulk materials, the existence of a rejuvenation process that is compatible with a cooperative mechanism.

Tuning the Structure of Molecular Glasses through the Kinetic Arrest of Liquid-Liquid Phase Transitions
Lian Yu; Univ of Wisconsin-Madison, Madison, Wisconsin, United States.

The structure of a glass is usually considered just amorphous and not much different from the structure of its precursor liquid. There has been increasing evidence, however, that the structure of molecular glasses can be engineered to a great extent to achieve high density and high structural order – properties desired for many applications. These “new glasses” can be prepared by physical vapor deposition and by the kinetic arrest of first-order transitions in the liquid state. We discuss two examples in the latter category. In the case of D-mannitol (and the previously studied triphenyl phosphite), two glasses can be prepared with a large difference in enthalpy (60 J/g) and density (2 %), one by quenching the ordinary liquid and the other by annealing the ordinary liquid to induce a polyamorphic transition. In the case of itraconazole, the transition to layered liquid-crystalline structures can be bypassed partially or completely by varying the cooling rate, producing glasses with continuously tunable smectic order. For this rod-like molecule, kinetic arrest of the end-over-end rotation controls how much smectic order gets trapped in the glassy state. These two examples illustrate the potential to manipulate the structure of amorphous materials to improve their properties, and the role of FDSC in understanding liquid-liquid phase transitions. Ref.: Zhu, M.; Yu, L. J. Chem. Phys. 2017, 146, 244503. Teerakapibul, R.; Huang, C.; Gujral, A.; Ediger, M. D.; Yu, L. Phys. Rev. Lett. 2018, 120, 055502.

Phase Transformation in Nano-Structured Materials Measured by Fast Differential Scanning Calorimetry
Juergen E. Schawe; Mettler Toledo GmbH, Schwerzenbach, Switzerland.

Fast differential scanning calorimetry (FDSC) is a non-adiabatically chip calorimetry technique. The commercial available Flash DSC 2+ enables typical heating and cooling rates in the order of 40,000 K/s in a temperature range between -100 °C up to 1000 °C. This technique is used to study the formation of differently structured glasses and non-isothermal nucleating processes in bulk metallic glass alloys. Depending on the thermal history and the heating conditions monomorphic polymorphic phases can be formed which can be transformed into the more stable phase on different pathways. Furthermore, we discuss a method to distinguish between heterogeneous and homogeneous nucleation processes.

Conjugated Polyelectrolytes are Feeling the Heat—A Ratiometric Nanothermometer for Solution, Hydrogels and Thin Polymer Films
Pierre Karan; Chemistry, American University of Beirut, Beirut, Lebanon.

Temperature is a fundamental variable that controls and drives many chemical, biological and physical processes. Nowadays, there is a tremendous drive to explore and understand processes at the nanoscale level in many fields of science and technology. We report a self-referencing ratiometric nanothermometer based on short conjugated polyelectrolytes (CPEs). The probe is prepared by complexing a phenylene-based polymer with polyvinylpyrrolidone (PVP), an amphiphilic macromolecule that destabilizes the CPE π-π stacking. This makes it possible to shift the equilibrium between the less emissive aggregated state of the CPE (520 nm) and its more emissive single chains (450 nm) within a useful temperature range (15.0–70.0 °C). The probe is used as a noninvasive fluorescent method for mapping thermal fluctuations in solution, hydrogel matrices and thin film polymers using an unmodified commercially available digital single-lens reflex camera (DSLR). We are currently exploring thermal processes in microwell structures. The reported temperature sensor has the potential to provide a wealth of information when thermal mapping is correlated with chemical or physical processes.

1:30 PM *TP02.05.01
Nano-Scale Dynamic Measurements—Flash DSC and Nanobuble Inflation of Ultra-Stable Amorphous Fluoropolymers
Gregory B. McKenna and Heedong Yoon; Texas Tech University, Lubbock, Texas, United States.

The advent of novel experimental techniques that make it possible to work with nanogram quantities of material has revolutionized the study of nanofluidic materials. Furthermore, the relevant techniques have also made it possible to investigate novel materials that are only made in extremely small quantities. It is this latter case that we address here. We have succeeded in making and characterizing ultra-stable amorphous fluorocarbon films made by vacuum pyrolysis deposition (VPD). The ultra-stable amorphous fluorocarbon is very deep in the energy landscape or deep glassy section of the “unexplored region” of glasses between the a very low fictive temperature Tf and the glass temperature Tg. By combining rapid chip scanning calorimetry (Flash DSC) with the Texas Tech nanobuble inflation method we not only determine that the deposition conditions lead to a value of Tg that is very near to the Kauzmann temperature Tk, but we are also able to measure the viscoelastic response in the temperature regime encompassing Tk to slightly above Tg and determine the temperature dependence of the dynamics in this regime. The question ultimately addressed is whether or not the relaxation time (or viscosity) diverges at a finite temperature above absolute zero and near to Tk as anticipated in theories in which an ideal glass transition is postulated. The measurements near to and above Tg give upper bounds to the equilibrium relaxation times because in the regime where T>Tg the material has a lower specific volume and lower enthalpy than the equilibrium glassy state. Furthermore, because the Tg is approximately equal to Tk, which is 56 K below the Tg in this case, the range of measurements is greater than previously achieved using a 20 million year old amber material. For the amber the glass had a fictive temperature some 43.6 K below Tg. Our results confirm the amber results and are consistent with the idea that the observed Vogel-Fulcher behavior of glass-forming liquids seen above the Tg does not persist into the deep glassy state where T>Tg. Rather the response deviates from the super-Arrhenius behavior of the Vogel-Fulcher function and tends towards an Arrhenius-like behavior, albeit with very high apparent activation energy. These results challenge theories that demand divergence of the relaxation times or viscosities at a finite temperature as well as the idea of an ideal glass transition. The studies were only possible because of our ability to make dynamic, both calorimetric and viscoelastic, measurements on nano- to micro-gram quantities of material.

2:00 PM TP02.05.02
Profiles in Local Glass Transition Temperature Near and Across Polymer Interfaces
Connie B. Roth; Emory University, Atlanta, Georgia, United States.

Local thermal analysis using fluorescence has made it possible to map out the profile in local glass transition temperature Tg(c) as a function of
position z across a glassy-rubbery polymer-polymer interface. Starting with the weakly immiscible system of polystyrene (PS) and poly[n-butyli
te] methacrylate] (PnBMA) whose bulk \( T_g \) values differ by 80 K, we observed a broad and asymmetric dynamical profile in \( T_g(z) \) spanning 350–400 nm from one bulk \( T_g \) value to another [J. Chem. Phys. 2015, 143, 111101]. We have since observed similar behavior in a number of weakly immiscible systems, consistently showing a longer-ranged \( T_g(z) \) perturbation for a lower \( T_g \) polymer next to a hard interface than a higher \( T_g \) polymer next to a soft interface [J. Chem. Phys. 2017, 146, 203307]. More recently we have explored this difference of hard vs. soft neighboring domain by investigating the \( T_g(z) \) profile in PS next to polydimethylsiloxane (PDMS) with varying crosslink density to systematically change the modulus of the neighboring domain without also changing the chemistry of the interface. We observe that the local \( T_g(z) \) in PS at a distance of \( z \approx 50 \) nm away from the PS/PDMS interface can vary by 45 K when the PDMS modulus changes from –1 to 3 MPa, supporting theoretical predictions that modulus is a controlling variable. Interestingly, the length scale \( z \approx 70–90 \) nm at which bulk \( T_g(z) \) of PS is recovered for this more strongly immiscible system is significantly shorter than what would be expected (\( z \approx 225–250 \) nm) for this soft neighboring domain based on our previous results. Our studies have also discovered that this strong coupling of the dynamics across dissimilar polymer-polymer interfaces only occurs if the interface has been well formed and annealed to equilibrium suggesting that some aspect during polymer interface formation (broadening of interface, chain interpenetration, or interfacial roughening) may be significant in controlling the observed behavior. Efforts to separate these different factors have led us to investigate rough interfaces and substrates with end-tethered chains finding that low grafting densities, coinciding with the “mushroom-to-brush” crossover regime, result in large increases in local \( T_g \) with \( T_g(z) \) profiles consistent with a hard polymer interface [ACS Macro Letters 2018, 7, 269-274].
Influence of Temperature on Microstructure and Mechanical Properties of Polymer Composites

We believe that cavity-optomechanics based probes are broadly-applicable and will benefit a wide range of AFM-based dynamic observations in conducting measurements in water. Finally, I will discuss our efforts to further increase the PTIR throughput by 200-fold, i.e. 500,000x with respect to conventional measurements and to conduct measurements in water.

We validate these new capabilities using polymer films and measure the intrinsic thermal conductivity (\(\eta\)) of metal-organic framework (MOF) individual microcrystals, a property not measurable by conventional techniques. MOFs are a class of nanoporous materials promising for catalysis, gas storage, sensing and thermoelectric applications where accurate knowledge of \(\eta\) is critically important. Additionally, the improved sensitivity enables measurement of nanoscale IR spectra of monolayer this sample with high signal to noise ratio (\(\approx 170\)).

Recently, new AFM modes, improved modeling, better calibration, and more optimal probe design have become available[5], expanding the possibilities for quantifying mechanical properties at the nanoscale. This presentation will demonstrate the use of this new capability in examining microscopic domains and interphase regions within a polymer composite over a wide range of frequencies and temperatures.

Influence of Temperature on Microstructure and Mechanical Properties of Polymer Composites

The relationship between the microstructure and mechanical properties of microscopic domains within polymer composites is important due to their influence on macroscopic material performance and function. Mechanical properties of polymers are time-dependent, so a full understanding requires measurements over a range of frequencies and temperatures. Ideally, one would like to observe the mechanical behavior of these domains while they pass through their glass transitions in order to better understand the influence of size effects and confinement.

Atomic Force Microscopy (AFM) has the nanometer level resolution and sensitivity needed to investigate these samples, but accurate comparisons with established rheological measurements have proven to be more elusive. Resonant methods like TappingMode[1] and contact resonance[2] provide mechanical property maps at discrete frequencies that are many orders of magnitude higher than bulk measurements. Non-resonant methods like force spectroscopy[3] and PeakForce Tapping[4] provide a better match in frequency, but face challenges in calculating intrinsic mechanical properties like loss tangent and storage modulus.

Recently, new AFM modes, improved modeling, better calibration, and more optimal probe design have become available[5], expanding the possibilities for quantifying mechanical properties at the nanoscale. This presentation will demonstrate the use of this new capability in examining microscopic domains and interphase regions within a polymer composite over a wide range of frequencies and temperatures.

Quantitative Thermometric Scanning Thermal Microscopy and Thermomechanical Nanoindentation from Room Temperature to >1,000°C

The functionality and performance of polymeric materials is largely determined by a complex interplay of chemical and mechanical properties, often at the nanoscale. In order to understand these complex material systems and further improve them, it is necessary to measure and map them at that same nanoscale. Macroscopic polymer behavior is often characterized with temperature dependent mechanical analysis measurements such as dynamic mechanical analysis (DMA). Previous approaches to making similar measurements on the nanoscale, while having some success at quantifying stress and...
strain as a function contact area and frequency have relied on indirect measurements of the tip-sample contact temperature. Using a combination of a laser heated tip with a unique, an integrated thermocouple combined with a scriptable DMA interface, we can quantitatively evaluate temperature and frequency dependent polymer properties with sub-100nm resolution. This approach has enabled three key advances we will cover in this presentation:

1. High temperature Scanning Thermal Microscopy. The probes discussed here, coupled with photothermal heating can routinely operate at temperatures in excess of 1,000°C.

2. Localized thermal analysis combined with quantitative nanomechanical imaging. The ability to quantitatively ramp the tip temperature (estimated at rates in excess of 10⁶°C/minute) allow quantitative and highly localized measurements of phase transitions, mechanical and other temperature dependent properties.

3. Fouled tip cleaning. A common problem in AFM, fouling of the tip with material from the sample, can be greatly mitigated with localized heating of the tip. We will demonstrate that repeatable quantitative modulus measurements[1] can be accomplished by cleaning the tip with a simple protocol.

The tip structure of the thermocouple integrated probe has been described elsewhere [2]. During the experiments the tip and the thermocouple materials were found to be stable in the excess of 1000°C, expanding the regime of the DMA of the polymeric material that were not possible with existing technologies.

4:30 PM TP02.06.04
Development of a Multimodal Imaging Platform Based on Photoinduced Thermal Desorption and Analysis by Atmospheric Pressure Chemical Ionization Mass Spectrometry Oleq Orcheminskyy,1, 2 Matthias Lorenz,2 Stephen Josse,2 Mario Viani,1 Aleksander Labuda3 and Roger Proksch1; 1 Asylum Research, Santa Barbara, California, United States; 2 Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The key to advancing materials is to understand and control their structure and chemistry. Thorough chemical characterization can be challenging since many existing techniques analyze only a few properties of the specimen, thereby requiring multiple measurement platforms to acquire the necessary information. The multimodal combination of atomic force microscopy (AFM) and mass spectrometry (MS) transcends existing analytical capabilities for nanometer scale spatially resolved correlation of the chemical and physical properties of a sample surface. We recently introduced the utilization of a photoinduced cantilever heating technology developed by Oxford Instruments for the localized thermal desorption and analysis and presented a closed cell design for sampling on an Oxford Instruments Cypher ES microscope to interface with a Thermo Orbitrap Velos Pro mass spectrometer using inline atmospheric pressure chemical ionization (APCI). The photoinduced cantilever heating technology works with standard AFM probes that are compatible with advanced AFM modes for the nanomechanical and electromechanical characterization of samples. We previously demonstrated below 500 nm spatial resolution for the spot-sampling by thermal desorption from thin layers and the chemical analysis of small organic molecules in full scan MS mode.

We demonstrate the application of multiple and advanced AFM measurement modes such as AMFM nanomechanical characterization on a single AFM cantilever, combined with photoinduced thermal desorption and analysis by mass spectrometry to link chemical composition with material functionality. We show the chemical analysis by mass spectrometry of gas phase species evolving from polymeric material in contact with a heated AFM probe, spatially resolved with nanometer resolution, and identify small organic molecules and characteristic fragments and pyrolysis products from the polymer. We present results from systematic studies of factors limiting the efficiency of transport and ionization of material evolving from the sample surface, with the objective to enhance the achievable spatial resolution and compound coverage of the multimodal imaging platform. Parameters studied include the timing of the photothermal cantilever heating and analysis by mass spectrometry, transport conditions for the gaseous material from the closed desorption cell to the mass spectrometer, and the operating conditions of the inline ionization stage. Computational fluid dynamics (CFD) simulations were used to study the uptake and transport of material. Experimental studies on prototype cell models prepared by additive manufacturing provide support for the modeling data.

Calibration Techniques for Robust Quantitative Scanning Thermal Microscopy—A Comparison of Strategies and Best Practices Adam A. Wilson1, 2; 1 US Army Research Laboratory, Adelphi, Maryland, United States; 2 National Research Council, Washington, District of Columbia, United States.

As we continue to improve our ability to miniaturize, manipulate and leverage materials and devices down to the nanoscale, the limit to advancement in many fields leveraging nanotechnology is accurate measurement of material properties at these scales. Scanning thermal microscopy (SThM) boasts the best available spatial resolution among thermal metrology techniques, leveraging the nanometer-scale resolution afforded by atomic force microscopy. However, SThM has suffered from a lack of consistent, reliable quantitative usage. This is largely due to tip-sample interaction, with the sample’s topography leading to artifacts in the observed signal. Several recent efforts have attempted to more robustly calibrate the probe-sample thermal interaction and account for topographically-induced artifacts. Among the most commonly used thermal exchange parameter calibration strategies are the implicit (curve fitting) method, the step method, and the intersection method, which each rely on at least two materials as reference samples, while recent advancements include single-sample calibration strategies. However, to date, there has not been a comparative study between calibration methods, or efforts to demonstrate the limits of each technique.

This work compares the performance and suitability of probe-sample thermal exchange calibration strategies, discusses the most frequent failure modes, and offers guidance for best practice in quantitative usage of SThM. As an example of determination of accuracy of calibration and best practices, we demonstrate that under conditions previously published using the intersection technique (kref = 1.1 Wm⁻¹K⁻¹ and kref = 1.5 Wm⁻¹K⁻¹), significant deviation (>50%) in measured sample thermal conductivity is observed when measuring samples with thermal conductivity values larger than those of the reference samples, but we demonstrate that by calibrating with reference samples having a wide range of sample thermal conductivity (kref = 0.5 Wm⁻¹K⁻¹ and kref = 50 Wm⁻¹K⁻¹), the measured values may be expected to be accurate to within 20% for the entire range. Similar analysis will be performed on data from both previously published studies and new experimental results using the step method, the implicit method, and the novel single-sample calibration strategies to demonstrate which method(s) provide the most accurate values for local thermal conductance measurement and in what ranges and experimental conditions the quantitative accuracy may hold. This work is poised to offer a timely comparison between several emerging and widely used calibration techniques for SThM, and aims to unify efforts for improved accuracy and reliability in future quantitative studies using SThM.
In this work, the indentation size effect (ISE) is studied for temperatures ranging from 300K to 475K using nanoindentation experiments and molecular dynamics simulations. CaF2 single crystals are indented using a high temperature nanoindenter and the pop-in load was observed to decrease with increasing temperature. Increasing the temperature of the material also led to a reduction in the material dependent plasticity length scale defined in the Nix-Gao relation as well as the hardness at infinite depths.

The experiment is supplemented with MD simulations of nanoindentation into a free surface of CaF2. A suitable CaF2 potential for high temperature was first selected via comparisons between simulated and experimental vacancy formation energy as well as melting point temperatures. Changes in dislocation structure with increasing indentation depth were then studied for various temperatures for the (111) planar direction. The study thus provides much insight into the relationship between temperature and dislocation mechanisms during nanoindentation and underscores the effect of temperature on dislocation structure and formation.

Reduction in thermal conductivity by phonon confinement effect of In0.53Ga0.47As nanofilms

Reduction in thermal conductivity of the nanostructured materials has been widely known for having the reduced phonon mean free path by its nano-size boundary scattering. At even smaller size, the phonon confinement effect from the decrease of the phonon group velocity can happen in nanostructured materials leading to further reduction in the thermal conductivity. We measured the thermal conductivity of In0.53Ga0.47As nanofilms with various thicknesses from 70 to 10 nm by the T-bridge method, and analyzed it by the Callaway’s thermal conductivity model. It is found that the calculated thermal conductivities of below 20-nm-thick nanofilms based on the bulk In0.53Ga0.47As group velocity cannot accurately predict the measured thermal conductivities. The group velocities of nanofilms are evaluated by the calculation of the phonon dispersion relation, and these show that there is a significant reduction in the group velocity along the decrease in the thickness. According to these reduced group velocities, the re-calculated thermal conductivities of below 20-nm-thick nanofilms are successfully agreed with the measured ones. The phonon confinement effect is found to be another key factor to explain the low thermal conductivities of below 20-nm-thick In0.53Ga0.47As nanofilms.

Extraordinary Electronic Contribution to Thermal Transport in Free-Standing Graphene Nanoribbons with Low-Disorder Edges

Previous research on thermal transport in graphene has focused on the lattice contribution while the electronic contribution is regarded as 0.1%-1%. Here, we report experimental evidence of extraordinary electronic contribution to heat conduction in graphene nanoribbons (GNRs) with low-disorder edges. By the electrical self-heating method, the thermal conductivity of a plasma-CVD-grown 43nm-wide suspended GNR with near-zigzag edges was measured to be below 5% of that of large pristine graphene and exhibits a temperature dependence that indicates width confinement. The electronic thermal conductivity, which is converted from the measured electrical conductivity by the Wiedemann-Franz law, reaches as high as ~20% of the total thermal conductivity at 120-360K. This finding is attributed to the different effects of edge scattering on phonons and electrons for the particular edge structure, as well as the cleanliness of the as-grown sample. Even the low level of edge disorder in the near-zigzag GNR can lead to strong phonon-edge scattering, but the superior electron transport is preserved, which agrees well with previous simulations. Our work highlights the importance of electronic thermal conductivity in GNRs, and suggests the edge manipulation as a promising way to independently control electron and phonon transport in GNRs for potential thermoelectric applications.

Non-Contact Temperature Difference Measurement of Cleavage Plane Nanogap Electrodes with Large Surface Area

Vacuum nanogap electrodes are expected to significantly improve thermal power generation efficiency, which is considered difficult with conventional thermoelectric materials. In order to apply the vacuum nanogap electrodes as a thermal power generation element, the properties of nanogap, especially heat transfer at the nanogap should be investigated because enhancement of the heat transport due to the near-field heat radiation effect cannot be ignored in the vacuum gap of nanometer order. However, the measurement is difficult because it needs high temperature and spatial resolution. In addition, it is difficult to create a spatial temperature difference in a nanometer scale region. Furthermore, it is also challenging to achieve both large area and uniform narrow gap by conventional fabrication methods such as electron beam lithography, metal plating, and focused ion beam processing, where the opposing surfaces of the gap are neither parallel nor flat. Also, the emission area achieved by the aforementioned methods are only of the order of several nm², which makes these vacuum nanogap electrodes impractical from the viewpoint of the power generation. In this research, we have proposed a method to make nanogap electrodes by exploiting the advantages of interplanar cleaving in single crystal silicon, choosing (111) as cleavage plane. In cleavage fracture, a smooth fracture surface parallel to the crystal plane is exposed, so it is expected that the opposing surface of the obtained nanogap electrodes will become parallel and smooth. We fabricated MEMS devices with silicon-on-insulator wafers with device layer thickness of 5 um, oxide sacrificial layer thickness of 2 um, handle layer thickness of 400 um, device layer surface orientation (110). Silicon beam in the device, oriented in <111> direction was cleaved by applying tensile stress using a micromanipulator. As a result, nanogap electrodes having a parallel and smooth surface area of several tens of um² were obtained, which makes the cross-sectional area several thousand times larger than conventional nanogap electrodes. Comb drive actuators and a gold wire for joule heating were integrated in the device, and the gap distance control and heating near the nanogap electrodes were carried out. For temperature measurement, micro-Raman spectroscopy was used. The temperature resolution in our measurement was about 1 K and the spatial resolution was 1 um or less. We were successful to produce and maintain a spatial temperature difference of up to 60 K in a 180 nm size distance. However, in order to evaluate the proximity effect of heat transfer in the vacuum nanogap, higher temperature resolution and accuracy is needed; therefore, we continue to
We have studied a conducting oxide CaCu4RuO8 as an alternative conducting material for Pt as various high temperature operating electrical devices such as solid oxide fuel cells and gas sensors. The resistivity of CaCu4RuO8 is lower than 1 mΩcm even at 500 °C, and the temperature dependence of resistivity is metallic. In our previous study, we have successfully formed CaCu4RuO8 thick film on alumina substrate by screen-printing process, which is one of the practical process, via mixing with CuO as a sintering additive [1]. Then, we have fabricated a SnO2 gas sensor using CuO-mixed CaCu4RuO8 thick film as both electrodes and a heater on an alumina substrate (3.0 × 2.5 × 0.3 mm). In this study, we investigated the heat generation property of the CuO-mixed CaCu4RuO8 thick film heater in the sensor in order to evaluate the potential of CaCu4RuO8 [2]. The temperature of the CuO-mixed CaCu4RuO8 thick film heater increases at least up to 600 °C without any problems such as thermal runaway and hot spots, and the temperature is linearly changed with applied voltage. The heater remains intact after long-term operation at high-temperature and a large temperature change of 500 °C within 10 s. We conclude that the CuO-mixed CaCu4RuO8 thick film heater is proven to be robust and reliable, and can replace Pt heaters in gas sensors.

crucible, homogeneous solidification behaviour with deep undercooling was observed. The microstructure was different between crucible solidified sample, and levitating solidified sample. Deep undercooling in homogeneous solidification induces fast growth of primary dendrite arm, on the other hand heterogeneous solidification induced thick and short primary dendrite arms. Finally, Microstructure was investigated to figure out solidification behaviour of each condition and to control mechanical and thermal properties of W-Ta alloys. Likewise to previous research, deep undercooling sample had long primary dendrite arms and low secondary dendrite arm spacing, which can induce higher yield strength than heterogeneous solidification sample. Ultimately, because the study of properties near melting temperature of W-Ta alloys is deficient for lack of systematic experiment, this study can be a touchstone to study measuring property of ultra-high temperature refractory alloys.

TP02.07.09
The Role of Molecular Chain Length and Side Group Weight on Thermal Transport In Electrosynlow Vinyl Polymer Nanofibers Xin Zhang1, Yin Zhang2, Lin Yang1, Qian Zhang1, Akara Ueda2, Matthew Fitzgerald3, Richard Mu2, Deyu Li4 and Leon Bellan1; 1Vanderbilt University, Nashville, Tennessee, United States; 2Southeast University, Nanjing, China; 3Fisk University, Nashville, Tennessee, United States; 4Tennessee State University, Nashville, Tennessee, United States.

Polymeric materials have found extensive use in a variety of applications due to their facile synthesis and processing, low-cost and tunable and attractive properties. Since a recent studying employing molecular dynamics techniques suggested that a single-chain polyethylene (PE) could possess extremely high thermal conductivity (≈300 Wm⁻¹K⁻¹) several research efforts have been devoted to investigating a variety of factors that may result in the enhanced thermal transport in polymer nanofibers. Recent experimental results have demonstrated that the thermal conductivity of an individual ultra-drawn polyethylene nanofiber can achieve ≈104 Wm⁻¹K⁻¹, which is three orders of magnitude larger than that of bulk PE. However, the dependence on several critical factors, such as molecular chain length and side group composition, is still not understood.

To explore the influence of molecular chain length, we prepared PE nanofibers with four different molecular weights (Mₚ) using the electrospinning process. The thermal conductivity of various electrosyn low PE nanofibers was determined using a well-established thermal bridge device composed of suspended microheaters/thermometers. Our results indicate that nanofibers composed of higher molecular weight polymers exhibit larger thermal conductivity, which is attributed to more efficient energy transport along the polymer chain direction compared to cross chain direction. It is noteworthy that PE fibers with lower Mₚ (35,000 and 125,000) exhibit monotonically increasing thermal conductivity versus temperature, typical for amorphous materials. However, for higher Mₚ PE fibers (420,000 and 3,000,000), a peak thermal conductivity appears as temperature increases, which is a signature of phonon Umklapp scattering in crystalline materials.

To investigate the impact of side group composition, we electrospun three types of vinyl polymer nanofibers, namely polyvinylidene fluoride (PVDF), polyvinyl alcohol (PVA) and polyvinyl chloride (PVC). These polymers have the same planar-zigzag carbon backbones as PE, but with one or two hydrogen atoms replaced by different heavier side groups (OH, CI or F) in each monomer unit. In order to examine the role of side groups, we purposely choose the molecular weight of all polymers such that their polymer chain lengths were as close as possible. The measured thermal conductivity of four different types of polymer fibers shows a clear trend indicating κ_PVDF > κ_PVA > κ_PVCL > κ_PE, which implies that thermal conductivity decreases as the side group becomes heavier. Additionally, it is believed that the enhanced thermal conductivity of electrosyn low nanofibers may correlate with their increases in Young’s modulus. As such, we measured the Young’s modulus of several individual electrosyn low PVA, PVC and PVDF nanofibers using an atomic force microscope. The measured Young’s modulus of PVA was larger than that of PC and PVDF, which agrees with the thermal conductivity trend.

TP02.07.10
Tuning Thermal and Electrical Properties of NiO Films by UV/O3 Treatment for Resistive Memory Applications Sanchit Deshmukh1, Raisul Islam1, Christopher Saltonstall2, Eilam Yalon3, Thomas Beecham4, Krishna Saraswat1 and Eric Pop1; 1Stanford University, Stanford, California, United States; 2Sandia National Laboratories, Albuquerque, New Mexico, United States.

Resistive random access memory (RRAM) devices store information by switching a sub-50 nm diameter, locally conductive filament (CF) in insulating materials such as oxides like NiOx [1]. Because switching an individual CF needs both high fields and elevated temperatures, sufficient Joule heating is necessary for device operation. In this context, the thermal interfaces of the CF with surrounding oxides and metal electrodes need to be properly understood, as they govern the operation of RRAM devices. The CF thermal physics is also complicated by vacancies, whose role is not adequately understood in such oxides [2,3].

Here we probe RRAM oxide interfaces by studying vacancy-dependent thermal properties of sub-stoichiometric NiOx for the first time. We demonstrate that tuning the vacancy concentration at such interfaces can aid in tuning the electrical contact resistivity (ρC) and thermal boundary conductance (TBC) to Ni-vacancy rich NiOx films. We deposit 400 nm thick NiOx films using sputtering in an Ar:O2 ambient from a NiO target, with stoichiometry close to 1:1. We tune the Ni vacancy concentration at the top surface by treating the films with O3 under UV light for different durations. Previous work [4] shows that we can tune the electronic properties of NiOx films using this technique. Circular transfer length measurements (C-TLM) on these treated films reveal a decreasing ρC from 3.8 × 10¹⁰ to 1.5 × 10¹⁰ Ω·μm² with increasing treatment time from 0 to 30 min, while NiOx film resistivity reduces from 15 to 1 kΩ·cm.

We use similarly treated films with 60 nm thick Pt blanket top deposition post-treatment for thermal measurements. We perform time-domain thermoreflectance (TDR) measurements to separate out the film thermal conductivity and the TBC at the top metal-film interface. With increasing UV/O3 treatment time from 0 to 30 min, we see an increase in the TBC from 175 to 420 MW/m²K, with a negligible change in the corresponding NiOx thermal conductivity ~7 W/mK. The contribution of the electronic component of NiOx thermal conductivity, calculated from the Wiedemann-Franz Law, remains negligible with treatment. With increased vacancy density at the interface, there is a decrease in the electrical and thermal contact resistance to the NiOx films. This suggests that increased vacancy concentration in an oxide, as observed in a CF, enhances electronic and thermal conduction across the metal-oxide interface, in general. These results show that electronic and thermal energy transport can be tuned across interfaces of RRAM oxides by controlling the vacancy concentration, an important step in designing energy-efficient RRAM devices.

