The performance of lithium-ion batteries is not only determined by the used active cathode and anode materials, as these components only set the maximum achievable values for capacity and rate capability. The energy and power densities actually achieved in the cells are influenced primarily by the inactive additives and by the processing conditions. In order to understand the impact of additives and processing on cell properties, it is necessary not only to know material specific properties but also to analyze the entire structure of the electrodes. From this, it is feasible to derive processing-structure-property relationships that can close the understanding gap between the applied processing conditions and the resulting electrodes properties.
Structural and chemical investigations of electrodes can be carried out on different length scales. The study of interface effects, such as contact resistance or binder adhesion, is performed on the nanoscale range. For many macroscopic effects, however, distribution of components on meso- and microscopic orders of magnitude is relevant. On the one hand, the mesoscale formation of clusters between the binder and carbon black and their localization in the proximity of the active particles is important for the fundamental mechanical and electronic properties of the electrode. On the other hand, the overall electrode properties are also determined by the distribution of binder and conductive additives on a microscale level, i.e., over the entire cross-section and surface of the electrode.

Investigations of the electrode structure are challenging not only by the different orders of magnitude of the structural units, but also by the large number of materials used. As a result, the standard method for structure elucidation of diverse electrodes does not exist. Instead of that, one must have a pool of methods available and make appropriate adjustments for various electrodes. Examples, which illustrate these limitations, as well as successful application of methods, will be shown for common cathode and anode systems. The focus is placed on determining the microscopic binder distribution of standard electrodes, as knowledge of this feature is an essential prerequisite for understanding and optimizing of drying conditions. Most investigations are performed by using SEM based methods, which are available in many laboratories. A rather new user-friendly approach applies laser-induced breakdown spectroscopy for achieving a 3D elemental mapping of the entire electrodes, which can be used either for a rapid screening of 3D binder distribution or for post-mortem analysis of electrochemical degradation processes.

WITHDRAWN 10/31/2018 ET07.10.06 Al-Air Rechargeable Batteries on Flexible Polyimide Substrates Anming Hu1,2; 1University of Tennessee Knoxville, Knoxville, Tennessee, United States; 2Beijing University of Technology, Beijing, China.

We reported a rechargeable Al-air battery fabricated on polyimide substrates. For air anode, Pt decorated carbon particles mixed with TiC nanoparticles worked an OER/ORR catalyst. This combination has a better performance than individual Pt catalyst or TiC. Ionic liquid (1-ethyl-3-methylimidazolium chloride) mixed with AlCl3 as electrolyte. For Al cathode, we have compared Al foils, later-nanostructured Al foils and 3D printed Al nanoparticles. A stable charge-discharge of capacity of 0.3 mAh/cm2 is achieved for more than 100 cycles.

11:30 AM ET07.10.07
Wire-Shaped Supercapacitor Fabricated via Layer-by-Layer Assembly with Enhanced Voltage Window Kayeon Keum1; Geumbbee Lee2 and Jeong Sook Ha1,2; 1Korea University, Seoul, Korea (the Republic of); 2KU-IST Graduate School of Converging Science and Technology, Seoul, Korea (the Republic of).

As wearable electronics receives vast interest nowadays, various shapes and forms of wearable devices have been studied. Among them, wire-shaped supercapacitor (WSS) shows a great potential as a wearable energy storage device because its 1-dimensional structure makes it highly flexible and be easily incorporated into conventional textile substrates. Here, we report a thin, reproducible WSS fabricated via layer-by-layer (LbL) assembly of multi-walled carbon nanotubes (MWCNTs) with organic electrolyte of propylene carbonate (PC) – acetonitrile (ACN) – lithium perchlorate (LiClO4) – poly-(methyl methacrylate) (PMMA), extending the voltage window to 1.6 V. LbL assembly gives uniformly deposited MWCNTs on a curved surface of Au wire, resulting in linearly increased areal capacitance of the fabricated WSS. Vanadium oxide is encapsulated onto LbL-assembled MWCNTs electrode to induce pseudo-capacitance, enhancing overall capacitance of the fabricated WSS. Cyclic stability of the WSS is enhanced via optimizing the mixing ratio of PC to ACN in the electrolyte. As a result, the fabricated WSS exhibits areal capacitance of 5.23 mF/cm2 at 0.2 mA/cm2, energy density of 1.86 μWh/cm2, and power density of 8.5 mW/cm2, in addition to 94% capacitance retention after 10,000 galvanostatic charge-discharge cycles. Furthermore, the WSSs are easily integrated into a textile to drive integrated μ-LEDs. This work demonstrates a high potential of the scalable WSS as an energy storage device in application to high performance textile electronics.

SESSION ET07.11: Novel Energy Devices and Materials
Session Chairs: Peter Smyrek and Yuefei Zhang
Thursday Afternoon, November 29, 2018
Hynes, Level 3, Room 312

1:30 PM ET07.11.01
Fabrication and Performance Analysis of All-Solid-State Flexible Porous 3D Graphene/Waste Composite Micro-Supercapacitor Gourav Bhattacharya1, Sam Fishlock2, James McLaughlin2 and Susanta Sinha Roy1; 1Department of Physics, Shiv Nadar University, Gautam Buddha Nagar, India; 2NIBEC, University of Ulster, Newtownabbey, United Kingdom.

Rapid depletion of non-renewable energy resources and ever-increasing demands for power made researches to focus into advanced energy materials for power generation and green energy storage. Among several other energy storage devices, supercapacitor has garnered large attention as an alternative portable power source and storage device. Recently, to encounter the huge global requirement of portable and wearable electronics, high-performance, flexible, inexpensive, and sustainable micro-supercapacitor systems are being studied. Herein by employing electrochemical technique, the potential application of an all solid-state flexible solid-state hybrid micro supercapacitor was investigated. A 3-D hierarchically porous graphene nano-ribbon structure (LIG) with high surface area, was synthesized on a flexible polymer substrate (polyamide) using Laser scribing technique. An industrial waste material red mud which is an abundant source of iron oxide (Fe2O3) was further mechanically processed to produce metal oxide nanoparticles. These nanoparticles were decorated on the LIG film and acted as the pseudocapacitor component of the hybrid electrode. The composite electrode material was further characterized using transmission electron microscopy (TEM), field effect scanning electron microscopy (FESEM), Raman spectroscopy, cyclic voltammetry (CV) etc. An interdigitated planar hybrid micro-supercapacitor device was fabricated over the polymer substrate where polymer-based composite ionic liquid-gel electrolyte was casted over the hybrid electrodes. Inkjet printing was further employed to print silver and was acted as the current collector. The performance of the device was monitored using CV, charging/discharging (CD) and electrochemical impedance spectroscopy (EIS). The device exhibited a high sp. capacitance within an active working potential of ~3.8 V which further enhances the energy density of it. The micro-supercapacitor also exhibited good long-term cycling stability. The swift lateral ion movement in the planar device, more accessible electrochemically active surface area, better charge transfer kinetics, presence of composite electrolytes contributed to the high electrochemical performance of the device. The inexpensive, lightweight, easy to construct device is thus a great potential and can offer new opportunity for integration of energy storage units with flexible electronic devices.

Ultra-High-Rate Aqueous Zinc-Ion Batteries for Shape-Conformal Integration of Wearable Electronics Chanhoon Kim1, Bok Yeop Ahn1, Teng-
The push towards miniaturized electronics requires the development of smaller battery, which has typically been one of the biggest components in the small electronics. With the selective miniaturization, customized geometries of the batteries may allow unprecedentedly comfortable and form-fitting design in the miniaturized electronics as well as wearable electronics. Nevertheless, the conventional battery design is confined to the rigid shapes, limiting its versatility. Here, we introduce the customized battery geometries for miniaturized and wearable electronics by optimized combination of 3D printing, electrospinning, and laser micromachining techniques. Pursuing easy processing and high safety, we have devised aqueous zinc-ion battery (ZIB) system in the customized geometries which consist of a conductive polyaniline (PANI) coated carbon fiber cathode, a porous separator, and a zinc (Zn) anode. The highly conductive 3D structured CF mat facilitates fast electron transfer even for relatively thick cathodes (~320 um) and the highly porous PANI conformally coated on the CF also significantly contributes to fast ion diffusion in cathode layers. By the virtue of the rationally designed cathodes, the ZIBs were charged to about 50% and 20%, respectively. Moreover, we use laser micromachining for customizing cell components (electrodes, separator, and terminals) corresponding to the shapes of SLA-printed packaging geometries. Notably, this is the first demonstration of the SLA technique, which has been widely used in many fields for prototyping custom-shaped complex plastic structures in ~ 100 μm resolutions for designing small batteries. The ZIBs with various geometries, including rectangular, cylindrical, H-, and ring-shapes retained the excellent electrochemical performances. Furthermore, we fabricated a wearable photosensor by shape-conformally integrating a ring-shape battery pack with electronic components to demonstrate the merit of our approach. We believe that the ability to fabricate power sources in any shapes and sizes as needed may open new revenues to shape-conformal integration of miniaturized and wearable electronics.

2:00 PM ET07.11.03
Light-Assisted Polymer-Based Electrochemical Energy Storage
Abdelaziz M. Gouda1, Ri Xu1, Francesca Soavi2 and Clara Santato1; 1Engineering Physics, Ecole Polytechnique Montreal, Montreal, Quebec, Canada; 2Chemistry, University of Bologna, Bologna, Italy.

The development of efficient solar energy conversion/storage technologies is critical to limit the negative effects of anthropogenic climate change on Earth. Electrochemical technologies have been widely investigated to capture the power generated from intermittent sources, like the Sun. High performance storage solutions, such as batteries and supercapacitors, make use of toxic electrode materials and organic electrolytes with limited environmental sustainability. Nature could be the source of abundant and environmentally benign materials to be used in next generation batteries and supercapacitors, paving a way towards a sustainable use of resources. Among natural materials, eumelanin is a functional biomacromolecule found in flora and fauna with fascinating properties, such as strong broadband UV-visible absorption, redox activity, metal binding affinity, humidity-dependent electrical response as well as good thermal and photostability [1]. DH1 (5,6-dihydroxyindole) and DHICA (5,6-dihydroxyindole-2-carboxylic acid) are the two building blocks of melanin. The synergy between the reduction/oxidation (redox) activity of the building blocks and the capability of several of their functionalities to reversibly bind cations constitutes the foundation for the use of eumelanin in energy storage systems [2]. Photoconductivity of melanin in different form such as pellets and thin films has been reported in the literature [3] motivating current efforts for using this photoactive bio-pigment in solar assisted electrochemical energy storing systems. [2][4][5]. We were capable to overcome the limited processability of melanin by adopting a solid state polymerization strategy for its fabrication. In this way we could keep the environmental friendliness of the melanin controlling its (supra)molecular structure and processability.

In this work, we report about a two symmetric electrode-system based on chemically controlled melanin wrapped with PEDOT: PSS on carbon paper current collectors. PEDOT:PSS enhances electronic transport and intermolecular connectivity between the melanin chains [6]. The electrode materials are processed by simple, solution-based methods. The electrochemical storage properties are evaluated for different chemically controlled eumelans: polyDHI, polyDHICA and polyDHI:polyDHICA in dark and light condition, using cyclic voltammetry and galvanostatic charge/discharge cycles.

2:15 PM ET07.11.04
Electrodeposition of MoS2 on Three-Dimensional Graphene/Nickel Foam for Electrocatalytic Water Splitting
Narasimman Rajaram, Mannoohansingh Waldiya, Indrajit Mukhopadhyay and Abhijit Ray; Pandit Deendayal Petroleum University, Gandhinagar, India.

Rapidly depleting fossil fuel and CO2 emission from the utilization of fossil fuels lead to the development of sustainable, clean and renewable alternate energy sources. Hydrogen is considered as a suitable candidate because it is having high energy density and zero gas emission. Among the various methods of production of hydrogen, electrochemical water reaction (HER) in electrochemical water splitting is considered as the most promising and environmentally friendly approach. Noble metals like Pt, Pd, etc., are known to effectively catalyst the HER, however, scarcity and high-price is restricting the large-scale production of hydrogen. Transition metal dichalcogenides (TMDC) such as MoS2, WS2 are widely studied electrocatalysts for HER in acidic medium. Also, three-dimensional (3D) electrodes are advantageous because of the porous and interconnected structure which increases the surface area and effective mass transport. In this study, we have electrodeposited MoS2 on to the graphene coated nickel foam (graphene/nickel foam). Graphene/nickel foam was prepared by APCVD technique at 800°C. The graphene was coated uniformly on nickel foam and it consists of 5-8 layers. The graphene/nickel foam was used as the electrode for the electrochemical deposition of MoS2. The cathodic electrodeposition of MoS2 on graphene/nickel foam was carried out by applying the potential of -1.2 V vs. (Ag/AgCl) for 20 mins. The morphology was evaluated by scanning electron microscopy and formation of MoS2 was confirmed by Raman spectroscopy. Freshly prepared samples were evaluated for HER in 0.5 M H2SO4 by linear sweep voltammetry, Tafel slope and electrochemical impedance study.

Enhanced Photoelectrochemical Water Splitting of Heteroisopetaxial Grown Hematite Nanowires
Kirtiman D. Malviya and Avner Rothscheld; Technion–Israel Institute of Technology, Haifa, Israel.

Hematite (α-Fe2O3) is a promising photoanode candidate for photoelectrochemical (PEC) cells for solar water splitting due to a unique combination of visible light absorption, stability in alkaline aqueous solutions, low cost, and abundance. However, the performance of the hematite photoanode is reported to be low and therefore different nanostructuring, and novel design microstructure is adopted to improve PEC performance. A simple and optimal design to facilitate the charge transfer in bulk is paramount important to achieve enhanced solar to fuel efficiency. Herein we report a simple and highly reproducible method of fabrication of multilayer heteroepitaxial grown Nb-doped SnO2/ hematite film on c-plane Al2O3 single crystal substrate and a series of systematic experiments to elucidate the effect of the microstructural variation on the photoelectrochemical properties. The microstructure varies from dense film to...
nanowire to defected porous structure depending on the growth conditions. To the best of our knowledge first time, we are reporting the heteroepitaxial growth of thin film hematite consists of dense nanowires (~10-30 nm diameter and ~600 nm length) with a photocurrent of 1.3 and 1.1 mA/cm² at reversible (1.23 V_RHE) and thermonutral potentials (1.48 V_RHE) respectively with bare hematite. Also, the reported results are higher than the most of the recently reported state-of-art fabrication methods. In this work, we have investigated the effect of polycrystalline/heteroepitaxial film thickness, the deposition temperature, oxygen partial pressure and the dopant concentration and their effect on the bulk and surface charge separation and injections efficiency. The effect of the surface treatment and the deposition of co-catalyst can further enhance the PEC properties which will be discussed during the presentation.