Thermal Characterization of High-Al Composition AlGaN High Electron Mobility Transistors Samuel H. Kim and Samuel Graham; Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

AlGaN-channel high electron mobility transistors (HEMTs) are promising candidates of ultra wide-bandgap transistors for power and RF applications. Their promise derives from the large breakdown field. The breakdown voltage of high-Al composition Al(x)Ga(1-x)N (x > 0.5) is expected to be about 3x higher than that of GaN. Also, thermal conductivity of AlN is 6x higher than sapphire, and 1.5x – 2x higher than GaN. These lead to significantly high power and RF figure of merit, especially at elevated temperatures, when Al(x)Ga(1-x)N (x > 0.5) channel layers are used instead of GaN in HEMTs. One study showed that, the 3 μm thick high quality AlN buffer layers over sapphire substrates provide excellent thermal conduction, enabling stable device operation.
operation with negligible drain-current degradation up to 250 °C. Unlike GaN/AlGaN HEMTs, however, there is no thermal characterization study reported for these ultra wide-bandgap transistors.

In this study, we investigate thermal response of high-Al composition AlGaN HEMTs. Thermal characterization techniques have been developed to evaluate the temperature distribution of wide band gap electronics that will be applied to these AlGaN HEMTs. We utilize Raman thermometry, IR thermal imaging, and transient thermoreflectance imaging to investigate the temperature distribution of these devices. Raman thermometry has been well established to be spatially and temperature accurate when monitoring the thermal response of devices under steady state DC biasing conditions. IR micro thermal imaging is a widely used tool to image temperature distributions of electronic devices. Lastly, transient thermoreflectance imaging will be used to not only monitor the formation of the hotspot under pulsed biasing, but also image temperature distribution across the channel.

SESSION TP02.08: Thermal Devices and Sensors
Session Chairs: Ming Su and Zichao Ye
Wednesday Morning, November 28, 2018

8:00 AM TP02.08.01
Development of In Situ High-Temperature High-Resolution Transmission Electron Microscopy Using a Picometer Scale Sample Manipulation System Manabu Tezura, Hideki Kobayashi, Takuya Okamoto, Koichi Murakami and Tokushi Kizuka; Division of Materials Science, Faculty of Pure and Applied Sciences, University of Tsukuba, Tsukuba, Japan.

Heath resistant materials, which are subjected to high temperatures up to ~1700 K at strong external force, are key advanced structural materials. Microstructural dynamics of materials in phase transformation, precipitation, behavior of point defects, grain-boundaries, and interfaces at actual using environments should be investigated to design and improve such materials. In situ high-temperature transmission electron microscopy (HTTEM) can be applied to the observations of texture and deformation process at high temperatures [1]. However, in most of previous HTTEM, the observation was performed at conventional magnifications. In this study, we developed a new type of HTTEM for the investigation of microstructural dynamics during mechanical deformation using a piezodriving system [2-4].

A molybdenum mesh heater was mounted on a sample holder for HTTEM. A direct current was applied to the heater to increase its temperature due to Joule heating. The heater temperature while applying bias voltages was measured using a pyrometer. The heater temperature successfully increased up to the maximum temperature, i.e., approximately 2000 K [2]. In situ HTTEM observation was carried out with an acceleration voltage of 200 kV in a vacuum of 1 x 10^{-8} Pa. The fracture and deformation processes of gold nanocontacts at 930 K could be observed at the atomic resolution.

8:15 AM TP02.08.02
A Study on the Thermal Coefficient of Resistance Dependency of Infrared Microbolometer Jun Kyo Jeong1, Byeong Jun Jeong1, Jaeseop Oh2, Hi Deok Lee1 and Ga Won Lee1; 1Chungnam National University, Daejeon, Korea (the Republic of); 2National Nanofab Center, Daejeon, Korea (the Republic of).

An uncooled infrared microbolometer is a principle that measures temperature changes due to infrared absorption as a change in resistance. Compared with the cooling type infrared microbolometer, the process is comparatively simple and can be manufactured with a high yield, and is advantageous in terms of packaging. This advantage is useful as a next-generation infrared sensor. The uncooled infrared microbolometer is fabricated as a focal plane arrays with high performance combined with the microbolometer and signal detection circuit fabricated using MEMS (Micro Electro Mechanical System) technology.

In order to produce a high-performance infrared microbolometer, sensitivity and response speed must be improved. The main issues of infrared microbolometer are good thermal isolation, high absorption, good sensitive layer and good stability structure thermal transfer. In order to solve these problems, the application of the shape of the floating structure and the optimization of the geometry of the support structure to reduce the heat loss, High thermal coefficient of resistance (TCR) performance sensing membrane research for high sensitivity sensing, and stability for physical structure and simulation for optimizing heat transfer. In this paper, we have studied the temperature dependence of TCR, which defines thermal properties using COMSOL simulation for the fabrication of high-performance uncooled infrared microbolometer. The structure of the uncooled infrared microbolometer designed in this study has an air-gap corresponding to λ/4 of the far-infrared wavelength, mainly 8 μm, that is to be detected. The structure consists of cantilever, absorption layer, resistance layer, and passivation layer. The uncooled infrared microbolometer measures the current change due to the joule heating caused by the driving voltage and the incident infrared energy. simulations were conducted in COMSOL Multiphysics 5.3a software to verify and optimize the device design. The device was simulated as a 3D model using Electric Currents module, Heat Transfer in Solids. To improve the accuracy of the simulation, the TCR of the resistive layer a-Si was set as a function of temperature. In addition, the heat generation of the device is set to be the same as that of the actual device in consideration of heat loss to the outside. Although the TCR has been widely known as a parameter that greatly affects the characteristics of the bolometer, the influence of temperature dependence of the TCR on the device performance has not been fully considered. Through this study, we tried to show that the characteristics of the device can be more efficiently optimized by simulating the physical properties (resistivity, TCR, etc.) of the absorption layer and resistance layer of the uncooled microbolometer.

8:30 AM *TP02.08.03
Phase Change Nanoparticles for Biosensing, Barcoding and Enhanced Cooling Ming Su; Northeastern University, Boston, Massachusetts, United States.

Nanomaterials have been widely studied for their electronic, magnetic, mechanical, and chemical properties. We have studied the unique thermal properties of a new type of nanomaterials, nanoscale phase change materials (i.e., nano-PCMs). This group of materials may have any chemical composition, as long as there is a solid-liquid phase transition when temperature is changed. We have made a number of nano-PCMs and explored their applications in biosensing, barcoding, and enhanced cooling. Metallic nano-PCMs and organic nano-PCMs have been made with precise thermodynamic properties (melting temperature and enthalpy) based on phase diagram knowledge. These nano-PCMs have been used to enhance heat transfer capability of a variety of fluids, to detect multiple molecular biomarkers of diseases, to create cover barcodes that can be added into objects, and to prevent catalytical reactors from thermal runaway.
Different semiconductor materials including amorphous Si, Ge and MoS2 flake are tested. As nanomaterials are blooming up in recent years, the properties of individual nanostructures have attracted a lot of interests, which were reported to be significantly distinct from their bulk counterparts in many cases [1-4]. Based on specific in-situ testing platforms, routine mechanical experiments [1,2], chemical/electrochemical reactions [3,4] can be carried out on micro/nanometer-scale specimens in SEM/TEM. Nevertheless, the thermal management of small specimens remains challenging. A few of solutions are available for nanothermometry. For instance, nano-thermometers, like Ga in CNT were developed to measure temperature in TEM [5]. Nanometer-sized particles with low melting point were employed to indicate the temperature distribution of specimens irradiated by electrons [6]: VO2 nanowires were used to estimate the temperature of nanomaterials [7]; Even the temperature distribution of Al foil was mapped directly by electron energy loss spectrum [8]. While to figure out heat transfer through nanostructures, MEMS devices have to be fabricated, and careful analysis of thermal circuit is necessary [9]. Recently, we developed a new method to investigate the thermal properties of nanostructures in TEM. In this study, we are introducing a new nanoscale heat flow meter based on an individual VO2 nanowire, which can be utilized to quantify the thermal conductivity of nanostructures. The thermal conductivity of SnSe was measured as 1.86±0.21 W.k-1.m-1. According to literature, our measurement is close to the calculated value in the first-principles study, 1.55 W.k-1.m-1 [10]. We believe that our platform will open an avenue to exploring thermal properties of nanostructures.

References:
develop a first-order one-dimensional heat-transfer model to establish the temperature response of ultra-long hot films in a fiber microfluidic channel. The improved flow sensing range in a multi-segment sensor, as predicted by the 1D analytical model, is corroborated by numerical simulations and experiments.

Record-setting flow-rate sensitivity was demonstrated in this work over an ultra-wide flow-rate range and unprecedentedly low pressure drop. The successful incorporation of high-TCR, high-resistance conductive polyethylene as the temperature-sensitive hot film yields a voltage response of 0.8 V/K and a flow-rate sensitivity of 384 mV/(uL/min) between 0 and 20 uL/min. This ultrahigh voltage response allows the fiber sensor to operate at a maximum temperature rise of merely 20 °C, 5–10x smaller than that in typical MEMS sensors and important for handling biomedical samples. In addition, this ultrahigh voltage response enables ultralow pressure drop of 8 Pa at 100 uL/min, orders of magnitude lower than conventional MEMS thermal flow sensors. More importantly, we have realized a high-pressure sensitivity measurement range of 5–200 uL/min through a multi-segment structure where each segment reaches its peak sensitivity at different flow rates.

Our work combines novel material systems and new device structures that deliver new functionality and significant improvements in performance. This unconventional form of flow sensors paves the way towards a complete functional overhaul of microfluidics feed lines needed in large-scale multi-chip integration in microfluidics and opens new possibilities in lab-on-fiber technologies.

Thermal Analysis of Nanophotonic Structures Using Noise Thermometry and the Thermoelectric Effect
Kelly W. Mauser1, Phillip Jahelka1, Rebecca Gladell1, Michael Kelzenberg1, Colton R. Bukovsky1, Seyoon Kim2, K. C. Schwab1 and Harry A. Atwater1; 1California Institute of Technology, Pasadena, California, United States; 2ICFO–The Institute of Photonic Sciences, Barcelona, Spain.

Generating localized, high electric field intensity in nanophotonic and plasmonic devices has many applications, including enhancing chemical reaction rates, thermal radiation steering, chemical sensing, and photovoltaics. Along with a strongly localized electric field comes a temperature rise in non-lossless photonic materials, which can affect reaction rate, photosynthetic efficiency, and other properties of the system. Measuring temperature rises in nanophotonic structures is difficult, and methods commonly employed suffer from various limitations, such as low spatial resolution (Fourier transform infrared microscopy), bulky and expensive setups (scanning thermal microscopy), intrusive methods that interfere with nanophotonic structures (Pt resistive thermometry), or the need for specialized materials (temperature-dependent photoluminescence). We overcome these limitations with the first-ever demonstration of temperature measurements of nanophotonic structures by employing both room temperature noise thermometry and the thermoelectric effect under ambient conditions without external probes, by utilizing the properties of the materials that make up the nanophotonic structure itself. We have previously estimated the ΔT in a nanophotonic device using the thermoelectric effect [1], but could not determine the absolute temperature of the system. In the application we will discuss, the absolute electron temperature of the nanophotonic material itself is measured. Because Johnson-Nyquist noise is material independent and is a fundamental measure of absolute temperature, there is theoretically no need for calibration as in the case of resistive thermometry. To measure the temperature rise of a nanophotonic resonant region remotely, the Seebeck coefficient of the material is first carefully measured using noise thermometry, then the thermoelectric voltage generated in the nanophotonic materials themselves is measured from electrical leads spanning the resonantly excited region. To accomplish this, we have developed a metrology technique capable of simultaneously measuring electrical noise at two locations on the nanophotonic structure as well as the electrical potential between the two points, under chopped laser illumination that heats the structure via nanophotonic absorption, thus providing drift-corrected light-on/off temperature information.

Furthermore, this method can be used to deduce thermal time constants of the system, which will be discussed. We have successfully measured temperature rises in a room-temperature guided mode resonant nanophotonic system using the described method from several degrees above ambient to 320 K with high fidelity and reproducibility, and these results show an excellent match to simulation.

Environment Sensing with Porous Photonic Structures
Francisco Gallego-Gómez and Cefe López; Consejo Superior de Investigaciones Científicas, Madrid, Spain.

Photonic colloidal crystals, also referred to as artificial opals, for their photonic properties, have wide applicability in many fields such as sensing, light harvesting, etc. Understanding their ability to transduce fluids adsorption and confinement into a photonic response [1-3] allows to envisage new perspectives for integrated platforms for accurate control of liquid-solid interplay [4-5]. In particular, simple spectroscopic monitoring of the photonic bandgap allows to study vapor adsorption and condensation, wetting, inhibition and confined flow within their porous network. (Opals may offer a number of benefits compared to current devices. Beside the easy and versatile fabrication in different scales with diverse materials and post-manufacture treatments, the main advantage of artificial opals resides on the photonic nature of the output, which ensures high sensitivity and fast response, while no further sensors or imaging devices are required.)

Here we gather recent achievements that prove the potential of opals as photonic devices with extremely sensitive response to adsorption and condensation phenomena, both humidity and temperature dependent. On the one hand, water condensation in the nanoporous opal network under saturated vapor conditions was studied near the dew point [6]. As a particularly interesting feature, the photonic signal sharply changed at the onset of dew formation, and allowed in situ monitoring of the condensation process. As the dew point sensitively depends on both opal and atmosphere temperatures, the opal response can be employed for precise control of temperature in versatile situations. On the other hand, distinct opal response can be obtained from selective pore filling in a gaseous environment, as demonstrated in a hierarchically porous carbon opal [7]. Specifically, the photonic signal sharply reacts to the filling of microporosity, a fact that, for a given gas pressure, drastically depends on the thermal energy of the adsorbate molecules. Thus, we propose the unique photonic response of microporous opals as a novel, powerful means for thermal analysis.

10:45 AM TP02.08.09
Effect of Band Parameters on Generation-Transport-Recombination (GTR) of Minority Carriers
Sadid Muneer, Helena Silva and Ali Gokirmak;
For semiconductor devices under extreme electrical stress, substantial number of minority carriers are generated (G) at high temperature, are transported (T) under electric field, and recombine (R) at some place away from the generation location, creating an effective heat pump that adds to the symmetric Joule heating, leading to an asymmetric thermal profile [1]. Our electrothermal finite element model captures the impact of the GTR process and shows the general trend of the correct asymmetry. However, the asymmetry observed in the experiments with silicon microwires is much stronger than the modeling results [1]. An alternative to better model the non-equilibrium processes that give rise to GTR is to use a semiconductor modeling approach. However, the conventional semiconductor models’ transport and band parameters are not tailored for extremely high temperatures. As an example, the equilibrium carrier concentration for silicon near melting is predicted as ~10^20 cm^-3 with conventional semiconductor physics instead of the melt concentration of ~10^22 cm^-3 [2]. We have constructed a detailed non-equilibrium finite element semiconductor modeling platform, including electron and hole continuity equations, Poisson’s equation for local potential calculation, and associated recombination mechanisms (SRH, Auger), to quantify and better understand the carrier-carrier and carrier-lattice interactions that gives rise to the GTR process and the consequent asymmetry [3],[4]. In the present work we specifically investigated temperature dependence of intrinsic carrier concentration [5], screening of Auger recombination at high carrier density [6], and collapse of bandgap near melting [7]. The results show that careful calibration of these parameters is essential to model GTR phenomenon and capture the correct direction and extent of the asymmetry.

Morphology, Device Performance and Thermal Behavior of a Molecular Liquid Crystalline/Fullerene Blend Alexander J. Bourque1, Chad Snyder2, Sebastian Engmann2, Lee Richter2 and David Jones1; 1The University of Melbourne, Melbourne, Victoria, Australia; 2National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The morphology and performance of thin-film photovoltaic devices comprising an active layer blend of a molecular liquid crystalline material (BQR) and a fullerene derivative (PC$_7$BM) were investigated here to assess the impact of thermal processing. In-situ grazing incidence x-ray scattering (GI-SAXS, GI-WAXS), differential scanning calorimetry (DSC) and photoluminescence spectroscopy (PL) were applied to study the active layer across a range of blend compositions to correlate morphological changes, thermal behavior and photoactivity, respectively. Enhanced BQR crystallinity and phase purity was observed for increasing temperatures with optimal device performance peaking at 120°C; device performance suffered at progressively higher temperatures due to over-coarsening of acceptor/donor domains. DSC measurements were paired with in-situ GI-WAXS measurements subject to the same thermal history to identify multiple liquid crystal and crystalline transitions in the blend. Finally, melting point depression theory was applied to estimate the Flory-Huggins interaction parameter for the binary blend.

Micro-Thermocouples with Extreme Sensitivity Daniel R. Assumpcao1, Shailabh Kumar2, Vinayak Narasimhan2 and Hyuck Choo1, 2; 1Electrical Engineering, California Institute of Technology, Pasadena, California, United States; 2Medical Engineering, California Institute of Technology, Pasadena, California, United States.

High-resolution detection of temperature changes in small scales could open up a new scientific vista by, for example, providing valuable intuition for energy distribution in nanophotonic structures or revealing functional details of cell biology based on subtle temperature differences [1]. Thermocouples are temperature-sensing devices that have been widely used in many applications for their simple fabrication, ease of measurements, and accuracy [2]. Micro-scale thermocouples made of IC-process-compatible metals such as Ni, Cr, or Au layers have been demonstrated for various applications [2], but they suffer from small Seebeck coefficients and consequently poor sensitivity, yielding temperature-sensing resolutions larger than 2 °C. The use of rare and expensive alloys such as bismuth and antimony telluride with high Seebeck coefficients could improve the sensitivity but requires sophisticated fabrication processes [3].

By taking the advantage of the high Seebeck coefficient of silicon, we have demonstrated a new approach for designing metal-on-silicon thermocouples with a noticeably high Seebeck coefficient of 9.17×10^-4 V/°K and temperature-sensing resolution of 0.01 °K (theoretical limit: 0.00055 °K). We have also kept the device fabrication straightforward: it only involves photolithography and metal-lift-off on a silicon substrate because we chose materials with appropriate electronic properties and selectively formed Schottky barriers and Ohmic contacts to establish electrical isolations and conduction without adding fabrication steps. The Seebeck coefficient of our thermocouple is 30 times larger than values reported for standard thin metal-film thermocouples and comparable to Seebeck coefficients of rare alloy-based thin-film thermocouples that require sophisticated and costly fabrication processes. The temperature measurements were highly linear, with a linearity coefficient of 1. Our circuit analysis performed on the metal-on-silicon thermocouples shows that these devices can be further miniaturized down to a few micron size and arranged in a dense array format with an inter-device spacing of a micron without degrading the performance.

Furthermore, we applied this approach to demonstrate a highly flexible metal-on-silicon thermocouple with enhanced thermal sensitivity (bending radius: 1.51 cm). The outstanding performance of our thermocouples combined with an extremely thin profile, bending flexibility, and simple fabrication process will proliferate its use in diverse thermography applications in the micro- and nanoscales.

Understanding the Superior Temperature Stability of Iridium Light-Emitting Electrochemical Cells Melanie Bowler, Tianle Guo, Anton Malko and Jason D. Slakey; The University of Texas at Dallas, Richardson, Texas, United States.

Gallium nitride (GaN) and its alloy AlGaN are being increasingly pursued for power electronics as their low specific resistivity, high mobility, and ultrawide bandgaps provide a pathway to smaller devices, a “smarter” grid, and better utilization of renewable energy sources. Per their moniker, power devices must handle—and dissipate—tremendous energy loads. These loads, in turn, can lead to self-heating sufficient to dampen both performance and reliability. To minimize self-heating, it is necessary to assess how the thermal properties of GaN and AlGaN are modified from their “textbook” value during device processing. Here, using a combination of time domain thermal reflectance (TDTR) measurements with material modeling, significant size-induced reductions in thermal conductivity are found in both GaN and AlGaN for layer thicknesses typical of devices. These reductions emerge from the interaction with the EM wave is still poorly understood, but we have started to provide analytic explanation to the collected experimental results.

SESSION TP02.08.13
Mechanics of Materials Interaction with Electromagnetic Wave Diana Gamzina, Emilio Nanni, Paul Welander and Sami Tantawi; Technology Innovation Directorate, SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Advances in understanding RF breakdown have led to improvement in accelerator performance, but detailed knowledge of the temporal material changes due to its interaction with RF continues to be an unknown. It has been observed that an RF structure can be conditioned to handle significantly higher accelerating gradients by slowly ramping up RF power levels fed into the structure and that the RF breakdown rate can be reduced by utilizing copper with higher hardness numbers. While surface imaging post operation clearly show surface damage, the practical findings provide limited insight into material’s behavior under RF loading. We evaluate the mechanics of material during its interaction with an electromagnetic (EM) wave. This analysis impacts the development of advanced RF accelerators and sources; it also informs the development of materials resistant to EM radiation damage and of material synthesis techniques that utilize EM fields for achieving far-from-equilibrium material states.

During RF heating, a sub-micron thick material surface layer is heated instantaneously creating steep and non-linear thermal gradients, which eventually (on sub-ms scale) evolve into linear thermal gradients. The transient thermal gradients and the boundary conditions imposed on the material cause the state of stress to temporally evolve. Furthermore, even though cubic material like copper has an isotropic coefficient of thermal expansion, its elasticity is highly anisotropic. Polycrystalline copper that is used for the manufacturing of RF cavities undergoes multiple high temperature thermal cycles that fully anneal the material so that the resulting material grain size is on the order of a few millimeters. As a result, local material response to the EM heating then also depends on the orientation of the crystal structure with respect to the material surface. It has been observed that highly compliant (100) direction oriented grains show significantly less damage than stiff (111) direction oriented grains; similar results were reported for laser induced damage in copper. Significantly higher stress levels are induced in the (111) grain when compared to the (100) grain for the same thermal strain values because of the difference in the elastic moduli. Conditioning of the RF structures is analogous to a strain-hardening process, but with temporally varying strain rate conditions. Similar to other strain hardening methods, the dislocation density eventually saturates with increasing strain values and, as a result, the RF structure reaches its peak RF operation gradient. Starting with a harder material (high dislocation density) allows one to jump to higher gradient levels (strain values) without generating additional dislocations. The evolution of the material surface during the interaction with the EM wave is still poorly understood, but we have started to provide analytic explanation to the collected experimental results.
breakdown voltage. While much effort goes into the electrical characterization of these devices, complete thermal characterization is lacking. The diodes used in this study consisted of a 420 µm n-GaN substrate on which MOCVD was used to grow 15 µm n GaN (Si), 500 nm p-GaN (Mg), and 30 nm p'-GaN (Mg). The completed chips consist of diodes with diameters of 100 µm, 300 µm, 500 µm, and 1000 µm. One set of devices was subjected to passivation with a polyimide film, while the other set of devices was non-passivated. Electroluminescence (EL) was performed on both sets of devices, and it was found that non-passivated devices demonstrated increased EL intensity at the mesa edges, most likely due to enhanced surface recombination, and subsequently showed IV characteristics that outperformed the passivated devices in terms of power handling capabilities at high forward voltages. When a high-power operating point is set for a diode, there can be a significant increase in temperature, which leads to thermal expansion, and other reliability issues inherent in the cyclic operation of a power device. To investigate the thermal response, we used time domain thermoreflectance (TDTR) to evaluate the thermal conductivity of a vertical GaN p-n diode as a function of depth. Transient thermoreflectance imaging was used to observe variations in heating profiles across devices of different diameters when operated at the same power densities, and to observe the transient temperature rise and fall for each of the diodes.

Thermal Analysis of GaN HEMTs Using Near Bandgap Thermoreflectance Imaging
Georges Pavlidis1,2, Dustin Kendig2, Luke Yates3, Banafsheh Barabadi1, Brian Foley1 and Samuel Graham1; 1Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2CNST, National Institute of Standards and Technologies, Gaithersburg, Maryland, United States; 3Massachusetts Institute of Technology, Boston, Massachusetts, United States; *Microsanj LLC, Santa Clara, California, United States.

Transient thermoreflectance imaging (TTI) is a CCD based thermometry technique that can map the temperature distribution across a surface. For materials, such as gold, where the thermoreflectance signal has a strong linear temperature dependence, TTI has shown to have a high spatial (300 nm/pixel) and temporal resolution (50 ns). Consequently, the technique has been primarily used to monitor the gate metal temperature distribution in GaN High Electron Mobility Transistors (HEMTs) and enable characterization of the device's transient thermal dynamics. The origin of the extreme localized heating in GaN HEMTs, however, is known to be in the active GaN layer and thus accurate characterization of the temperature across the channel is necessary. Using a UV LED excitation source with a wavelength near the bandgap of GaN, TTI of the GaN channel in GaN HEMTs is presented and verified for the first time via the comparison of the gate metal temperature. A pixel by pixel calibration method is implemented to improve the spatial accuracy and account for any variability in the thermoreflectance coefficient across the device. Performing full transient scans, the time constants associated with the GaN region are found to be shorter than those measured via the gate metal. To ensure a strong thermoreflectance signal from the GaN surface, the importance of using an excitation wavelength near the bandgap of the GaN channel is highlighted. Through the analysis of HEMTs with different residual stresses in the GaN channel (engineered by using superlattice structures), the effect of the bandgap on the magnitude and the linearity of the thermoreflectance coefficient is presented and discussed. Overall, the improvements of TTI discussed in this study make the technique an accurate and effective method to measure the temperature distribution of both the gate metal and GaN.

Electro-Thermal Analysis of Ultra-Wide Bandgap Electronics
Sukwon Choi; The Pennsylvania State University, University Park, Pennsylvania, United States.

To extend further the electrical performance envelope of wide bandgap (WBG) power and radio frequency (RF) electronics based on gallium nitride (GaN) and silicon carbide (SiC), device engineers are actively pursuing the development of generation-after-next ultra-wide bandgap (UWBG) devices. At the time being, aluminum gallium nitride (AlGaN), β-gallium oxide (Ga2O3), and diamond are technologically relevant UWBG materials that have bandgaps larger than that for GaN (3.4 eV). While UWBG devices are built to operate under higher power densities compared to current state-of-the-art WBG counterparts, the thermal conductivities of AlGaN and Ga2O3 are lower than those for GaN and SiC by an order of magnitude. Therefore, self-heating is one major challenge for these UWBG devices. Electro-thermal interactions that lead to self-heating in AlGaN and Ga2O3 devices need to be accurately assessed and understood to accomplish the successful transition from WBG devices to the UWBG technology.

In this work, we will demonstrate the use of an integrated optical thermography scheme (Raman thermometry, thermoreflectance imaging, and infrared thermography) to study the steady-state and transient thermal characteristics of state-of-the-art AlGaN and Ga2O3 devices. These include AlGaN high electron mobility transistors (HEMT), Ga2O3 Schottky Barrier Diodes (SBD), and lateral Ga2O3 metal-oxide-semiconductor field-effect transistors (MOSFET). Results are validated through the use of coupled electro-thermal modeling. In addition, we will report our recent progress on the development of new optical temperature and stress metrology techniques suitable for UWBG electronics including “2-D transducer-assisted Raman thermography.”

4:00 PM TP02.09.05
Spectral Focusing of Thermal Conductivity in GaN—A First Principles Study
Jivtesh Garg; University of Oklahoma, Norman, Oklahoma, United States.

We find using first-principles analysis of thermal conductivity (k) in isotopically pure GaN that almost 60% of the heat is conducted by phonons in a very narrow frequency range of 5–7 THz (spanning only 9% of the frequencies in GaN). This spectral focusing of thermal conductivity is found to be due to a combination of two effects – large increase in lifetimes of phonons through suppression of anharmonic scattering in the 5–7 THz frequency range, coupled with a large phonon density of states at the same frequencies. Understanding of the effect is provided by solving the phonon Boltzmann transport equation in the single mode relaxation time approximation along with the use of harmonic and anharmonic force constants derived from density functional theory. The results can have important implications for engineering thermal performance of devices based on GaN.

4:15 PM TP02.09.06
Electron-Beam Probing of Vibrational Modes Across Semiconductor Interfaces with Nanometer Spatial Resolution
Zhe Cheng1, Juan Carlos Idrobo2 and Samuel Graham1; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

As the relentless miniaturization of microelectronics, thermal management becomes an integral challenge for sake of device reliability and safety. Due to the highly-scaled architecture of these electronic systems, heat dissipation can be significantly influenced or even dominated by interfaces. A fundamental understanding of vibrational modes near interfaces which contribute to interfacial heat transfer is still missing, especially at nanoscale spatial resolution. The development of a modern monochromated aberration-corrected scanning transmission electron microscopy (STEM) system makes it now possible to probe vibrational modes with a spatial resolution better than 1 nm and with an energy resolution better than 15 meV. In this work, a GaN+5 nm AlN+SiC...
interface sample was grown by molecular beam epitaxy and cut into a cross-section STEM sample (around 100 nm thick) using a Focused Ion Beam. Electron energy-loss spectroscopy (EELS) line profiles across the interfaces were collected. The spectra show vibrational peaks arising from SiC optical phonons (110 meV) across all data points. The detected SiC peaks in the AlN and GaN layers are long-range evanescent phonon fields (the beugrenzunf)gelfect). Acoustic phonons are also detected in the energy range between 30–40 meV, which originate from GaN, AlN and SiC. The most interesting feature of EELS results is the presence of an enhancement of the phonon intensity near the interface for both optical and acoustic phonon modes. For three positions near the two interfaces (GaN/AlN and AlN/SiC), the phonon intensities are larger than those measured in the GaN and SiC layers, which may be attributed to surface phonon resonance or interface modes. Here, we will discuss our experimental results and present a theoretical understanding of the observed features in light of improving thermal management at the nanoscale. [1]

[1] The electron microscopy part of this research was conducted at the Center for Nanophase Materials Sciences, which is a Department of Energy Office of Science User Facility (JCI). This research was conducted, in part, using instrumentation within ORNL’s Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

4:30 PM *TP02.09.07
Advances in Sub-Micron and Nanosecond Resolution Thermal Characterisation of Wide Bandgap Semiconductor Devices and Materials James W. Pomeroy, Martin Kuball and Babar Omer; University of Bristol, Bristol, United Kingdom.