Exploration of V Doped SnO2 Nanocrystals for Thermochemical H2 Generation Vined Kumar1, Dinesh Gupta2 and Sachin Kumar Sharma3; 1Conversion & Catalysis Division, Indian Institute of Petroleum, Dehradun, India; 2Chemistry, KIITR Mal College, University of Delhi, Delhi, India; 3Chemical Engineering, Indian Institute of Technology Delhi, Delhi, India.

Production of energy is the global concern, which needs to be addressed soon; otherwise, we will be in great problem. Dihydrogen is one of the reliable green energy source having high caloric value. There are several techniques to generate hydrogen as a fuel such as electrolysis, photoelectrochemical, photocatalytic approach, thermochemical water splitting etc. However, practically mass production, economic value, storage and usage of hydrogen as a fuel is still a challenging task. The hydrogen generation by splitting of water using various metal oxides has been reported for many years but their use is not applicable off-sun hours, cloudy or rainy day that restrict them for their commercialization. However practically mass production and usage of hydrogen as a fuel is still a challenging task. An alternative approach needed to be explored for commercial mass production of hydrogen. It is an hour of need to explore better approach for commercial and economical production of dihydrogen. Among these techniques, thermochemical water splitting can be utilized for mass production of hydrogen as a fuel. Several materials have been used for thermochemical water splitting especial binary metal oxides CeO2, TiO2, SnO2, CuO2, MnO etc. CeO2 is having the good efficiency for 100 cycles but require high thermal energy. SnO2 may be the promising material; in reversible (1.23 V_RHE) and thermonutral potentials (1.48 V_RHE) respectively with bare hematite. Also, the reported results are higher than the most of the SnO2 at lower thermal energy and show good efficiency for 10 cycles.

Low Temperature Fabrication of Dense Y-Doped BaZrO3 Electrolyte by Utilizing the Co-Firing with the Anode Substrate Shrinking Well for Proton Conducting Solid Oxide Fuel Cell Yuki Yamaguchi, Hiroyuki Shimada, Toshiaki Yamaguchi, Hirofumi Sumi, Katsuhiro Nomura and Yoshinobu Fujishiro, AIST, Nagoya, Japan.

Y-doped BaZrO3(BZO) is widely known as a proton conducting material which shows the high ionic conductivity at intermediate temperature between 400 and 700°C. Thus, it is promising candidate of electrolyte material for the intermediate temperature solid oxide fuel cells (IT-SOFC). BaZrO3(BZO) base proton conducting material has a good durability for CO2-composed with BaCeO3 base materials. However, the sintering temperature of BZO is quite high. High temperature heat-treatment more than 1700°C is required to obtain the dense body of BZO. Particularly for the fabrication of anode supported type SOFC, an electrolyte layer was prepared by co-firing with anode substrate. When the cells are fired at higher temperature to obtain the dense electrolyte, the porosity in anode will be disappeared due to the densification of anode. Therefore, we developed the low temperature fabrication process of the proton conducting SOFC by utilizing the fine powder of BZO having a good sinterability, in this study.

BZO powders were prepared by the novel low temperature synthesis which can prepare the BZO by only mixing the zirconia hydrous gel and the barium hydroxide octahydrate at 100°C for 12 h. The 2 mol% doped BZO had ca. 30 nm of primary particles with quite high crystallinity. Y doping amount could be controlled up to 30 mol% by the addition amount of Y ions to the zirconia hydrous gels. For the strongly shrinking anode substrate, Sr and Ti co-doped BZO powders were also prepared by the same method. It has been reported that the addition of some metal elements, such as Zn and Ni, were effective to decrease the sintering temperature of BZO. However, the cell voltage of BZO was decreased by the hole conduction in the electrolyte layer, because the holes were generated in the BZO electrolyte by the substitution of lower valence metal elements to Zr⁴⁺ sites. In this study, Sr²⁺ and Ti⁴⁺ were substituted to Ba²⁺ and Zr⁴⁺ sites, respectively. The sintering temperature of Sr and Ti co-doped BZO (BSZTY) powder was 200°C lower than that of BZO. BSZTY could be sintered at 1400°C. Then, BZO electrolyte layers were fabricated on the anode substrates including BZY-NiO by firing at 1400°C. When the BZO electrolyte layer was fabricated on the anode including the BZY-NiO, the electrolyte layer could not densify due to the high sintering temperature. In the contrast, the dense BZO electrolyte on the anode substrate of BSZTY-NiO was successfully obtained by firing at 1400°C. Besides, the grain growth of BZO was also observed. It was considered that the large shrinkage of anode substrate including BSZTY enhanced the sintering the BZO electrolyte layer. Using the BSZTY for anode material, the proton conducting cell having BZO electrolyte could be obtained by co-firing at 1400°C. This cell showed a high open circuit voltage (OCV) more than 1.0 V at 600°C. It was considered that the excessive hole generation did not occur.

3:45 PM ET07.11.08

Titanium Oxynitride Thin-Films with Large Power Conversion Efficiency in Photovoltaic Solar Cells Nikhil R. Mucha1, Michael Froeschle2, Mark Anderson3, Panupong Jaipan1, Hemali Rathnayake2, Christian Binek3, Jeffrey Shield3 and Dhananjay Kumar1; 1North Carolina A&T State University, Greensboro, North Carolina, United States; 2Nanoscience, University of North Carolina at Greensboro, Greensboro, North Carolina, United States; 3Earth Science, University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 4Physics, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

A novel TiO₃N₂(Ti-N-O) material system in thin film form has been synthesized using a pulsed laser deposition method. The photovoltaic solar cells constructed out of Ti-N-O in ITO-TiNO-Cu configuration have yielded a maximum power conversion efficiency (PCE) of 12.5% with short circuit current
density ($J_{sc}$) of 36.50 mA/cm², open circuit voltage ($V_{oc}$) of 0.21 V, and fill factor (FF) of 57.4%. This is the highest PCE reported to date for any derivative of thin film based-Ti-N-O system as an active layer material in bulk heterojunction (BHJ) solar cells. The extraordinarily high values of power conversion efficiency have been attributed to the existence of a multi-bandgap-mediated electron-hole transfer pathway. X-ray diffraction and x-ray photoelectron spectroscopy measurements lend evidence in support of multi-bandgap mediated transfer of charge carriers by confirming the presence of Ti-N-O, Ti-N, and Ti-O chemical bonding states. The titanium oxynitride (TiNₓOᵧ) system has the potential to absorb visible light in the full solar spectrum.

4:00 PM ET07.11.09
MnFe₂O₄ Nanoparticle-Pigmented High-Temperature, Thermodynamically-Stable, Long-Term Antioxidation Solar Selective Absorber Coatings Eldred Lee¹, Can Xu¹, Katerina Kekalo¹⁻², Jifeng Liu¹ and Xiaoxin Wang¹; ¹Dartmouth College, Hanover, New Hampshire, United States; ²U.S. Air Force, Hanover, New Hampshire, United States.

Photovoltaic (PV) technology for solar electricity is in high demand but the flexibility on long term energy storage. Therefore, concentrated solar power (CSP) systems need to complement the PV technology to increase energy output. The efficiency of CSP systems can improve with high absorption in the solar spectrum regime and low emittances in the infrared spectrum. However, CSP systems can be expensive. High-temperature, air-stable solar selective absorbers made with cermet composite materials that have optimal properties of both ceramic and metal can be the solution to this goal; however, this achievement has been difficult due to metal oxidation at high temperatures. Here, we demonstrate outstanding optical responses of thermodynamically-stable, high-temperature, low-cost long-term antioxidation cermet solar selective absorbers using MnFe₂O₄ nanoparticles (NPs) with silicone precursors as low-cost Si-rich matrices that undergo interdiffusion reaction with Stainless Steel 310 (SS310) and Inconel 625 substrates. Current state-of-the-art product such as the Pyromark® black paint has a significantly high solar absorbance (~95%) in the solar spectrum regime but also has a high emittance loss (~87%) in the infrared spectrum. To decrease the emittance while maintaining high absorbance, we have undergone antioxidation interfacial engineering in Ni/SiO₂ by creating low-cost solution-processed Ni nanochain-SiO₂ (X<2) selective solar thermal absorber coatings. When these coatings are deposited on metal substrates, the oxidation of the metal as well as the interdiffusion between the coatings and the substrates can exceed the optical responses of the coatings themselves. As there are low-cost NPs that exceed the optical responses of Ni in the desired spectrum, further investigation has been done with interdiffusion-induced selectivity testing using silicone precursors with varying molecular weight as low-cost Si-rich matrices for interdiffusion reaction with different low-cost NPs that have metal-like optical absorption properties and ceramic-like chemical stability and metal substrates. Thin layers of various NP-silicone matrix coatings were deposited on metal substrates using market-available low-cost perfume sprays. To test the stability, the samples were annealed in air at 750°C up to 1000 hours. Up to this date, solar selective absorber coatings with 28nm MnFe₂O₄ NPs and a high molecular weight silicone matrix on SS310 and Inconel 625 substrates result in the most ideal absorption up to 97% in the solar spectrum regime and the reduction of emittance down to 30-40% in the infrared regime, which are confirmed by UV/VIS/NIR spectrophotometer and an FTIR spectrometer. These coatings on SS310 and Inconel 625 substrates were found to be stable in air in 750°C and the optical responses in the desired spectrum have either maintained or improved. Such solution can lead to a newer and innovative approach to create better low-cost and improved solar selective absorber coatings.

A Solvent Toolkit for Electrochemical Characterization of Hybrid Perovskite Films Mehdedhi Hasan¹, Dmitry Lyashenko¹, Jason D. Slinker² and Alex Zakhidov¹; ¹Texas State University, San Marcos, Texas, United States; ²The University of Texas at Dallas, Dallas, Texas, United States.

Organohalide lead (hybrid) perovskites have emerged as competitive semiconducting materials for photovoltaic devices due to their high performance and low cost. To further the understanding and optimization of these materials, solution based methods for interrogating and modifying perovskite thin films are needed. In this work, we report hydrofluoroether (HFE) solvent based electrolyte for electrochemical processing and characterization of organic-inorganic trihalide lead perovskite thin films. Organic perovskite films are soluble in most of the polar organic solvents and thus allow electrochemical characterization of the electronic structure, investigation of charge transport properties and potential electrochemical doping of the films with in situ diagnostic capabilities.

4:30 PM ET07.11.12
Spray-on “CdO:Mn:Sn/PhS:Na:CdS” Thermoelectric Energy Harvester Francesco Javier Gonzalez²⁻¹, Isaiah Oladeji²⁻³ and Robert E. Peale²⁻⁴; ¹Universidad Autonoma de San Luis Potosí, San Luis Potosí, Mexico; ²Truentive LLC, Orlando, Florida, United States; ³SISOM Thin Film LLC, Orlando, Florida, United States; ⁴Physics, University of Central Florida, Orlando, Florida, United States.

Thermoelectric (TE) thin films have promise for harvesting electrical energy from waste heat, which could power wearable electronics and enable conformal application to complex surfaces for enhanced thermal coupling. We demonstrate an n-type CdO-Mn:Sn and p-type P6S:Na:CdS thin-film TE device that was deposited by aqueous spray deposition on glass and flexible Uplex S substrates using a shadow mask. With the junction at 100 deg C, the open circuit voltage between p- and n-type free ends at 25 deg C is +13.6 mV. The short circuit current is 15 nA, giving ~0.2 mW of power for the single junction and the given temperature difference. Several thermocouples connected electrically in series and thermally in parallel will multiply the output voltage. The Seebeck coefficient (thermoelectric power) for this first device is ~0.2 mV/C, which is comparable to known values for other semiconductor thermocouples and may be improved by optimization. Numerical simulations using COMSOL. Multiphysics are used to obtain figures of merit for comparison to experimental results.

Synergy of Optimized Topological Structure and Phase-Composition Boosts Ultrahigh Discharge Efficiency in High-Energy-Density Polymer Nanocomposites Jianyong Jiang, Yang Shen and Ce-Wen Nan; Tsinghua University, Beijing, China.

Poly(vinylidene fluoride) (PVDF)-based dielectric polymers are in great demand for the future electronic and electrical industry because of their high

Here we introduce a sustainable and general method for fabricating 2D heterostructures from solution. Assembly of 2D materials from solution may allow fabrication of 2D heterostructures. There has not been any systematic study and attempt at developing a method to systematically optimize these solutions for Layer-by-Layer self-assembly of multilayered pillared structures. These results can pave the way for large-scale production of 2D heterostructures.

The problem, however, is that stacking of 2D materials at large scale and with high precision is difficult. It has been suggested that Layer-by-layer assembly of 2D materials from solution may allow fabrication of 2D heterostructures. There has not been any systematic study and attempt at developing a method to systematically optimize these solutions for Layer-by-Layer self-assembly of multilayered pillared structures. These results can pave the way for large-scale production of 2D heterostructures.

The climax of photocatalytic overall water splitting in powder suspension form is the simultaneous occurrence of electrocatalytic hydrogen evolution and oxygen evolution. In order for a semiconductor powder to achieve both reactions, the chemical potential at the surface should be shifted negatively and positively at the redox sites. It is however difficult to quantitatively describe such potentials of the powder suspension system. Knowledge transfer from electrocatalytic measurement to photocatalysis is effective to estimate the difficult-to-measure potentials of the photocatalytic system. This contribution discusses the effectiveness of electrocatalytic measurements to understand photocatalytic behavior, mainly focusing on hydrogen evolution catalysis and water-forming back reaction.

Successful photocatalytic overall water splitting is achievable when the water-forming back reaction from H2 and O2 to form H2O does not prevail. Although decoration of hydrogen evolution catalysts on the semiconductor powder is often essential to achieve high photocatalytic efficiency, the same catalyst surfaces often introduce the thermodynamically-favorable back reaction. We show that the suppression of the back reaction is achievable when the semiconductor powder is decorated with highly dispersed noble metal catalysts, such as Pt species, with tungsten carbide nanoparticles, or with hydrogen-evolving catalysts covered with membrane-function layers, such as CrOx, MoOx, and SiOx. To elucidate the catalytic rates for both forward (hydrogen evolution) and backward (water formation) reactions, electrocatalytic measurements are effectively utilized where the potential of the catalysts is determined.