GaN has transformed high-power, high-frequency RF amplifier and power switching technology, enabling more compact and efficient devices. Increasing the operating power density has enhanced device performance, although effective heat dissipation at the channel length scale becomes more critical. Concentrated Joule heating close to the gate generates large heat fluxes in GaN HEMTs: In extreme cases temperature gradients of 100°C/μm can be generated locally. Accurate temperature measurement in and around the transistor channel is essential to predict the meant time to failure (MTTF) and ensure reliability. Measuring the temperature distribution on this length scale also allows us to identify and improve any thermal resistance bottle-necks between the device channel and the heatsink. Conventional temperature measurement methods (e.g. IR thermography, Electrical) underestimate the channel temperature due to their limited spatial resolution, or in the case of pulsed operation, temporal resolution. The requirement for sub-micron spatial and nanosecond temporal resolution has driven the recent development of novel optical thermal characterisation techniques. We review a variety of techniques: Time resolved Raman thermography, including the application of solid immersion lenses for sub-micron resolution 3-D mapping; Raman nano-particle thermometry for surface temperature measurement on a variety of materials; UV transducer-less thermoreflectance. Hyperspectral Quantum-dot Thermal Imaging (HOTI) will be introduced – a very recently development. The application of these techniques to aid the development of next-generation devices and materials is discussed, including GaN-on-diamond and other wide bandgap semiconductors.

SESSION TP02.10: Thermal Properties of Reactive Materials
Session Chairs: Jeffery DeLisio and Karsten Woll
Thursday Morning, November 29, 2018
Sheraton, 3rd Floor, Fairfax AB

8:00 AM TP02.10.01
Sample Controlled Thermal Analysis for Studying Energetic Materials Pierre-Henry Esposito1, Renaud Denoyel1, Thomas Neisius2 and Marie-Vanessa Coulet1; 1MADIREL - UMR, CNRS and Aix Marseille University, Marseille, France; 2Féderation de Chimie, CNRS and Aix Marseille University, Marseille, France.

Among nanoenergetic materials, aluminum powders are at the center of numerous works since they remain an additive of choice in many energetic formulations [1]. In all those applications, it is the highly exothermic reaction of aluminum with an oxidant that confers to the powders their reactive and propulsive properties. The underlying idea of replacing micropowders by nanopowder is to take advantage of the enhanced reactivity that the nanoscale confers to the system. Whatever the scale under consideration, any aluminum particle is covered by a thin alumina layer whose thickness does not vary much with the size of the aluminum core [2]. At low heating rates, the oxidation is controlled by a diffusion mechanism in which this alumina layer plays an important role due to its various polymeric transitions [3,4]. The enhanced reactivity of aluminum nanopowders is thus linked to size reduction effects of the particles but also to structural changes of the alumina layer. Recently, morphology of the particles and grain nanostructureation of the aluminum core were also proposed as relevant parameters that could allow tuning the material properties [5].

In this contribution, we show that thermal analysis is a useful tool for understanding the oxidation mechanisms in aluminum powders. Powders with different morphology (sphere or flakes) and various sizes (from micro- to nano-scale) are compared. Firstly, it is shown that combined thermogravimetric (TG) and differential thermal analysis (DTA) performed up to 1500°C allows to establish reliable criteria of reactivity that can be extrapolated to realistic conditions. Secondly, the oxidation reaction is studied using kinetically controlled thermal analysis [6]. In this mode where the oxidation rate is constant, the kinetics equations are simplified which facilitates the modeling of the experimental data. This modeling, together with ex-situ oxidation studies [7], enables to predict the oxidation behavior as a function of structural parameters such as specific surface area and morphology.

The Direction Générale des Armées (DGA) is acknowledged for financial funding.

8:15 AM TP02.10.02
Characterization of Cure of Polymeric Materials by Dielectric Analysis (DEA) Yanxi Zhang; Netzsch Instruments North America, LLC, Burlington, Massachusetts, United States.
A variety of questions may arise during the curing process. For example, at which temperature, or after how much time, does the resin begin curing? How high is the reactivity? When is curing complete? How can the curing cycle be optimized? Is there any potential for post-curing? The answers to questions such as these can be investigated by using Dielectric Analysis (DEA), not only in the laboratory environment, but also in-process.

Dielectric Analysis (DEA) allows for the measurement of changes in the dielectric properties of a resin during curing. This technique can be used in studying the curing behavior of thermosetting resins, adhesives, paints, and coatings in nearly any application.

Various application examples about epoxy and other polymeric materials are included in the presentation, including heat cure and UV cure.

8:30 AM TP02.10.03
Time-Resolved Speciation and Calorimetry of Reactive Nanolaminates at High Heating Rates

Jeffery B. DeLisio1, Feng Yi2, David LaVan2 and Michael R. Zachariah3; 1Department of Chemistry and Biochemistry, University of Maryland, College Park, Maryland, United States; 2National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Sputter deposited reactive nanolaminates are of great interest for “on chip” energetic applications, but standard analytical techniques lack the ability to characterize these materials on timescales representative of a combustion event. In addition, the simple geometry at the fuel/oxidizer interface of multilayered nanolaminates provides an ideal system to further study the oxygen transport in thermite based reactions, making it possible to probe factors such as the influence of interface-to-volume ratio and its effect on ignition and energy release. Previously, temperature jump (T-Jump) time-of-flight mass spectrometry (TOFMS) was employed to characterize ignition/decomposition temperatures and gas phase speciation of these systems at high heating rates, but this system lacks the ability to measure the energetics of a reaction. Recently developed chip-based nanocalorimeters are capable of making thermal measurements at sufficient frequencies to characterize the energetics of these reactions. In this work, a chip-based nanocalorimeter developed at NIST was integrated with a TOFMS system to enable simultaneous measurement of temporal thermal dynamics and detection of evolved gas species at heating rates up to ~10^6 K/s. This integrated system was first tested by analyzing the decomposition of electrospray deposited salts and metal oxide particles. Reactive nanolaminates were then directly sputtered onto the nanocalorimeter sensors and the effect of bilayer number and thickness was characterized. For an aluminum/copper oxide (Al/CuO) reactive nanolaminate system, one reaction step was observed for a sample with a bilayer thickness of 33 nm. However, a two-step reaction mechanism was observed as the bilayer thickness was increased to 66 nm and beyond: solid-state reaction occurring at the interfaces of Al and CuO before the melting of Al and a much faster liquid−solid reaction right after the melting of Al. In addition, analyzing the measured power from nanocalorimetry provides a more direct method, compared to optical emission and mass spectrometry based methods, for determining the ignition temperature while also being able to measure actual energy output from films with nanoscale thicknesses.

9:00 AM TP02.10.04
Tailoring the Microstructure of Metallic Thin Films Utilizing Heating Rate Effects on Phase Transformations in Reactive Al/Ru Nanolaminates

Karsten Woll1, Tobias Neuhauser1, Christoph Pauly2, Gemma Tinti3, Nicola Casati3 and Anna Bergamaschi3; 1Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany; 2Materials Science & Engineering, Functional Materials, Saarland University, Saarbruecken, Germany; 3Paul Scherrer Institut, Villigen, Switzerland.

Reactive metallic nanolaminates or multilayers undergo exothermic runaway reactions when heated with rates larger than about 10^4 K/s. This behavior creates an interest of reactive nanolaminates for applications where local heat sources are required, e.g. in microscale-joining technology. The presented study considers another type of leveraging the reaction attributes. We address the question whether the exothermic phase transformations during ignition, that typically occur under high heating rates, can be utilized for microstructure tailoring of metallic thin films. From a fundamental point of view, the phase transformations occur at solid-solid or liquid-solid interfaces and are still an open field of research. As a model system, we chose Al/Ru nanolaminates and explore for subcritical heating how an increase in heating rate up to about 10^4 K/s affects the phase evolution and how this increase alters the properties of precipitating phases such as stoichiometry or morphology. In greater detail, we use conventional thermal analysis, namely differential scanning calorimetry, to reveal the phase transformations under slow heating and analyze the kinetics of the phase growth within a Johnson-Mehl-Avrami-type model. Complementary, in situ X-ray diffraction with synchrotron radiation enables us to determine the type of the growing phase and to corroborate the growth kinetics. In conjunction with the experiments, we apply classical nucleation theory combined with the diffusion kinetics to estimate the nucleation temperature observed during thermal analysis. The latter analysis protocol at low heating rates serves as reference for our high heating rate study. The advent of nanocalorimetry in the field of reactive materials enables us now to systematically analyze the transformational behavior under the rates of interest < 10^4 K/s. We perform experiments on Al-rich Al/Ru nanolaminates in the subcritical heating rate regime in combination with time-resolved X-ray diffraction using synchrotron radiation. In addition, we study the microstructure in the transmission electron microscope to correlate changes in the precipitating phase with the increase in heating rate. Eventually, we suggest pathways how the latter effects may help to tailor microstructures in thin films, e.g. to fabricate nanocomposites with optimized mechanical properties.

9:15 AM TP02.10.05
Frequency-Domain Thermal Conductivity Measurement for Reactive Solids and Melts at High Temperatures

Matthew Winger1, Andrew Z. Zhao1, Yasuhiko Kodera1, Hongwu Xu2, Stephen J. Obrey2 and Javier E. Garay1; 1University of California, San Diego, La Jolla, California, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

High temperature materials and melts are increasingly being investigated for next generation energy technologies such as batteries utilizing molten compounds, and high temperature heat transfer fluids (HTFs), and thermal energy storage (TES) materials. Such systems aim to take advantage of the chemical and transport properties of the melts or the higher intrinsic thermodynamic efficiencies that come with higher temperature. To utilize such compounds for melt-based systems and as HTFs in TES systems their thermal transport properties from the solid phase through the melt should be well characterized to understand how best to extract or retain heat and mitigate thermal design issues. Additionally, these materials can be highly corrosive or reactive at elevated operating temperatures and for specific material chemistries requiring that any thermal measurement technique can withstand harsh thermal and chemical sample environments in addition to being sensitive to the thermal properties under consideration. Here we describe a hot-wire geometry based thermal measurement system for accurate thermal conductivity measurements of solid compounds and melts. The chosen wire geometry is highly suitable for high temperature measurements of both solids and, particularly, liquids due to its relatively simple design and extensive working temperature range. Traditional hot-wire thermal measurement techniques pass a DC current through a thin resistive wire element suspended within a
Besides the influence of the choice of the halide, we will present the impact of a variation of the A-site cation (Cs vs. MA). An average thermal for the corresponding thin-film samples, which are treated by a planar hot pressing procedure to avoid topography artifacts (surface roughness <1 nm) [5].

crystals and thin films by means of dynamic Scanning Near-field Thermal Microscopy (SThM) [4]. The thermal conductivity of CH3NH3PbX3 single challenging, and only a few studies exist [2-4]. Recently, we reported on the thermal conductivity of methylammonium lead halide perovskite single importance for optimal performance and reliability [1]. As the thermal conductivity of perovskites is relatively low, it's experimental assessment is

Inkjet-Assisted Nanocalorimetry for Optimization of Trace Detection Feng Yi, Jeffrey Lawrence, Matthew Staymates, Greg Gillen and David LaVan; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Nanocalorimetry is capable of generating rapid and arbitrary heating profiles to gather thermal and thermodynamic measurements with high sensitivity. Here, we are studying the dynamics of the heating cycle to optimize trace detection. For the sample preparation, Inkjet printing is used to pattern samples on the active area of the nanocalorimeter and also allows for an estimate of the sample mass. Procedures have been developed to print exemplar trace materials onto nanocalorimeter sensors with precise control of position and sample mass. Nanocalorimetry results on several materials are shown to demonstrate the measurement capability.

Phase Evolution in Al/Ni Multilayer Thin Films Studied by Combined Nanocalorimetry and Sub-Millisecond X-Ray Diffraction Tobias Neuhäuser1, Gemma Tinti2, Harald Leiste1, Nicola Casati1, Anna Bergamaschi2, Michael Stüber1 and Karsten Woll1; 1IAM, Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany; 2OFLC/001, Paul Scherrer Institut, Villigen, Switzerland; 3WLGA/229, Paul Scherrer Institut, Villigen, Switzerland.

High strength typically compromise deformability in metallic materials. To overcome this conflict, we strive to develop thin film nanocomposites where hard intermetallic phases are embedded in a ductile metallic matrix. Our approach considers metallic nanolaminates or multilayers as starting materials. PVD sputter deposited Al/Ni multilayers serve as model materials. To generate hard phases at the nanoscale, we utilize phase separation where intermetallic phases precipitate predominantly at interfaces and/or grain boundaries upon annealing. Based on theoretical calculations, the chosen heating rate up to values of about 106 K/s have an impact on the phase formation. However, when heated with an overcritical rate to a specific ignition temperature, these materials exhibit uncontrolled runaway exothermal reactions. Up to now, the phase formations driving the ignition are not yet understood. The challenging task in terms of investigation is the highly dynamic character of the reaction, where transformations occur within microseconds. Traditional characterization tools operate at time scales that are too slow to reveal the individual transformations in detail. We developed an in situ technique where we combine chip-based nanocalorimetry and time-resolved X-ray diffraction with synchrotron radiation. Eventually, the achieved time resolutions of 50 μs enabling us to correlate the calorimetric information with the microstructure evolution during the reaction. In greater detail, we explore the role of interdiffusion, phase formation and melting for the runaway reaction initiation under high heating rates. Kinetic considerations are performed via nanocalorimetry with integrated pulse heating combined with ex situ X-ray diffraction. Effects of the high heating rates during ignition as well as the influence of the multilayer geometry on the early stages of phase formation are studied. Eventually, the elucidation of the transformations occurring at the threshold of ignition enables us to develop guidelines for microstructure development of nanocomposites.
conductivity $\lambda$ of 0.36 $\pm$ 0.08 W/(mK) is determined for cesium-lead-bromide perovskite thin films. These results fit very well with the data published for CsPbBr$_3$ single crystals [3]. We demonstrate that the observed standard deviations of $\lambda$ are attributed to high local variance of $\lambda$ within the measured area. In order to determine the low thermal conductivity in perovskite thin films with high spatial resolution using the 3w-technique, we employ a thermal conductivity mapping in the frequency domain, for the first time. This technique allows us to detect simultaneously the topography, the local thermal conductivity, and the thermal diffusivity. Hereby, we will demonstrate that thermal conductivity variations between 0.33 to 0.38 $\pm$ 0.01 W/(mK) can even be found within one single crystal grain. The differences in thermal conductivity, even between the individual grains, are explained by different dimensionalities of Ca-based perovskites (3D: CaPbBr$_3$, 2D: CaPb$_2$Br$_5$), which are evidenced by X-ray diffraction to be present. The local differences in the product of the density and specific heat capacity are examined and will be discussed. The setup and properties of this system will be presented from the engineering point of view taking different mixing techniques into account. The advantage of our advanced measurement technique will be discussed with respect to phase separation analyses.

11:00 AM TP02.11.03

Zirconium pentatelluride (ZrTe$_5$) has recently attracted renewed interest owing to its high anisotropy in its thermal properties, which may find applications in nanoscale electronic devices. In this work, we have measured the thermal conductivity and thermal diffusivity of ZrTe$_5$ single crystals using a 3w-technique. The results show that the thermal conductivity is strongly influenced by the crystal orientation, with a value of $\lambda = 0.31 \pm 0.01 \text{ W m}^{-1}\text{K}^{-1}$ at room temperature for the [110] direction and $\lambda = 0.42 \pm 0.02 \text{ W m}^{-1}\text{K}^{-1}$ for the [001] direction. The anisotropy factor, $\eta = \lambda_{[110]} / \lambda_{[001]}$, is found to be 1.34, indicating a significant anisotropy in the thermal transport properties of ZrTe$_5$. These results are in agreement with previous studies on ZrTe$_5$ single crystals and suggest that ZrTe$_5$ is a promising material for applications requiring low thermal conductivity.

11:15 AM TP02.11.04
Impact of Ultrafine Nanostructuring on the Phonon Wave Transport of Si Phononic Crystals Kouhei Takahashi$^1$, Takashi Kawasaki$^2$, Naoki Tambo$^3$, Masaki Fujikane$^1$, Kunihiko Nakamura$^1$, Tatsuya Naito$^1$, Yuxuan Liao$^2$, Makoto Kashigawa$^2$ and Junichiro Shiomi$^1$; 1. Panasonic Corporation, Osaka, Japan; 2. Panasonic Corporation, Tokyo, Japan; 3. University of Tokyo, Tokyo, Japan.

Phonon engineering has attracted much attention for developing new thermal transport properties in solids. In phonon engineering, nanostructuring plays an essential role. The effect of nanostructuring on the thermal transport is mainly twofold: (i) enhance the phonon boundary scattering and (ii) change the dispersion relation of phonons. The former mechanism is traditional, while the latter mechanism is still under debate. In this work, we have investigated the impact of ultrafine phononic crystals on the thermal transport properties of silicon. We have fabricated silicon nanowires with different pitches using electron-beam lithography and subsequent dry etching. We have measured the thermal conductivity of these nanostructures using time-domain thermoreflectance (TDTR) and found that the thermal conductivity decreases significantly with decreasing the pitch size of the nanostructures. We have modeled the thermal transport using the effective-medium theory and found that the reduction in thermal conductivity is due to the increased boundary scattering at the interfaces of the nanostructures.
electrical conductivity. The RT through-plane lattice thermal conductivity analyzed by time-domain thermoreflectance (TDTR), however, is surprisingly found to be defect-insensitive, indicating phonon-phonon interaction dominates the thermal scattering. Furthermore, a strong correlation is observed between the lattice thermal conductivity and the out-of-plane lattice dimension such that the elongation of the out-of-plane lattice parameter can suppress the thermal conductivity from ~7.8 W/mK to ~1.2 W/mK. By engineering the lattice and defects, we successfully realized the selective and independent manipulation of the thermal conductivity (by ~7-fold) and the electrical conductivity (by ~5 orders of magnitude) in single-phase epitaxial WO3 thin films. It not only enriches the functionalities of WO3, but also sheds light on designing new thermoelectric and thermal interface materials.

11:45 AM TP02.11.06
Comprehensive T-Type Method for the Thermal and Thermoelectric Properties Measurement of Micro/Nano Wires and Ribbons Shaoyi Shi, Weigang Ma and Xing Zhang; Tsinghua University, Beijing, China.

Micro/nano wires and ribbons have large technological applications and new fundamental physical phenomena. Especially in nanoscale, the properties of nanowires and nano-ribbons may be significantly different from bulk, and the measurement method for bulk materials even cannot be applied. Development of the precise measurement method for micro/nano wires and ribbons is becoming the frontier research and has been attracting intense interest. We have developed an integrated T-type method for comprehensively measuring the thermal and thermoelectric properties of micro/nano wires and ribbons. In the T-type method, the dc heating-dc detecting, four probe, and ac heating-dc detecting modes are applied to measure the thermal conductivity, electrical conductivity and Seebeck coefficient, respectively. The thermal and thermoelectric properties can be comprehensively determined on the same sample in the same measurement configuration. By applying the T-type method, some typical micro/nano wires and ribbons, including graphene fiber and single bismuth sulfide nanowire, have been studied.

1:30 PM *TP02.12.01
Advances in Ultrafast and Nanoscale Thermoreflectance Thermal Imaging Ali Shakouri1, Kerry Maize1, Sami Alajlouni1, Amir K. Ziabari1 and Dustin Kendig2; 1Birck Nanotechnology Center, Purdue University, West Lafayette, Indiana, United States; 2Microsanj LLC, Santa Clara, California, United States.

Static and dynamic hot spots and temperature non-uniformities limit the performance and reliability of electronic devices and integrated circuits. Here we review recent advances in transient thermoreflectance imaging to characterize temperature distribution in active devices. Imaging de-blurring techniques have been used to increase spatial resolution down to 100nm and temporal resolution is down to sub-nanosecond levels for full-field imaging and 100fs for single point measurements. While the lock-in or boxcar averaging techniques measure the change in surface or interface reflection coefficient very accurately, calibrating the thermoreflectance coefficient is essential to obtain absolute temperature profiles. A key challenge in thermal imaging of power devices is the separation of temperature induced change in reflected light due to thermal expansion. Both effects scale with the power dissipation in the device. Auto-focus and digital alignment can alleviate many of the edge effects in the thermal image, and multi-spectral thermoreflectance imaging can provide one of the most robust calibration methods to accurately obtain absolute temperature rise in power devices. Calibration of the thermoreflectance coefficient in micron-sized regions is further complicated due to sample movements when the stage temperature is changed. Here, we show that the transient temperature distribution can be used to calibrate thermoreflectance coefficient of unknown surfaces. Finally, semi-transparent coatings can create optical interferences in the reflected light which leads to a non-linear thermoreflectance coefficient. Methods to accurately extract the temperature in the presence of a non-linearity are presented. Several examples, including power GaAs, SiC, and GaN devices as well as through-the-substrate thermoreflectance imaging in silicon flip-chip bonded chips are presented. Finally, we briefly discuss the issue of defining temperature and what is actually measured in submicron regions. For Si, GaN, and many other semiconductors, Fourier law fails when the diameter of the heat source or the thermal penetration depth is less than a micron at room temperature.

2:00 PM TP02.12.02
Direct Imaging of Suppressed Thermal Transport near Individual Grain Boundaries in Polycrystalline Diamond Aditya Sood1, Ramez Cheaito1, Tingyu Bai2, Heungdong Kwon1, Yekan Wang2, Chao Li2, Luke Yates3, Thomas Bougher3, Samuel Graham3, Luke Yates3, Thomas Bougher3, Samuel Graham3, Mehdi Ashleghi2, Mark S. Goorsky2 and Kenneth E. Goodson1; 1Birck Nanotechnology Center, Purdue University, West Lafayette, Indiana, United States; 2Microsanj LLC, Santa Clara, California, United States; 3Georgia Institute of Technology, Atlanta, Georgia, United States.

Understanding the impact of lattice imperfections on nanoscale thermal transport is crucial for diverse applications ranging from thermal management to energy conversion. Grain boundaries (GBs) are ubiquitous defects in polycrystalline materials, which scatter phonons and reduce thermal conductivity (κ). Historically, their impact on heat conduction has been studied indirectly through spatially-averaged measurements, that provide little information about phonon transport near a single GB. Here, using spatially-resolved time-domain thermoreflectance (TDTR) measurements in combination with electron backscatter diffraction (EBSD), we make the first localized measurements of κ within few μm of individual GBs in boron-doped polycrystalline diamond. We observe strongly suppressed thermal transport near GBs, a reduction in κ from ~1000 Wm⁻¹K⁻¹ at the center of large grains to ~400 Wm⁻¹K⁻¹ in the immediate vicinity of GBs. Furthermore, we show that this reduction in κ is measured up to ~10 μm away from a GB [1]. A theoretical model is proposed that captures the local reduction in phonon mean-free-paths due to strongly enhanced phonon scattering near the disorder-rich grain boundaries. Our results provide a new framework for understanding phonon-defect interactions in nanomaterials, with implications for the use of high κ polycrystalline materials as heat sinks in electronics thermal management.

2:15 PM TP02.12.03
Rethinking Phonons in Disordered Solids—Crystals with Defects/Impurities and Random Alloys Hamidreza Seyf and Asegun Henry; Georgia Institute of Technology, Atlanta, Georgia, United States.

Current understanding of phonons treats them as plane waves/quasi-particles of atomic vibration that propagate and scatter. The problem is that conceptually when any level of disorder is introduced, whether compositional or structural, the character of vibrational modes in solids changes, yet nearly
all theoretical treatments continue to assume phonons are still waves. For example, the phonon contributions to alloy thermal conductivity (TC) rely on this assumption and are most often computed from the virtual crystal approximation (VCA). Good agreement is obtained in some cases, but there are many instances where it fails—both quantitatively and qualitatively. Here, we show that the conventional theory and understanding of phonons requires revision because the critical assumption that all phonons-normal modes resemble plane waves with well-defined velocities is no longer valid when disorder is introduced. Here we show, surprisingly, that the character of phonons changes dramatically within the first few percent of impurity concentration, beyond which phonons more closely resemble the modes found in amorphous materials. We then utilize a different theory that can treat modes with any character and experimentally confirm its new insights.

2:30 PM TP02.12.04
Effect of Quenched-in Vacancies on Precipitation in Aluminium Alloys Measured by Differential Fast Scanning Calorimetry Bin Yan1,2, Benjamin Milkeret1,2, Olaf Kessler4,5 and Christoph Schick1,2,3,4,5; 1Institute of Physics, University of Rostock, Rostock, Germany; 2Competence Centre CALOR, University of Rostock, Rostock, Germany; 3Kazan Federal University, Kazan, Russian Federation; 4Faculty of Mechanical Engineering and Marine Technology, University of Rostock, Rostock, Germany.

Quenched-in vacancies are point defects that can be present in materials after quench from high temperature. Quenched-in vacancies increase the rate of solute diffusion and therefore the kinetics of phase transformations. In this study different concentrations of vacancies were froze-in by quenching from solution annealing temperature at different cooling rates up to 3×10^6 K/s by differential fast scanning calorimetry (DFSC). Then artificial aging at different temperatures and time followed by a differential reheating method (DRM) enables both time and temperature-dependent investigations of vacancy-induced precipitation in aluminium alloys. The method can potentially be transferred to similar systems or related solid-state phase transformation systems also beyond the particular system analysed in the present study.

2:45 PM TP02.12.05
Effect of Vacancies and Domain Walls on the Thermal Conductivity of PbTiO3 Thin Films David Bugallo-Ferrón1, Elias Ferreiro-Vila1, Eric Langenberg2,3, Gustau Catalán1, Neus Domingo1, Darrell G. Schronym2 and Francisco Rivadulla1; 1CiQUS-University of Santiago de Compostela, Santiago de Compostela, Spain; 2Materials Science and Engineering, Cornell University, Ithaca, New York, United States; 3Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC, Barcelona Institute of Science and Technology, Barcelona, Spain.

We report the effect of ferroelastic domain walls on the thermal conductivity of thin films of PbTiO3. We fabricated a series of films by Molecular Beam Epitaxy on SrTiO3 (001) substrates over a wide range of Pb/Ti ratio. X-ray diffraction and Piezoelectric Force Microscopy were used to correlate the thermal conductivity results with the distribution of ferroelastic domains as a function of Pb/Ti. Our results show that stoichiometric strained PbTiO3 films show an anomalously reduced thermal conductivity, comparable to that of highly defective samples. These results suggest that ferroelastic domain walls have a large effect on the thermal conductivity of this material, opening the possibility for reversible modulation of thermal conductivity by an external stimulus in ferroelastic oxides.

3:30 PM TP02.12.06
Determining the Mechanical and Thermodynamic Properties of Iron Meteorites Below 300 K Matthew Bonidie1, Christopher Noyes1, Roy Forrestano1, Daniel Britt1, Robert Macke1, Guy Consolmagno3 and Cyril Opeil1; 1Boston College, Chestnut Hill, Massachusetts, United States; 2Physics, University of Central Florida, Orlando, Florida, United States; 3Spectola Vaticana, Vatican City, Italy.

Iron meteorites are primarily kamacite or taenite based Fe-Ni polycrystalline alloys that solidify from planetary cores over a timespan of 1×10^7 years via thermal radiation into the vacuum of space. Depending on their Ni composition and cooling rates, iron meteorites crystallize into either fine octahedrite, coarse octahedrite, or haxahedrite crystal structures.

Through the use of resonant ultrasound spectroscopy, the elastic constants and Young’s modulus were measured as a function of temperature from 10-300 K, allowing a comparison of how Ni percentage, crystallographic structure, and impact history effect the mechanical behavior of these meteorites. In addition, specific heat capacity, thermal conductivity, and thermal inertia of the iron meteorites will also be discussed.

This work is supported by NASA, SSERVI (Solar System Exploration Research Virtual Institute) and CLASS (Center for Lunar and Asteroid Surface Science) under grant No. NNA14AB05A.

3:45 PM TP02.12.07
Thermal and Phonon Spectral Transport Analysis for New High Thermal Conductivity Materials Joon Sang Kang, Man Li, Huuduy Nguyen, Huan Wu and Yoonjie Hu; University of California, Los Angeles, Los Angeles, California, United States.

Understanding the origins of high thermal conductivity is of great importance to thermal science and applications of thermal management and energy conversion, but remains a significant challenge in the field. Recent theoretical work including first-principles has predicted new class of thermal materials with high thermal conductivity beyond state-of-the-art materials and approaching that of diamond (>1000 W/mK). However, experimental demonstration and understanding have been limited by materials synthesis, measurement accuracy, and theoretical tools. Here, we describe our current progress in developing high conducting thermal materials using advanced chemical synthesis approach to achieve high quality single crystalline crystals and analyzing the spectral phonon mode contributions using density functional theory and Boltzmann transport equations[1]. The heat conduction and phonon transport with size dependence are carried out by thermal mapping spectroscopy technique[2]. We investigate the effects to thermal conductivity from defects, interfaces, and grains. Our work aims for systematic investigation and material improvement for ultrahigh thermal conductivity and brings the promise of rational material design to achieve its theoretical limit. The significant impacts of this research in improving the efficiency of thermal energy conversion and management will also be illustrated.