In a similar way, the importance of electrolyte identity is evaluated mainly at near-neutral pH by effectively comparing electrocatalysis and photocatalysis. It is well accepted that buffering action is considered inevitable especially at high rates, but our elucidation pins down such effects quantitatively, dividing the functions into solution resistance, concentration overpotential, and kinetic contribution in a photocatalytic system. Such electrolyte engineering may lead to the discovery of new reaction environments for water electrolysis in more benign conditions and more towards membrane-less systems.

8:30 AM *ET08.01.01
Elucidation of Electrocatalysis to Understand Photocatalytic Overall Water Splitting Kazuhiro Takanabe1, 2; 1The University of Tokyo, Toride, Japan; 2King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

The developing of renewable fuel sources requires highly efficient and robust pathways to convert earth abundant resources into high energy fuels, as well as efficient methods to convert the energy stored in chemical bonds into useable power. At each step of the fuel cycle, high performance catalysts are essential. Transition metal phosphides (TMP) have proven to be highly active and stable catalysts and are of great interest for the hydrogen evolution reaction (HER), oxygen evolution reaction (OER), oxygen reduction reaction (ORR) and carbon dioxide reduction to hydrocarbon fuels. However, a detailed understanding of the role of phosphorous is still emerging, and even for the case of HER the performance has previously lagged behind that of the Pt benchmark.

We presented a detailed theoretical and experimental study in which we synthesize nanocrystalline CoP, particles with highly uniform size, allowing a systematic comparison of performance. The phosphorous rich CoP and CoP2 TMPs, as oppose to Co2P, are highly effective and selective catalyst toward HER and ORR. In fact CoP2 exhibits Pt-like performance at small overpotential of 39mV to achieve -10 mA/cm2 and long term stability. The role of P in promoting catalysis must be understood by considering multiple effects: reducing the number of tightly bound multi-coH adsortion sites, increasing the surface disorder, and increasing the Co-H bond length. We will present both data from our recent publication (Adv. Mater. 2018, 30, 1705796) as well as our new results for high-performance CoP2 HER catalysts. The conclusions drawn from this study will be highly relevant to the broader energy catalysis community, and the study of TMP catalysts in particular.

Comprehensive Kinetic Analysis of Photocatalytic Water Oxidation and Reduction at TiO2 Surface Maning Liu1 and Yasuhiro Tachibana1, 2; 1RMIT University, Bundoora, Victoria, Australia; 2Osaka University, Osaka, Japan.

Solar water splitting is one of the most attractive energy generation reactions to utilize solar energy. Light generated hydrogen is clean energy source, since their consumption for energy generation produces only water. Moreover, it can be stored and used whenever required. Semiconductor TiO2 is known as a photocatalyst and was investigated for solar water splitting reactions over the last several decades. TiO2 has still been employed to assess the capability of photocatalysis reactions. The water splitting kinetic reaction mechanism at the TiO2 surface has been elucidated, particularly employing transient absorption spectroscopy, however detailed understanding of the mechanism remains to be clarified.

In this presentation, we will demonstrate quantitative assessment of photocatalytic water splitting mechanism at the TiO2 surface by employing a series of transient absorption spectroscopies covering from fs to 10 s over UV-VIS-NIR wavelength ranges. The reaction paths and their dynamics at the charge trap states will be discussed.

This work was partly supported by JSPS KAKENHI Grant Number 16K05885, Japan. We also acknowledge supports from ARC DP fund (DP180103815) and ARC LIEF fund (LE170100235), Australia, and Office for Industry-University Co-Creation at Osaka University.

9:15 AM ET08.01.03

The developing of renewable fuel sources requires highly efficient and robust pathways to convert earth abundant resources into high energy fuels, as well as efficient methods to convert the energy stored in chemical bonds into useable power. At each step of the fuel cycle, high performance catalysts are essential. Transition metal phosphides (TMP) have proven to be highly active and stable catalysts and are of great interest for the hydrogen evolution reaction (HER), oxygen evolution reaction (OER), oxygen reduction reaction (ORR) and carbon dioxide reduction to hydrocarbon fuels. However, a detailed understanding of the role of phosphorous is still emerging, and even for the case of HER the performance has previously lagged behind that of the Pt benchmark.

We presented a detailed theoretical and experimental study in which we synthesize nanocrystalline CoP, particles with highly uniform size, allowing a systematic comparison of performance. The phosphorous rich CoP and CoP2 TMPs, as oppose to Co2P, are highly effective and selective catalyst toward HER and ORR. In fact CoP2 exhibits Pt-like performance at small overpotential of 39mV to achieve -10 mA/cm2 and long term stability. The role of P in promoting catalysis must be understood by considering multiple effects: reducing the number of tightly bound multi-coH adsortion sites, increasing the surface disorder, and increasing the Co-H bond length. We will present both data from our recent publication (Adv. Mater. 2018, 30, 1705796) as well as our new results for high-performance CoP2 HER catalysts. The conclusions drawn from this study will be highly relevant to the broader energy catalysis community, and the study of TMP catalysts in particular.

9:30 AM ET08.01.04
Defect-Engineered Interface Assembly for Efficient Electrocatalyst Kishwar Khan and Zhengtang Luo; Hong Kong University of Science & Technology, Kowloon, Hong Kong.
The expansion of economical, effective, and durable electrocatalysts for the oxygen reduction reaction (ORR), oxygen evolution reaction (OER), and hydrogen evolution reaction (HER) have significant importance aimed at numerous electrochemical devices, such as fuel cells, water electrolyzer, and rechargeable metal-air batteries. Heterometal-doped catalyst has arisen as one of the best emergent candidate to replace the metal based marketable catalyst for electrochemical reactions. But, their delicate structure parameters to optimize the catalytic capability, and atomic-level mechanistic understanding are still a challenging issue. Herein, we advocate the assembly of separate single atoms of Ni and Fe (SSAs-NiFe) dual sites, anchored in defects engineered graphene (DG) substrate prepared by a facile nitrogen (N) elimination procedure from an N-doped precursor by an adsorption-calcination strategy. The concept of defect mechanism, exhibited the topological defect (e.g. multiple pentagon—octagon—pentagon or pentagon—heptagon—pentagon rings) correspondingly appeared in carbon atoms combination that avoid dislocations and disclinations. We believe that these specific combination of carbon atom rings in defective substrate with the decoration of Ni and Fe SSAs can provide more active sites, better electrical conductivity, and lowest energy barrier during catalytic reaction. We used the combination of high resolution transmission electron microscopy/high-angle annular dark field (HAADF) images established in scanning transmission electron microscopy (S/TEM) for studying the atomic structure of Ni and Fe isolated atoms on DG. At very low magnification (1nm) the individual atoms Ni and Fe in the field of view is detected through S/TEM, and resolved in graphene lattices. The electron energy loss spectroscopy (EELS) atomic spectra are used to identify the Ni/Fe SSAs in DG. The chemical insights structure of the material are examined by pre-edge peaks in X-rays absorption near edge structure (XANES) spectra. We demonstrated the electrocatalytic performance of SSAs-NiFe-DG hybrid material in acidic/alkaline mediums, and found it very active and stable trifunctional electrocatalyst for ORR, OER and HER. This work offers new prospects and underscores the importance of identifying the active species for multiple reactions catalysts and demonstrates how such knowledge can be applied to develop better multifunctional catalysts.

Carbon Nanodots as Efficient Photosensitizers for “Green” Solar Fuel Production Demetra S. Achilleos, Haticke Kasap and Erwin Reisner; Christian Doppler Laboratory for Sustainable SynGas Chemistry, Department of Chemistry, University of Cambridge, Lensfield Road, Cambridge CB2 1EW, UK., University of Cambridge, Cambridge, United Kingdom.

The accelerated consumption of fossil fuels and the emerging ecological concerns, due to the alarming concomitant rise in greenhouse gas emissions, emphasize the need for the society to move towards renewable “green” resources. Photocatalysis is a promising approach for mitigating simultaneously both the energy and environmental concerns, since it allows the storage of the abundant solar energy in high energy density fuels, such as H2(120 MJ/kg,1) in benign aqueous media. However, the development of economically sustainable processes for this purpose, creates the pressing need for new photosensitizers and catalysts of low cost and toxicity, which however maintain substantial performances. Carbon dots (CDs) can efficiently serve as photocatalysts for this purpose since they fulfill all these requirements.2-4 In particular, CDs are hydrophilic nanoparticles of low toxicity, which can be synthesized at low cost, are chemically and photochemically robust and show optimum photocatalytic properties upon pre-designed synthesis.5-6 In this work, we focus on the synthesis of CDs from naturally abundant and inexpensive biopolymers of various compositions and nanoarchitectures, which bestow the derived photocatalysts with distinctive photocatalytic performances. These light harvesters when combined with noble-metal free molecular catalysts in aqueous-based photocatalytic systems, not only allow for substantial “green” fuel synthesis but also simultaneously facilitate waste oxidation. Such substrates which originate from numerous resources and are abundantly available at no cost, serve as electron donors to quench the photogenerated holes and maintain the photocatalytic stabilities of the systems. The use of waste materials for this purpose, eliminates the need for additional sacrificial reagents,4 traditionally used in great excess, which add to the overall cost of the processes, and often result in by-products which need to be disposed. We anticipate that this approach, could be a breakthrough in the development of scalable, economically and environmentally sustainable photocatalytic systems, which could efficiently serve the increased energy needs of our societies.

References
spectrum up to the visible region, as well as to achieve a high quantum efficiency in the photocatalytic process. Introducing two-step photoexcitation (i.e., Z-scheme) in water splitting has been recently proven as one of the most promising strategies for harvesting a wider range of visible light. In this system, the water-splitting reaction is broken up into two stages: one for H₂-evolution, and the other for O₂-evolution. These are combined using a shuttle redox couple in solution. In Z-scheme water splitting systems with an IO₃⁻/I⁻ redox couple, the reduction of IO₃⁻ on O₂-evolving photocatalysts via a six-electron process often represents the rate-determining step of the overall process, and therefore necessitates effective cocatalysts such as RuO₂ and Ru₂O₃. However, these cocatalysts cannot be loaded onto thermally unstable materials via conventional impregnation processes involving calcination. In the present study, we introduce a new Ru-based cocatalyst that can be loaded without calcination and effectively promotes the reduction of IO₃⁻ on various photocatalysts, including non-oxide materials. The results reveal for the first time that the Ru species adsorbed via simple stirring of photocatalyst particles such as WO₃ in an aqueous RuCl₃ solution effectively trigger O₂ generation in the presence of IO₃⁻ as electron acceptor; moreover, the O₂ evolution rate on the present Ru-

Solar to hydrogen (H₂) energy conversion represents the Holy Grail of energy science and technology. For decades, numerous materials have been developed and used as photocatalysts for this purpose. However, their inadequate visible light absorbance, poor stability and fast charge recombination have prevented their widespread industrial-scale deployment. Additionally, the use of noble metal-based co-catalysts and the toxicity of the majority of electron donors employed in these photocatalytic systems limit the profitability of this technology. This study aims to tackle these issues using a two-fold strategy. Firstly, we systematically studied the impact of different transition metal-based co-catalysts towards the photocatalytic water reduction, when they are physically mixed with the visible-light active MIL-125-NH₂. All co-catalyst/MIL-125-NH₂ photocatalytic systems were found to be highly stable after photocatalysis, with some systems exhibiting high hydrogen (H₂) evolution rates of >2000 μmol h⁻¹ g⁻¹. Secondly, we investigated how different electron donors affected the stability and H₂ generation rate of the best photocatalytic system and found that triethylamine fulfills both requirements. We then replaced the electron donor with dyes that are commonly used as simulant organic pollutants, with the aim of integrating the visible-light driven H₂ evolution with dye degradation in a single process. This is the first study where a metal-organic framework (MOF) system is used for this dual-photo catalytic activity under visible light illumination and our proof-of-concept approach envisions a sustainable waste-water remediation process driven by the abundant solar energy, while H₂ is produced, captured and further utilized. **Resolution of Electronic and Structural Factors Underlying Oxygen-Evolving Performance in Amorphous Cobalt Oxide Catalysts**

David M. Tiede¹, Gihan Kwon², Hoyoung Jang², Jun-Sik Lee², Anil Mane¹, Alex Martinson¹, Hacksung Kim³ and Jungho Kim³; ¹Materials Science Division, Argonne National Laboratory, Argonne, Illinois, United States; ²Stanford Synchrotron Radiation Light Source, SLAC National Accelerator Laboratory, Menlo Park, California, United States; ³Chemical Sciences and Engineering Division, Argonne National Laboratory, Argonne, Illinois, United States; ⁴X-ray Science Division, Argonne National Laboratory, Argonne, Illinois, United States.

Non-noble-metal, thin-film oxides are widely investigated as promising catalysts for oxygen evolution reactions (OER). A key challenge for gaining insight into mechanisms for thin-film photo- and electro-catalytic OER function lies in resolving the interplay between intrinsic catalytic activity of
catalytic sites and the electronic structure and charge transport properties of the thin-film OEC. Transition metal (oxy)hydroxides show linked electron-proton conductivity which confers a volume rather than a surface area dependent activity to the films. This is understood to arise from homogeneously distributed and accessible catalytic sites though out the film, and with the catalytic current densities determined by the product \( \kappa_{a} \kappa_{e} \) of the catalytic rate, \( \kappa_{a} \), and electron-proton conductivity, \( \kappa_{e} \). As a result, understanding OER function for transition metal (oxy)hydroxide requires the structural basis for both catalysis and electron-proton conductivity to be addressed.

We have investigated amorphous cobalt oxide films electrochemically formed in the presence of borate (CoBi) and phosphate (CoPi) as a means to resolve structural and electronic factors that underlie OER performance in cobalt (oxy)hydroxides. CoPi and CoBi share a common cobaltate domain building block, but differ significantly in OER performance that has been proposed to derive from different electron-proton charge transport properties. In this report, we provide a comparison of CoBi and CoPi OER performance and bulk electronic properties, and correlate these to the electronic and structural properties measured at the atomic scale using a combination of soft X-ray absorption (XAS), resonant X-ray emission (RXES), resonant inelastic X-ray scattering (RIXS), and resonant vibrational Raman scattering (RR) techniques. This combination of analytical approaches show CoBi and CoPi to have characteristic differences in electronic structure that provide a basis for understanding enhanced conductivities for CoBi compared to CoPi as thin film OEC. In particular, the results show that the cobaltate domains for these OEC differ in the content of tetrahedral Co(II) “defect” sites, the extent of oxygen-mediated metal-metal delocalization, and mesoscale ordering that can be understood to combine and support enhanced electron-proton conductivity in CoBi compared to CoPi. More generally, this work demonstrates opportunities to use the combination of soft XAS, RXES, RIXS for investigating the interplay between intrinsic catalytic activity of catalytic sites and the electronic structure and charge transport properties of thin-film catalysis.

Dinuclear Heterogeneous Catalyst on Metal Oxides for Solar Water Oxidation
Yanyan Zhao, Ke. R. Yang, Xingzu Yan, Zechao Wang, Sufeng Cao, Yifan Ye, Qi Dong, Xiux Zhang, James Thorne, Lei Jin, Kelly Materna, Antonios Triplasis, Sirine Fakra, Shashu Zhu, Xiaoyan Zhong, Peng Wang, Xiaoxing Pan, Jinghua Guo, Maria Flytzani-Stephanopoulos, Gary W. Brudvig, Victor Batista, Dunwei Wang
1Boston College, Chestnut Hill, Massachusetts, United States; 2Yale University, New Haven, Connecticut, United States; 3University of California–Irvine, Irvine, California, United States; 4Tsinghua University, Beijing, China; 5Tufts University, Medford, Massachusetts, United States; 6Lawrence Berkeley National Laboratory, Berkeley, California, United States; 7Ernst Ruska-Centre for Microscopy and Spectroscopy with Electrons, Jülich, Germany; 8Nanjing University, Nanjing, China.

Atomically dispersed catalysts refer to substrate-supported heterogeneous catalysts featuring one or a few active metal atoms that are separated from one another. They represent an important class of materials ranging from single atom catalysts (SACs) and nanoparticles (NPs). While SACs and NPs have been extensively reported, catalysts featuring two atoms with well-defined structures are poorly studied. The difficulty in synthesizing such structures has been a critical challenge. Here we present preparing dinuclear heterogeneous catalysts (DHCs) by a facile photochemical method that produces catalytic centers consisting of two iridium metal cations, bridged by O and bound to a support. Direct evidence unambiguously supporting the dinuclear nature of the catalysts anchored on metal oxides is obtained by aberration-corrected scanning transmission electron microscopy. In addition, different binding modes have been achieved on two metal oxides with distinguishable surface oxygen densities and interatomic distances of binding sites. Side-on bound DHCs was demonstrated on iron oxide where both Ir atoms are affixed to the surface with similar coordination environment. The three-fold hollow binding sites on the OH-terminated surface of Fe2O3 anchor the catalysts to provide outstanding stability against detachment or aggregation. The competing end-on binding mode, where only one Ir atom is attached to the substrate and the other one is dangling was observed on WO3. Evidence supporting the binding modes was obtained by in situ Diffuse Reflectance Infrared Fourier Transform Spectroscopy. The resulting catalysts exhibit high activities toward H2O photooxidation. Density functional theory calculations provide additional support for atomic structure, binding sites modes on metal oxides, as well as insights into how DHCs may be beneficial for solar water oxidation reactions. The results have important implications for future studies of highly effective heterogeneous catalysts for complex chemical reactions.

Bismuth Substituted Strontium Cobalt Perovskites for Catalyzing Oxygen Evolution
Jiayu Peng, Denis A. Kuznetsov, Livia Giordano, Yuriy Roman and Yang Shao-Horn
1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The distribution and on-demand use of electrical energy from sustainable resources requires storage technologies that are cost effective and involving earth-abundant elements [1-2], such as storing solar energy in form of chemical bonds by water splitting or CO2 reduction. The efficiency of these storage technologies is, however, severely limited by the catalysis of the oxygen evolution reaction (OER) [3], which is characterized by slow kinetics and the need for precious metal catalysts such as RuO2 and IrO2 [4]. The development of the efficient electrocatalysts for OER composed of earth-abundant materials is therefore crucial for the large-scale implementation of these technologies. Here we employ the recently reported inductive effect [5] associated with metal substitution to examine the redox potentials and OER activity of cobalt-based perovskites, where bismuth-substituted strontium cobalt perovskite, Bi4Sr3CoO9.6, showed a record intrinsic activity for OER in basic solution. OER kinetics of Bi4Sr3CoO9.6 were found to have a low Tafel slope (<30 mV/decade) and pH dependence on RHE scale implying the decoupling of proton and electron transfer during one of the OER steps. The enhanced OER kinetics of Bi4Sr3CoO9.6 relative to other active catalysts such as SrCoO2, δ can be attributed to the presence of electronegative strong Lewis acid Biδ+ ions which can influence the surface charge facilitating deprotonation kinetics, and also enhance oxide stability by having lowered O p band center of Bi4Sr3CoO9.6 relative to the Fermi level via partial Co reduction and inductive effect. This work demonstrates a novel design strategy for enhancement of the OER activity and stability of oxide catalysts by the inductive effect induced by metal substitution to enable efficient and sustainable energy storage.

Ultraporous Amorphous Iron-nickel Boride Nanosheets for Highly Efficient Electrocatalytic Oxygen Production
Jean Marie Vianney Nsanzimana and Xin Wang
1Nanyang Technological University, Singapore, Singapore.

Electrochemical Hydrogen production has gained great interest over the past decades as a cleaner, higher purity and sustainable production technology for carbon-neutral alternative fuel sources. However, poor oxygen evolution reaction (OER) thermodynamic up-hill reaction limits the efficiency of H2 production from water electrolysis and photoelectrolysis routes to large-scale energy storage. Thus, it is crucial to develop efficient and low-cost.
material to boost the sluggish kinetics step of four-electron OER process. The state-of-the-art are the precious metal-based catalyst which suffers from higher cost and makes them lesser desirable for industrial applicable scale. Thus, developing low cost, durable, earth-abundant, and high-performance non-precious metal electrocatalyst for oxygen evolution reaction (OER) is a cornerstone for energy technologies. Despite a well-documented approach for synthesizing metal borides, it is recently that the application as promising OER electrocatalyst has emerged.\textsuperscript{2, 3} Furthermore, the synergetic effect had been reported for multimetal borides materials which were found to be the most OER among the reported metal borides materials.\textsuperscript{4} Additionally, an improvement in metal borides based catalyst had been reported when supported on a higher conductive substrate such as graphene.\textsuperscript{5}

A cost-effective and efficient electrocatalyst for oxygen evolution reaction during water electrolysis is highly desired. In an effort to develop an economical material for replacing precious metal-based catalysts, a novel and self-standing, amorphous ultrathin nanosheets of bimetallic iron-nickel boride (FeNiB NSs) on Ni foam is presented, which displays better oxygen-evolving activity compared to precious metal catalyst RuO\textsubscript{2}. In 1.0 M KOH electrolyte, it requires an overpotential of only 237 mV to reach a current density of 10 mA/cm\textsuperscript{2} with a small Tafel slope of 38 mV/dec\textsuperscript{1} and shows prominent longterm electrochemical stability. The synergistic effect between highly abundant catalytically active sites on 3D porous substrate, improved electron transport arising from the presence of highly negative boron, and high conductivity of the substrate results in an outstanding electrocatalytic activity. The advanced catalytic activity, facile electrode fabrication, and low cost makes it a potential oxygen evolving material which may be extended to other energy conversion and storage technologies.

\textbf{CoSb\textsubscript{2}O\textsubscript{6} as a Stable Oxygen Evolution Catalyst in Acidic Media} Taylor A. Evans and Kyoung-Shin Choi; Chemistry, University of Wisconsin-Madison, Madison, Wisconsin, United States.

The electrochemical generation of hydrogen fuel via water reduction requires a counter reaction, typically the oxidation of water. This four electron, kinetically complex reaction has been intensely studied in basic media using a variety of inexpensive metal oxide materials (NiO\textsubscript{x}, FeO\textsubscript{x}, CoO\textsubscript{x}, etc). However, in acidic media these catalysts have been shown to be unstable and degrade rapidly. While noble metal oxides, such as RuO\textsubscript{2} and IrO\textsubscript{2}, are able to perform water oxidation in a stable manner with relatively low overpotentials in acidic media, their scarcity and high cost leave significant room for the development of inexpensive novel catalysts. Antimony (V) oxides are expected to be stable under oxidizing conditions in acidic media on account of their high oxidation state and low solubility in acid. In this presentation, the investigation of CoSb\textsubscript{2}O\textsubscript{6} as a stable water oxidation catalyst is reported. Synthesized through a facile electrochemical method, CoSb\textsubscript{2}O\textsubscript{6} films are demonstrated to be stable in acidic media while applying the necessary potentials for water oxidation. CoSb\textsubscript{2}O\textsubscript{6} opens the door as a possible replacement for noble metal oxide catalysts and encourages the investigation of other transition metal antimony oxide materials for use as water oxidation catalysts in acidic media.

\textbf{Porous Transition Metal Oxides for Selective Oxidations} Steven L. Suib\textsuperscript{1, 2, 3}; \textsuperscript{1}Chemistry, University of Connecticut, Storrs, Connecticut, United States; \textsuperscript{2}Chemical and Biomolecular Engineering, University of Connecticut, Storrs, Connecticut, United States; \textsuperscript{3}Institute of Materials Science, University of Connecticut, Storrs, Connecticut, United States.

This presentation will focus on synthesis, characterization, and applications of novel microporous and mesoporous materials. Such mesoporous metal oxide materials have crystalline walls, high thermal stability, and monomodal pore size distributions. These systems can be made for most elements throughout the periodic table. They have unique catalytic activity in a number of reactions including selective oxidations, total oxidations, coupling reactions, water splitting, one pot Wittig reactions, dehalogenations, and others. A key focus is on the mechanisms of these selective oxidation reactions. The role of reactive oxygen species in these reactions is of considerable interest. This presentation will focus on synthesis, characterization, and selective catalytic oxidations applications using both microporous and mesoporous materials. Reactive oxygen species can be detected with a variety of methods. \textit{In situ} methods to observe these species have been developed. How such reactive oxygen species are important in selective oxidation reactions will be discussed.

4:00 PM ET08.02.07
\textbf{Advanced Structural Characterization of Ni-NW Catalysts Showing Enhanced OER Electroactivity} Sagar Prabhudesai\textsuperscript{1}, Minghui Hao\textsuperscript{2}, Sebastien Garbarino\textsuperscript{2}, Daniel Guy\textsuperscript{2} and Gianluigi A. Bottoli\textsuperscript{1}; \textsuperscript{1}McMaster University, Hamilton, Ontario, Canada; \textsuperscript{2}INRS, Montreal, Quebec, Canada.

Hydrogen is arguably one of the most promising energy carriers which can mirror all the appealing attributes of electricity. To answer whether it can meet the global demand for energy while at the same time also be an effective clean and sustainable energy carrier, however, requires a low-cost and environmentally friendly means of production. Although Electrolytic methods of producing Hydrogen provide an attractive pathway to producing Hydrogen renewably (e.g., from water), they further entail employing electrolyzer systems such as the Anionic Polymer Electrolyte Membrane Water Electrolyzers that are yet to be optimized for their Oxygen Evolution Reaction (OER) kinetics.

In this work we discuss a new class of Ni-Nanowire Catalysts that were found to exhibit a significant decrease in the OER Overpotential (~200 mV) at 10 mA/cm\textsuperscript{2} current densities. With the use of advanced electron microscopy tools for structural and compositional characterization we provide insights into their entire synthetic pathway, where a template-assisted electrodeposition procedure first formed the Ni-filled Aluminium Anodic Oxide (AAO) membranes, from which the usable pristine 1D Ni nanowires were then recovered by electrochemical dissolution of the AAO in 1M KOH. A detailed analyses of their SEM and high-resolution TEM images reveals that the as-received AAO membrane bears a close resemblance to the hexagonal assembly of pore arrangement, which is still preserved even in the case of pristine Ni NWs that are recovered in the final synthetic step. More importantly, a detailed analyses of the NW micrographs post electrochemical testing using advanced image processing methods suggests that the hexagonal assembly can be further retained, thus highlighting the electrochemical stability observed in this 1D Ni-NW catalysts.

Similar to the above analyses performed with TEM-imaging, we performed a detailed investigation of the NW compositions using electron energy loss
Mechanistic Investigations of Alkaline Hydrogen Electrocatalysis via Kinetic Modeling and Single-Crystal Voltammetry

In order to deduce the thermodynamic phase of the oxide layer formed (i.e., NiO vs. Ni(OH)₂) in the two samples (NWs pre-/post- treatment in 1M KOH), we further estimated their Ni-L3/L2 white-line intensity ratios over the core- and surface- regions. Our results indicate that the L3/L2 ratio in the shell-region for the Pristine is comparable to the Ni(OH)₂ state, and there is no apparent changes in the chemical state of Ni following the extensive electrochemical characterization.

4:15 PM ET08.02.08
Origin of High Activity of Mn₃O₄ Nanoparticle in Oxygen Evolution Reaction—An Atomic-Resolution STEM/EELS Study

We have explored the atomic structure and electronic structure of Mn₃O₄ nanoparticles using aberration-corrected STEM and EELS to understand its high resolution local compositional variations between the NW core/shell regions. Our results indicate that the NW surfaces form an oxide layer over the metallic core, surrounded by the (011) and (001) facets, and both of the facets undergo the surface reconstructions. In addition, the EELS analysis reveals that the surface reconstructions are accompanied with the suppression of Mn³⁺ ions on the surface. Importantly, such Mn³⁺ ions are still exposed at the edge of the nanoparticle. Currently, it is recognized that Mn³⁺ ions are deeply correlated to active sites of OER in Mn-based electrocatalysts[1]-[4]. Our results suggests that the edges are the active sites of Mn₃O₄, therefore, Mn₃O₄ nanoparticles encloed by active edges compactly can show remarkably high activity in OER whereas its bulk counterpart which mostly has reconstructed surfaces do not have catalytic property.