**Thermal Conductivity Evaluation of Polymer Crystals—An Ab Initio Study**

Keishu Utimula1, Tom Ichihba2, Ryo Maezono2 and Kenta Hongo3, 4, 5; 1School of Materials Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 2School of Information Science, Japan Advanced Institute of Science and Technology, Nomi, Japan; 3Research Center for Advanced Computing Infrastructure, Japan Advanced Institute of Science and Technology, Nomi, Japan; 4PRESTO, Japan Science and Technology Agency (JST), Kawaguchi, Japan; 5Research and Services Division of Materials Data and Integrated System, National Institute for Materials Science, Tsukuba, Japan.

Lattice thermal conductivity (LTC) has been calculated mainly using linear lattice models or molecular dynamics simulations, but their theoretical reliability strongly depends on empirical parameters and choice of force field. With the advent of massively parallel computers, a more systematic and reliable approach to the evaluation of LTC has emerged, i.e., *ab initio* anharmonic lattice dynamics calculations, where the linearized phonon Boltzmann equation is used to approximate a LTC formula, Peierls- Boltzmann equation, at the cubic anharmonic level. This approach has successfully reproduced LTC for several inorganic semiconductors in a wide range of LTC from ~1 to ~10² W/mK. However, few works have ever applied this approach to polymer systems, although the LTC of polymers is one of the most important quantities for industrial purpose. It is well known that higher crystallinity in polymers increases LTC, indicating that polymer crystals are expected to have the highest LTC. Experimentally, however, perfect crystallizations are not realized for most polymers. Hence their upper limits of LTC are still unknown, though such values would provide useful guidelines for high-LTC polymer design. On the other hand, it is easy to model the polymer crystal structures and apply the simulations to calculate the LTC values, which are regarded as the theoretical upper limit of those of the polymers.

We have applied *ab initio* anharmonic lattice dynamics simulations to both chain and crystal polyethylene in order to evaluate their LTC values. It is established that their temperature dependences of LTC agree well with previous experiments. In addition, we found that polyethylene has comparatively long phonon lifetime, which mainly gives good LTC to the polymer. In this talk, we will report on not only these results but also several typical polymers such as polyethylene terephthalate and phenylene sulfide.

**An Inverse Problem Framework for Extracting Phonon Properties from Thermal Spectroscopy Measurements Including Systems Featuring Interfaces with Unknown Properties**

Mojtaba Forghani and Nicolas G. Hadjiconstantinou; Massachusetts Institute of Technology, CAMBRIDGE, Massachusetts, United States.

Thermal spectroscopy has been established as a promising experimental method for characterizing the transport behavior of materials and as a useful alternative to density functional theory (DFT) calculations which are expensive and not always in agreement with real experimental measurements. While there have been significant advances enhancing the reliability and accuracy of this experimental technique, the inverse problem of extracting material properties from the experimental observations remains an open problem. In particular, it was recently shown [Forghani et al., Phys. Rev. B 94, 155439 (2016)] that techniques based on assuming validity of Fourier's law are invalid, unless a set of rather restrictive conditions are met.

We have recently proposed an inverse problem framework [Forghani and Hadjiconstantinou, Phys. Rev. B 97, 195440, (2018), Forghani et al., Phys. Rev. B 94, 155439 (2016)] that can be employed to extract mode dependent material properties, such as relaxation times or interface transmissivities, from thermal spectroscopy measurements. The proposed technique solves the inverse problem by iterating between solutions of the forward (relaxation) problem and thus requires solutions that capture the mode-dependent physics; these solutions can be either analytical or numerical, including stochastic.

In this presentation we focus on applications of this technique to the extraction of phonon properties using *ab initio* anharmonic lattice dynamics calculations, where the linearized phonon Boltzmann equation is used to approximate a LTC formula, Peierls- Boltzmann equation, at the cubic anharmonic level. Specifically, we show that our method is able to reconstruct phonon free path distributions from experimental measurements obtained from a transient thermal grating setup. We also show that the proposed method can be used to extract phonon free-path distributions from systems featuring interfaces with unknown properties. We also discuss the extension of the method for reconstruction of the interface properties.

We expect that due to the generality of the proposed method, extension to other quantum mechanical particles, other material properties, and other numerically/analytically available algorithms for solving the forward problem, will be feasible.

**Thermal Characterization of Sodium-Sulfides at High Temperature**

Andrew Z. Zhao1, Matthew C. Wingert1, Yasuhiro Kodera1, Hongwu Xu2, Andrew Z. Zhao1, Matthew C. Wingert1, Yasuhiro Kodera1, Hongwu Xu2, Stephen J. Obrey3 and Javier E. Garay1; 1University of California, San Diego, San Diego, California, United States; 2Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Metal sulfides have a unique range of electronic and mechanical properties that has resulted in their exploration for next generation batteries, catalysts, semiconductors, and thermoelectrics. Many functional metal-sulfides must operate at high temperatures, but their thermal properties under extreme conditions have not been extensively studied and are not well understood. Measuring the thermal properties of highly reactive materials, such as metal-sulfides, has been challenging due to the corrosion and breakdown of sensor and containment materials at high temperatures. To advance the development of functional metal-sulfides, we seek to understand their structure and thermal properties at high temperatures. Here, we present a frequency-domain hotwire technique to measure the thermal conductivity of various sodium-sulfides at high temperatures. Unlike traditional hotwire measurement techniques, which apply a heat flux to a large sample volume to probe the temperature of the sample versus time, our custom system and sensor reduce the necessary sample volume to below 5 mL and probe the sample’s thermal response in the frequency domain. Our system and sensor have been designed to survive corrosive chemical environments at temperatures up to 750 degrees Celsius. The thermal conductivity of sodium-sulfides at high temperatures have been measured for the first time and are presented here. The structure of the sodium-sulfides is examined using x-ray/neutron diffraction and electron microscopy; this approach helps provide structural insights into the experimental and theoretical thermal transport properties of sodium-sulfides.
Lattice Dynamics Across the Temperature- or Pressure-Induced Structural Phase Transition in SnSe and SnS

Tyson Lanigan-Atkins1, Shan Yang1, Jennifer Niedziele2, Dipanshu Bansal1, Hao Hong2, Songxue Chi2, Andrew May2, Daniel Pajerowski2, Georg Ehlers1 and Olivier Delaire3; 1Duke University, Durham, North Carolina, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

SnSe and SnS are two promising thermoelectric materials, which have demonstrated outstanding figure-of-merits, but whose transport properties exhibit strong anisotropies tied to their layered crystal structure. At high temperature or high pressure, they undergo a continuous structural phase transition between a low-symmetry Pnma phase and a higher-symmetry Cmcm phase (SnSe: Tc ~ 805K and Pc ~10GPa, SnS: Tc ~880K). In order to rationalize the strong anharmonicity and anisotropy in thermal conductivity, we have used time-of-flight (TOF) and triple-axis inelastic neutron scattering (INS) to map the phonon dispersions and density of states (DOS) of both compounds at high temperature across the phase transition. Our results show a striking, extended softening and broadening of phonon excitations with temperature and the soft mode character of this transition is clearly revealed. We extracted the phonon scattering rates by deconvoluting instrumental resolution effects, for both time-of-flight and triple-axis measurements. Scattering rates calculated from the two methods agree remarkably well. We performed systematic first-principles simulations of the temperature-dependent phonon dynamical structure factor, S(Q,E), and scattering rates, which we compare with our experimental results. Furthermore, we have used TOF neutron diffraction, inelastic X-ray scattering and Raman spectroscopy to track the transition as a function of pressure finding good agreement with the previously reported transition pressure of ~10GPa. The projected DOS is tracked with pressure in order to follow the anisotropy of the lattice dynamics with pressure. We contrast some of the behaviors observed in our measurements and simulations with roskalt chalcogenides (SnTe, PbTe, PbSe).

Thermal Stability Enhancement of Alpha Tin Films by Strain Engineering Jinshin Yao1,2, Huanhuan Song1,2, Shunji Xia1,2, Yu Gu1,2, Yuanfeng Ding1,2 and Hong Lu1,2; 1College of engineering and Applied Sciences, Nanjing University, Nanjing, China; 2National Laboratory of Solid State Microstructures, Nanjing University, Nanjing, China.

Alpha tin (α-Sn, also known as gray tin), a metastable phase of tin, is a zero band gap semimetal with a diamond structure. Since Fu and Kane [1] predicted that alpha tin could be a topological insulator under certain strain, a lot of work have been done to study the topological properties of this material [2-4]. However, the growth of high quality alpha tin film remains challenging due to its low phase transition temperature and lack of appropriate substrates. We have successfully grown a series of alpha tin films on InSb (001) substrates by molecular beam epitaxy (MBE). The film thickness varies from 10 nm up to 400 nm. Atomic force microscope (AFM) shows a smooth surface morphology with roughness under a few nanometers. Transmission electron microscope (TEM) confirms the diamond structure of the alpha films.

It is known that bulk alpha tin is only stable up to 13.2 °C. Our interest is to utilize strain to enhance the thermal stability of alpha tin films, and the strain is tuned by varying the film thickness during the epitaxial growth process. The InSb substrate provides a compressive strain (0.14%). We have used temperature dependent XRD (T-XRD) and temperature dependent Raman for this study. The temperature range covers from -100°C to 250°C. The XRD results show the high crystalline quality of the alpha tin films. Clear thickness fringes are observed for all the samples, and reciprocal space mapping (RSM) shows that the alpha tin films can be strained up to 400 nm. Temperature dependent results show that the phase transition temperatures of our films can be increased to 120°C, and the transition temperature increases as the film thickness decreases. This enhancement is confirmed by both temperature-dependent XRD and Raman results. The linear thermal expansion coefficient of alpha tin film is extrapolated for the first time to be 7.14x10^-6/°C.

Our study shows that strain is an effective way to engineer the thermal stability of the alpha tin films. The thermal stability enhancement ensures the reliability of all the following electrical and thermal characterizations above room temperature. We have observed magnetoresistance and superconductivity in these films.

9:00 AM TP02.13.03
Anisotropic and Quasi-Ballistic Thermal Transport in Nanostructure Embedded GaSb Thin-Film Semiconductors Yee Rui Koh1,2, Hong Lu3, Arthur Gossard4 and Ali Shakouri1; 1Purdue University, West Lafayette, Indiana, United States; 2Birck Nanotechnology Center, West Lafayette, Indiana, United States; 3Electrical and Computer Engineering, Purdue University, West Lafayette, Indiana, United States; 4University of California, Santa Barbara, Santa Barbara, California, United States; 5Nanjing University, Nanjing, China.

Gallium antimonite (GaSb) is a promising candidate for the high speed electronic and long wavelength photonic devices, e.g. infrared detectors, photovoltaic, diode lasers, etc. Previous measurements and theoretical studies focused on the bulk thermal conductivity of the GaSb. [3][2] For submicron devices, or at high frequencies, it is important to study thermal transport in the GaSb thin films. Time-domain thermoreflectance (TDTTR) is used to study thermal transport in 2μm thick GaSb film with embedded semimetallic ErSb nanoparticles. [3] We show that GaSb is among few non-alloy semiconductors showing the phonon quasi-ballistic effects. The apparent cross-plane thermal conductivity of pure GaSb thin film sample drops by ~15% when the pump modulation frequency is increased from 0.8 MHz to 10 MHz at room temperature. The frequency dependence of the cross-plane thermal conductivity disappears with the presence of 3%-20% ErSb nanoparticles. We also employed the beam reduction TDTTR method [4] to study the anisotropic thermal transport in GaSb thin films. The ratio of cross- to in-plane thermal conductivity of the ErSb: GaSb samples vary from ~0.2 for pure GaSb to ~0.7 for GaSb with 20% ErSb nanoparticles volume concentration. Potential causes of the anisotropy from lattice mismatch with the substrate to self-organization of embedded nanoparticles in nanowire forms are discussed. Detailed temperature dependence measurements for both in-plane and cross-plane thermal conductivity of the ErSb:GaSb samples are also presented.

9:15 AM TP02.13.04
Thermal-Optical Readout of Multi-Level Thermal Emissivity Ge2Sb2Te5 Patterns Miao Wang, Sichao Hou and Ming Su; Northeastern University, Boston, Massachusetts, United States.

Ge2Sb2Te5 thin film (100 nm) can be patterned with multi-level crystalline and thermal emissivity states using laser in large scale. Various patterns can be fabricated by tuning laser power and speed. X-ray diffraction (XRD) and infrared analysis results show that Ge2Sb2Te5 thin film has different thermal emissivity at different crystalline states. In-situ repeated heating of the Ge2Sb2Te5 thin film confirms the tendency between crystalline and thermal emissivity change. Both the infrared image and thermal emissivity can be readout by infrared camera. The colorful infrared image enables easily identification of Ge2Sb2Te5 crystallite change. The multi-level emissivity states of patterns produce multi-level optical data storage for future phase-change devices.

9:30 AM TP02.13.05

Phase change memory (PCM) stores information in the phase (conductive crystalline or resistive amorphous) of glass forming materials, typically a chalcogenide. One of the largest hurdles for PCM is the tradeoff between data retention and switching speed. Wang et al. [1] demonstrated increased switching speed without decreased retention by reducing grain size in phase change materials. We propose grain boundary melting (GBM) as the mechanism behind this improvement. With nanocrystalline phase change materials, reset may be achieved with only partial amorphization of the active volume, leaving isolated crystalline nuclei. This decreases the volume of amorphization required for reset while providing multiple sites for simultaneous crystallization for set, reducing power and time requirements for both reset and set operations. Additionally, classical nucleation theory (CNT) predicts that the minimum stable grain size \( r_c \) increases with temperature, effectively lowering the melting temperature for smaller grains.

We model GBM based on thermodynamic properties of Ge\(_2\)Sb\(_2\)Te\(_5\) (GST). We obtain phase and temperature dependent specific heats \( C_p \) as explained in our previous work [2] with an additional constraint of the specific heat difference for the liquid and crystalline phases \( \Delta C_p \) at the glass transition extracted from the fragility [3] based on ultra-fast DSC measurements of GST [4]. We determine the temperature dependent \( r_c \) with CNT using free energy and entropy differences between phases \( \Delta G \) and \( \Delta S \) calculated from \( \Delta C_p \). Finally, we obtain temperature and size dependent GBM rates based on \( \Delta G \) and the kinetic growth velocity \( U_{\text{gb}} \) extracted from ultra-fast DSC measurements [4]. We incorporate GBM in our finite element phase change model [5]–[8] and simulate reset and set for reported device and grain sizes [1]. We show that GBM reduces set and reset times as grain sizes decrease and contributes to increased PCM variability due to device-to-device and cycle-to-cycle gain map changes.

High frequency RF, laser diodes and some silicon ASIC devices are a particular class of devices where power densities are pushing limits of kw/cm². Many of these devices are now reaching the limit of current heat spreading technologies. Consequently, there is a continual need to improve thermal performance while reducing the cost.

To date, the integration of SiC (400 W/mK) substrates with GaN has provided the best option for GaN HEMT and MMIC technology for high power applications. However, despite the use of SiC substrate, adequate heat spreading is still the limiting factor in determining the maximum power dissipation for GaN based electronics. As such, the path to long-term reliability is often achieved by de-rating the maximum power dissipation. A far better heat spreading solution incorporating CVD diamond (2000 W/mK) has the potential for a factor of 3× or higher increase in power density relative to current state-of-the-art GaN devices.

In this presentation we demonstrate success in integrating a thinner layer of very high thermal conductivity CVD diamond with lower thermal conductivity CVD diamond consistent with targeted thermal performance at lower cost. In the built of this hybrid material, the high thermal conductivity material will be the bonding interface to the RF/microwave device to enable immediate heat spreading. The lower thermal conductivity material will be the bonding interface to the heat sinking side, enabling cost effective heat transport. The integration of the layers is achieved through back to back deposition of the bi-layers. The challenge is to make the synthesis conditions conducive to achieving material quality and matching of the bi-layers mechanical properties to fabricate a robust final product.

The presentation will report on the analysis and results obtained by using Lee, S et al, to establish the limit of spreading layer thickness (layer 1). The model indicated that for a 100 mm x 100 mm hot spot, minimum thermal spreading resistance is achievable with minimum thickness of about 150-200 mm. The confirmation of a minimum spreading that would lead to minimum spreading resistance was verified for Biot numbers varying from <1 to >100.

Required layer 2 thickness (low thermal conductivity material) to maintain lowest thermal resistance and maintaining mechanical integrity and thickness specifications was established by classical heat transfer solutions. Additionally, an Abaqus model for typical multi-finger RF device with and without a diamond heat spreader was developed to compare the effect of graded concept where the thickness of high/low thermal conductivity is part of the sensitivity analysis and part of this presentation.

Three different techniques were used to judge the quality and success of the output material. These are through plane characterization using optical and thermal methods and in-plane measurement using heated bar and the results of those findings are a part of this presentation.

SESSION TP03.01: Organic and Polymer Thermoelectrics I  
Session Chairs: Christian Muller and Shannon Yee  
Monday Morning, November 26, 2018  
Sheraton, 3rd Floor, Gardner AB

8:00 AM *TP03.01.01  
PEDOT-Based Thermoelectric Materials and Devices Qingshuo Wei; National Advanced Institute of Science and Technology, Tsukuba, Japan.

In this talk, we are going to focus on two topics. The first one is understanding of the doping mechanism of poly(3,4-ethylenedioxythiophene). We have shown that PEDOT was doped by protons. The doping and de-doping processes using protonic acid and base are fully reversible. We are going to demonstrate that the use of protonated EDOT moieties as an end group to prepare organic conductors is a promising approach toward highly conductive organic materials. In the second part, we are going to present proof-of-concept studies of organic thermoelectric devices fabricated by thermal lamination. With an air-cooled heat sink, the device exhibited a power output of ca. 100 microwatt, which is sufficient to power practical devices.

8:30 AM TP03.01.02  
Thermoelectric Polymer Films with High Power Factor Arising from the Significant Seebeck Coefficient Enhancement by Surface Energy Filtering Guan Xin, Zeng Fan and Jianyong Ouyang; Materials Science and Engineering, National University of Singapore, Singapore, Singapore.
Thermoelectric (TE) materials are important for sustainable development because they can be used to directly convert heat into electricity. Compared with inorganic TE materials, polymers have advantages of lower cost, high abundance, high mechanical flexibility and low or no toxicity. However, the Seebeck coefficient of the poly(3,4-ethylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS) can be enhanced by coating second layer materials. The Seebeck coefficient enhancement is ascribed to the surface energy filtering induced by these materials. The surface energy filtering can increase the mean electron energy and thus the Seebeck coefficient of the PEDOT:PSS films. After coating second layer on PEDOT:PSS films sequentially treated with acid and base can give rise to a power factor of 401.2 μW m⁻¹ K⁻² with the Seebeck coefficient of 47.2 μV K⁻¹ and electrical conductivity of 1801 S cm⁻¹.

8:45 AM TP03.01.03
Analyzing the Effect Preferred Orientation and Doping on the Transport Properties of Bi₂Te₃₋ₓSex Alloys for Thermoelectric Power Generation Applications

When attempting to find new alternative energy resources new technological developments must be made to bring society one step closer to a cleaner environment. Thermoelectric devices take thermal heat, either directly from solar energy or as a byproduct of fuel burn, and transform it to electricity. At its core is to prepare high performance TE nanocomposites, both p- and n-type, in a time and energy efficient way. The performance of thermoelectric devices is assessed by the dimensionless figure of merit ZT of the material, defined as $ZT = \frac{\alpha^2 \sigma}{k}$, where $\alpha$, $\sigma$, $k$ and $T$ are the Seebeck coefficient, the electrical and thermal conductivities, and the absolute temperature, respectively. The thermal conductivity is a combination of thermal conductivity via electrons, $\kappa_e$, and via phonons, $\kappa_l$. The main difficulty in improvement of the efficiency of a thermoelectric device is due to the complex relation between $\alpha$, $\sigma$ and $k$. Improving the performance of thermoelectric materials is usually done either by improving the power factor, $\alpha^2 \sigma$, or by applying phonon scattering methods in order to lower the thermal conductivity.

Bismuth-telluride-based alloys are of great importance not only as the best thermoelectric materials with the maximal ZT values close to unity near room temperature, but also due to the potential for further performance improvement. In this study Bi₂Te₃₋ₓSex compositions were electronically optimized by various CH₃ doping levels, preferred alignment of the crystallographic orientation, and its scaling performances. Finally, we will show a few examples, including porous materials and thin films. [1] www.openbte.org [2] G. Romano and J. 9:00 AM TP03.01.04
OpenBTE—An Open-Source Solver for the Phonon Boltzmann Transport Equation in Multi-Dimensional Structures

Over the last decades, Fourier’s law has been challenged by measurements of heat transport at small length and time scales. In fact, when the mean free path (MFP) of heat carriers (i.e. phonons) becomes comparable to the characteristic length, heat travels quasi-ballistically, therefore deviating from standard diffusive theory. The Boltzmann transport equation (BTE) has been the mainstream model of non-diffusive heat transport and has been applied successfully to simple cases, such as thin films and nanowires. However, as complex geometries become increasingly accessible experimentally, a more flexible BTE solver is needed. In this talk, we will present OpenBTE [1], an open-source solver for the space-dependent phonon BTE in three-dimensional structures. The code is interfaced to first-principles calculations from which bulk-related data is collected, and to a Fourier’s solver to model low-MFP phonons, so that the framework is entirely parameter-free across all the scales. Furthermore, thanks to its finite-volume formulation, OpenBTE can easily handle complex-shaped geometries, offering a unique capability of thermal conductivity tuning. OpenBTE groups phonons based on their MFPs, an approach that boosts the computational efficiency, especially for complex-unit cell materials [2]. We will also describe the adopted parallelization scheme and its scaling performances. Finally, we will show a few examples, including porous materials and thin films. [1] www.openbte.org [2] G. Romano and J. C. Grossman. *Heat conduction in nanostructured materials predicted by phonon bulk mean free path distribution.* Journal of Heat Transfer137.7 (2015): 071302.

9:15 AM TP03.01.05
Chain Morphology Effect on Thermal Conductivity of Polymer-Based Materials

Polymers are an attractive alternative to inorganic thermoelectric materials as they are lightweight, generally of low cost to manufacture, offer freedom-of-design as well as having low thermal conductivity. However, our fundamental understanding of thermal transport in polymeric systems needs to be drastically improved to gain the capability to design systems for thermal applications from the outset. The abundance of variety of polymers systems renders this task highly challenging. For instance, while blending is a well-known route for the manipulation of polymer properties, little is known how various blending options affect the thermal conductivity of the blend components and the overall blend. Here, we use polymers with model functional groups and discuss the effect of blending on chain conformation and how, in turn, this changes the thermal transport of the overall material. We draw comparisons to other multicomponent systems such as organic/inorganic hybrid materials and present data that start allowing us to establish design rules and how structural features – both in blends and inorganic/organic hybrids – affect thermal conductivity. Ultimate goal is to provide a general understanding on a broad range of systems that can be used to tune the thermal conductivity of polymers to the final required properties.

9:30 AM TP03.01.06
Thiophene Polymers for Thermoelectric Blends and Composites

The ability to control the carrier energy levels, functional group polarity, and film morphology make organic and polymeric semiconductors (OSCs) especially attractive for various energy interconversions. Their mechanical flexibility, low temperature processing, potential printability, capability of blending to form composites, and use of common elements are additional attractive features. In this presentation, we focus on thiophene polymers blended with dopants and Fermi level-setting additives for thermoelectric applications. Two thiophene polymers, poly(bisdodecylthioquaterthiophene) and poly(bisdodecyl thioquaterthiophene) (PQT12 and PQTS12, respectively), were used in active layers. From measurements of cyclic voltammetry and the electronic characteristics, we found that the introduction of sulfars into the side characteristics traps found in films of the PQTS12. Doping the polymer with sulfur in side chains (PQT512) with the strong oxidant nitrosountemonium tetrafluoroborate (NBOF4), we obtained a very high conductivity up to 350 S cm⁻¹, which is the highest reported nonionic conductivity among films made from dopant-polymer solutions. We found the combination of efficient charge transfer, tighter π-π stacking and strong intermolecular coupling is responsible for the high conductivity. Furthermore, the high conductivity is stable in air without extrinsic ion contributions that are associated with the polymer most often used for high conductivity, poly(ethylenedioxythiophene) (PEDOT:PSS). The thermoelectric power factor compared favorably with prior reports for p-type polymers that were made by the alternative process of immersion of polymer films into dopant solutions, and fit the established models for thermoelectric polymers. Additional data obtained from thiophene
copolymers containing the ethylenedioxiithiophene subunit supported these conclusions. The applicability of these polymers in hybrid composites will also be considered.

10:00 AM BREAK

SESSION TP03.02: Organic and Polymer Thermoelectrics
Session Chair: Howard Katz
Monday Afternoon, November 26, 2018
Sheraton, 3rd Floor, Gardner AB

1:30 PM *TP03.02.01
Bulk Doping Strategies for Plastic Thermoelectrics Christian Muller; Chalmers University of Technology, Goteborg, Sweden.

Molecular doping of conjugated polymers is a widely explored tool for the preparation of highly conducting materials for organic thermoelectrics. While doping of thin films is well understood, there is a lack of doping strategies that can be applied to bulk materials. Hence, the up to millimeter thick architectures, which are needed to construct the legs of a thermoelectric generator, are more challenging to realize. In this talk two bulk doping strategies are presented. Foams of poly(3-hexylthiophene) can be sequentially doped without compromise in thermoelectric performance. Further, conjugated polymers with more polar oligo ethylene glycol side chains show improved compatibility with the dopant. As a result, thermally stable p-doped films with a high electrical conductivity of 100 S/cm can be prepared. The same concept is also applicable to n-type polymers, with conductivities reaching 0.3 S/cm.

2:00 PM TP03.02.02
Intrinsically Conductive Polymers with a Power Factor of >700 μW/(m K²) Jianyong Ouyang; National University of Singapore, Singapore, Singapore.

Organic thermoelectric materials have drawn great interest because of their advantages including mechanical flexibility, easy availability, non-toxicity and low thermal conductivity. Thermoelectric materials with high ZT are required for highly efficient thermoelectric conversion. But the electrical conductivity and Seebeck coefficient of thermoelectric materials are interdependent. Hence, the power factor of organic thermoelectric materials is remarkably lower than their inorganic counterpart.

Here, I will present some of our works in developing intrinsically conductive polymers with high thermoelectric power factors. We developed methods to enhance both the Seebeck coefficient and electrical conductivity of intrinsically conductive polymers. We observed an ultrahigh power factor of >700 μW/(m K²) on intrinsically conductive polymers.

2:15 PM TP03.02.03
Polymer Morphology Dominates Over Energy-Dependent Scattering in Organic-Inorganic Hybrid Thermoelectrics Pawan Kumar, Edmond Zaia, Erol Yildirim, D V M. Repaka, Shao-Wang Yang, Jeffrey Urban and Kedar Hippalgaonkar; 1IMRE, Singapore, Singapore; 2Chemical Engineering, University of California, Berkeley, California, United States; 3IHPC, Singapore, Singapore; 4Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Hybrid (organic-inorganic) materials have emerged as a promising class of thermoelectric materials, achieving power factors (S²σ) exceeding those of either constituent. The mechanism of this enhancement is still under debate, and pinpointing the underlying physics of transport has proven difficult. In this work, we combine transport measurements with extensive theoretical simulations and first principles calculations on a prototypical PEDOT:PSS-Te(Cux) nanowire hybrid material system to understand the effect of templating and charge transfer at inorganic-organic interface on the observed high thermoelectric performance. Further, we apply the framework of the recently developed Kang-Snyder universal charge transport model to show that scattering of holes in the hybrid system, defined by the energy-dependent scattering parameter (s), remains the same as in the host polymer matrix; performance is instead dictated by polymer morphology manifested in an energy-independent transport coefficient. We build upon this universal language to explain thermoelectric behavior in a variety of PEDOT and P3HT based hybrids.

2:30 PM TP03.02.04

New smart or electronic textiles cross conventional uses to include functionalities such as light emission, health monitoring, climate control, sensing, storage and conversion of energy, etc. Here, thermoelectric textiles not only hold great promise in becoming the power source of next generation wearable electronics, but also could become on-spot climate control devices. Further, thermoelectric textiles are also interesting from an industrial perspective since their flexibility and conformability make them suitable for energy recovery from curved surfaces in the mid to low temperature range. For example, a thermoelectric textile could be designed to be wrapped around a steam pipe to harvest waste heat.

Intrinsically conductive polymers have gained attention in the field of thermoelectric textiles because they are made of earth-abundant elements, they show, in general, good mechanical properties and flexibility, they can be processed using low cost large-scale methods such as solution processing and they have an intrinsically low thermal conductivity.

Aqueous dispersions of PEDOT:PSS can be processed into fibers using a traditional wet-spinning process where the polymer solution (dope) is coagulated using a non-solvent (Okuzaki et al. 2003). In this work, we study how the variation of typical wet-spinning parameters such as the dope concentration, composition of the coagulation bath, applied draw, flow rate, etc., affect the thermoelectric properties of PEDOT:PSS wet-spin fibers. Additionally, we also explore possible post-treatments to enhance further the thermoelectric properties of these fibers.

2:45 PM BREAK
Disordered Transport in Highly Doped Materials—Vapor Doping of a Model Small Molecule System

Experimental evidence of the effect of quantum interference on the room-temperature electrical conductance of single-molecules opens the possibility of exploiting quantum interference in single molecules and self-assembled molecular layers.

Groningen, Groningen, Netherlands.

The choice of dopant and the method used to introduce a dopant can greatly influence the resulting electronic and thermoelectric properties of conjugated polymers. In this work, we systematically examine the effects of the side chains of a series of fullerene derivatives by varying their polarity and length. By carefully controlling the doping level, we find an electrical conductivity of 2.3 S/cm with a power factor of 23.1 μW/mK² which leads to an estimated figure of merit of 0.12.

Electrostatic interactions. This is accomplished by tailoring their side chains. We find that both the miscibility and doping efficiency are improved by using polar side chains.

The fullerene derivative with a hydrophilic triethylene glycol side chain (PTEG-1) is used as the host and 4-(1,3-dimethyl-2,3-dihydro-1H-benzoimidazol-2-ylphenyl) dimethyamine (n-DMB) as the dopant. It is found that PTEG-1 molecules readily form layered structures parallel to the substrate after solution processing. The fullerene cage plane is alternated by the triethylene glycol side chain plane; the n-DMB dopants are mainly incorporated in the side chain plane without disturbing the π-π packing of PTEG-1.

Since the polar side chains offer the space for accommodating dopant molecules and influence the molecular order, their length also plays a key role in the doping process. We systematically examine the effects of the side chains of a series of fullerene derivatives by varying their polarity and length. By optimizing the side chains, we find an electrical conductivity of 2.3 S/cm with a power factor of 23.1 μW/mK² which leads to an estimated ZT value of 0.1.

The effectiveness of polar side chains for n-doping conjugated polymers is also verified in the case of the poly[N,N'-bis(2-octyldodecyl)-naphthalene-1,4,5,8-bis(dicarboximide)-2,6-diyl-alt-5,5'-4,2'-thiophene)] (N2200) system. Replacing the alkyl side chains of N2200 with polar side chains causes a 200 times enhancement in electrical conductivity. The underlying charge transport mechanism in molecularly doped fullerene derivatives and n-polymer is also explored. Our work offers insights into the roles of side chains in n-type organic thermoelectrics.
we investigate the influence of large molybdenum complexes as dopants vs. smaller iron complexes on the electrical conductivity and Seebeck coefficient of several conjugated polymers. For multiple polymers we find that the large molybdenum complexes lead to electrical conductivities that are over an order of magnitude higher than that of the iron complexes at low doping concentrations. With the same number of polarons present based on absorbance measurements, the larger molybdenum complexes lead to higher electrical conductivities than the smaller iron complexes. We attribute the greater electrical conductivity achieved with the molybdenum dopants to lower coulombic attraction energies that result in more delocalized polarons. However, the electrical conductivity of the polymers doped with the molybdenum complexes saturate at lower doping concentrations than the iron complexes. Thus, the iron complexes can lead to overall greater electrical conductivities and higher power factors than the molybdenum complexes. Surprisingly, ferric chloride can dope PDPP-4T efficiently and lead to higher electrical conductivities than with Mo(tfd)$_3$, despite the ionization energy of PDPP-4T being 0.4 eV higher than the electron affinity of ferric chloride.

8:00 AM *TP03.03.01
Can Polymer–Carbon Nanotube Composites Ever Be Better Thermoelectrics Than Pristine Materials? 
Mariano Campoy-Quiles; Institute of Materials Science of Barcelona, Bellaterra, Spain.

It has been recently suggested that once the polymer chains have done their role helping to disperse the nanotubes, the thermoelectric properties of a polymer-carbon nanotube (CNT) composite would be better if the polymer is removed altogether. This vision does not, however, consider that the polymer can offer other benefits, such as helping to dope the CNTs, varying the system thermal conductivity, changing the microstructure or serving as binder for the respiratory hazardous CNTs. In this talk I will describe different polymer-CNT combinations and fabrication protocols and show some cases examples in which composting is a good option.

First I will show the case of nanocellulose-CNTs films grown by bacteria. By introducing the CNT dispersions in the culture media, bacteria produce nanocellulose films in which the CNTs are finely dispersed. The resulting films are thermally stable at least until 500°C, can be bended completely, and even wrapped around heat sources of random shapes, greatly enhancing the thermal boundary conductance. Using Raman thermometry, we show a 20-fold reduction of the in-plane thermal conductivitiy of the composite with respect to the reference bulky paper. The ZT of the composites is similar to that of the reference, while saving about 90% of the expensive component, the CNTs.

Then, I will describe several cases of CNT doping by the polymer, including changing the character from p- to n-type. Finally, I will discuss the properties of polymer-CNT structures in which the polymer is on top of the CNTs.

8:30 AM TP03.03.02
Optimization of Potential Barrier for Enhanced Thermoelectric Performance of PEDOT: PSS/Bi$_2$Te$_3$ Composite Films via Polar Solvent Vapor Annealing
Wan Sik Kim$^1$, Gopinath Anoop$^1$, Hyejeong Lee$^2$, Hyun Bin Kim$^2$, Soo Hyeon Kim$^3$, Gi Won Goo$^3$, Hyeumyoung Lee$^3$, Hyeon Jun Lee$^3$, Bongjin S. Mun$^4$, Ji-Woong Park$^1$, Eunji Lee$^1$ and Ji Young Jo$^1$; $^1$Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); $^2$Korea Atomic Energy Research Institute (KAERI), Jeongeup, Korea (the Republic of); $^3$Korea Basic Science Institute (KBSI), Daejon, Korea (the Republic of).

The efficiency of TE materials can be evaluated by the dimensionless figure of merit $ZT = \sigma T / \kappa$ or power factor $P = \sigma^2 T / \kappa$, where $\sigma$ is the Seebeck coefficient, $\kappa$ is the electrical conductivity, $\kappa$ is the thermal conductivity, and $T$ is absolute temperature. The equations of $ZT$ and $P$ imply that high $\sigma$, high $\kappa$, and low $\kappa$ are required for achieving a high efficiency from the TE materials. High $\sigma$ and $\kappa$ reduce Joule heating as well as improve the energy conversion efficiency of heat to electricity, while a low $\kappa$ prevents thermal shorting between two ends. However, because of the conflicting relationship between $\sigma$ and $\kappa$, it is challenging to enhance the efficiency of a single TE material. For example, an enhancement of $\sigma$ is usually accompanied by a decrease of $\kappa$ and an increase of $\kappa$, which has restricted in achieving a maximized $ZT$.

To solve these problems, the energy filtering effect, which occurs at an interface between two different components in nanocomposites and superlattices, has been found to be successful in solving the conflicting relationship of TE factors via enhancement of $\kappa$ without significant reduction of $\sigma$. However, experimentally, an enhanced $P$ or $ZT$ has not been achieved in many composites. The reason is because, in reality, the $\sigma$ of the nanocomposites has been significantly reduced by the inappropriate potential barrier at the interface of the component materials. This implies that the introduction of any potential barrier is not the key, but an appropriate barrier to simultaneously enhance $\sigma$ and $\kappa$ so that to achieve a maximized $P$ or $ZT$.

Here, we synthesize the poly(3,4-ethylene dioxythiophene) polystyrene sulfonate (PEDOT:PSS)/Bi$_2$Te$_3$ nanowires (NWs) composites films treated by polar solvent vapor annealing (PSVA) to systematically investigate the TE factors and optimize potential barrier energy at their interface for enhanced TE performance. The PSVA treatment results in enhancement of $\sigma$ and variable work function of PEDOT:PSS due to changes in structure and PEDOT to PSS ratio. The composite films are annealed for 10, 30, 60, and 120 min using dimethyl sulfoxide to modulate work function of PEDOT:PSS for variable potential barrier energies of composite films. Enhanced $\sigma$ is attributed to two different (phase separation and PSS de-doping) structural changes of PEDOT:PSS as PSVA duration. The $\kappa$ is varied by different magnitude of energy filtering effect caused from various potential barrier energies. The highest $\sigma$, $\kappa$, and $\kappa$ at room temperature are 44.3 mV/K, 1015 S/cm, and 203 mW/mK$^2$, respectively in 120 min PSVA treatment of PEDOT:PSS/Bi$_2$Te$_3$ NWs composite film which exhibits 0.11 eV of potential barrier energy. This work highlights simultaneous enhancement of both $\sigma$ and $\kappa$ by the energy filtering effect, which is controlled through tuning the potential barrier energy at interface in organic-inorganic composite materials.

8:45 AM TP03.03.03
A New Approach for Enhanced Thermoelectric Performance of Polymer/Inorganic Bulk Composites
Kaya Wei$^1$ and George Nolas$^1$; $^1$University of South Florida, Tampa, Florida, United States; $^2$National High Magnetic Field Laboratory, Tallahassee, Florida, United States.

Polymers are currently of great interest for thermoelectric applications, primarily due to a specifically unique combination of properties that are atypical of inorganic material, including mechanical flexibility, low cost, low temperature and cost processing, and general non-toxicity. Moreover, for specific polymer/inorganic composite-enhanced thermoelectric performance, as compared to the conducting polymer alone, has been realized. Here we employ PEDOT:PSS/thermoelectric Bi$_x$Sb$_{1-x}$Te$_3$-alloy p-type composites as a model system to demonstrate a new approach to enhanced performance in polymer/inorganic composites: Ethylene Glycol (EG) treatment of PEDOT:PSS, to enhance conductivity in the polymer, and spark plasma sintering (SPS) processing, to consolidate the composites into dense, bulk materials with less distortion of the polymer chains therefore resulting in even higher electrical conductance. Together with a low thermal conductivity, we achieved greatly enhanced thermoelectric performance as compared to the EG treated polymer.
alone. Moreover, our approach allows for the preparation of polymer/inorganic thermoelectric composites to be processed in a form that allows these composites to be incorporated in existing applications of current refrigeration devices. In addition, we demonstrate that SPS processing is the only method that can provide such results, since hot pressing, cold pressing or mold forming results in extensive distortion of the polymer chains whereas SPS does not, in part due to the current flowing through the composite material during SPS processing.

9:00 AM *TP03.03.04
Less is More—Thermoelectric Performance Enhancements in Polymer-Free Semiconducting Single-Walled Carbon Nanotube Networks Andrew Ferguson and Jeffrey Blackburn; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

There is growing interest in carbon nanostructures for a variety of electronic and optoelectronic applications. We will present studies aimed at understanding and improving the thermoelectric (TE) performance of single-walled carbon nanotube (SWCNT) thin film networks, built upon polymer-based extraction of semiconducting SWCNTs that eliminates metallic SWCNTs and other impurities. Rational choice of the starting SWCNT material and polymer allows us to sensitively tune the semiconducting SWCNT diameter distributions within the composites. When employed in conjunction with a doping process that allows exquisite control over the charge carrier density, we demonstrate that the peak performance, as determined by the TE power factor, is dependent on the SWCNT diameter.2 Modification of the extraction process produces semiconducting SWCNT thin films where nanotube bundling is minimized during network formation and the polymer can be completely removed in the solid state, resulting in intimate tube-tube contacts. By controlling the bundle size and extent of polymer remaining in the semiconducting SWCNT network we demonstrate TE power factors that double the performance of semiconducting SWCNT networks previously demonstrated.2,3 We trace the improved performance to enhanced electrical conductivity, resulting from improved doping and strongly enhanced charge carrier mobility, and analyze our data within the framework of a recently developed TE transport model. We show that removal of the polymer from the semiconducting SWCNT network has negligible impact on the thermal conductivity, which appears to be limited by dopant-induced phonon scattering.

9:30 AM TP03.03.05
Optimization of the Thermoelectric Figure of Merit in the Conducting Polymer PEDOT:PSS Films Through Incorporating 1-d Nano-Structured BiTe Compound Junyoung Lim, Sangwon Jo and Yongsok Seo; Seoul National University, Seoul, Korea (the Republic of).

Thermoelectric materials can generate electricity from unused waste heat and natural heat sources. To fabricate efficient thermoelectric materials, novel nano-structuring approach of mixing inorganic semiconductors of BiTTe alloys with highly conducting polymer (PEDOT: PSS) was devised. This thermoelectric nanocomposite material was prepared through the alloy nanorods forming process in the PEDOT : PSS solution. Two step reduction process allows easy formation of the alloy. Uniform alloy nanorod-PEDOT:PSS composite suspension was obtained which spread well on the substrate with ease of controlling the thickness. High conductivity of PEDOT: PSS provides excellent passage of electrons with low thermal conductivity. The nano-composite has a Seebeck coefficient 48mVK−1 and an electrical conductivity of 1300 Scm−1 at room temperature. The corresponding power factor was 316 mWm−2K−2 to yield a figure of merit [ZT]=0.41, which makes this nano-composite materials useful for waste energy harvesting at low temperature.

9:45 AM TP03.03.06
Multifunctional Thermoelectric Yarn Based Smart Textiles for Energy Harvesting, Cooling and Tactile Sensing Yuanyuan Zheng, Xinzhi Hu and Kun Zhang; Donghua University, Shanghai, China.

In contrast to thin-film based thermoelectric generators (or 2D-TEGs), three-dimensional deformable textile-shaped thermoelectric generators (T-TEGs) show great appeal for smart textiles owing to their excellent structural compatibility with textiles and diverse capabilities of powering wearable electronics, microclimate controlling, adaptively temperature and tactile sensing. However, there have been no reported T-TEGs that can simultaneously accommodate the demands for practical application. In this work, we manufacture organic-based T-TEG with multifunctionality by assembling segmentally-doped carbon nanotube yarn (CNTY) with PEDOT: PSS (P-type) and polyetherimide (N-type) inks into a spacer fabric. As an electricity generator, the T-TEG shows superior voltage and power output of 51.5 V/m² and ~786 μW/m² at a temperature difference of 20 K, respectively. Interestingly, applying one-volt electrical input can lead to the surface temperature drop of approximately 2-5 kelvins, causing a typical sensation between cool and cold, showing exceptional potential for human thermoregulation in smart textiles. Moreover, we shows the excellent wearing performance of T-TEG and ultrahigh sensitivity to the tactile touch including pressure (1.388 KPa−1) and thermal (11.623 K°) stimuli. [q11] To our knowledge, all these results make the developed T-TEG outperforming all reported organic-based F-TEGs and T-TEGs. The developed strategy can inspire the manufacturing of cost-effective T-TEGs with the well-established industrial processes.

10:00 AM BREAK

SESSION TP03.04: N-Type Organic Thermoelectrics
Session Chairs: Michael Chabinyc and Shannon Yee
Tuesday Morning, November 27, 2018
Sheraton, 3rd Floor, Gardner AB

10:30 AM *TP03.04.01
Self-Dopant Design Principles in N-Type Organic Thermoelectrics Daniel Powell, Jonathan Ogle and Luisa L. Whittaker-Brooks; Chemistry, University of Utah, Salt Lake City, Utah, United States.
Small molecule n-type semiconductors are typically doped by blending the semiconductor with extrinsic compounds that readily generate radicals, necessitating that the semiconductor and dopant be co-soluble. In perylene diimides these solubilizing groups, and also the dopants themselves, tend to be sterically bulky and can disrupt the packing structure of organic films; decreasing the electronic coupling between adjacent molecules and hindering charge mobility. The dopants may also aggregate during film casting, decreasing the number of charge carriers available to the system and creating additional grain boundaries. Additionally, the introduction of dopants modifies the density of states near the Fermi-energy such that populated states now exist at some energy relative to the LUMO of the organic semiconductor. Upon charge transfer the energies of these states distort in ways that may be very difficult to predict, leading to a broader density of states. The molecular design of the semiconductor, and also the selection of the proper dopant is a difficult process with several convoluted considerations. These challenges may be mitigated by intrinsically doping the n-type organic semiconductor via a process dubbed self-doping. Herein, we have investigated the effects of self-dopant structure on the processability and doping efficiency in a variety of perylene diimide n-type organic semiconductors. We believe our findings provide fundamental design rules for the fabrication of effective self-dopants geared toward increasing the thermoelectric properties of n-type organic semiconductors.

11:00 AM TP03.04.02
Air-Stable Thermoelectric Materials Based on N-Type Nickel-Coordination Polymers for Energy Harvesting Akanksha K. Menon, Rylan Wolfe, Seth Marder, John R. Reynolds and Shannon Yee; Georgia Institute of Technology, Atlanta, Georgia, United States.

Over 60% of available waste heat is at temperatures below 250 °C. Low cost and large scale thermoelectric devices based on conducting polymers can capture this heat and convert it directly into electricity. Organic materials are suitable for low grade thermal energy harvesting as they can be synthesized from abundant elements and can be processed from solution using low cost fabrication techniques. Furthermore, their low thermal conductivity and flexible nature enable new device architectures and applications. Despite these advantages, polymer-based thermoelectric devices have not made an impact and this is largely attributed to the lack of high performance n-type polymers (power factor > 10 µW/m-K²). To address this, we investigate metallo-organic polymers (also known as coordination polymers) as a suitable class of n-type polymers that are electrically conducting and maintain their stability in air. First, we present the synthesis, characterization and thermoelectric properties of n-type poly(nickel-ethenetetrathiolate) or NiETT. By modifying the reaction conditions and film post-treatment by annealing, the thermoelectric properties can be simultaneously enhanced to obtain a high performing n-type polymer that maintains its stability under ambient conditions. Specifically, to address challenges with the reproducibility of air-oxidized NiETTs, a chemical oxidant is used to systematically tune the thermoelectric properties. Furthermore, the observations and insight gained from the ETT study are extended to other metallo-organic polymers such as the poly(nickel-tetrathioxalate) or NiTTO. This is another coordination polymer that is easier to control synthetically as it is polymerized electrochemically. Herein, we present for the first time the thermoelectric properties of NiTTO films in a PVDF matrix, as well as its thermoelectric properties with varying counterions. Finally, temperature-dependent thermoelectric property measurements reveal that these polymers show semiconducting behavior that is consistent with thermally-activated hopping transport. The development of these two high performance and air stable n-type materials enables their application in realistic devices for thermoelectric energy harvesting.

Organometallic Coordination Polymers for Thermoelectric Applications Bob C. Schroeder and Zilu Liu; Chemistry, University College London, London, United Kingdom.

Over the decades, scientific evidence has mounted that the emission of anthropogenic greenhouse gases is the main reason for the increase of surface temperatures observed on Earth. Abandoning fossil fuels in the short term, however, is both technologically difficult and economically risky. Therefore, it would be advantageous to use the produced energy more efficiently thereby curbing the overall energy production and ultimately the greenhouse gas emissions. Around 60% of the energy input is lost after conversion as waste heat, of which half is so-called low temperature (~<200°C) waste heat. A technology suitable to recover waste heat and transform it into usable electricity is thermoelectric generators. Due to the so-called Seebeck effect, applying a temperature differential across a suitable material will generate an electric voltage. Recovering the low-temperature waste heat however via thermoelectric generators is challenging, mainly because current technologies are based on rare, often toxic elements (i.e. tellurium, lead, …); and as a result, thermoelectric modules are rather expensive and can only be efficiently operated at elevated temperatures. It is therefore paramount to develop new thermoelectric materials, able to harvest low-temperature waste heat efficiently.

The ideal thermoelectric material possesses a high electrical conductivity, while at the same time being an excellent thermal insulator. Whereby it is relatively straightforward to find materials which fulfil one of these critical requirements, it is much more difficult to find a single material accomplishing both. Materials based on organometallic coordination polymers are attractive candidates for thermoelectric materials because they have shown promising electrical conductivities, while at the same time maintaining low thermal conductivities. This paper will discuss several synthetic approaches leading towards different organometallic coordination polymers with various geometries, and will investigate not only the effect of the molecular geometry on the thermoelectric properties, but also the effects of the coordinated metal cations.

11:30 AM TP03.04.04
Anisotropic Thermal Conductivity Measurements of Semiconducting and Thermoelectric Polymers Using a Suspended Film 3-Omega Technique Sampath Kommandur and Shannon Yee; Georgia Institute of Technology, Atlanta, Georgia, United States.

Anisotropic thermal conductivity can complicate the performance of semiconducting polymer thin-films in applications such as thermoelectrics. Anisotropic measurements of low thermal conductivity polymers are challenging and there are a limited number of appropriate measurement techniques. Suspended film 3-omega is an appropriate technique but has often required unfavorable microfabrication. Herein, we report on the utility of the suspended 3-omega technique that uses shadow masking, and no other microfabrication techniques, in performing anisotropic (in-plane and through-plane) thermal conductivity measurements of semiconducting polymers - P3HT and commercially available N2200, and n-type thermoelectric polymers - poly-nickel ethenetetraitolates (poly(Ni-ETT)) and poly-nickel tetrathioxalates (poly(Ni-TTO)).

The necessary conditions for the validity of a 1D heat transfer model and experimental guidelines for in-plane thermal conductivity measurements of polymer thin-films are developed. Measured thermal conductivities are compared with predictions from the conventional k-min model and a recent empirical model that more accurately predicts the temperature dependence.

11:45 AM TP03.04.05
Soluble Alkali-Metal CNT Salts for N-Type Thermoelectric Composites Bernhard Dorling and Mariano Campoy-Quiles; ICMAB-CSIC, Bellaterra, Spain.

We report on a promising method that allows to simultaneously disperse and n-dope carbon nanotubes (CNTs). This is achieved by reducing CNTs with Alkali metals like Potassium [1]. The resulting polyelectrolyte salts spontaneously dissolve in polar solvents like DMSO, without requiring any deleterious mechanical methods like sonication, which are known to reduce CNT length. We have explored a range of commercially available CNTs, and show that this method allows to disperse even very long CNT species, which are near-intractable to process without
introducing defects otherwise.

Apart from making them soluble, a pleasant side effect of the reduction is that after the solvent has evaporated, the Alkali metals remain in the film and dope the CNTs, resulting in buckypapers that exhibit a negative Seebeck coefficient. The obtained n-type power factors reach hundreds of μWm⁻¹K⁻², on par with the p-type power factors of the neat CNTs. Furthermore, inspired by previous art [2,3], we show that the CNT solubility can be strongly increased by adding crown ethers to the solution [2], which also improves the doping efficiency and air-stability of the formed films [3].

Finally, we will discuss our results on n-doped CNT-polymer composites prepared using this method.

SESSION TP03.05: Thermoelectrics and Organic Electronics

The Development and Use of Dopants to Modulate the Electrical Properties of Conjugated Polymers Seth R. Marder; School of Chemistry and Biochemistry, School of Materials Science and Engineering and Center for Organic Photonics and Electronics, Georgia Institute of Technology, Atlanta, Georgia, United States.

Conjugated polymers have attracted interest for thermoelectric applications due to their potential for use in low-cost, large-area, devices. In this talk I will discuss the development of n- and p- dopants and the role they can play in modulating the electronic properties of conjugated polymers.

2:00 PM TP03.05.02
Flexible, Multi-Functional Organic-Inorganic Composites for Passive Thermal Management via Conduction and Radiation Luis M. Lozano; 1, 2, Seong Don Hong; 1, 4, Hadi Zandavi; 1, Yi Huang; 1, Gang Chen; 1, Richard M. Osgood; 3 and Svetlana V. Boriskina; 1, 3, 4 and Galen D. Stucky; 3 and 4. 1Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Escuela de Ingeniería y Ciencias, Tecnológico de Monterrey, Monterrey, Mexico; 3U.S. Army Natick Soldier Research, Development and Engineering Center, Natick, Massachusetts, United States; 4Defense Agency for Technology and Quality, Seoul, Korea (the Republic of).

Thermal management is nowadays focused on overcoming several challenges for energy savings in buildings, as well as for improving reliability and preventing premature failure in electronic devices. Passive thermal management strategies that enable cooling without any electricity input could therefore have a significant impact on global energy consumption. Consequently, there are both needs and opportunities for novel materials to help address some of these thermal management challenges, which fuel the research progress on developing new materials with high thermal conductivity and tailored thermal emittance properties. In this regard, polymers continue to infiltrate modern technologies due to their unique combination of properties, such as light weight, durability, flexibility, corrosion resistance, low cost, and ease of processing. However, the application of polymers in thermal management has been largely hampered by their low thermal conductivities. Here we report the fabrication of ultra-drawn polyethylene-based thin films filled with inorganic nanoparticles that show both spectrally-tailored absorptance/emittance properties and lateral heat-spreading functionalities. The high thermal conductivity is achieved by the alignment of polyethylene chains, which have a backbone structure of carbon-carbon bonds, while the inorganic filler provides the means to engineer optical properties of films in the broad spectral range. Furthermore, the filler dispersion within the polymer matrix is improved after the drawing process, which even generates better mechanical properties in the composite film. These results provide a feasible route for large-scale fabrication of passively cooling surfaces for heat management in terrestrial and space-based applications.

This work was supported by the NSRDEC ‘Thermal Management of Fibers and Films’ program, through ARO sponsored ISN.

Evidence for Low Disorder, Narrow-Band Charge Transport in the Thermoelectric Response of Semicrystalline Polymer Semiconductors Riccardo Di Pietro; Hitachi Cambridge Laboratory, Cambridge, United Kingdom.

Semiconducting polymers possess unique mechanical, thermal and electrical properties that make them interesting candidates for thermoelectric applications. However, the recent development of semicrystalline polymer semiconductors with field-effect mobilities comparable to and sometimes exceeding those of amorphous silicon has exposed the limitations of commonly used disorder-based charge transport models which were developed originally for more disordered, lower mobility materials. This is especially true when including in the picture the thermoelectric properties of this class of materials.

I will present our work on the structural, electric and thermoelectric characterisation of semicrystalline polymers for which we have recently shown a correlation between charge density dependence of mobility and the size of the crystalline domains in the polymer film [1]. We have characterised the temperature and charge carrier dependence of the Seebeck coefficient and found it in contradiction with charge transport models based on energetic and positional disorder. On the very contrary these measurements provide direct experimental evidence for narrow band conduction at the charge densities typically observed in thin film transistors. The comparison with the conductivity measurements highlights an additional aspect which is the need to include electron-electron interactions to consistently explain the measured properties.[2]

Based on these findings, we propose an alternative charge transport model that explicitly accounts for the presence of interspersed crystalline and amorphous regions within the polymer film and for local electron-electron interactions. This approach captures all the unique features observed experimentally and highlights new directions which can lead to a further improvement of both electric and thermoelectric performance of polymer semiconductors.

The flexible thermoelectric generator (f-TEG) is a very promising technology for energy harvesting to enable self-powered wireless sensors and wearable devices, an area of exponential growth. Here, we present a scalable and cost-effective additive manufacturing process to fabricate f-TEGs using colloidal nanocrystals, and an innovative and highly efficient photonic sintering method to sinter large areas of printed films using pulsed light. Flexible TE films and devices were printed using screen printing and aerosol jet printing, followed by pulsed photonic sintering process. The pulsed sintering confines the delivered thermal energy within the printed film region without over heating the substrate, enabling TE film sintering on flexible polymer based substrates with relatively low melting point. In addition, the pulsed sintering limits grain size growth due to an ultrafast heating and cooling process, and lower thermal conductivity can be achieved than films sintered by conventional thermal processing.

Until recently, research into thermoelectrochemical cells had primarily focused on aqueous electrolytes, predominantly with the ferri/ferrocyanide redox couple. The electrochemical potential of this redox couple depends on temperature, and therefore in a device with two electrodes held at different temperatures a potential difference is created. Thus, these cells allow direct thermal to electrical energy conversion with no carbon emissions. 

Until recently, research into thermoelectrochemical cells had primarily focused on aqueous electrolytes, predominantly with the ferri/ferrocyanide redox couple. The electrochemical potential of this redox couple depends on temperature, and therefore in a device with two electrodes held at different temperatures a potential difference is created. Thus, these cells allow direct thermal to electrical energy conversion with no carbon emissions. 

The highest power outputs to-date for thermoelectrochemical cells using IL electrolytes have been achieved through our use of a high entropy change CoII/IIIbpy3 redox couple. Here we discuss our research into the use of a range of Fe and Co-based complexes in different IL and IL/solvent mixtures for thermal energy harvesting. The Seebeck coefficient and thermoelectrochemical cell performance is shown to be strongly influenced by the nature of the redox couple and the IL. We also discuss our recent research into the development of quasi-solid state electrolytes using either water-based or IL-based electrolytes.

(p × n)-type transverse thermoelectrics are introduced as an alternative to conventional or “longitudinal” thermoelectrical materials for applications at room temperature and below. A microscopic theory for such materials is explained, based on a simple two-band anisotropic effective mass model for conduction and valence bands. Such materials are predicted to have performance advantages over standard thermoelectrics in small-scale devices as well as at cryogenic temperatures.

Transverse thermoelectrics drive heat orthogonal to an applied electric current. As such they have the geometric advantage that the heat-flow cross section is independent of the current-flow cross section. As the name suggests, this unique behavior of (p × n)-type transverse thermoelectrics results from having a Seebeck tensor with orthogonal p- and n-type Seebeck behaviors. One feature of such materials is that the bandgap should be of order several kT at the optimal operation temperature, and that the optimal performance occurs near intrinsic doping. Whereas conventional thermoelectrics must be extrinsically doped n-type or p-type to function, these intrinsic materials will not suffer from dopant freeze-out, opening a new cryogenic range of operation for solid state cooling.

Transverse thermoelectrics have the device advantage of having full thermoelectric performance in a single-leg. This single-leg structure makes it trivial to achieve “infinite stages” of Peltier cooling, for example, which can only be achieved with standard thermoelectrics in a cascaded multi-stage structure. Single-leg (p × n)-TTE’s can also be scaled down to microscale devices, giving them niche applications that cannot be addressed by conventional multi-leg thermoelectric coolers or heaters.