4:30 PM ET08.02.09
Multiple Coordination of ZIFs with Transition Metal in Metal-Organic-Frameworks as Efficient Electrocatalysts for Energy Conversion

Clean energy technologies such as fuel cells, rechargeable metal-air batteries, and water splitting, are promising for future energy sources owing to their nature of no pollution and greenhouse gas emission. The key reactions in these technologies are the oxygen reduction reaction (ORR) and oxygen evolution reaction (OER) that generate power. The state-of-the-art electrocatalyst in OER is RuO₂ and in ORR is Pt, but their high cost and poor durability hindered their application in clean energy technologies. Zeolitic imidazolate frameworks (ZIFs), a subclass of metal organic frameworks (MOFs), mainly composed of a transition metal (TM) center and organic ligands, exhibits the excellent ability as electrochemical catalysts in clean energy conversion and storage. However, their ligand or coordination of metal ions must be modified to enhance their catalytic activities. To rationally design the ZIF catalysts, we have calculated the OER and ORR activities of TM-ZIFs and found an intrinsic descriptor which can describe the catalytic activities of the TM-ZIFs by density-functional theory (DFT) method. Our DFT calculations show that the unsaturated metal sites show high catalytic activities comparable to that of RuO₂ / Pt electrocatalyst. This theoretical result was confirmed by the experiment.

Mechanistic Investigations of Alkaline Hydrogen Electrocatalysis via Kinetic Modeling and Single-Crystal Voltammetry

Mechanistic Investigations of Alkaline Hydrogen Electrocatalysis via Kinetic Modeling and Single-Crystal Voltammetry

It has long been recognized that the reaction rates of the hydrogen oxidation and hydrogen evolution reactions (HOR /HER) are up to 200 times slower in basic than acidic electrolytes, even though the surface intermediate of adsorbed hydrogen is independent of solution pH [1]. The mechanistic origins of this difference have been hotly debated in the literature. In this work, we investigate possible explanations for the effect of pH by combining single-crystal voltammetry with microkinetic modeling and electroanalytical methods. We specifically determine the viability of the proposed ‘bifunctional mechanism’, in which slow water dissociation is overcome by mediation of adsorbed hydroxide [2].

Our previous work [3] has shown that on Pt(110) either a direct (hydroxide-as-spectator) or indirect (hydroxide-mediated) Volmer step can describe the measured reaction thermodynamics, but that only the direct Volmer step is consistent with realistic adsorption energies. Furthermore, increasing hydroxide adsorption strength via the electrolyte cation decreases kinetics, as observed by the dependence of peak-potential splitting on scan rate. Comparison with theory shows that this observation is consistent only with the direct mechanism. These results strongly suggest that adsorbed hydroxide serves as a competitive spectator in the alkaline Volmer step, and that the bifunctional HOR/HER mechanism plays only a minor role at best.

The inability of the bifunctional mechanism to describe experimental data is further reinforced by investigating a two-site model recently proposed in the literature [2], in which oxophilic ruthenium or nickel sites are responsible for facilitating water dissociation. We find that such chemical dissociation steps result in anomalous trends with potential, and that oxophilicity has no effect on hydrogen coverage or HER/HOR rates. Comparison with experiment strongly indicates that the observed bifunctional mechanism is unrelated to hydroxide binding strength [4]. Overall, our work resolves a long-standing paradox in electrocatalysis and surface science by determining that oxophilicity is not an accurate descriptor for alkaline hydrogen electrocatalysts. Other parameters, such as water orientation and non-covalent interactions, must play a greater role in overall activity. Efforts to identify and measure these parameters are ongoing.

The electrochemical reduction of CO2 into fuels and chemicals is an attractive route to store renewable electricity. Efficient CO2 reduction catalysts need to yield high activity, high selectivity, and low overpotential, simultaneously. The design of catalysts that exhibit tailored properties such as favourable facets for a given reaction, number of active sites, and oxidation state, is challenging: catalyst can undergo an extensive reconstruction under high productivity operating conditions such as high current densities, reducing potentials, and variable pH. Earth-abundant transition metals such as tin, bismuth, and lead have been proven stable and product-specific, but exhibit limited partial current densities. We present a strategy that employs bismuth oxyhalides as a template from which 2D bismuth-based catalysts are derived. The BiOBr-templated catalyst exhibits a preferential exposure of highly active Bi (110) facets, which we track in operando using grazing-incidence wide-angle X-ray scattering (GIWAXS) and X-ray absorption spectroscopy (XAS). The templated catalyst exhibit an enhanced CO2 reduction reaction selectivity to over 90% Faradaic efficiency for formic acid that is sustained up to stable current densities of 200 mA cm^-2. This represents more than a twofold increase in the production of the energy-storage liquid formic acid compared to previous best Bi catalysts.

8:15 AM ET08.03.02

Electrochemical transformation of CO2 into energy-dense fuels may prove key towards the realization of economically viable, renewable fuels. However, the rational design of CO2 reduction catalysts guided by well-grounded chemical intuition or first-principles computational approaches, have so far been met with limited success. To address this important question of how to activate a molecule as stable and unreactive as CO2 and convert it into complex hydrocarbons, there may be no better place to look than biological systems capable of CO2 activation, for crucial guidance and inspiration.

Recent findings have demonstrated the utility of MoS2 and MoSe2 edge sites in catalyzing the transformation of CO2 to CO. Although this is a promising start, CO is not an easy product to work with industrially nor to transport due to its gaseous nature. Meanwhile, a close look of formate dehydrogenase (FDH), the key enzyme in formate metabolism which catalyzes the reversible two-electron oxidation of formate or reduction of CO2, reveals a catalytic center that is defined by Mo4+/6+ or W4+/6+ coordination with sulfide ligands (from molybdopterin prosthetic groups and cysteine residues) and a selenocysteine side chain. Translation of these chemical moieties, which are recognized as integral to the FDHs architecture and functions, into solid-state semiconductor devices, would suggest that the inclusion of Se ions in Mo/WS2 semiconductors as a dopant may promote the preferred generation of liquid formate, rather than gaseous CO, from CO2. In this project, we want to explore interstitial Se doping of W/MoS2 materials as potential CO2 reduction cathodes, with the ultimate goal of generating reduced liquid hydrocarbon products.

8:30 AM ET08.03.03
Coupling Solar Energy into Catalytic CO2 Conversion Yujie Xiong; Department of Chemistry, University of Science and Technology of China, Hefei, China.

Considering the excessive emission of atmospheric carbon dioxide (CO2) caused by the combustion of fossil fuels, the sunlight-driven CO2 reduction into higher energy chemicals, such as carbon monoxide, formic acid, methanol or methane, offers a more promising approach to alleviate both global warming and energy crisis. Designing new photocatalytic materials for improving the photoconversion efficiency is a promising route to achieve this goal. Despite the invention of a large number of catalytic materials with well-defined structures, their overall efficiency in photocatalysis is still quite limited as the three key steps - light harvesting, charge generation and separation, and charge transfer to surface for redox reactions - have not been substantially improved. To improve each step in the complex process, there is a major trend to develop materials based on inorganic hybrid structures, in which surface and interface engineering holds the promise for boosting the overall efficiency. In this talk, I will demonstrate several different approaches to designing inorganic hybrid structures with improved photocatalytic performance via surface and interface engineering. It is anticipated that this series of works open a new window to rationally designing inorganic hybrid materials for photo-induced applications.

9:00 AM ET08.03.04
Development of Semiconductor-MOF Ternary Photocatalyst Toward Intensified Charge Carrier Density and Molecule Activation in Heterogeneous Photocatalysis Xiang He and Wei-Ning Wang; Virginia Commonwealth University, Richmond, Virginia, United States.

Heterogeneous photocatalysis, such as carbon dioxide (CO2) photoreduction, is a promising engineering approach to reduce atmospheric CO2 levels and simultaneously convert CO2 into hydrocarbon fuels. Among the numerous catalysts for CO2 photoreduction, semiconductors have been studied intensively because of their low cost, easy availability, nontoxicity, and exceptional chemical stability. However, the semiconductor-based CO2 photoreduction still suffers from low efficiency and selectivity, mainly due to low charge carrier density and weak ability to activate the adsorbed CO2 molecules. Towards addressing the aforementioned long-standing issues in CO2 photoreduction (i.e., low charge carrier density and inefficient CO2 activation), we herein report a rational development of MOF-based ternary nanocomposites composed of TiO2/CuO/Cu(OH)2 heterojunction and Cu(CBTC)3, where the roles of semiconductor heterojunction and MOF in charge transfer and CO2 activation are systematically explored. Specifically, the nanocomposites were synthesized via facile and rapid self-assembly of TiO2/CuO nanoparticles within microdroplets, followed by in situ growth of Cu(OH)2 (BTC)3 on the TiO2/CuO surface, where part of CuO serves as the sacrificial metal source. The unique ternary TiO2/CuO/Cu(CBTC)3 composite possesses heterojunction and abundant coordinatively unsaturated copper sites, which results in not only increased charge carrier density but also efficient activation of CO2 molecules, therefore leading to high CO2 conversion efficiency and preferential formation of CH4. With systematic measurements (e.g., gas chromatography, photoluminescence spectroscopy, X-ray photoelectron spectroscopy, and time-resolved in situ diffuse reflectance infrared Fourier transform spectroscopy), a plausible pathway of CO2 activation and subsequent reduction in this ternary system was proposed. The outcome of this work provides new insights in rational design of MOFs-based hybrid nanomaterials for efficient CO2 photoreduction.
Photocatalytic and Optoelectronic Studies of SnS2 Thin Film by Controlled Implantation of Carbon Ions

Tadesse Billo Reta, Indrajit Shown, Weiwen Woor, Rwei-San Chen, Chih-Hao Lee, Li-Chyong Chen and Kuei-Hsien Chen; Institute of Atomic and Molecular Sciences, Academia Sinica, Nangang, Taiwan; Department of Physics, National Central University, Taoyuan, Taiwan; Graduate Institute of Applied Science and Tech. National Taiwan University of Science of Technology (NTUST), Taipei, Taiwan; Department of Engineering and System Science, National Tsing Hua University, Hsinchu, Taiwan; Center for Condensed Matter Sciences, National Taiwan University, Taipei, Taiwan.

A significant increase of CO2 in the atmosphere has a profound impact on global climate change, which has become a central challenge of the 21st century. Photocatalytic reduction of CO2 into chemical fuel is an appealing strategy to resolve greenhouse gas emissions and alleviate the energy crisis. The efficiency of CO2 conversion relies on the catalytic sites and microstructure of photocatalyst. In this work, we successfully synthesized SnS2/SnO2 heterogeneous multi-shelled hollow spheres by the sequential templating approach. Multi-shelled hollow structures not only have the characteristics of the large specific surface area and high loading capacity; more importantly, they have multiple adjustable shells and inter-shell spaces, enabling sequential light reflection and scattering, which greatly improve the light-harvest capability and light conversion efficiency. These unique features make them promising candidate for photocatalytic reduction of CO2. The SnS2/SnO2 multi-shelled hollow spheres exhibited an enhanced efficiency and good stability for photocatalytic reduction of CO2 to CO. Photocatalytic activity of SnS2/SnO2 multi-shelled hollow spheres is increased with the shell number significantly. As a result, the quadruple-shelled SnS2/SnO2 hollow spheres steadily photocatalyzed CO2 to CO at a rate of 50 μmol g\(^{-1}\) h\(^{-1}\) under AM 1.5 G simulated solar irradiation, and the rate can maintain 72 hours without decline. This work paves the way for enhancing photocatalytic performance by structural design of the emerging materials.

10:00 AM BREAK

Designing Nanostructured Materials for Electrochemically Recycling Carbon Dioxide

Michael B. Ross and Peidong Yang; University of California, Berkeley, Berkeley, California, United States.

Electrochemical carbon dioxide (CO2) recycling enables the synthesis of high-value fuels and chemicals using renewable energy. Doing so requires the development of catalysts that both efficiently and selectively reduce CO2 into desirable products. Nanomaterials are particularly powerful for doing so due to their high surface areas, tunable chemical and physical properties, and unique reactivities that can differ from the bulk. Thus the synthesis, characterization, and integration of nanostructured electrocatalysts for CO2 reduction is a promising strategy for realizing breakthrough performance. Synthesis gas (syngas), a mixture of H\(_2\) and CO, can be converted into a variety of fuels and chemicals using established industrial processes that require different syngas compositions. Here we will describe the synthesis, characterization, and catalytic properties of nanostructured electrocatalysts that are versatile and modular, and which also provide dynamic access to a wide variety of desirable syngas compositions. Strategies for generating multi-carbon products will also be discussed.

11:00 AM ET08.03.08

Controlled Selectivity of CO\(_2\) Reduction via Electrochemical Potential Modulation

Kevin Kimura, Jin Suntivich and Tobias Hanrath; Cornell University, Ithaca, New York, United States.

We present the product distribution of the CO\(_2\) reduction reaction (CO\(_2\)RR) when the driving force is a pulse of electrochemical potential. The use of renewable electricity to convert CO\(_2\) into energy-dense fuels and high-valued feedstocks is an enabler of many sustainable energy and chemical technologies. The CO\(_2\)RR offers a pathway to achieve this goal using electrochemistry. However, the CO\(_2\)RR suffers from poor selectivity, especially on Cu, despite its ability to produce hydrocarbons (such as methane, ethylene, etc.). In this presentation, we present a strategy for manipulating the CO\(_2\)RR selectivity by applying the CO\(_2\)RR driving force (‘overpotential’) as pulses. By applying pulses of overpotential with controlled duration and magnitude, we demonstrate that the CO\(_2\)RR selectivity can improve > 97% of faradaic efficiency (FE) with respect to the competing hydrogen evolution reaction, and the selectivity toward methane can be as high as 83% FE. We will discuss the possible mechanisms for why the temporal control of the overpotential pulse can lead to the CO\(_2\)RR selectivity control and the possible implications on the timescale of the competing pathways in the CO\(_2\)RR.

11:15 AM ET08.03.09

Transition Metal Single Atom Electrocatalysts for Selective CO\(_2\) Reduction in Water—From Identification to Scaling-up

Haotian Wang; 1Harvard University, Cambridge, Massachusetts, United States; 2Rice University, Houston, Texas, United States.

The development of highly selective and earth-abundant electrocatalysts for CO\(_2\) reduction is becoming increasingly important for renewable energy applications. The challenge here is the strong competition from water reduction, as well as the low selectivity towards a desired product. In this talk I will introduce the rational tuning of electronic properties of catalytic materials for their significantly improved CO\(_2\) reduction performance. By dispersing transition metals into isolated single atoms with electronic structures significantly different from their bulk counterparts, we can dramatically suppress the competing hydrogen evolution and deliver an ultra-high CO\(_2\) reduction selectivity of more than 95% under ambient conditions in water. I will also talk about the successful scaling-up of both the catalytic materials synthesis as well as the CO\(_2\) reduction current density while maintaining ultra-high CO\(_2\) reduction efficiency.
selectivity.