Compared earlier transverse thermoelectric paradigms, the transverse Seebeck response in (p × n)-type transverse thermoelectrics is due to structural asymmetry in the band structure of a single crystal. Thus a simple two-band anisotropic effective-mass model is shown to be adequate to explain experimental data on such materials. From such a model, ambipolar resistivity Seebeck and resistivity tensors can be calculated. The predicted transverse thermoelectric behavior is shown to be maximized with the Fermi energy near mid bandgap. A transverse power factor PF is introduced, and from the published literature, we propose the following materials as candidate materials for (p × n)-type TTE: Re₂Sr, Cs₂BuTe, PdCoO₂, Na₂CoO₃ (ρ = 0.45, 0.55) and Li₂xMoO₃/7.
Thermoelectric effect, which is voltage generation under a temperature gradient, can be induced by electron or/and ion transport. Here the two different transport mechanisms and their thermoelectric properties are discussed, and the transport behaviors in polymer only and polymeric composites are compared. While thermoelectric voltage induced mainly by electrons is typically smaller than that of ions, the voltage can be continuously generated. Recently reported thermally-induced ion transport needs to be utilized in a non-continuous manner, but it exhibits extremely large thermally induced voltage. Based on thermally induced ion transport, novel methods have been developed for simultaneously harvesting and storing electrical energy without losing the benefit of solid-state non-moving part devices like conventional thermoelectrics. We called the device thermally chargeable supercapacitor (TCSC), and arrays of TCSC have been batch-fabricated, and connected together to raise the output voltage up to 2.1 V, suggesting excellent suitability for roll-to-roll mass manufacturing and practical implementation of thermal energy harvesting. The outcomes suggest that it may be feasible to eliminate needs for battery replacement and wired connections to power lines for various distributed electronic systems whenever and wherever a temperature gradient is present.

Ab Initio Design of a Transparent Thermoelectric Oxide—ZnSb2O6

Adam J. Jackson, Alex M. Ganose, Winnie Leung, Benjamin A. Williamson, and David O. Scanlon; Chemistry, University College London, London, United Kingdom; Thomas Young Centre, University College London, London, United Kingdom; Diamond Light Source Ltd., Didcot, United Kingdom.

Thermoelectric devices have a range of applications for energy conversion and recovery. As renewable technology reaches more ambitious scales, new requirements and opportunities emerge. Primarily the drive has been to identify materials with a high thermoelectric figure of merit $ZT$. Metal oxides are appealing due to their high chemical and thermal stability and avoid dependence on the limited supply of heavy anions such as Te. Electrical conductivity has been achieved in many wide-bandgap metal oxides and carrier concentrations can be manipulated by extrinsic doping. These transparent conducting oxide (TCO) materials form a vital component of devices including solar cells and display screens. So far, their thermoelectric performance has been limited by the relatively high lattice thermal conductivity of crystalline oxides, leading to an interest in nanostructuring.

We have performed third-order lattice dynamics calculations to predict the intrinsic lattice thermal conductivity of ZnSb2O6, which is found to be less than half that of ZnO across the whole operating temperature range. We have also examined the defect chemistry of the system, identifying appropriate dopants for an n-type zinc antimonate device. Device modelling identifies an optimal carrier concentration which is found to be achievable based on the study of defect transition levels. The corresponding value of $ZT$ is over 0.5: greater than existing n-type thermoelectrics. We conclude that ZnSb2O6 has the potential to form the n-type component of a high-performance transparent thermoelectric device.

Sanju Gupta and Romneey Meek, Western Kentucky University, Bowling Green, Kentucky, United States.

Three-dimensional scaffolds comprising different ratio of graphene nanosheets and multi-walled carbon nanotubes (GA-CNT, hereon) macro-assemblies. The resulting hydrothermally synthesized hydrogels are freeze-dried and thermally reduced to yield graphene and graphene-carbon nanotube aerogels with ultralow densities and tunable mesoscopic pore sizes. These 'all carbon' aerogels prepared as monolithic solids from suspensions of few-layer graphene oxide nanosheets and small diameter multiwalled carbon nanotubes in which organic wet chemistry is used to cross-link the individual sheets and with carbon nanotubes. In contrast to methods that utilize physical cross-links between graphene oxide nanosheets, this approach with polymeric linkers and organic functionalization provides covalent carbon bonding among the graphene sheets and molecular attachment with carbon nanotubes, respectively, thus facilitating rapid and facile electron transport. As a result they are expected to exhibit improved electrical conductivities, moderate thermal conductivity, highly interconnected multiplexed topology with large internal surface areas thus promoting enhanced surface ion adsorption which makes these mesoporous materials viable candidates for use in harvesting thermo-electrochemical energy and energy storage technologies. Thermoelectric property measurements for both the carbon nanotube aerogels by themselves and for hybrids with graphene nanosheets revealed promising and unprecedented ($p$-type and $n$-type) thermopower values, especially with electrolyte with an upper bound to 3.2 mV/K. We used complementary analytical techniques including electron microscopy, temperature dependent electrical property, and Raman spectroscopy while evaluating performance to establish microstructure-processing-property-performance correlations. This work is supported in parts by KSEF-RDE Grant, KY NASA EPSCoR and KY NSF EPSCoR Grants.

Continuous Thermal Tunability of VO2-SiO2 Nano-Composite Capacitors

Exploration of Organic Redox Couples for use in Thermogalvanic Devices
present thermogalvanic devices retain the drawback of coupled ionic and thermal conductivity which limits their conversion efficiency.

Here, we explore the use of organic active species in thermogalvanic devices. Organics are of interest due to their high entropy of reaction and heat capacity resulting in large Seebeck coefficients and open circuit potentials. Additionally, organics have tunable physical and electrochemical properties which expands the materials design space. To this end, we leverage recent technology developments in redox flow batteries (RFB) to improve performance of thermogalvanic generators. The proposed cell retains key advantages of RFBs, namely independent energy and power scaling, durability, and low cost while decoupling the conductive and thermal properties present in solid-state devices. We extend Tester’s results on an aqueous copper system [4] to organic active species with a novel reactor design. A range of organic active species are examined by cyclic voltammetry, bulk electrolysis, and other techniques at various temperatures and top-performers are transferred to the thermogalvanic cell for further performance analysis. In addition, we report a few engineering advances to the thermogalvanic cell to mitigate losses and improve cell potential.

measurements. These transport properties were studied in the temperature range between 85 and 300K. The thermoelectric performance of La(Ca)CoO ceramics was improved as a consequence of the decreasing of its electrical resistivity with Ca doping and metallic LaSrCoO adding. The composite exhibits maximum values for the thermoelectric power factor, PF and the figure of merit ZT close to 28 μW/K² cm and 0.5, respectively. Thus, the behavior observed in the transport properties become these composites promising materials for use in thermoelectric devices for low-temperature applications.

TP03.06.11
Transport properties of CNT-PEDOT/PSSA Polymer Composites
Sebastian Forest1 and Kofi Adu1, 2; 1Materials Research Institute, The Pennsylvania State University, University Park, Pennsylvania, United States; 2Physics, The Pennsylvania State University, Altoona, Altoona, Pennsylvania, United States.

Organic thermoelectric materials are receiving considerable attention due to the fact that they can be potentially used for fabricating flexible, printable, and low cost organic thermoelectric generators (OTEGs). Conjugated polymers such as poly(3,4-ethylenedioxythiophene) (PEDOT), poly(3-hexylthiophene) (P3HT) and polyaniline (PANI) are some examples of organic thermoelectric materials. However, for fabricating the OTEGs, the thermoelectric performance of the conjugated polymers needs to be improved further. Recently, carbon nanotubes (CNTs) have been used as effective additives for improving the thermoelectric performance of conjugated polymers. By adding CNTs to the conjugated polymer matrix, density of the electrical pathways in the nanocomposite increases; thereby, greatly enhancing the electrical conductivity. The enhanced electric conductivity results in enhanced thermoelectric performances of the CNT-conjugated polymer nanocomposite. We present our results on temperature dependence transport properties of CNT-PEDOT/PSS composite and boron doped composites of different CNT loading (0.1 wt%, 0.5 wt%, 1.0% 2.0% and 5.0 wt%) and correlate the CNT loading with the electrical conductivity.

TP03.06.12
Porous SnSe1-xSx Nanosheets as Promising Ternary Nanocrystals for Thermoelectric Applications
Hyun Ju Taeseob Oh, Dabin Park, Hyunwoo Oh and Joohoon Kim; Chung-Ang University, Seoul, Korea (the Republic of).

Herein we report a higher figure of merit (ZT) in SnSe based thermoelectric materials by markedly reducing the thermal conductivity, which is achieved via three promising strategies: substitution with isoelectric S atoms, exfoliation of nanosheets from a bulk ingot, and chemical transformation of the material into a porous structure. SnSe1-xSx nanosheets are prepared by hydrothermal Li-intercalation and subsequent exfoliation process from bulk SnSe1-xSx ingots. The substitution of S atoms into SnSe and the exfoliation of SnSe1-xSx nanosheets contribute to the scattering of phonons at numerous atomic disorders and nano-sized boundaries, resulting in effective reduction of the thermal conductivity and an enhanced ZT. The introduction of porosity into the SnSe1-xSx nanosheets through the chemical transformation process further reduces thermal conductivity, which leads to a higher ZT. Finally, the porous SnSe1-xSx nanosheets has an outstanding ZT of 0.12 at 310 K, significantly higher than that of pristine SnSe.

TP03.06.13
Thermal-Charging Electrochemical Cell for Converting Low Grade Heat in Isothermal Operation
Xun Wang and Shien Ping Feng; The University of Hong Kong, Hong Kong, Hong Kong.

A tremendous amount of energy is wasted in the form of low grade heat from source below 100 °C. Current thermoelectric or thermoelectrochemical technologies are still facing with low efficiency from limited temperature difference, balance between electric and thermal conduction, and construction on specific scenario such as thermal cycle. Here we proposed a new thermoelectrochemical system with graphene oxide(GO) as positive electrode and polyaniline(PANI) as negative electrode which can operated in isothermal condition to continuously converting low grade heat into electricity. We observed that GO had a high thermal response due to oxygen containing functional groups, and the electrochemical cell with GO as positive electrode and titanium foil as electrode could reach a high temperature coefficient of 3.5 mV/K. When heating up the cell, a heat induced voltage difference can be created and current can be generated by promoting the oxidation reaction of PANI if employing PANI as negative electrode. This system demonstrated a thermal-electricity energy conversion efficiency of 3.92% when operating in 90 °C. The findings show enormous potential to harvest low grade heat via thermoelectrochemical cell.

TP03.06.14
Synthesis of High Conducting and Thermoelectric PEDOT:PSS/Carbon Materials Aerogel for Dual-Sensors
Gyume Hyeon Yoon, Sang Woo Lee and O Ok Park; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Poly(3,4-ethylendioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) is one of the promising conducting polymers which exhibit p-type thermoelectric property, having the various characteristics such as water solubility, flexibility, and commercial availability. In this paper, we fabricated thermoelectric nanocomposite aerogel, composed of PEDOT:PSS and carbon nanotube (CNT) via an easy and reproducible freeze-drying methods. CNT could be simply dispersed in PEDOT:PSS aqueous solution, due to the secondary interactions between them, for example, pi-pi interaction and van der Waals interaction. At 140 degrees celsius, crosslinker, glycidoxypropyl-trimethoxysilane (GOPS) reacted –OH groups and epoxy group in the solution and robust nanocomposite aerogels were successfully formed. These nanocomposite aerogels showed better electrical conductivity and thermoelectric effect than those of pristine PEDOT:PSS aerogels due to embedding CNTs into PEDOT:PSS matrix. As an application of the fabricated aerogel, we also demonstrated highly sensitive pressure/temperature(P/T) dual-sensor using PEDOT:PSS/CNT aerogel. By simply mixing CNT and cross-linking agent in PEDOT:PSS solution, electrical and thermoelectric properties were improved as well as the sensitivity of the P/T dual-sensor.

TP03.06.16
Photo-Seebeck Effects in Doped P3HT Composites
Harold O. Lee and Sam-Shaing Sun; Norfolk State University, Norfolk, Virginia, United States.

As the global energy and environmental preservation needs continue to grow, the demand for renewable and clean energy conversion materials and devices continues to rise as well. Thermoelectric (TE) materials and devices can convert waste heat into electricity and therefore it can be a potential renewable and clean energy source. TE materials research and development has been mostly focusing on inorganic semiconductors such as Bi-Te or Sb-Te alloys with thermoelectric figure-of-merits (ZT values) around one at room temperature. Inorganic TE materials generally exhibit high electrical conductivity but also high thermal conductivity that is inversely related to the thermoelectric figure of merit (ZT values). Organic and polymeric materials typically exhibit low electrical conductivities, high Seebeck coefficients, and orders of magnitude lower thermal conductivities as compared to their inorganic counterparts. However, the electrical conductivities of organic/polymeric materials are tunable via doping or molecular engineering. In this study, a series of carefully doped P3HT composites are systematically evaluated for heat as well as light modulated devices. Along with a high absorption coefficient, when the polymer film thickness is less than the penetration depth of the incoming photons, the photo effects are significant and could be very useful for light modulations of thermoelectric functions. With further systematic studies and a better understanding of the mechanisms behind the photo-Seebeck effect, the development of potential high-efficiency multi-function materials and devices appears feasible.
It is well known that temperature sensitivity is one of the main drawbacks of photovoltaics (PV). Especially in the case of optically concentrated systems, the solar cell working temperature is always much higher than ambient temperature. High working temperatures increase carrier recombination, therefore decreasing solar cell performance. In this context heat recovery strategies are in principle a solution to balance this loss increasing the overall system efficiency. Among these solutions thermoelectric hybridization has already been shown to be an effective candidate. However, the field of solar cell thermoelectric hybridization is still burgeoning. Often, works in literature are contradictory and in some case the work reports unphysically large efficiency improvements. It is thought that the false efficiency improvement observed is due to incorrect experimental procedures, such as the implementation of very optimistic cold side temperatures, and the lack of normalization to active area when combining PV and TEG output contributions.

In this communication we report the development and the rigorous characterization of Gallium Indium Phosphide (GaInP) solar cells hybridized with Bismuth Telluride (Bi2Te3) thermoelectric generators (TEGs).

The results showed an inversion of the solar cell temperature sensitivity with an absolute efficiency gain of 2% (~15% of the sole PV efficiency) corresponding to an optimal working temperature of around 400 K. We find that the key to this improvement is the use of a wide-gap solar cell and the implementation of thermal strategies that prevent heat dissipation to the environment. In addition, the variation of both gain and optimal temperature as a function of the optical concentration were studied, showing the applicability of this kind of hybridization in different contexts.

These results, which are in excellent accordance with a more general theoretical model already reported by the authors, demonstrate in an accurate fashion the real potential of thermoelectric hybridization of solar cells.

Influence of the Mobility Ratio and Density of States Width on the Thermoelectric Properties of Polymer Blends Ashkan Abtahi1, Yadong Zhang2, Xuyi Luo1, Jianguo Mei1, Seth R. Marder3 and Kenneth R. Graham3; 1University of Kentucky, Lexington, Kentucky, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States; 3Purdue University, West Lafayette, Indiana, United States.

Conjugated polymers can be used in mechanically flexible and low cost thermoelectric (TE) devices, but their thermoelectric performance must be improved to make them commercially viable. The performance of thermoelectric materials depends on the electrical conductivity, Seebeck coefficient and thermal conductivity. In polymer based TE materials the polymer needs to be doped to become electrically conducting. The higher the doping concentration, the more electrically conductive the material becomes, but generally at the cost of a decrease in the Seebeck coefficient. Blending of π-conjugated polymers has been proposed as a method to minimize the tradeoff between electrical conductivity and the Seebeck coefficient, thus potentially allowing higher power factors to be reached. By blending polymers, the total density of states (D.O.S.) in the material will be manipulated, which may be used to alter the energy dependence of charge transport in the TE material. Manipulating the D.O.S., particularly by introducing highly conductive states at higher energies with respect to the Fermi energy, allows the energy dependence of charge transport to be enhanced and the Seebeck coefficient increased.

The major parameters that we expect to impact the power factor in polymer blends are the mobility ratios between the pure polymer and the shape of D.O.S. Here, we use a model introduced by Bässler and Arkhipov to theoretically probe how the mobility ratio and the shape of the D.O.S. impact the Seebeck coefficient and thermoelectric performance. These calculations are then used to fit experimental data of various polymer blends with varying mobility ratios and D.O.S. distributions. We find that a narrower D.O.S. and higher mobility of the added polymer with respect to host polymer can lead to an enhancement in the Seebeck coefficient of the TE material, but we do not observe increases in the power factor.

Thermoelectric Properties of Unsorted and Sorted Single-Walled Carbon Nanotube Sh Tsuyohiko Fujigaya1, 2; 1Kyushu University, Fukuoka, Japan; 2JST, Saitama, Japan.

Single-walled carbon nanotubes (SWNTs) especially their semiconducting type are promising thermoelectric (TE) materials due to their high Seebeck coefficient. In this study, we measured the electrical conductivity (σ), Seebeck coefficient (S) and thermal conductivity (κ) of sorted semiconducting SWNTs (s-SWNTs) and metallic SWNTs (m-SWNTs) together with their mixture and the unsorted SWNTs to study the effect of sorting for the conversion efficiency, which is often evaluated as the power factor (PF) and figure of merit (ZT = S²σT/κ). We found that as the s-SWNT purity increased, ZT increased, mainly due to the increasing of Seebeck Coefficient. Thermal conductivity on the other hand, remains the same with the increase of s-SWNT. Our group is the first to report thermal conductivity and ZT of SWNT sheet with different s-SWNT purity.

Dual-Beam Pulsed Laser Deposition of GaTe5/(Bi2Sb)2Te5 Nanocomposite Films for Thermoelectric Applications Bo-Yao Yu, Chih-Chuan Su, Po-Hung Chen and Chun-Hua Chen; Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan.

Heterogenization of nanomaterials has become one of the most promising strategies for modifying thermoelectric materials. The introduction of heterogeneous dopants could not only selectively improve intrinsically-poor specific properties of the base materials, but potentially break the physically coupled thermoelectric properties due to the created various heterogeneous functional interfaces for further enhancing the overall thermoelectric figure of merit (ZT). In this work, a series of novel Ga2Te5/Bi2Sb2Te5 heterogeneous nanocomposite films with different compositional ratios were successfully deposited on SiO2/Si substrates using a dual pulse laser deposition system. The optimized electrical conductivity of 303 S/cm and Seebeck coefficient of 295 μV/K found with the composition of Ga2Te5/Bi2Sb2Te5 of 45% and 40% higher than those reported for Bi2Sb2Te5. In overall, the corresponding power factor of 26 μW/cmK2 is approximately two times higher than that found for Bi2Sb2Te5.

Improving the Thermoelectric Power Factor in 2D Materials Using Periodic Potential Barriers Adithya Komminni and Zlatan Aksamija; University of Massachusetts Amherst, Amherst, Massachusetts, United States.

The conversion of waste heat to electricity using thermoelectric devices has the potential to improve our energy utilization efficiency. Significant research efforts over the past two decades have been devoted to increasing the efficiency of thermoelectric (TE) energy conversion via nanostructuring. One approach to improve the TE efficiency is electron filtering where "cold" (low energy) electrons are restricted from participating in transport by an energy barrier. However, the impact of electron tunneling through thin barriers and resonant states on TE properties, especially in two-dimensional (2D) mono- and few-layer materials, has been given significantly less attention. In our previous work, we simulated the effect of energy filtering and quantum-
mechanical (QM) tunneling through a series of potential barriers in silicon and found that tall, sharp barriers can significantly enhance the TE power factor. We extend our previous work to study the effect of energy filtering from a series of potential barriers in 2D materials, such as those arising from lateral or vertical van der Waals heterostructures, superlattices, or when a monolayer is exposed to a series of electrostatic gates. In this work, we develop a comprehensive transport model that includes electron-phonon coupling and electron-impurity scattering alongside with quantum effects arising from the potential barriers. Our model captures the carrier-potential interactions in the Wigner formalism as an additional force term called the “quantum evolution operator”, which is added to the semi-classical Boltzmann transport equation (BTE). The resulting Wigner-Boltzmann transport equation is solved using Rodeo’s iterative method, with the electronic structure data being pre-calculated from density functional theory (DFT). We then study the impact of height, width, and shape (smoothness) of the potential barriers on TE properties. Our simulations show a steady increase in TE efficiency with the height of the potential barrier in gated single layer (SL) molybdenum disulfide (MoS₂), reaching a maximum enhancement of approximately 25 percent. Further, we explore the impact of the barrier width and shape and find that, unlike 3D, sharp, narrow barriers are not always better. We attribute this to the unique step-like 2D electronic density of states. This study identifies ways to achieve high TE performance in nanoscale thermoelectric devices with periodic features, such as van der Waals heterostructures and superlattices. The improvement in TE efficiency helps in the development of energy-efficient devices ranging from wearables powered by scavenging body heat, to thermal sensors, and solid-state electronic cooling.

Tuning Band Structure and Electronic Transport in Multilayered Semiconductor Nanostructures Sanjumitha Neogi and Vitaly Proshchenko; University of Colorado Boulder, Boulder, Colorado, United States.

When the device size reaches the nanoscale, scattering at interfaces dictates the device functionality. Additionally, dimensional reduction significantly modifies the properties of carriers in the nanostucture. A complete treatment of transport in a multi-interface system requires solving the complex interplay between dimensional confinement and interface scattering. In this work, we investigate electron transport in layered Si/Ge superlattices with imperfect interfaces employing density functional theory in combination with semi-classical Boltzmann transport theory. We demonstrate tunability of electron transport in multilayered nanostructures by the introduction of compositional variability, engineered interface structures and external strain. The structural variability induces strain that strongly influences the bonding environment and therefore, the charge densities in these structures. The modified charge densities directly impact electronic band structures and subsequently, cross-plane electronic transport across the multilayered systems. Our work establishes a direct relationship between the introduction of local and global strain and cross-plane transport in multilayered semiconductor superlattice structures. One representative result from our study is that introduction of positive strain (tension) in the in-plane direction of Si/Ge superlattices leads to significant improvement of the Seebeck coefficient at higher carrier concentrations. Our work establishes strategies to attain a phonon-glass-electron-crystal regime in order to achieve a high ZT for thermoelectric applications. The project is funded by the DARPA (DSO) MATRIX program. This work used XSEDE, which is supported by NSF grant number ACI-1053575.

TP03.06.23
Thermoelectric Properties of MA P-Type BiSbTe-NFC Hydrogel Composite Films Under Applied Pressure Deepa Madan1, Eunhwa Jang1, Aswani Possapati1, Nathaniel Jang2 and Liangbing Hu3; 1University of Maryland Baltimore County, Baltimore, Maryland, United States; 2University of Maryland College Park, College Park, Maryland, United States.

Flexible Thermoelectric generators (TEGs) are attractive because they can potentially provide higher power density, can have higher aspect ratio elements, and are more scalable than conventional TEGs. Flexible TEG devices are printed on flexible substrates using thermoelectric (TE) inks consisting of TE particles, a suitable binder, and a solvent. Films printed using TE inks typically have much lower performance as compared to commercially available bulk TE pellets. A high amount of insulating binder present in inks deteriorates the electrical properties and overall performance of printed TE films. In this work, we explore a novel binder, synthesize efficient TE particles with suitable dopants, and perform cold-pressing to densify the films to improve the TE performance of p-type TE materials. We chose wood-based nanofoiber cellulose (NFC) hydrogel as a binder because a very small amount of hydrogel is sufficient to provide good adhesion strength and flexibility. We initially check the feasibility of use of NFC hydrogel as a binder with commercially available Sb₂Te₃ TE particles. Then, followed by synthesizing various mechanically alloyed (MA) particles using Te as a dopant with the objective of improving the TE performance. For optimizing thermoelectric inks we made films with different weight ratios of the binder and the TE powder (e.g., 1:100, 1:1000, and 1:10000). Unlike most other TE films with thermostet polymers that require high curing temperatures and long curing time, NFC hydrogel TE composite films are cured at the room temperature in a short time to achieve good properties. These films were then subjected to a range of uniaxial pressure (10 Mpa to 1000 Mpa) for 5 minutes to densify the films. A significant improvement in the electrical conductivity was achieved by varying the applied pressures. Optical microscope and SEM images showed that (1) the number of pores in the NFC hydrogel phase with particles decreased with an increase in the weight ratio of the TE powder, and (2) the NFC hydrogel phase and particles were compacted and densified. Because the particles aggregate with each other, the grain boundaries and scattering were reduced, helping improve the electrical conductivity. SEM cross-section images revealed that with higher TE particles concentration, the TE films have more uniform and denser surfaces. The best sample among various MA BiSbTe samples was 1:10000 binder to MA BiₓSb₁ₓTe₃ (which consists 8% extra Te) at 600 Mpa applied pressure. Its power factor of 1338.8 μW/mK² is approximately 15 times that of MA Bi₀.₅Sb₁.₅Te₃ sample for which no pressure was applied. Overall, the low mass loading of binder to particles ratio, the addition of extra Te to MA BiₓSb₁ₓTe₃ improved the power factor by approximately 130 times (1:10000, 600Mpa, MA BiₓSb₁ₓTe₃) as compared to Sb₂Te₃-NFC composite films without any external pressure.

The Transverse Seebeck Effect Oded Rubin1, Stuart Laurence2 and Nicholas Tiliakos3; 1University of Maryland, College Park, Maryland, United States; 2Innovercing LLC, Ronkonkoma, New York, United States.

In anisotropic single crystal materials the Seebeck coefficient tensor may contain non-zero off-diagonal elements. With proper crystal alignment, a unidirectional heat flux generates EMFs both parallel (normal Seebeck voltage) and perpendicular (transverse Seebeck voltage) to the temperature gradient. This presentation will highlight the theoretical and practical advantages and challenges in utilizing the transverse Seebeck effect in miniature high-speed heat flux sensors. Compatible with large scale microfabrication, this technology is suitable for microcalorimetry and fast thermal analysis of materials and processes.

TP03.06.25
Nanoporous V–VI Chalcogenides Nanoplates for Efficient Thermoelectrics with Preferential Interfacial Scattering Chaochao Dun4, Jian Wang5, Kirill Kovnir4, David L. Carroll3 and Yanliang Zhang1; 1Department of Aerospace and Mechanical Engineering, University of Notre Dame, Notre Dame, Indiana, United States; 2Department of Chemistry, Iowa State University, Ames, Iowa, United States; 3Physics Department, Wake Forest University, Winston Salem, North Carolina, United States.

Flexible Thermoelectric generators (TEGs) are attractive because they can potentially provide higher power density, can have higher aspect ratio elements, and are more scalable than conventional TEGs. Flexible TEG devices are printed on flexible substrates using thermoelectric (TE) inks consisting of TE particles, a suitable binder, and a solvent. Nanoporous architectures are known to have low thermal conductivities thanks to the enhanced phonon scattering at pore interfaces. In this paper, instead of the chemically engineered interface, we adopted the morphology engineered interface in V-VI systems to realize an electron-transmitting but phonon-blocking structure using preferential energy carrier scatterings determined by the modulation of geometric factors. The synthetic nanopore in the nanoplates offers superior control of both the pore size and the porosity in the consolidated nanostructured bulk pellets. Such versatility offers an additional degree to improve the thermoelectric properties. The effective multi-frequency phonon scattering along with minimal charge carrier scattering lead to a substantial reduction of lattice thermal conductivity and a slight increase of Seebeck coefficient. Thanks to the existence of pore boundaries, effectively multilayer preferential scatterings were achieved, which involves more phonons scattering than that of charge carriers, more low-energy charge carries scattering than high-energy carries, leading to an improved figure of merit of the V-VI systems.

**Investigation of Thermoelectric Performance of MoS2 Nanostructure Along with Its Secondary Phase**

Pratisha Gangwar, Sunil Kumar and Neeraj Khare; Physics, Indian Institute of Technology Delhi, New Delhi, India.

Thermoelectric materials have been the subject of intense research from both theoretical and technological point of view due to their ability to directly convert waste heat into the electricity and can provide an alternative approach to deal with the future energy crisis [1]. The energy conversion efficiency of thermoelectric material is evaluated from the figure of merit (zT=S²ρT/κ), a dimensionless quantity, where S is the Seebeck coefficient, ρ is the electrical conductance, T is the absolute temperature and κ (κ = κe+ κp) is the thermal conductance composed of the contributions from electrons (κe) and phonons (κp) [2]. For efficient energy conversion, the figure of merit should be greater than 1. The conventional thermoelectric materials possess low value of zT thus cannot be used for thermoelectric applications [1]. Thus to improve the zT value, materials which possess high Seebeck coefficient and high electrical conductivity or low thermal conductivity are required.

Recently, layered transition metal dichalcogenides (TMDCs) have gained a lot of research attention for thermoelectric applications due to the advantage of low thermal conductivity possessed by these materials [3]. Among TMDCs, molybdenum disulfide (MoS2) has been demonstrated as a good thermoelectric material due to its high value of thermo-EMF (or thermoelectric voltage) and low value of thermal conductivity [3]. But, low electrical conductivity limits its thermoelectric conversion efficiency [4]. So, the challenge is to increase its electrical conductivity without compromising the low thermal conductivity. One of the way is to enhance its electrical conductivity is by incorporating metal nanostructures in the semiconducting host matrix [1].

In the present work, we demonstrate thermoelectric properties of MoS2 by incorporating MoS2, a semi-metallic secondary phase of MoS2. The presence of semi-metallic MoS2 in MoS2 matrix enhances its electrical conductivity. Further, enhancement in Seebeck coefficient is also observed due the filtering of low energy charge carriers. For this study, we have synthesised MoS2 nanosheets (pristine and secondary phase incorporated) via hydrothermal method. By varying the growth time, 16 hours and 36 hours, we are able to get pristine MoS2 (labelled as M36) and MoS2 with secondary phases (labelled as M16). The structural and morphological analysis of as-synthesized MoS2 is performed with X-ray diffraction (XRD), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Furthermore, thermoelectric performance of the MoS2 samples (M16 and M36) is studied and analysed.