11:30 AM ET08.03.10
Rational Design of Terrace, Step and Corner Sites of The Metal or Bimetallic Catalysts for Hydrogenation and Hydrodeoxygenation of Biomass-Derived Platform Molecules
Shelaka Gupta, Tuhin Suverya Khan, Md. Imteyaz Alam and M. Ali Haider; Chemical Engineering Department, Indian Institute of Technology Delhi, New Delhi, India.

Deoxygenation and valorization of biomass-derived platform molecules was studied using ring-opening (RO), decarboxylation, hydrogenation and hydrodeoxygenation (HDO) reactions. The platform molecules studied here included cellulose-derived lactones, furans, 2-pyrones and lignin-derived phenolic compounds.

Study on the conversion of lactones was focused to understand the mechanism of RO and decarboxylation reaction. More specifically, oxocarbenium ions were proposed as an intermediate to play an important role in controlling the rate of RO step. The mechanism of RO and decarboxylation reaction in 2-pyrones formed an interesting case, wherein the reaction in partially saturated 2-pyrones followed a retro-Diels-Alder (rDA) route. Both solvents and substituents were expected to influence the rDA reaction of partially saturated 2-pyrones, which was studied using density functional theory (DFT) simulations.

6-arylt-α-pyrones (6PP) was suggested as a potential platform chemical, which may be obtained directly from the fermentation of waste lignocellulosic biomass. On RO and decarboxylation, 6PP was converted to C6 linear ketones which are proposed as precursors for jet and diesel range fuels. All of these catalytic transformations of 6PP can be integrated with the upstream fermentation of biomass to form a unique bio- and chemo-catalytic process for providing high value fuels and chemicals. However, biogenic impurities present in ppm levels (<100 ppm) along with the fermentation-derived molecules pose a detrimental effect to heterogeneous catalyst stability. Interaction of such impurities with the metal catalyst surface was studied using DFT simulations.

Bimetallic alloy of NiAu was proposed as a more stable surface for hydrogenation reactions. Catalytic hydrogenation reaction carried out on the Pd catalyst was an interesting case to further explore the influence of catalyst particle size and morphology on the selectivity of a desired product. Detailed mechanistic studies were carried out on Pd (111) and Pd (100) surfaces using DFT calculations to corroborate experimental finding. Since Pd (111) are the majority (~70%) sites, high selectivity observed towards the partially hydrogenated product (cyclohexanone) in the experiments is thought to be from the Pd (111) surface. Contrary to this prevalent thought, on using a combined theoretical and experimental approach, Pd (111) surface was demonstrated to selectively produce the cyclohexanol. Surprisingly, Pd (100), the minority (~25%) sites were selectively producing cyclohexanone. These results lead to the development of a comprehensive understanding on facet-dependent selectivity control in phenol hydrogenation on the Pd catalyst. Final reaction in this sequence was HDO of biomass-derived furan compounds, wherein the synergistic interaction of Zn with the Pd catalyst was studied using DFT simulations. Zn was shown to participate in C-O bond activation step while Pd surface participated in the hydrogenation step.

SESSION ET08.04: Novel Structures for Catalysis

Self-Assembly and Formation of Nanostructured Porphyrin Photocatalysts
Hongyou Fan1, 2; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2The University of New Mexico, Albuquerque, New Mexico, United States.

Design and engineering of the size, shape, and chemistry of photoactive building blocks enable the fabrication of functional nanocatalysts for applications in light harvesting, photocatalytic synthesis, water splitting, phototherapy, and photodegradation. Here, I will present our recent progress in the synthesis of such nanocatalysts through a surfactant-assisted interfacial self-assembly process using optically active porphyrins as a functional building block. The self-assembly process relies on specific interactions such as π–π stacking and ligand coordination between individual porphyrin building blocks. Depending on the kinetic conditions, resulting structures exhibit well-defined one- to three-dimensional morphologies such as nanowires, nanocatalysts, and hierarchically ordered internal architectures. At the molecular level, porphyrins with well-defined size and chemistry possess unique optical and photocatalytic properties for redox synthesis of metallic structures. On the nanoscale, controlled assembly of macrocyclic monomers leads to formation of ordered nanostructures with precisely defined size, shape, and spatial monomer arrangement so as to facilitate intermolecular mass and energy transfer or delocalization for photocatalysis. Due to the hierarchical ordering of the porphyrins, the nanoparticles exhibit collective optical properties resulted from coupling of molecular porphyrins and photocatalytic activities such as photodegradation of methyl orange pollutants and hydrogen production. The capability of exerting rational control over dimension and morphology provides new opportunities for applications in sensing, nanoelectronics, and photocatalysis.

Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525.

2:15 PM *ET08.04.02
Membrane Coated Electrocatalysts for Stable, Active and Selective Electrocatalysis
Daniel Esposito; Chemical Engineering, Columbia University, New York, New York, United States.

Conventional electrocatalysts used in fuel cells and electrolyzers are comprised of metallic nanoparticles that are attached to a conductive electrode support that allows for the transfer of electrons between an external circuit and the electrocatalyst/electrolyte interface. Typically, these nanoparticles are partially or fully exposed to a bulk liquid or gaseous phase to facilitate mass transfer of reactants and products. In contrast, this presentation describes recent studies on an emerging class of electrocatalysts for which the active metal electrocatalysts are completely encapsulated by ultrathin layers of permeable oxides that can exhibit membrane-like properties. These so-called membrane coated electrocatalysts (MCECs) offer many potential advantages over conventional electrocatalysts, including the ability to simultaneously mitigate degradation, alter reaction selectivity, and improve reaction kinetics at the buried interface between the overlay layer and active catalyst. This talk will describe three case studies of silicon oxide (SiOx)-encapsulated Pt electrocatalysts that separately demonstrate the ability of the SiOx overlayer to enhance catalyst stability, activity, and selectivity. Of particular interest to the last two studies are the task of developing a deeper understanding of the buried interfaces of MCECs, which represent confined environments where structure can, in principle, be tuned to alter reaction energetics and selectivity for a wide variety of electrochemical reactions.

**Colloidal Hexagonal Copper Phosphide (Cu₃P) Nanosheets for Selective and Low-Overpotential CO₂ Electroreduction to Ethylene**

Hui Li¹, Peng Wen², Dominique S. Iunza³, Zachary D. Hoed⁴, MiaoFang Chi⁵, Lin Jiang⁶, Yejun Qu⁷ and Scott M. Geyer¹; ¹Chemistry, Wake Forest University, Winston-Salem, North Carolina, United States; ²Department of Materials Science and Engineering, Harbin Institute of Technology, Shenzhen, China; ³Center for Nanophase Materials Sciences (CNMS), Oak Ridge National Laboratory (ORNL), Oak Ridge, Tennessee, United States; ⁴Institute of Functional Nano and Soft Materials (FUNSOM), Soochow University, Suzhou, China.

Electrochemical CO₂ reduction provides a fascinating pathway to produce valuable carbon-based fuels, but limited by low conversion efficiency, high overpotential for certain selectivity, and sluggish reaction rate. Herein, we report that colloidal hexagonal copper phosphide nanosheets (Cu₃P NSs) show a remarkable onset potential of -0.33 V vs. RHE and achieves a maximum Faradaic efficiency of 62% at -0.88 V vs. RHE for selective CO₂-to-C₂H₄ in a 1:1 volume ratio of EMIM-BF₄ ionic liquid and H₂O electrolyte. By contrast, Cu₃P and Cu nanoparticles (NPs) tend to selectively reduce CO₂ to CH₄ and CO/CH₄, respectively. DFT calculation reveals that the delocalized P atoms enhance the stabilization of CO* intermediate and the stepped facets of (111) on nanosheets favor C-C coupling step rather than the low-index (111) facets on nanoparticle. Moreover, only 8% decay for a high partial C₂H₄ current density of 20.6 mA cm⁻² at -1.0 V vs. RHE during 24 h stability test is observed on Cu₃P NSs.

3:00 PM ET08.04.04

**2-pyridinide as an Active Catalytic Intermediate for CO₂ Reduction on p-GaP Photoelectrodes—Lifetime and Selectivity**

Shenzhen Xu¹ and Emily Carter²; ¹Mechanical and Aerospace Engineering, Princeton University, Princeton, New Jersey, United States; ²School of Engineering and Applied Science, Princeton University, Princeton, New Jersey, United States.

The active intermediate responsible for the highly selective reduction of CO₂ to methanol at p-GaP photoelectrodes is currently under debate. Adsorbed 2-pyridinide (2-PyH*), produced from a two-electron reduction and protonation of adsorbed pyridine (Py*), was recently proposed by Carter and coworkers to be a key intermediate that facilitates hydride transfer (HT) to CO₂ to produce formate. However, the lifetime of 2-PyH*, most likely controlled by the rate of 2-PyH* protonation to form adsorbed dihydropropyridine (DHP*), is still in question. In this work, we provide evidence for the transient existence of 2-PyH* on a p-GaP surface by comparing the activation energy for HT to CO₂ to those predicted for 2-PyH* being protonated to form either DHP* or PyH*+H₂ via a hydrogen evolution reaction (HER). We predict that 2-PyH* situated next to an adjacent surface hydroxide (OH*) will be the most effective intermediate leading to CO2 reduction on p-GaP. Predicted high barriers of HER (via either 2-PyH* or H*) also explain the high selectivity toward CO₂ reduction observed in experiments.

3:45 PM ET08.04.05

**Facet-Controlled Palladium Nanocrystals for Selective Catalysis**

Younan Xia; Georgia Institute of Technology, Atlanta, Georgia, United States.

For a structure-sensitive reaction, the activity and selectivity of a heterogeneous catalyst can both be enhanced by controlling the type of facet and thus the arrangement of atoms on the surface of nanocrystals. This concept, however, could not be materialized until recently when it became possible to synthesize facet-controlled nanocrystals, including those with high-index facets. In addition, the size of a facet-controlled nanocrystal determines the surface-to-bulk atomic ratio and the proportions of different types of atoms (e.g., vertex, edge, vs. face). In this talk, I will use palladium (Pd) as an example to illustrate how facet-controlled synthesis has enabled the development of catalysts with enhanced activity and selectivity toward an array of reactions, including formic acid oxidation and selective hydrogenation.

4:15 PM ET08.04.06

**Morphological Effects of In Situ Reduction of Cuprous Oxide Interfaces for the Electrochemical CO₂ Reduction Reaction**

Hamed Mehrabi¹, James M. Lowe² and Robert H. Coridan³; ¹Microelectronics-Photonics, University of Arkansas–Fayetteville, Fayetteville, Arkansas, United States; ²Chemistry and Biochemistry, University of Arkansas–Fayetteville, Fayetteville, Arkansas, United States.

Copper-based electrodes have shown uncommon promise for catalyzing the electrochemical reduction of CO₂ to a variety of high-value products. Cuprous oxide (Cu₂O) is a particularly interesting starting material, as it can be reduced in situ to generate active Cu metal sites on the surface. In recent work, we have demonstrated that the electrochemical properties and nanoscale morphology of photoelectrodedeposited Cu₂O can be modified by the illumination conditions during growth. Photogenerated electrons have sufficient energy to induce the formation of Cu metal nano-inclusions in a predominantly Cu₂O matrix. The presence of Cu disrupts the micro-crystalline growth observed in Cu₂O electrodedeposited without illumination. Here, we will describe the experiments that study the effects of photodoping on electrodedeposited Cu₂O electrodes for the CO₂ reduction reaction. The transition from oriented microcrystals to disordered nanocrystalline films with increasing light intensity during growth has a significant effect on the reduction of the electrode surface. This alters the dynamics and electrochemical behavior of the electrode for CO₂ reduction. We will also explore how chemical modifications to the surface, such as the thermal oxidation of the Cu nano-inclusions or the addition of a co-catalyst, can affect the branching ratios and dynamics of electrocatalysis. The work outlined here helps to inform further use of electrodes prepared by the in situ reduction of Cu₂O for this application.

4:30 PM ET08.04.07

**Controlling Proton and Electron Transfer to Molecular Electro catalysts for Enhanced Selectivity**

Christopher Barile, Rajendra Gautam and Jason Mennel; University of Nevada, Reno, Reno, Nevada, United States.

The O₂ reduction reaction and the CO₂ reduction reaction are both central to important renewable energy devices. Since both reactions require the transfer of multiple electrons and protons, they can proceed by a variety of mechanisms depending upon the relative rates of these transfer events. We have developed electrode architectures that enable the modulation of proton and electron transfer kinetics to molecular catalysts such that the selectivity of catalysts can be improved. These electrodes are comprised of a metal-centered catalyst such as a Cu-triazole or an Fe-porphyrin attached via a self-assembled monolayer (SAM), which is then covered by a proton-permeable membrane. By altering the identity of the SAM, the kinetics of electron transfer to the bound catalyst can be tuned. Changing the proton permeability of the membrane enables control over the kinetics of proton transfer to the catalyst.

One of the major challenges in designing catalysts for both the O₂ and CO₂ reduction reactions is selectivity. Using a membrane-modified electrode, we
demonstrate that the selectivity of a Cu-based O2 reduction catalyst can be improved by controlling proton transfer rates such that the catalyst produces exclusively water. In contrast, the same Cu catalyst produces ~10% deleterious H2O2 side product when proton transfer is unregulated. We also explore how altering proton and electron transfer kinetics affects the selectivity of molecular CO2 reduction catalysts.

**ET08.04.08**

**Electrochemical CO2 Reduction to CO on Au—Isolating the Intrinsic Activity of the Most Common Crystal Facets**

Brian J. Seger1, Stefano Mezzavilla2, Ian E. Stephens2 and Ib Chorkendorff3; 1Technical University of Denmark, Kongens Lyngby, Denmark; 2Department of Materials, Imperial College London, London, United Kingdom.

Due to the drastic drop in renewable electricity prices, electrochemical CO2 reduction has received renewed interest. While CO2 reduction can lead to a wide variety of products, almost all go through a CO intermediate, thus understanding the electron transfer reaction of CO2 to CO is important not just for CO production, but also for products such as ethylene, ethanol, methane and others. Au has been shown to be the most active electrocatalyst for CO production, however major fundamental knowledge on this reaction has yet to be discovered. While most works focus on highly active nanostructured Au electrodes, there has yet to be a comprehensive study on the intrinsic electrochemical activity of individual Au facets.

This talk will discuss our work on the electrochemical conversion of CO2 to CO on single crystal Au <110>, <111>, <110>, and <211> facets as well as polycrystalline Au. Our results show a 25 fold difference between the least and most active crystal facets. All facets follow approximately the same Tafel slope between the tested potentials of -0.6 V to -0.8 V vs. RHE. Pb underpotential deposition (UPD) was used to deposit a monolayer of Pb on the Au gold surface to determine surface area. However, the potential at which Pb UPD deposits is facet dependent. By setting a correct potential we could selectively deposit lead on a given facet. While Pb UPD favored depositing on the most active sites, we still could gain fundamental catalysis knowledge. On polycrystalline Au, 20% of a monolayer of Pb yielded a 50% decrease in CO production, but only a 30% decrease in H2 production. 50% of a Pb monolayer on Au yielded a 95% decrease in CO production, but only a 50% decrease on H2 production. The decrease in CO production as a function of Pb coverage indicated that not only could we passivate the most active sites, but also that the facet dependent activity was quite different for CO production versus the competing H2 evolution side reaction.

To further utilize Pb UPD to isolate sites we reinvestigated one of our least active facets, Au <111>. Single crystals are never completely flat and thus there are always a small percentage of step sites. We used selective Pb UPD to deposit 4% of a monolayer in the attempt to passivate these sites. This led to a 50% decrease in CO activity, but the same H2 evolution activity. Covering the Au <111> with 15% of a monolayer led to a 90% drop in CO activity, but the same H2 evolution activity. These results suggest that the intrinsic activity of the least active facets is probably much lower than measured and the experimental results are actually dominated by a small number of highly active defect sites. While these results focus on Au, no single crystal is defect free. Thus these results may lead us to also question whether there are other situations where the non-optimal facets for a given reaction are actually much less active than originally thought.
Compared to traditional wash-coated powder-form catalysts, array ensembles of one-dimensional (1D) nanostructures possess stronger gas-solid phase interaction, larger surface area and enhanced materials utilization efficiency [1, 2]. Unlike a layer of ZSM-5 film (MF framework) grown on cordierite[3], array-structured ZSM-5 with c-orientation was synthesized by a secondary-growth hydrothermal method. Although the BET surface area and pore size distribution were similar with traditional film, the hydrocarbon trapping efficiency over as-synthesized ZSM-5 arrays was significantly improved. The higher extent of the exposed a- and b- planes to reactant molecules could facilitate the catalytic reactions and adsorptions by improving the mass transportation. The novel ZSM-5 array-structure could provide a promising class of structured devices for hydrocarbon trapping and separation.

Furthermore, first-principles Density Functional Theory (DFT) calculations are performed to investigate the Al substitution site preference on the ZSM structure, as well as the adsorption energetics of the reactant molecules.

ET08.05.04 Sulfur Segregation and Surface Site Vacancy Compensation During Methanol to Methoxy Reactions on MoS2 Prescott E. Evans1, Hae K. Jeong1, Zahra Hooshmand2, Duy Le2, Takat B. Rawal2, Sahar N. Alvillar4, Ludwig Bartels3, Tatat S. Rahman1 and Peter Dowben2, 1Daegu University, Gyeongsan, Korea (the Republic of); 2University of Central Florida, Orlando, Florida, United States; 3University of Nebraska–Lincoln, Lincoln, Nebraska, United States; 4University of California, Riverside, Riverside, California, United States.

Coverage dependent, sulfur vacancy defect formation on the MoS2(0001) basal plane resulting from the adsorption of methanol on MoS2 and its subsequent conversion into methoxy, was investigated utilizing scanning tunneling microscopy, photoemission, photoluminescence, and modeled by density functional theory (DFT). The adsorption of methanol on MoS2 at 110 K followed by annealing near 350 K or the adsorption of methanol on MoS2 at 350 K results in the formation of numerous point defects at the MoS2 basal plane. Larger patch defects, nominally ~2 nm in size as well as line defects on the MoS2 sample surface become increasingly apparent with multiple cycles of methanol exposure and annealing. X-ray spectroscopy studies of the exposure of MoS2 to methanol are consistent with a conversion to methoxy, and the production of defects, based on the reaction kinematics, and significant shifts in oxygen binding energies. Additionally, shifts in sulfur binding energy and temperature dependent sulfur to molybdenum integrated XPS intensities ratios near the critical 350 K formation temperature indicate sulfur segregation to the surface and compensation of surface vacancy sites. The experimental results indicate a small but persistent activation energy for the reaction consistent with DFT predicted energetics. The energy favorability of coinciding defect creation and methoxy formation is also suggested by DFT calculations. A strongly bound methanol surface kinetics is not favored on the defect free MoS2 surface.

ET08.05.05 Developing Descriptor of Keggin Heteropolyacid for Application in Biomass Conversion Catalysis Fiaz Ahmad, Tuhin Suvaraa Khan, Md. Inteyaz Alam, Kamal K. Pant and M. Ali Haider; Indian Institute of Technology Delhi, New Delhi, India.

Bio-renewable resources have great potential to supersede conventional fossil fuel to meet energy and chemicals demands. Nevertheless, most of the processes employed for biomass conversion essentially requires the presence of an acid catalyst for sustainable production of fuel and chemicals. In this context, catalysts belonging to the family of Heteropolyacids (HPA) are extensively used owing to their excellent activity in biomass conversion reactions[1]. Although a wide range of HPA’s have been classified based on their geometrical arrangements, Keggin HPA’s represented by general formulae, [XM12O40]n+ have prevalence in industrial applications owing to their super acidic nature, high thermal stability at elevated temperatures in liquid phase reactions and ease of synthesis as compared to other HPA’s. In general, the central atom X can be either P, Si, Ge, B, or Al whereas the heteroatom M can be either W6+ or Mo6+ or W6+ in which 12 linked octahedra containing addenda atoms (M2+O4) surrounds a central tetrathiod (XO4)4+. Interestingly, the higher activity of Keggin HPA’s is attributed to the combined effect arising from their stability, acidity, and structural accessibility, nevertheless no conclusive evidence has been suggested for the rational design of Keggin HPA’s. Moreover, the effect of changing central atom X on the activity of Keggin HPA’s is yet to be explored. Therefore, we have employed both theoretical and experimental approach to conclude deprotonation energy (DPE) as a suitable descriptor for rational design and selection of Keggin HPA’s. In this regard, Density functional theory (DFT) have been employed to calculate the DPE of known Keggin HPA’s with heteroatom W and Mo as well as propose the novel and futurist catalysts by changing the central atom with elements from group 13-17 of the periodic table. Parallally, esterification reactions have been performed with biomass-derived levulinic acid to produce additives for “green gasoline” in the presence of phosphotungstic acid and phosphomolybdic acid to validate the theoretical results. Interestingly, it was found that activity of Keggin HPA’s is a direct function of their DPE and difference in DPE remained constant when same elements from group 13-17 of the periodic table were put as central atom X in each of the Keggin HPA’s with W6+ and Mo6+ heteroatom. Nevertheless, change in the central atom of the Keggin HPA’s with W6+ and Mo6+ heteroatom caused a significant change in individual DPE’s, yet the overall difference in DPE remained constant when same central atoms were placed in both the catalysts. Interestingly, experimental results suggested similar trend and difference in activation barriers of both the catalysts with same central atom remained same even though esterification reactions were performed in different alcohols. Besides several tools and techniques such as XRD, BET, FT-IR, SEM, TEM, HPLC, GC-FID have been used for the characterization of catalysts and the product.

ET08.05.06 Deciphering Graphene Supported Metal-Nitrogen Active Center on CO Reduction Reaction—Structure, Magnetic and Catalytic Properties from First Principle Simulations Minjie Liu1, Guangjin Wang1 and Qin Wu1; Brookhaven National Laboratory, Upton, New York, United States; 1College of Chemistry and Materials Science, Hubei Engineering University, Xiaogan, China.

The dispersing single atom catalysts have been developed recently and reveal highly catalytic activities. The materials of single transition metal embedded in nitrogen-doped graphene display great potential as the catalysts for many reactions. For example, single atomic Ru in nitrogen-doped graphene exhibits excellent activity for oxygen reduction reaction [1]: single Fe-Co-Ni in Mn3C4 moieties show tunable electrocatalytic activity in oxygen evolution reaction [2], and Fe dispersed on nitrogen-doped graphene has been demonstrated as an efficient electrocatalyst for CO2 reduction reaction [3]. In those systems, the single atom center contributes as the active site, while the interaction between the single atom and the substrate is crucial. In our study, we applied density functional theory (DFT) simulations to elaborate different nitrogen doping concentrations and configurations surrounding the metal center. The stability of graphene supported metal-nitrogen active center, magnetic and catalytic properties have been explored. Take CO2 reduced into CO on Fe-N-graphene system as an example, our results show that the chemical environment around the single atom is critical, and the metal center and nitrogen atoms nearby determine the catalytic performance synergistically. Regulating single atom coordination tunes catalytic activity which will be instrumental for designing catalysts with the desired properties.
In this work, we investigated the effect of the Pt-precursor, on the catalytic properties of the PtCeO2-NR catalysts for H2 production. The CeO2-1D support was synthesized by the hydrothermal method, using a (NaOH) solution 10 M as precipitating agent [1,2]. The active phase Pt 0.5% (w/w) was impregnated to the catalytic support CeO2-1D by impregnation method. The Pt/CeO2-(X) catalysts were characterized by N2 adsorption, XRD, TPR, TEM and EDS. Afterwards, the activity and selectivity in the SRM reaction was evaluated by using a commercial system RIG-100-ISRI in a temperature range of 200 - 450 °C at atmospheric 204 Pressure. The reaction products were analyzed by using a Gow-Mac 580 Gas chromatograph with a thermal conductivity detector equipped with a two column system. The characterization results showed a specific surface area of 89 and 95 m2/g respectively for the support and the best Pt/CeO2-(Nit) catalyst. The XRD results showed the typical diffraction pattern of the fluorite cubic structure for CeO2 and a peak associated with Pt is not detected, which confirms a small particle size and a high dispersion of the metal. TPR profiles of the Pt/CeO2-(X) catalysts, showed peaks of H2 consumption associated with the reduction of PtO, to Pt° at low temperature as well as a partial reduction of surface ceria from Ce4+ to Ce3+, associated to the presence of the noble metal on the surface of the support [3]. Catalytic activity in the steam reforming methanol reaction, the Pt/CeO2-(Nit) catalyst exhibited a higher catalytic activity reaching a conversion yield of 99% at 350 °C, as well as higher H2 production. In addition, it exhibited a higher yield, as well as the lower production of CO and CH4. None of the synthesized catalysts exhibited a significant deactivation over the evaluated time period.

Tuning of Activity and Selectivity of Ni(Al)-SBA-15 Catalysts in Hydrogenation of Naphthalene
Tatiana Klimova, Haydee Vargas Villagran and Mark Eugenii Martinez-Klimov
Universidad Nacional Autónoma de Mexico, Ciudad de Mexico, Mexico.

In the present work, two series of nickel catalysts with 4 wt. % of Ni loading were evaluated in the hydrogenation of naphthalene in order to elucidate the effect of surface acidity (Broomsted or Lewis) and preparation method used on the catalyst's activity and selectivity. On the one hand, two supports, SBA-15 silica and Al-SBA-15 with Si/Al molar ratio ~ 30, were synthesized by hydrothermal method in order to obtain 2D nanostructured supports with and without Broomsted acidity. On the other hand, three Ni catalysts were prepared by the incipient wetness impregnation method using two different nickel precursors: nickel nitrate (N) and a Ni-EDTA complex (ED). We were also interested in the effect of the preparation method on the nickel dispersion and the acidity of the prepared catalysts.

Prepared catalysts were labeled as: Ni/SBA(NN), Ni/SBA(ED), Ni/AlSBA(NN) and Ni/AlSBA(ED). Characterization of the catalysts was performed by nitrogen physisorption, powder X-ray diffraction, temperature programmed reduction, temperature programmed desorption of ammonia, infrared spectroscopy of adsorbed pyridine and high resolution transmission electron microscopy. Characterization results showed that both SBA-15 and Al-SBA-15 supports had attractive textural properties. However, the characteristic hexagonal pore arrangement of SBA-15 was not preserved in the Al-SBA-15 support. The IR of adsorbed pyridine allowed us to confirm and quantify the Broughton (B) and Lewis (L) acid sites present in the SBA-15 and Al-SBA-15 catalysts prepared from both precursors used, being the Ni/AlSBA(ED) catalyst the most acidic one. Catalytic activity of the catalysts in hydrogenation of naphthalene increased in the following order: Ni/SBA(NN) < Ni/AlSBA(NN) < Ni/AlSBA(ED) < Ni/SBA(ED). Acidity of the catalysts and the dispersion of the reduced Ni nanoparticles also affected the selectivity of the catalysts to decalins (completely saturated products). Both catalysts prepared using a Ni-EDTA complex (Ni/SBA(ED) and Ni/AlSBA(ED)) showed high selectivity to decalins, whereas those prepared from a nickel nitrate solution (Ni/SBA(NN) and Ni/AlSBA(NN)) were selective for tetralin production. Therefore, the nickel precursor used and the support’s acidity affected the activity and selectivity of the tested Ni catalysts.

Enhanced CO2 Reduction in Lead-Free Perovskite CsxSb2Br6 Nanocrystals—Performance and Selectivity
Chang Lu, Xiao Ma, Dominique S. Itanze, Hui Li and Scott M. Geyer; Wake Forest University, Winston Salem, North Carolina, United States.

The last decade has witnessed the burgeoning development of halide perovskite materials with a significant focus on solar and light-emitting diodes applications. However, halide perovskites have received less attention as a catalyst for energy application, for example, water splitting and CO2 reduction reaction. Moreover, the development for Pb-free perovskite is highly desired for all applications. To this end, in our work, we developed a facile synthesis method for Sb-based halide perovskite nanocrystals (NCs). These exhibit structure uniformity and high thermal stability, with only a 2 % weight drop (attributed to the ligand loss) under 200 °C annealing. For solar driven CO2 reduction the Cs2Sb2Br6 produces 400 umol(CO)/g, a 40-fold more improvement in CO per gram compared to CsPbBr3. Interestingly, the use of Pb-based perovskite also generates CH4, which is not observed in Sb-based reaction batch, and we will present DFT calculation results to shed further light into the differences in reaction mechanism for the Pb-based and Sb-based system. This brings new insights into the emerging field of Pb-free perovskite alternatives and perovskite materials for catalytic applications.