**TP03.06.27**

**Effect of In as a Substitute and not a Filler on Thermoelectric Properties of CoSb3 Skutterudites**

Keshav P. Dabral and Satish Vitta; Indian Institute of Technology Bombay, Mumbai, India.

CoSb3 with an open structure which can accumulate several fillers has been extremely studied due to its phonon glass electronic crystal character. In the earlier studies In has been added to CoSb3 as a filler to reduce thermal conductivity due to its large size compared to both Co and Sb. In the present work however its effect on the thermoelectric performance when used as substitute for Sb has been investigated in detail. The substituted alloys, CoₓSbₓ₋ₓInₓ with x=0.5 and 1.5 were synthesised by standard technique and hot pressed at 600°C under a pressure of 60Mpa for 12 minutes into circular pellets. Structure characterization by X-ray diffraction shows that for x<0.5 and 1.0 , the alloys consist of essentially single phase indicating that In has gone into solution as substitute for Sb. The alloy with x=1.5 however shows phase segregation. The skutterudite phase, CoSb3 is present along with CoSb3 and Sb. Hence this alloy was not investigated further. The variation of electrical conductivity with temperature shows a weak metallic behaviour for x<0.5 while that of x=1.0 exhibits a weak semiconducting behaviour. Both the alloys show very weak temperature dependence with conductivity varying between 9×10⁴ and 1.1×10⁷ sm⁻¹ when the temperature increased from 300K to 800K. The Seebeck coefficient of the alloys in the complete temperature range is negative indicating electrons to be the dominating charge carriers. The Seebeck coefficient of x=0.5 alloy is found to be higher varying from 152 µVK⁻¹ to 200 µVK⁻¹ compared to x=1.0 alloy in which it varies from 125 µVK⁻¹ to 175 µVK⁻¹. At ~600K bipolar transport begins in the both alloys clearly showing the presence of low energy charge carriers. The high Seebeck coefficient and electrical conductivity of x<0.5 alloys results in a large power factor of 3.7mWm⁻¹K⁻² at ~650K. The thermal conductivity of both compound x=0.5 and x=1.0 alloys is found to be low in the complete temperature range, 300K to 800K varying between 2.5 Wm⁻¹K⁻² and 3.5 Wm⁻¹K⁻². The thermal conductivity of x=0.5 alloy however is found to be lower than that of x=1 alloys at almost the temperatures. The relatively low thermal conductivity and extremely large power factor of x=0.5 alloy results in a high figure-of-merit of 0.82 at 773K. These results clearly show that low levels of substitution of Sb with In is highly beneficial in increasing the power factor substantially compared to the reduction in the thermal conductivity.

**Gaussian Process Regression of Electron-Phonon Coupling Matrix Elements with Applications in Thermoelectric Materials Research**

Jeeyoun Kim, Semi Bang and Daehyun Wee; Ewha Womans University , Seoul, Korea (the Republic of).

Electronic transport coefficients in semiconductors can be obtained by solving the semiclassical Boltzmann transport equation within the relaxation time approximation. The main task is the evaluation of the inverse of the electron energy relaxation time induced by the electron-phonon (el-ph) interaction. Here, we investigate a method, the electron-phonon averaged via Gaussian process regression (EPA-GPR) method, of predicting the Seebeck coefficient and electrical conductivity by estimating the electron-phonon coupling. This method results from the combination of the electron-phonon averaged (EPA) method and the Gaussian process regression (GPR) strategy. With the electron-phonon averaged (EPA) method, the momentum-dependent electron-phonon coupling matrix, [gₘₙ(ν,k)q]², is approximated by its energy-dependent equivalent, gₘₙ(ν,εₘ,εₙ)q. gₘₙ(ν,εₘ,εₙ) is modeled as a Gaussian process which is a collection of random variables, any finite number of which can have a joint Gaussian distribution. During the regression, the characteristic length-scale of the covariance function of the Gaussian process can be estimated within the type two maximum likelihood (ML-two) approximation. To reduce the computational cost, we use the KISS-GP (Kernel Interpolation for Scalable Structured Gaussian Processes) method, in which the evaluation of the covariance function is replaced with interpolation on a well-defined grid. The calculation on the grid can exploit its underlying Kronecker-Toeplitz structure to boost the calculation speed. A potential thermoelectric half-Heusler compound, HfCoSb, is considered as a test case. Thermoelectric properties, including the Seebeck coefficient and the electrical conductivity, are estimated. The results of the two different approaches are compared in order to show the advantages of the EPA-GPR method as a practical method for estimating thermoelectric properties of materials.

**TP03.06.29**

**Accelerating Evaluation of Converged Lattice Thermal Conductivity**

Guangzhao Qin and Ming Hu; University of South Carolina, COLUMBIA, South
Designing materials with specific properties is a long-term goal in materials science. High-throughput \textit{ab-initio} materials screening and design is a new and rapidly growing area in computational materials research. The application of high-throughput calculations has recently made formidable progress and led to novel insights in this field. The lattice thermal conductivity (\(\kappa\)) is a crucial physical property of crystalline materials for enormous practical implications, such as electronic cooling, thermoelectricity, phase change memories, and etc. Therefore, the fast evaluation of reliable \(\kappa\) for variety of materials plays a key role in identifying suitable materials for targeted applications. Currently, first-principles based anharmonic lattice dynamics (ALD) method coupled with phonon Boltzmann transport equation (BTE) is one of the most featured methods to obtain the \(\kappa\), which involves calculation of interatomic force constants (IFCs). Especially, the anharmonic IFCs are evaluated based on the third order derivatives of the total energy with respect to the atomic displacements, which requires huge computational costs. However, severe problem arises for choosing an appropriate (usually not large enough) cutoff distance (\(r_{\text{cutoff}}\)) when calculating the anharmonic IFCs. Thus, the high-throughput evaluation of reliable \(\kappa\) remains a challenge due to the large resources costs and time-consuming procedures in calculating the anharmonic IFCs for the convergence test. In this work, based on the analysis of the harmonic (second order) IFCs, we propose a concise strategy to efficiently accelerate the evaluation process of obtaining accurate and converged \(\kappa\) by solving the cutoff distance problem. The proposed strategy is efficient for directly determining when the \(\kappa\) converges with respect to \(r_{\text{cutoff}}\) and how to fast get satisfactorily converged \(\kappa\). With this strategy, we study the divergence problem of thermal conductivity of graphene, a long debate of two-dimensional heat conduction in literature. The feasibility of the method is also confirmed by other systems. In addition, the computing speed with our approach could be one order of magnitude faster compared to the traditional method in most situations, where the \(20^{\text{th}}\) nearest neighbors are considered. The quantitative strategy proposed herein can be a good candidate for fast evaluating the reliable \(\kappa\) and thus provides useful tool for high-throughput materials screening and design with targeted thermal transport properties.
This indicates that coupling of Au-thiol heterojunctions is much stronger than coupling of the ligands to water. Our work facilitates better understanding of heat transfer at atomic scale.

Magnetically Driven Heat Transport in Field-Induced Weyl Semimetals
Dung Vu, Koen Vandaele, Nandini Trivedi and Joseph P. Heremans; The Ohio State University, Columbus, Ohio, United States.

Theory predicts\(^1\) that the Fermi arcs in Weyl semimetals (WSM) induce entropy transport driven by circulating electronic currents in a magnetic field. Here, we report the first experimental observation of that theory. Fermi arcs are projections of Weyl nodal crossings in the surface Brillouin zone. This new transport phenomenon has no net charge transport, but a net heat transport that contributes to the magneto-thermal conductivity of the material.

Experimental demonstration of the circulating current in a traditional WSM is difficult since the effect scales with thickness, yet the growth technology for thick, high-quality films of traditional WSMs is not well developed. Bi\(_x\)Sb\(_{1-x}\) alloys with varying Sb concentrations have bands that close at \(k=\pi\) and have a Dirac point at the \(L\)-point of the Brillouin zone\(^2\). In strong magnetic fields, this Dirac point theoretically is expected to split into two field-induced Weyl points. Here we experimentally demonstrate the new, magnetically-driven enhancement of thermal conductivity in bulk Bi\(_x\)Sb\(_{1-x}\). Samples report a strong, positive magneto-thermal conductivity at the Sb concentration and magnetic field where the Weyl points are expected to appear.

This work is supported by the OSU Center for Emergent Materials, an NSF MRSEC, Award Number DMR-1420451.

Giant Anomalous Nernst Effect Observed in Single Crystal MnBi
Bin He, Stephen Boona, Brian C. Sales\(^2\) and Joseph P. Heremans\(^1\); The Ohio State University, Columbus, Ohio, United States; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

MnBi is a high temperature ferromagnet (\(T_{\text{Curie}}\approx 630\)K) and crystallizes in the HCP structure. Its thermal transport properties have remained uninvestigated. The anisotropic transport properties (including resistivity, thermal conductivity, thermopower and Nernst effect) of two MnBi single crystals are measured and presented here separately from 80K to 300K in magnetic field up to 1.4T along different crystalllographic axis. We observed a giant anomalous Nernst thermopower in both \(\alpha_{xy}\) and \(\alpha_{xy}\) configurations (the first index indicates the direction of the flux, the second of the measured field, the third of the applied magnetic field, \(\alpha=\text{hexagonal axis}\)). The anomalous Nernst thermopower in \(\alpha_{xy}\) configuration decays with temperature while in the \(\alpha_{xy}\) configuration the anomalous Nernst effect strengthens. Anomalous Hall effect is also observed. We suspect the presence of a strong magnon contribution to the anomalous Nernst effect. This can be understood as a self-Spin Seebeck effect, whereby a thermally driven magnon flux in the sample generates a spin polarization of the conduction electrons through magnon-electron scattering. This in turn gives rise to an inverse spin-Hall effects via spin-orbit coupling in the materials itself.

Work supported by the National Science Foundation under Award Number DMR-1420451.

Nernst Thermopower in Bi - MnBi Composites
Koen Vandaele, Bin He, Stephen Boona and Joseph P. Heremans; The Ohio State University, Columbus, Ohio, United States.

Magnetic materials in which thermal transport involves the generation of spin fluxes provide new opportunities to improve the thermal-to-electric energy conversion efficiency over that of conventional, electron-based thermoelectrics. In bulk ferromagnetic (FM) metals such as Co, Fe, and Ni, magnon dynamics in the material result in a magnonic contribution to total thermopower, as shown by Watzman et al.\(^1\) In thin-film structures composed of a normal metal (NM) film, such as Pt, deposited on an electrically insulating FM, such as yttrium iron garnet (YIG), a thermally driven spin flux injected from the FM into the NM layer gives rise to inverse spin-Hall voltage in the NM layer.\(^2\) This voltage is perpendicular to the temperature gradient and the applied magnetic field.\(^2\) Although these thin-film structures are not suitable for power generation applications, it was shown by Boona et al.\(^3\) that it is possible to obtain a contribution from the spin-Seebeck effect (SSE) to the Nernst thermopower in bulk nanocomposite structures composed of a NM (Pt) with strong spin-orbit interactions and a FM (Ni). In this work, Bi, which has a large spin-Hall angle and Nernst effect, will be used as a NM and MnBi as the FM. Bulk composites composed of Bi and MnBi needles will be studied specifically in a Nernst geometry to determine the SSE contribution to Nernst thermopower.

9:45 AM TP03.07.07
Investigation of Electron Transport via Quantum Mechanical Estimation of Electrical Conductivity in Thermoelectric Materials
Semi Bang\(^1\), Georgy Samsonidze\(^2\), Boris Kozinsky\(^3\) and Daehyun Wae; \(^1\)Environmental Science and Engineering, Ewha Womans University, Seoul, Korea (the Republic of); \(^2\)Research and Technology Center, Robert Bosch LLC, Cambridge, Massachusetts, United States; \(^3\)Harvard John A. Paulson School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

A quantitatively accurate description of electron transport from first principles would greatly enhance our ability to design new materials or optimize existing materials via prediction of electronic transport properties. In particular, electrical conductivity is a key property determining the performance of many types of bulk materials for energy storage and conversion including thermoelectrics (TE). However, relatively little work has been done on fully ab-initio prediction of electrical conductivity for realistic TE materials. In this study, we perform the validation study of a newly developed computational prediction method of electrical conductivity, i.e., the electron-phonon-averaged (EPA) approximation, in order to verify the feasibility of first-principles screening applications for various realistic and complex TE materials. Regarding target TE materials, we study the pnictogen-substituted ternary skutterudites (PSTSs), which are formed by isoelectronic replacement of pnictogen atoms with group 14 (Ge, Sn) and group 16 (S, Se, Te) elements. PSTSs are considered as the attractive features to be investigated as potential thermoelectric materials. Nevertheless, the rigorous understanding of the chemical substitution effect on transport phenomena of the PSTSs still remains largely unexplored. Therefore, we investigate the effect of pnictogen-substitution on electron transport via estimation of interrelated electronic transport properties in skutterudite compounds. Based on these results, certain guidance for the rational design of next-generation TE materials is also provided.

10:00 AM BREAK
It has been almost three decades since Nanoscale Thermal Science and Engineering became a well-established research field. Various major breakthroughs in fundamental understanding of thermal transport (phonons, photons, and electrons) at the nanoscale have been achieved in these three decades; however, the impact of these fundamental insights has been primarily targeted toward microelectronics and thermoelectrics applications. In this talk we provide examples of other applications such as Lithium ion battery thermal management, building thermal insulation, and high density thermochemical storage where molecular and nanoscale thermal science has a significant role to play.

11:00 AM TP03.08.02

Thermoelectric technology has key benefits and strengths in many terrestrial energy recovery applications. Thermoelectric system cost is a key factor governing final decisions on the use of thermoelectric energy recovery systems in all terrestrial applications; thus cost being just as important as power density or efficiency for the adoption of waste energy recovery (WER) thermoelectric generators (TEG). New integrated cost analysis / thermoelectric analysis approaches have shown key relationships and interdependencies between overall TEG system costs, including TE material costs, manufacturing costs, and specifically heat exchanger costs; and the TE performance design metrics such as TE material properties, TE device design parameters, heat exchanger performance metrics such as hot-side and cold-side conductances and UA values, and hot side heat flux in achieving optimal TEG WER designs. These new approaches have led to a new thermoelectric system economics paradigm that strongly influences TEG cost and performance decisions. While work by Yee et al. and LeBlanc et al. provided foundations for the latest cost scaling analysis / TE performance analysis, this new work takes prior work to new insights and understandings and provides the basis for new thermoelectric system economics. Optimum TEG system cost conditions can now be tied directly to the TE materials, TEG design parameters, and heat exchanger design parameters through critical non-dimensional analysis. The non-dimensional analysis and metrics show the TEG system cost and performance interdependencies and interlinks in one unifying and cohesive relationship. Prior work has shown that the system design that minimizes cost (e.g., the G [$/W$] value) can be close to designs that maximize power, but these design regimes are not necessarily aligned with high system conversion efficiency or high specific power. This paper will explore the key sensitivities and interrelationships between critical cost metrics and critical TE performance and design metrics in the new thermoelectric system economics paradigm, provide quantitative data showing these sensitivities, and their serious implications on TEG system design in terrestrial WER applications. Critical non-dimensional parameter mapping has shown where heat exchanger cost-dominated conditions, TE material or manufacturing cost-dominated conditions, and combinations of cost conditions control and drive the overall TEG cost and performance. This new cost-performance paradigm shows the required pathways and challenges to achieving TEG system costs of $1-$3/Wdec.

11:15 AM TP03.08.03
Optimization of Thermoelectric Power Generators for Low-Grade Heat Recovery Kazuaki Yazawa, Yee Rui Koh and Ali Shakouri; Purdue University, Minneapolis, Minnesota, United States.

The most suitable thermoelectric properties for low-grade heat recovery is very well matched to the material in Peltier devices for general cooling application. This is based on an analytical modeling and optimization with temperature dependent material properties. The analytic model is validated based on experiments with commercially available thermoelectric modules. This highlights the importance of the geometric aspect ratio of the thermoelements which is key for thermal impedance matching with the heat transfer coefficients at both hot and cold contacts. Especially, reduction of thermal conductivity has bigger impact compared to the TE power factor. At the same time, however, relative thermal conductivity of TE material compared to the gap fill material has a big impact on the performance. The latter is often neglected in high temperature applications. The talk will go over the experimental results of TE systems optimized for small temperature differences for various heat transfer conditions. The cases include (a) Heat energy harvesting from inaccessible two parallel water pipelines with 10 cm separation and 10-20 deg-C temperature difference for powering wireless sensors transmitting self-diagnostic information about heating and cooling supplies in datacenters. (b) Reversible body heat recovery and spot heating for winter sport jackets with compact heat exchanger design. In the experiments, power generation is measured at room temperature with water chiller and adjusted with temperature-dependent material properties to determine the performance in real conditions. The power output at the level of 1-100 mW with a 40 mm x 40 mm off-the-shelf module were observed depending on the heat/water flow path. At the optimum design, 1.2 V can be generated with electrical series transmitting self-diagnostic information about heating and cooling supplies in datacenters. (b) Reversible body heat recovery and spot heating for winter sport jackets with compact heat exchanger design. In the experiments, power generation is measured at room temperature with water chiller and adjusted with temperature-dependent material properties to determine the performance in real conditions. The power output at the level of 1-100 mW with a 40 mm x 40 mm off-the-shelf module were observed depending on the heat/water flow path. Experimental Proof of Thermoelectric Charge Generation and Separation within p-i-n Junction TEGs Franziska Maculewicz; Khaled Arzi, Timo Wagner and Roland Schneebeli; 1Institute of Technology for Nanostructure & CENIDE, University of Duisburg-Essen, Duisburg, Germany; 2Components for High Frequency Electronics, University of Duisburg-Essen, Duisburg, Germany.

Common thermoelectric generators are built from unipolar p- and n-legs and use the Seebeck-effect for power generation. In theoretical studies (Span et al.) a p-i-n structure operated parallel to the temperature gradient was proposed. A big advantage of this device concept is beside the conventional thermoelectric effect is the additional ability to harvest energy from thermal excited bipolar carriers in the space charge region (+-region) and their separation in the built-in field of the p-i-n TEG. Here we present for the first time the experimental evidence of thermal excited bipolar carriers in the space charge region and its contribution to the electrical output power of the TEG. Silicon p-i-n TEGs were fabricated by laser sintering of highly doped boron and phosphorus nanoparticles on each side of an intrinsic silicon wafer. $II$-characteristics were measured under different temperature gradients. The hot side was heated to a temperature around 300 °C. The fundamental characteristics of this complex 2-dimension problem, could be explained by a simple lumped equivalent circuit. It is shown that an additional physical mechanism, beside the regular Seebeck-effect is needed to describe the measured behavior. This indicates the present of a second
independent energy conversion process, as predicted by Span et al. This energy which is assigned to the separation of thermally excited bipolar charge carriers within the region can be measured by excluding the contribution from the p- and n-legs. In this experiment the Seebeck-effect which occurs mainly in the p- and n-region is canceled by electrically short circuiting the p- and n-legs of the TEG with a full metallization of the legs. The short-circuited device assures a direct access to the thermally excited bipolar charge carriers in the i-region. The output power of the short-circuited devices kept raising with the hot side temperature, which confirms the mentioned assumption. The extracted electric power from the i-region by bipolar charge separation is compared to the Seebeck-effect of the bare i-region. This comparison underlines again the different nature of both mechanism. Besides that, device simulations are carried out on same structures and achieved a good agreement to the measured data. The generated power dependency on the i-region thickness is currently investigated to maximize the contribution of thermally generated bipolar carriers in the i-region to the p-i-n TEG power output.

11:45 AM TP03.08.05
Ferroelectric Energy Conversion by First Order Phase Transformation in the Small Temperature Difference Regime
Ashley Bucek1, William Nunn2, Bharat Jalali2 and Richard James1; 1Aerospace Engineering and Mechanics, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; 2Chemical Engineering and Materials Science, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

Ferroic materials respond to external stimuli by undergoing spontaneous changes in macroscopic behavior via advanced deformation mechanisms such as a reversible phase transformation. This includes ferroelastics or shape memory alloys, ferromagnetics, ferroelectrics, and multiferroics. For instance, ferroelectrics that undergo a reversible phase transformation can alternate between one phase that is a strong ferroelectric and another phase that is non-ferroelectric. The transformation between one phase and the other can be induced through small changes in temperature. This material system is incredibly promising for society-improving technological advances in direct energy conversion from heat to electricity, where “direct” means that the material itself generates the electricity. Furthermore, the ferroelectric heat recovery system is ideal for operation in the “small temperature difference regime,” e.g. solar-thermal sources, waste heat from air conditioners, data centers, or even hand-held electronic devices. We present a thermal energy conversion device that utilizes the first order phase transformations in ferroelectric capacitors. We demonstrate the validity of such a device, present a theoretical framework to model and optimize the circuit parameters, and discuss using phase engineering to achieve extreme cyclic repeatability.

SESSION TP03.09/BM08.09: Joint Session: Thermoelectrics and Organic Polymers Toward Applications in Wearable Devices
Session Chairs: Kedar Hippalgaonkar and Dongyan Xu
Wednesday Afternoon, November 28, 2018
Sheraton, 2nd Floor, Grand Ballroom

1:30 PM *TP03.09.01/BM08.09.01
Ionic Effects in Organic Thermoelectrics
Rachel Segalman, University of California, Santa Barbara, Santa Barbara, California, United States.

Thermoelectric materials for energy generation have several advantages over conventional power cycles including lack of moving parts, silent operation, miniaturizability, and CO2-free conversion of heat to electricity. Molecular materials and hybrid organic-inorganics bring the promise of inexpensive, solution processible, mechanically durable devices potentially suitable for wearable applications. While highly conductive polymers are now commonplace, they generally demonstrate lower thermopower at a given conductivity than inorganic counterparts. Ion conducting materials have previously been demonstrated to have very large Seebeck coefficients, and a major advantage of polymers over inorganics is the high room temperature ionic conductivity. Notably, PEDOT:PSS demonstrates a significant but short-term increase in Seebeck coefficient which is attributed to a large ionic Seebeck contribution. We have recently shown that doping with protic ionic liquids and other proton conductors can be used to control the thermoelectric power factor. In this talk, I will discuss how electrochemical transistor geometries can be used to understand the scaling of thermopower with carrier concentration and to begin to untangle the intertwined ion/electron effects in mixed conductor thermoelectrics. I will also discuss how electrochemistry can be utilized to stabilize the Seebeck enhancement leading to stable improvements to power factor in mixed conductor thermoelectrics.

2:00 PM TP03.09.02/BM08.09.02
Design and Fabrication of Textile-Based Wearable Thermoelectric Devices
Hend M. Elmoughni, Akanksha K. Menon, Shannon Yee and Rylan Wolfe; Georgia Tech, Atlanta, Georgia, United States.

Textile fabrics as substrates for wearable thermoelectric generators (WTEG) are attractive for body heat harvesting. Textile-based WTEGs can be integrated into clothing to convert temperature differences between the human body and ambient into electricity. One target application of the technology is powering body mounted electronics with low energy consumption that ranges from 1μW to 10mW. Transformation of the conventionally rigid thermoelectric devices consisting of p- and n-type inorganic semiconductors into flexible fabrics offers various advantages including: better conformity to the skin which maximizes the temperature difference needed for power generation, light weight structure which does not restrict mobility or comfort, and easy integration of the technology into clothing. Development of WTEGs has been mainly focused on employing additive printing techniques such as screen printing to deposit the thermoelectric material onto the flexible substrate. While this approach has demonstrated great potential, a number of challenges have to be overcome before a fully functioning textile-based WTEG can be realized. Device-level challenges include small fill factors ~0.2 requiring large areas to generate appreciable amounts of power, low fabric thickness that results in small temperature differences, and dominant interconnect and electrical contact resistances for thin-film devices that hamper the power output; these factors need to be considered when designing WTEGs in order to maintain device structure flexibility and high power density. Furthermore, a material-level challenge lies primarily in the development of p- and n-type thermoelectric ink formulations that can be compatible with a cost-effective, scalable fabrication technique without compromising thermoelectric properties. Herein, we present strategies to overcome the aforementioned challenges and fabricate a knitted-base WTEG capable of human body heat harvesting using a through-plane temperature difference. Both the proposed device design and proof-of-concept prototype are presented to demonstrate the feasibility and potential of this technology for low grade heat energy harvesting.

2:15 PM TP03.09.03/BM08.09.03
Towards a Thermoelectric Fabric—3D-Extruded Thermoelectric Threads
Jun Peng1, Ian Witting1, Nicholas Geisendorfer1, Mingyi Wang1, Mingchiang Chang1, Ramille N. Shah1, 2, Jeff J. Snyder1, Matthew Grayson1 and Adam Jakus2; 1Northwestern University, Evanston, Illinois, United States; 2Dimension Ink, Evanston, Illinois, United States.

Thermoelectrics (TE) have the potential for diverse applications in energy harvesting, however the rigid configuration of typical TE modules can be a limiting factor whereas flexible platforms would find much broader use. Here, we realize continuous, flexible thermoelectric threads via three-dimensional
Thermoelectric generators (TEGs) are promising for harvesting waste heat from the environment to power wireless sensor nodes in smart buildings. In this talk, I will share our recent research effort on developing non-flexible micro-TEGs by integrating pulsed electroplating with microfabrication processes. We systematically studied the effects of the pulsed electroplating conditions on the composition, microstructure, and thermoelectric properties of the electroplated Bi2Te3 thin films. Our results show that the thermoelectric figure of merit of the electroplated Bi2Te3 films can be enhanced by increasing the pulse off-to-on ratio, which is mainly due to the reduced thermal conductivity and the increased Seebeck coefficient. A maximum ZT of 0.16 is obtained at the pulse off-to-on ratio of 50 at room temperature. Based on the fundamental materials research, we further developed cross-plane micro-TEGs on a SiO2/Si substrate. The device consists of a total of 127 pairs of n-type Bi2Te3 and p-type Sb2Te3 thermoelectric pillars embedded in a SU-8 matrix. Both thermoelectric pillars and interconnectors are formed by electroplating, which is advantageous because of low parasitic electrical resistances. The micro-TEG we developed demonstrates a maximum power of 3 mW at a temperature difference of 52.5°C, corresponding to a power density as high as 9.2 mW cm⁻². The power density of our TEG is more than two times the highest value reported for the electroplated TEGs in the literature, which can be attributed to the low internal resistance and high packing density of thermoelectric pillars.

With expediting trends in electronic device miniaturization, thermoelectric energy harvesting becomes increasingly valuable, especially in wearable technologies and sensors for the internet-of-things. However, it has been impossible to match the device thermal impedance with the natural heat gradient using the thin-film thermoelectric materials much needed for device miniaturization. This limitation has prevented thermoelectrics from competing as a technology and environmental pollution. It is crucial to develop clean and renewable energy technology for the sustainable development of human society. Targeting at scavenging thermal energy, thermoelectric effect has been utilized to develop thermal energy harvesting technology. Compared to the pyroelectric energy harvester which has little energy output, thermoelectric devices have been widely recognized as more effective and efficient technologies which have been utilized to develop thermal energy harvesting technology. However, it has been impossible to match the device thermal impedance with the natural heat gradient using the thin-film thermoelectric materials much needed for device miniaturization. This limitation has prevented thermoelectrics from competing as a technology.

In this work, we report on a flexible photo-thermoelectric nanogenerator (PTENG) by hybridizing MoS2/PU photothermal layer with tellurium (Te) nanowire based thermoelectric device. The MoS2/PU film which is flexible and transferable exhibits excellent photothermal characteristics due to exceptional surface-area-to-mass ratio of MoS2 nanoclusters. Te nanowire is chosen for the thermoelectric nanogenerator because of its reported outstanding thermoelectric properties, such as low thermal conductivity and a wide temperature range. By integrating the photothermal layer with
thermoelectric device, the PTENG can absorb infrared light to form a temperature difference across the device. With this, a potential difference between two electrodes can be established and used for electrical energy generation. Therefore, the PTENG can generate electricity without a spatial temperature gradient. Furthermore, the PTENG which is flexible and shape-adaptive can demonstrate great practical application of photo-thermoelectric energy harvesting for wearable electronics and implantable electronics.

1.0, 10 and 50 mM doped films showed n-type nature of the films. Interestingly, we found that Seebeck coefficient of 1.0 mM doped film changed to positive, while 10 mM doped film showed stable negative value. From above results, we conclude that the mechanism of the air-stabilization of n-doping is the passivation effect by the formation of o-MeO-DMBI layer onto the surface of SWCNT films. [2] Bao, Z. et al. Nano Lett. 2013, 13, 1890. [1] Nakashima, Y.; Nakashima, N, Fujigaya, T. Synth. Met. 2017. 225. 76.

Concentration of o-MeO-DMBI solution was studied. It is noted that the films were kept under air condition at room temperature to evaluate the air stability. DIPS (Meijo Nano Carbon, EC1.5) was used as SWCNT. SWCNT films were dipped in the 0.01, 0.1, 1.0, 10 and 50 mM ethanol solutions of o-MeO-DMBI for 10 min and dried in vacuum at room temperature for 12 h. The time course of Seebeck coefficient of the SWCNT films doped with various concentration of o-MeO-DMBI solution was studied. It is noted that the films were kept under air condition at room temperature to evaluate the air stability of the o-MeO-DMBI-doped SWCNT films. Positive value of Seebeck coefficient for 0.01 and 0.1 mM doped films indicated p-type, and negative value for 1.0, 10 and 50 mM doped films showed n-type nature of the films. Interestingly, we found that Seebeck coefficient of 1.0 mM doped film changed to positive, while 10 mM doped film showed stable negative value. From above results, we conclude that the mechanism of the air-stabilization of n-doping is the passivation effect by the formation of o-MeO-DMBI layer onto the surface of SWCNT films.

Thermoelectric (TE) conversion is one of the most promising methods for the generation of cost-effective electricity. TE devices have applications in many fields especially microelectronics devices due to their simple device structures. TE generation using Seebeck effect requires both n-type and p-type TE materials for the efficient conversion; however, deterioration of n-type nature due to air oxidation has been the critical issue. Recently, we reported single-walled carbon nanotubes (SWCNT) sheet doped by 2-(2-methoxyphenyl)-1,3-dimethyl-2,3-dihydro-1H-benzimidazole (o-MeO-DMBI) showed n-type property and remarkable air-stability. We chose o-MeO-DMBI because of the following reasons; i) o-MeO-DMBI is stable under atmospheric conditions, ii) the cationic form of o-MeO-DMBI is also stable and, iii) n-doping of the other carbon materials such as fullerene and graphene has already been reported.[2,3] Here, we study the mechanism of the air stability of o-MeO-DMBI-doped SWCNT films by changing the doping level. eDIPS (Meijo Nano Carbon, EC1.5) was used as SWCNT. SWCNT films were dipped in the 0.01, 0.1, 1.0, 10 and 50 mM ethanol solutions of o-MeO-DMBI for 10 min and dried in vacuum at room temperature for 12 h. The time course of Seebeck coefficient of the SWCNT films dipped with various concentration of o-MeO-DMBI solution was studied. It is noted that the films were kept under air condition at room temperature to evaluate the air stability of the o-MeO-DMBI-doped SWCNT films. Positive value of Seebeck coefficient for 0.01 and 0.1 mM doped films indicated p-type, and negative value for 1.0, 10 and 50 mM doped films showed n-type nature of the films. Interestingly, we found that Seebeck coefficient of 1.0 mM doped film changed to positive, while 10 mM doped film showed stable negative value. From above results, we conclude that the mechanism of the air-stabilization of n-doping is the passivation effect by the formation of o-MeO-DMBI layer onto the surface of SWCNT films.
for higher temperature application, reducing conductivity mass for higher mobility or band convergence for dramatic increase in density of states (Pb(Se,Te), Mg(Si,Mn), Bi(Se,T,Te)3). In principle all of these defects can be better controlled by engineering chemical potentials through phase boundaries. Even if the Ni content MnSn (M = Ti, Zr, Hf) Half-Heusler thermoelectrics can be sufficiently altered to make substantial differences in electronic properties. The excess Ni produces impurity states in the band gap that changes the effective band gap and leads to additional electron and phonon scattering.

8:30 AM TP03.10.02 YbSiGe—A Promising Thermoelectric Material with High Power Factor at Room Temperature Sora-At Tanusilp1, Yuji Ohishi1, Hiroaki Muta1, Akinori Nishide2, Jun Hayakawa2 and Ken Kurosaki1,2,4, Osaka University, Osaka, Japan; 3Hitachi, Ltd., Tokyo, Japan; 4University of Fukui, Fukui, Japan; 5JST, PRESTO, Saitama, Japan.

Metal silicide-based thermoelectric (TE) materials have been widely attracted attention, because they are less toxic, low production cost, and high chemical stability. Recently, it has been reported that YbSi1.8 shows high electrical conductivity (σ) accompanied by uncommonly large Seebeck coefficient (S) probably due to intermediate valence mechanism of Yb (Yb2+/Yb3+), leading to high-power factor (σS) 2.2 mW/mK2 at room temperature [6–8]. Here, we demonstrated that Yb(Si1.8Ge0.2) is a more promising TE material. The substitution of Ge on the Si site changes the Yb2+/Yb3+ ratio and transform the phase from the AI2B type (random defects in the Si site) to the ThPd1 type (ordered defects in the Si/Ge site). It is revealed that the x = 0.5, i.e., YbSiGe, is the best composition with the highest power factor 3.6 mW/mK2 at room temperature, which is comparable to or higher than those of conventional TE materials. Furthermore, the lattice thermal conductivity (κ/l) of Yb(Si1.8Ge0.2) is significantly reduced because the substituted Ge acts as scattering centers of heat carrying phonons. The enhanced S and reduced κ/l lead to 80% enhancement in the zT value is 0.13 at room temperature.

8:45 AM TP03.10.03 Creating Zipper-Like van der Waals Gap Discontinuity in Low-Temperature-Processed Nanostructured PbBi2nTe1+3n for Enhanced Phonon Scattering and Improved Thermoelectric Performance Yue Wu and Wei Zheng; Iowa State University, Ames, Iowa, United States.

Nanoengineered materials can embody distinct atomic structures that deviate from the bulk-grain counterpart and induce significantly modified electronic structure and physical/chemical properties. Besides, the phonon structure and thermal properties that can also be potentially modulated due to the modified atomic structure in nanostructured material, however, are seldom investigated. In this presentation, we will discuss a mild approach to fabricate nanostructured PbBi2nTe1+3n using solution-synthesized PbTe-Bi2Te3 nanoheterostructure as a precursor. The as-obtained monoliths have unprecedented atomic structure differing from the bulk counterpart, especially the zipper-like van der Waals gap discontinuity and the random arrangement of septuple-quintuple layers. These structural motifs break the lattice periodicity and coherence of phonon transport, leading to ultra-low thermal conductivity and excellent thermoelectric zT. We anticipate that this strategy can be widely applicable to fabricate existing thermoelectric compounds into their nano forms with unique atomic structures and good performances.

9:00 AM TP03.10.04 Thermoelectric Properties of All-Inorganic Halide Perovskite Nanowires Wooshal Lee; Mechanical Engineering, University of Hawaii at Manoa, Honolulu, Hawaii, United States.

Controlling the flow of thermal energy is crucial to numerous applications ranging from microelectronic devices to energy storage and energy conversion devices. I will present experimental ultralow lattice thermal conductivities of solution-synthesized, single-crystalline all-inorganic halide perovskite nanowires composed of CaPbI3, CsPbBr3, and CsSnI3. I will also discuss mechanisms behind ultralow thermal conductivity values of all-inorganic halide perovskites. Further, I will present a rare combination of ultralow thermal conductivity and high electrical conductivity of CsSnI3, which is a promising candidate for thermoelectric applications.

9:15 AM TP03.10.05 Hyper-Doped Nanocrystalline Silicon Thin Films for Low-Temperature ThermoElectric Harvesting—Energy Filtering and the Role of Hydrogen Dario Narducci, Laura Zuliani, Carlos J. Álvarez, Andrea P.C. Campos, Claude Alfonsi, Marion Descoins, Dominique Mangelinck, Xanthipp Zanni and Ahmed Charal; 1Department Materials Science, University of Milano Bicocca, Milan, Italy; 2Laboratoire IM2NP, CNRS, Aix Marseille Université, Marseille, France; 3Dept. of Aircraft Technology, Technological Educational Institution of Sterea Ellada, Psachna, Greece.

Despite its intrinsic low thermoelectric figure of merit, silicon has found applications in low-temperature thermal microharvesting due to the available know-how for planar manufacturing [1,2]. In recent years, many groups have revived the interest toward enhancing silicon ZT [3]. This can be achieved either by reducing the thermal conductivity of single-crystalline silicon [4] or increasing the power factor (PF) of polycrystalline silicon. Some of the present authors reported in 2010 [5] first evidence about the possibility of enhancing the power factor (PF) of nanocrystalline silicon by a factor 10 through the controlled precipitation of second phases at grain boundaries. Such results were extensively confirmed [6–8], and modeling showed that enhanced PF was mostly related to energy filtering by potential barriers at grain boundaries [9,10]. However, effort to move these results toward production has shown that PF enhancement is more elusive than expected, with a puzzling dependence upon sample size. This communication reports about the analysis of the dependence of PF upon sample size in hyper-doped p-type nanocrystalline Si thin films. Nanocrystalline Si thin films were deposited by PECVD on SiO2 and then ion-implanted with B+ After damage recovery, samples were cut to varied sizes and submitted to annealing for 2 h at 1000 °C in Ar. Their electrical conductivity and Seebeck coefficient were found to depend on the sample size, with a standard PF of 1.3 mW/mK2 in 200-nm wafers that raises to 13.6 mW/mK2 in 5x50 mm2 chips. Analyses by transmission electron microscopy, high-resolution scanning electron microscopy, and atomic probe tomography could prove that the disappearance of PF enhancement in wafer-scale samples was due to the combined effect of B-H complexation and incomplete implantation damage recovery at film surface. These results indicated proper remediation measures, therefore opening the path toward full industrial exploitation of silicon as a high-performance material for heat microharvesting in the low-temperature range. Possible applications of integrated thermoelectric harvesters will be discussed.

References
Al2Fe3Si3 phase forms a narrow band gap near the Fermi level and has shown potential as a thermoelectric material. We demonstrated that fine tuning of phonon scattering improved the power factor at mid temperatures using machine-learning-assisted synthesis [3]. However, a remaining important issue is to develop the anomalously low observed value being in fact due to microstructure, i.e. to grain boundary scattering of phonons due to polycrystallinity, which we model by Casimir scattering (anisotropy and isotopic scattering affect the conductivity at the level of 10% at room temperature). We use the calculated thermal conductivity to estimate $\kappa_T$ for a range of different situations, also including effects of grain boundaries on electrical conductivity and Seebeck effect.

Internal-Strain Softening Significantly Reduces Thermal Conductivity and Leads to High ThermoElectric Efficiency PbTe—Reconsidering Phonon Scattering Riley C. Hanus1, Matthias T. Agne1, Zhiwei Chen1, Yanzhong Pei1, Peter W. Voorhees1 and G. J. Snyder1; 1Northwestern University, Chicago, Illinois, United States; 2Materials Science and Engineering, Tongji University, Shanghai, China.

The influence of micro/nanostructure on thermal conductivity is a topic of great scientific interest and of particular technological importance to thermoelectrics. The current paradigm of understanding is that structural defects primarily decrease thermal conductivity through phonon scattering where the phonon dispersion (and thus the speeds of sound) are fixed when describing the thermal transport, especially when chemical composition is unchanged. Experimental work on a PbTe model system is presented which shows that the speed of sound significantly decreases in PbTe with increasing internal-strain which completely accounts for the reduction in lattice thermal conductivity without assuming an increase in phonon scattering centers. Furthermore, we experimentally show that internal-strain is linearly related to the materials speed of sound, which provides evidence for the thermodynamic origin of this phenomena. It is also shown that this mechanism is a major part of the reduction in thermal conductivity and the resulting improvement in thermoelectric figure of merit in high efficiency PbTe ($\kappa_T > 1$). This presents new avenues to engineer thermal conductivity, beyond phonon scattering, by modifying the phonon dispersion relation (i.e. speeds of sound and lattice stiffness) with microstructural defects and internal-strain, and shines new light on studies of thermal conductivity in fields of energy materials, microelectronics, and nano-scale heat transfer.

10:45 AM TP03.10.09
Development of Low-Cost and Non-Toxic Al2Fe3Si3 Thermoelectric Material—Experiment, Theoretical Calculation and Machine Learning Prediction Yoshiki Takagiwa1, Yukihiro Isoda1, Masahiro Goto1, Yosikazu Shinohara1, Zhufeng Hou1, Yibin Xu1 and Koji Tsuda2, 3; 1National Institute for Materials Science, Tsukuba, Japan; 2The University of Tokyo, Kashiwa, Japan.

To develop new thermoelectric materials that are low-cost and non-toxic with sufficient power output toward practical applications, in particular, at a low-temperature region below 400 K, we performed materials screening of Al-Fe-Si ternary system using band structure calculations [1,2]. We found that $\tau_1$-Al2Fe3Si3 phase forms a narrow band gap near the Fermi level and has shown potential as a thermoelectric material. We demonstrated that fine tuning of the $\tau_1$ ratio could control its conduction type and enhance power factor without chemical substitutions [2]. Relatively large power factors exceeding 500 $\mu$W/mK$^2$ were obtained for both p- and n-type materials below 400 K, which can be used in such as sensor applications. Recently, we succeeded in an enhancement of power factor at mid temperatures using machine-learning-assisted synthesis [3]. However, remaining important issue is to develop the single phase of Al2Fe3Si3 and optimize the sample composition for better thermoelectric performance. In this presentation, we will review the recent progress of newly developed thermoelectric material Al2Fe3Si3 and discuss how to enhance the power output toward practical usage.

11:00 AM TP03.10.10
High Sn-type Thermoelectric Power Factor and Efficiency in Ba$_2$Sb$_5$ from a Highly Dispersive Band Junsoo Park1, 2, 4, Yi Xia1 and Vidvuds Ozolins5, 6; 1Materials Science and Engineering, University of California, Los Angeles, Los Angeles, California, United States; 2Applied Physics, Yale University, New Haven, Connecticut, United States; 3Center for Nanoscale Materials, Argonne National Laboratory, Argonne, Illinois, United States; 4Energy Sciences Institute, Yale University, West Haven, Connecticut, United States.

Using first-principles density-functional theory calculations, we predict the potential for unprecedented $\xi T$ge5$ at 800 K in SnS-type Ba$_2$Sb$_5$. The $\xi T$ value reaches 7$\mu$W/mK$^2$ at 800 K, which is significantly higher than that of other SnS-type materials. Such a high efficiency arises from intrinsically ultralow lattice thermal conductivity coupled with very high power factor reaching 7
mW m$^{-1}$K$^{-1}$, which is higher than that of PbTe. The main reason for such a high $zT$ was low thermal conductivity, i.e., 1.09 W/mK at 923 K. Our developed modeling based on dependent phonon scattering, i.e., coherent phonon scattering, adequately explain extremely low thermal conductivity of SnTe nanocomposites. We found that with same concentration of impurities which scatters phonons, coated grain nanocomposite shows lower thermal conductivity compared with that of nanoparticle nanocomposite.

1:45 PM TP03.10.11

Thin Film Tin Selenide (SnSe) Thermoelectric Generators Exhibiting Ultra Low Thermal Conductivity Matthew R. Burton1, Tianjun Liu2, James McGettrick3, Shahin Mehraban1, Jennifer Baker1, Adam Pocock1, Trystan Watson1, Oliver Fenwick2 and Matt Carnie1; 1Swansea University, Swansea, United Kingdom; 2School of Engineering and Materials Science, Queen Mary University of London, London, United Kingdom.

Tin selenide (SnSe) has attracted much attention in the field of thermoelectrics since the discovery of the record figure of merit ($zT$) of 2.6 ± 0.3 along the $b$-axis of the material. The record $zT$ is attributed to an ultralow thermal conductivity that arises from anharmonicity in bonding. Whilst it is known that nanosstructuring offers the prospect of enhanced thermoelectric performance, there has been minimal studies in the literature to date of the thermoelectric performance of thin films of SnSe. Tin selenide (SnSe) has attracted much attention in the field of thermoelectrics since the discovery of the record figure of merit ($zT$) of 2.6 ± 0.3 along the $b$-axis of the material. The record $zT$ is attributed to an ultralow thermal conductivity that arises from anharmonicity in bonding. Whilst it is known that nanosstructuring offers the prospect of enhanced thermoelectric performance, there has been minimal studies in the literature to date of the thermoelectric performance of thin films of SnSe. In this presentation, we will demonstrate the first known example of a working thin-film SnSe thermoelectric generator [1], fabricated in an extremely simple thermal evaporation method. Seebeck coefficients are comparable to that seen in bulk SnSe, whilst materials characterisation reveals that the microstructure of the SnSe material is of a preferentially orientated porous network of thin film SnSe nanosheets which exhibited an unprecedentedly low thermal conductivity of 0.08 W m$^{-1}$K$^{-1}$ between 375 K and 450 K which can be primarily attributed to the reduction of the lattice component.

1:30 PM TP03.10.12

Copper Iodide-Based Composite Materials for Thermoelectric Application Shiejiang Bai; Institute of Materials Research and Engineering, A*STAR, Singapore, Singapore.

Novel hybrid thermoelectric materials have attracted great attentions for their potential applications for thermal energy conversion and sustainable environment. As an environment-friendly, abundant, economic and semiconducting material with broad band gap values, copper iodide has been systematically investigated in the research areas of photophysics, photochemistry and light-emitting diodes. A recent report demonstrates a promising room temperature thermoelectric performance of ZT = 0.21. We are exploring inorganic-organic thermoelectric composites using molecular materials. In this presentation, a series of copper iodide-based thermoelectric composites with robust pellets and low densities shall be introduced. The fabrication procedure, structures, recyclable electrical conductivities and Seebeck coefficients will be discussed.

SESSION TP03.11: High Temperature Inorganic Thermoelectric Materials

1:30 PM TP03.11.01

Coherent Phonon Scattering in SnTe Nanocomposite Resulting in High Thermoelectric Performance Junphil Hwang1,2, Jisook Hong1, Mi-Kyung Han2, Ji Hoon Shim3, Sung-Jin Kim2, Ying-Shi Jin2, Hoon Kim2, Jiyoung Kim1, Hwanjoo Park1 and Woohul Kim1; 1School of Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of); 2Department of Chemistry and Nano Science, Ewha Womans University, Seoul, Korea (the Republic of); 3Department of Chemistry, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

We are reporting that coherent phonon scattering can induce severe thermal conductivity reduction while maintaining electrical transport which is ideal for thermoelectric application. SnTe has been drawn attention for last several years to replace Pb containing thermoelectric materials especially PbTe. However, larger thermal conductivity compared with that of PbTe hinders higher thermoelectric performance. We synthesized polycrystalline SnTe where the grain boundaries were coated by nanosized CdTe, SnO2, SnTe particles which were clarified by TEM study. The thermoelectric figure of merit ($zT$) for the SnTe nanocomposites is 2.18 at 923 K which is higher than that of PbTe. The main reason for such a high $zT$ was low thermal conductivity, i.e., 1.09 W/mK at 923 K. Our developed modeling based on dependent phonon scattering, i.e., coherent phonon scattering, adequately explain extremely low thermal conductivity of SnTe nanocomposites. We found that with same concentration of impurities which scatters phonons, coated grain nanocomposite shows lower thermal conductivity compared with that of nanoparticle nanocomposite.

1:45 PM TP03.11.02

Low Cost Scalable Printed Tin Selenide (SnSe) for Thermoelectric Generators Matthew R. Burton, Shahin Mehraban and Matt Carnie; University of Swansea, Swansea, United Kingdom.

Tin selenide (SnSe) sparked much interest in the field of thermoelectrics when Zhao et al.[1] reported an unprecedented ZT of 2.6 ± 0.3 at 923 K along the $b$-axis. This discovery was observed in single crystals formed at high temperature (1223 K) over several hours. Whilst doping SnSe with elements such as Na[2] and Bi[3] have also shown promising thermoelectric performance, these too were shown on single crystals with expensive and lengthy fabrication techniques which are unfavorable for commercial applications. Since the discovery of the record ZT in single crystal SnSe,[1] studies on the thermoelectric performance of polycrystalline SnSe have been reported.[4]–[12] These fabrication techniques presented in the literature, however, require high temperature, lengthy fabrication times and in most cases high pressure. This makes these processes of fabrication unfavorable for commercial development.

In this work we present a cheap, facile and scalable technique, with the aim of producing a commercially viable thermoelectric device. Polycrystalline SnSe
was fabricated by low-cost ball milling of the constituent elements. Films were printed in a water-based ink using carboxymethyl cellulose as a binder. The effect of variation of the binder concentrations on properties (including electrical conductivity, Seebeck coefficient and thermal conductivity) were studied. Thermoelectric characterization of the printed polycrystalline SnSe, reveals peak ZT ~0.14 at 760 K, which is comparable to examples in the literature for polycrystalline SnSe.

A lack of control over the dopability of thermoelectric materials continues to limit the efficiency of potentially good material systems. Phase boundary mapping has recently been shown to be an effective means of engineering defects in materials such as Mg2Sb, where Mg-rich conditions are required to overcome “killer defects” and achieve n-type behavior. Herein, we demonstrate that defect engineering is critical for efficient doping in a PbTe model system, validating the principles of phase boundary mapping in a material system that does not have a history of difficult dopability. PbTe ingots with increasing levels of n-type iodine dopant were annealed at 700 °C under Pb-rich and Te-rich partial pressures and quenched. Ingots annealed in Pb-rich conditions have degenerate, n-type thermoelectric properties typical of a good thermoelectric material, while the same materials annealed in Te-rich conditions show intrinsic, poorly performing properties and are p-type at lower doping levels. The drastic difference in performance agrees with expectations from a defect model and demonstrates the effectiveness of phase boundary mapping to engineer dopability in PbTe. Using the same experimental technique, it was possible to repeatedly switch between degenerate n-type and non-degenerate p-type conduction in a single material. This behavior corresponds to the subtle change in composition associated with crossing the small phase width of the single-phase region of the phase diagram.

The AgSbTe2 compound is a promising p-type semiconductor. The δ phase, which is stable between about 600 and 550° C, and exists metastable after reducing conditions show intrinsic, poorly performing properties and are p-type at lower doping levels. The drastic difference in performance agrees with expectations from a defect model and demonstrates the effectiveness of phase boundary mapping to engineer dopability in PbTe. Using the same experimental technique, it was possible to repeatedly switch between degenerate n-type and non-degenerate p-type conduction in a single material. This behavior corresponds to the subtle change in composition associated with crossing the small phase width of the single-phase region of the phase diagram.

Research on thermoelectric (TE) materials has experienced a considerable increase in interest within the last years. The design of different microstructures and new classes of materials like complex chalcogenides is considered a promising approach for improving the efficiency of potential TE materials [1]. TE materials directly convert heat into electricity through the Seebeck effect. The conversion efficiency is determined by the dimensionless figure of merit, ZT, which depends on the thermal conductivity κ, electrical conductivity σ, and the Seebeck coefficient S and the temperature T. Attempts to optimize ZT require reducing κ, while maintaining relatively high values of σ and S.

TE Thin-Film Materials from Organic Electronics Xizu Wang; IMRE, Singapore, Singapore.

In the past two decades, materials and thin film structures that were well-known for their applications in organic electronic devices, such as LEDs and solar cells, had found new applications through engineering of their semiconductor properties, nanoscale structures, and designs. In our research, we have found many thin film materials in organic solar cells to be the strong candidates for novel applications in thermoelectric devices. Here we report some high performance thermoelectric thin films based on materials commonly used in organic electronics, including PEDOT:PSS, ITO, P3HT and inorganic-organic MAPbI₃ perovskite crystals. The high electrical conductivity of 2980 S/cm and correspondingly high power factor of 142 µW/mK² are observed in anhydrous, treated PEDOT-PSS thin films. Ultra-high Seebeck coefficient and low thermal conductivity are obtained in a centimeter-sized perovskite single crystal. Furthermore, we discover some newly optimized methods for the enhancement of thermoelectric properties of ITO, P3HT and AZO thin films and devices. Our investigations show that materials discovery and development for thermoelectric applications can be accelerated by re-engineering of materials conventionally used in organic electronics.

Atomically-resolved imaging of materials has become the mainstay of modern materials science, as enabled by advent of aberration corrected scanning transmission electron microscopy (STEM). However, the wealth of quantitative information contained in the fine details of atomic structure or spectra remains largely unexplored. In this talk, I will present the new opportunities enabled by physics-informed big data and machine learning technologies to extract physical information from static and dynamic STEM images, ranging from statistical thermodynamics of alloys to kinetics of solid-state reactions on a single defect level. Synergy of deep learning image analytics and real-time feedback further allows harnessing beam-induced atomic and bond dynamics to enable direct atom-by-atom fabrication. Examples of direct atomic motion over mesoscopic distances, engineered doping at selected lattice site, and assembly of multilitermic structures will be demonstrated. These advances position STEM towards transition from purely imaging tool for atomic-scale laboratory of electronic, phonon, and quantum phenomena in atomically-engineered structures.

**Biography:**
Sergei Kalinin is the director of the Institute for Functional Imaging of Materials (IFIM) and distinguished staff member at the Center for Nanophase Materials Sciences at Oak Ridge National Laboratory. He received his MS degree from Moscow State University in 1998 and Ph.D. from the University of Pennsylvania (with Dawn Bonnell) in 2002. His research presently focuses on the applications of big data and artificial intelligence methods in atomically resolved imaging by scanning transmission electron microscopy and scanning probes, as well as mesoscopic studies of electromechanical and transport phenomena via scanning probe microscopy. Sergei has co-authored >600 publications, with a total citation of >25,000 and an h-index of >77. He is a fellow of MRS, APS, IoP, IEEE, Foresight Institute, and AVS; a recipient of the RMS medal for Scanning Probe Microscopy (2015); Presidential Early Career Award for Scientists and Engineers (PECASE) (2009); Burton medal of Microscopy Society of America (2010); 3 R&D100 Awards (2008, 2010, and 2016); and a number of other distinctions.
Recent advances in soft electronics have attracted great attention due in large to its potential applications in personalized bio-integrated healthcare devices. The mechanical mismatch between conventional electronic/optoelectronic devices and soft human tissues/organs often causes various challenges, such as the low signal to noise ratio of biosensors, inflammations and/or excessive immune responses near implanted sites, and discomfort and consequent stress to users. Ultra-flexible and stretchable electronic devices have low system modulus and intrinsic softness, and thereby have potential to solve these issues. Nanomaterials are particularly beneficial in realizing these flexible and stretchable electronics due to their intrinsic ultraflexibility thanks to nanoscale dimensions. Here, our unique strategies in the synthesis of nanomaterials, their seamless integration with electronics, and unconventional biomedical device designs toward implantable and wearable bioelectronics are presented. These implantable and wearable bioelectronic systems combine recent breakthroughs in unconventional soft electronics to address unsolved issues in the clinical medicine.

Biography:
Dae-Hyeong Kim obtained B.S. and M.S. degree in Chemical Engineering from Seoul National University, Korea, in 2000 and 2002, respectively. He received Ph. D. degree in Materials Science and Engineering from University of Illinois at Urbana Champaign in 2009. From 2009 to 2011, he was a post-doctoral research associate at University of Illinois. He joined Seoul National University in 2011 and is currently an associate professor in the School of Chemical and Biological Engineering of Seoul National University. He has published more than 75 papers and 25 international and domestic patents. He has been recognized with several awards including George Smith Award (2009), MRS Graduate Student Award (2009), Green Photonics Award (2011), TR 35 award (2011), Hong Jin-ki Creative Award (2015), SCEJ Award (2016), and Korea Young Scientist Award (2017).

What is Next for Solar PV Technology? Mariana I. Bertoni; Arizona State University, Tempe, Arizona, United States.

The solar PV market is far from slowing down in demand or popularity and in the last seven years we have seen it moved from niche generation to reaching grid parity and becoming a mainstream electricity generation source. The reality of silicon module prices below US$0.4/W and projections of US$0.2/W has fundamentally changed solar R&D.

As we move towards an “electric-powered world” and everything around us starts demanding electricity in a clean and efficient way, new challenges arise. Similar to many consumer applications, solar margins will improve and R&D hurdles centered around aesthetics, customization and functionality will be part of our everyday life. In this talk, I will introduce approaches to achieve high power in small areas and the use of sustainable materials for device manufacturing. I will discuss the importance of understanding the defects that underpin performance under real operating conditions and how can we accelerate discovery and defect engineering to facilitate high-power, portable and reliable devices.

Mariana Bertoni is an assistant professor at Arizona State University and the lead of the Next Generation Modules Testbed at the Quantum Energy and Sustainable Solar Technology Engineering Research Center. She received her BS and MS degree from the Buenos Aires Institute of Technology and her PhD degree in Materials Science from Northwestern University in 2007. She held senior scientist positions at two start-up firms in the photovoltaic industry and her previous postgraduate experience includes a postdoctoral appointment at MIT and a Marie Curie postdoctoral fellowship in Germany.

Biography:
She is a pioneer in correlative X-ray microscopy approaches to engineer defects in solar absorbers. She has received numerous awards, including the Edward C. Henry Award from the American Ceramic Society, a Marie Sklodowska-Curie Fellowship from the EU and a Fulbright Scholarship. She was selected to NAE’s 2017 U.S. Frontiers of Engineering. She has co-founded two companies commercializing technology from her lab.

Bottom-Up Grown Nanowire Quantum Devices Erik P. Bakkers1, 2; 1Department of Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 2QuTech and Kavli Institute of NanoScience, Delft University of Technology, Delft, Netherlands.

Signatures of Majorana’s have been obtained in devices based on InSb nanowires coupled to a superconductor [1]. Different schemes for uncovering their
unique non-Abelian statistics are proposed, for which a nanowire network assembly is needed. Here, we demonstrate a generic process by which we can design any proposed nanowire network device by manipulating an InP substrate and thereby the nanowire growth position and orientation [2]. Nanowire “hashtag” structures are grown in which phase coherent transport is demonstrated by the Aharonov–Bohm (AB) effect. In addition, we can in-situ grow epitaxial Al islands on the nanowires, resulting high quality interfaces. We employ here self-shadowing structures, such that complete device can be realized by bottom-up grown techniques. With these new devices we have observed a quantized Majorana signal [3].

Biography:
After obtaining his PhD in nanoelectrochemistry at the University of Utrecht, Erik started working at Philips Research in Eindhoven in 2000. He started his own research group, and the team focused on nanowires - lines of material with a width of several tens of nanometers- an area he continues to research, looking at integration into semiconductors in particular. In 2010, his growing interest in fundamental research resulted in Erik joining the Technical University of Eindhoven as well as Delft Technical University as part-time professor in the Quantum Transport group. His current interest is in Quantum Materials, to detect and manipulate Majorana states, and in Hexagonal Silicon, to demonstrate and exploit the predicted direct band gap in this material. He has received the Technical Review award from MIT, VICI grant, ERC CoG, and the Science AAAS Newcomb Cleveland Prize.