Development of Catalytic La-Based Perovskite Redox Materials for Solar Thermochemical Conversion of CO2 into Syngas
Rahul R. Bhosale and Gorakshnath Takalkar; Department of Chemical Engineering, Qatar University, Doha, Qatar.

The energy consumption of the world today is around 15TW and it is expected that it will raise up to 30TW by the year 2050. In addition to this, due to the excessive utilization of fossil fuels (for the production of required energy), the concentration of CO2 in the environment increases rapidly. The production of syngas (which can be used as a precursor for the production of liquid transportation fuel) by using H2O, CO2, and solar energy provides a promising path.
to solve the issues associated with the utilization of fossil fuels and increase in the CO₂ concentration.

Direct photo-reduction of syngas via thermolysis of H₂O and CO₂ is possible; however, it needs a very high temperature and chances of forming a gaseous explosive mixture of H₂ and O₂ is also very high. Utilization of solar driven metal oxide based catalytic thermochemical H₂O and CO₂ splitting cycle reduces the requirement of higher temperatures and avoids the formation of explosive gas mixture. Various non-volatile redox materials have been investigated towards the thermochemical production of solar fuel via H₂O and CO₂ splitting reactions. In addition to the ferrite and ceria based materials, recently the researchers are focused towards perovskite based redox materials as an active catalyst for the solar splitting process. In particular, La-based perovskite materials are of particular interest as they are capable of producing higher amounts of O₂ and H₂/CO₂ at lower operating temperatures as compared to ceria and ferrites.

In this study, a variety of La-based perovskite materials were synthesized using combustion method and tested towards multiple H₂O/CO₂ splitting cycles using a high temperature thermogravimetric analyzer. It is very important to note that in most of the previous investigations the maximum number of cycles performed in case of La-based perovskites are 3 to 4. Hence, this study has a uniqueness that it tested the La-based perovskites in more than 50 thermochemical cycles.

Enhancement of CO₂ Reduction Activity Under Visible Light Irradiation Over Zn-Based Metal Sulfides by Combination with Ru-Complex Catalysts
Tomiko M. Suzuki¹, Tomoaki Takeyama¹, Shunsuke Sato¹, Akihide Iwase², Akihiko Kudo² and Takeshi Morikawa³; ¹Toyota Central R&D Labs Inc, Nagakute, Japan; ²Tokyo University of Science, Tokyo, Japan.

The reduction of CO₂ to obtain useful energy-rich chemicals utilizing photocatalysts has attracted attention as a potential means of artificial photosynthesis operating under sunlight irradiation. Although the use of powdered systems for CO₂ reduction is challenging owing to the inherent difficulty in achieving the highly selective reaction of CO₂ in solution, the system is attractive as a practical cost-effective system to utilize sunlight [1]. In this regard, we have demonstrated visible light-induced selective reduction of CO₂ to HCOOH using metal-complex/semiconductor hybrid photocatalyst consisting of a Ru-complex and a p-type metal oxide semiconductor particles (N-doped Ta₂O₅) in acetonitrile (MeCN)/triethanolamine (TEOA) solution with quantum efficiencies of 1.9% and more [2, 3]. Among various semiconductors, Zn-based sulfide are also attractive semiconductor for the hybrid photocatalyst, because ZnS possesses a relatively negative conduction band minimum (E_{CBM}) formed by the Zn 4s4p orbitals, which facilitates the electron transfer from the CBM of the semiconductor to the metal-complex.

In the present study, the powdered Zn-based sulfides which were reported to be active for sacrificial H₂ evolution, were investigated in combination with various Ru-complex catalysts with regard to the promotion of visible light driven CO₂ reduction. Hybrid photocatalysts consisting of a Ru-complex and a semiconductor anchored by organic groups were prepared by an adsorption method. Photocatalytic CO₂ reduction was performed in MeCN/TEOA solution under visible light (≥410 nm) irradiation. The photocatalytic activities were largely dependent on the basic characteristics of the Ru-complex and the metal sulfide. The results demonstrate that several of semiconductors improve the photocatalytic CO₂ reduction selectivity of the hybrid system, and that n-type (AgIn)₀.₂₂Zn₁.₅₆S₂ [4] and ZnS:Ni (Ni 0.2 mol%) [5] linked with a neutral Ru-complex containing phosphonate anchors ([Ru(dpbpy)(CO)₂Cl]², dpbpy: 4,4'-diphenyl-2,2'-bipyridine) exhibited highest turnover number with above 100 after 16 h irradiation. The carbon source for the HCOOH evolved in the reaction over the hybrid photocatalysts was confirmed to be CO₂ based on ¹³C analyses [6].

These results suggest that Zn-based metal sulfide are potential candidates for use in powdered semiconductor/metal-complex systems for active and selective CO₂ photoreduction. Our results also suggest that future success in powdered Z-scheme systems utilizing water as an electron donor and proton source.

High Yield Preparation of Two-Dimensional Cu Nanocatalysts for Carbon Dioxides Reduction Reaction
Shutang Chen and Gugang Chen; Honda Research Institute USA Inc., Columbus, Ohio, United States.

Cu-based nanostructures have been explored for catalyzing CO₂ electroreduction due to their lower working function and cost, and higher earth-abundancy. However, the practical application of CO₂ electroreduction reaction requires Cu catalysts hold a high percentage of exposed surface atoms, which can improve the utilization efficiency of catalysts and products selectivity. Here we reported a high temperature reduction method to prepare Cu nanosheets in hydrophobic system. The feeding molar ratio of trioctyphosphine/Cu ion precursor plays a critical role for the formation of Cu nanosheets. The shape of Cu nanosheets were controlled by adjusting the reaction interval, the types of Cu ion precursor, and the purity of trioctylphosphine. The size and thickness of Cu nanosheets were variable from 50 nm to 13 μm and 15 nm to 500 nm, respectively. Moreover, pure Cu nanosheets are stable in solution for more than three months. As a result of high percentage {111} of surface area, these nanosheets as catalysts have demonstrated the enhanced catalytic activity and selectivity to convert CO₂ to fuels.

CO₂ Activation on Defective MoS₂ Surfaces for CO₂ Photo-Reduction Applications
Yi-Fan Huang¹, Hsiang-Ting Lien², He-Yun Du², Ying-Ren Lai², Ting-Li Lin¹, Yu-Chung Chang³, Michitoshi Hayashi³, Li-Chyung Chen² and Kuei-Hsien Chen²; ¹Academia Sinica, Taipei, Taiwan; ²National Taiwan University, Taipei, Taiwan.

CO₂ activation on catalyst surface is the very first and critical step in CO₂ photo conversion into valuable chemicals. However, CO₂ is a thermodynamically stable and chemically inert molecule. How to select and treat the photocatalyst surface to enhance the chemisorption of CO₂ and improve its reactivity remains a scientific challenge. Photocatalyst surfaces with functional modifications, such as creating atomic vacancies on surface by H₂ plasma treatment are promising candidates for this purpose.

This report reveals the essential first step of CO₂ adsorption/activation on a defective MoS₂ surface by using near ambient pressure X-ray photoelectron spectroscopy (APXPS), scanning tunneling microscope (STM) experiments and density functional theory (DFT) calculations. These studies not only suggest the atomic sulfur defects on the MoS₂ surface particularly play a critical role in activating CO₂ to form chemisorbed CO₂, but also provide further mechanistic information for the intermediates species, thus guiding the design of better photocatalyst in the future.

Nanoscale Chemical Reactor Based on Localized Surface Plasmon Energy in Environmental Transmission Electron Microscope
Caifeng Wang¹,², Wei-Cheng D. Yang¹,² and Renu Sharma³; ¹National Institute of Standards and Technology, Gaithersburg, Maryland, United States; ²University of Maryland, College Park, Maryland, United States.
Minimizing chemical processes in a research context has many advantages, including the ability to examine the reaction at atomic resolution, the reduced usage of costly and/or hazardous chemical reagents, and the ability to be integrated into analytical devices. [1-2] However, current efforts towards miniaturizing chemical processes have been limited by the achievable minimum reaction volume and the lack of precision control over the reaction locations. Herein, we demonstrate a nanoscale chemical reactor, utilizing localized surface plasmon (LSP) resonance as the energy source, in an aberration-corrected environmental transmission electron microscope (ETEM). This approach allows us to confine the reaction within the proximity of the nanoparticle while taking advantage of the high spatial resolution measurement capability of the electron microscope to monitor the reaction.

Plasmonic nanoparticles, such as Au or Al, are placed in a reactive environment inside the ETEM. The composition and partial pressure of the gases are controlled by a gas handling system and analyzed using a residual gas analyzer. Electron energy-loss spectrum (EELS) imaging is used to acquire both elemental and LSP maps from the same nanoparticle. This allows the mapping and quantification of different gas adsorption on the nanoparticle surface. The energy required for the reaction of interest is provided by the LSP resonance excited by the high energy electron beam. The reaction location is confined within the proximity of the nanoparticle due to the local field enhancement of the LSP resonance. Using a non-negative matrix factorization machine learning algorithm, we map the energy transfer pathways from the electron beam to the nanoparticle at nanometer spatial resolution and 0.08 eV energy resolution. The temperature distribution of the nanoparticle is monitored with few-nanometer spatial resolution using time-resolved EELS. Reaction processes, including morphological changes and transitions between crystalline phases, are monitored using atomic-resolution movies. By utilizing LSP resonance to initiate the reaction, we show that chemical processes can be confined within a nanometer scale volume, and modulated by electron flux. Important parameters of the reaction, including composition of the reactants, adsorption of gases, transfer of energy, change of temperature, as well as reaction dynamics, can be monitored with nanometer or atomic resolution. Our approach paves the way to understanding a wide range of chemical reactions at the atomic scale. [3]

Co-Based Bimetallic Nitride Flakes Grown on N-Doped Carbon Nanofibers as an Efficient Bifunctional Electrocatalysts for Oxygen Evolution and Reduction Reactions
Seokwun Song and Il Doo Kim; Korea Institute of Science and Technology, Daejeon, Korea (the Republic of)

In recent years, oxygen electrocatalysis has attracted great attention due to the desire for many energy storage or conversion devices such as metal-air batteries, fuel cells, and water electrolyzer. However, the sluggish kinetics of oxygen-based electrochemical reactions hinder the efficiency. Although, noble metal-based electrocatalysts are widely used to reduce the energy loss, their high cost is critical limitation for broad and practical applications. Thereby, many trials to replace noble electrocatalysts with highly efficient and inexpensive non-noble metal-based oxygen electrocatalysts by employing transition metals such as Co, Mn, and Ni. Especially, transition metal nitriles such as Co4N are considered as a promising candidate material due to their superior electrical conductivity and chemical stability. Furthermore, bimetallic compounds can further induce oxygen-based catalytic activity by effective tuning of d-band structure.

Here, we proposed facile synthetic method for Co-based bimetallic nitride flakes grown on n-doped carbon nanofibers (Co-M-N@NCNF, M = Ni, Mn, Fe) by using Co-based bimetallic leaf like zeolite imidazole framework (ZIF-L), which is composed of cobalt and other metal ions (Ni, Mn, Fe) with organic linkers. Firstly, electrospun Polyacrylonitrile (PAN) nanofibers were treated by NaOH for smooth growth of Co-based bimetallic leaf like zeolite imidazole framework (ZIF-L), which is composed of cobalt and other metal ions (Ni, Mn, Fe) with organic linkers. Secondly, electrospun Polyacrylonitrile (PAN) nanofibers were treated by NaOH for smooth growth of Co-based bimetallic leaf like zeolite imidazole framework (ZIF-L), which is composed of cobalt and other metal ions (Ni, Mn, Fe) with organic linkers. Finally, the Co-N based ZIF-L nanofiber was precipitated in a solution of ammonium hydroxide, resulting in amorphous Co-N nanofiber. Followed by subsequent stabilization and nitridation process under ammonia gas, it converted to Co-M-N@NCNF. The Co-M-N@NCNF nanofibers showed remarkable electrochemical properties for both oxygen evolution reaction (OER) and oxygen reduction reaction (ORR). We demonstrated enhanced catalytic activity of Co-M-N@NCNF for both OER and ORR in terms of overpotential, Tafel slope, and charge transfer. These are mainly attributed to the synergistic effects from Co-based bimetallic compounds with nitrogen atoms. Also, unique structure of active two dimensional flakes grown on one dimensional carbon nanofiber fiber offered more exposed active sites and high surface area. The proposed strategy of ZIF-derived bifunctional nanomaterials provides prospects for developing highly active electrocatalysts in electrochemical energy devices.

Minimizing Energy Use for Surface Reactions by Using Both Light and Heat—Plasmonic Catalysts and Non-Plasmonic Catalysts Enabling Photocexcitation of Adsorbates
Chanyeol Kim and Hyunjo Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of)

Many heterogeneous catalytic reactions occur at high temperatures, which may cause a large energy cost, poor safety, and thermal degradation of catalysts. Here, we propose a “light-assisted surface reaction”, which catalyze the surface reaction using both light and heat as an energy source. Plasmonic metal nanoparticles absorb light energy and release the energy through radiative or non-radiative channels. Surface catalytic reaction would take advantage of the non-radiative energy relaxation of plasmon with enhanced activity. Particularly, binary nanoparticles are interesting because diverse integration would be possible consisting plasmonic part and catalytic part. Herein, we demonstrated ethanol dehydrogenation under light irradiation using Ag-Ni binary nanoparticles with different shapes, snowman and core-shell, as plasmonic catalysts. The surface plasmon formed in the Ag part enhanced the surface catalytic reaction that occurred at the Ni part, and the shape of the nanoparticles affected the extent of the enhancement. The surface plasmon compensated the thermal energy required to trigger the catalytic reaction. The absorbed light energy was transferred to the catalytic part by the surface plasmon through the non-radiative hot electrons. Non-plasmonic conventional metal catalysts such as Ru, Rh, Pt, Ni, and Cu were tested for CO2 hydrogenation, and Ru showed the most distinct change upon light irradiation. CO2 was strongly adsorbed onto Ru surface, forming hybrid orbitals. The energy gap between the HOMO and LUMO was reduced significantly upon hybridization. Hot electrons could be generated by jumping the shortened energy gap upon light irradiation, enhancing CO2 dissociation. The light-assisted CO2 hydrogenation used only 37% of the total energy with which the CO2 hydrogenation occurred using only thermal energy. The CO2 conversion could be turned on and off completely with a response time of only 3 min, whereas conventional thermal reaction required hours to terminate the CO2 conversion. These unique features can be potentially used for on-demand fuel production with minimal energy input.
Light interacting with catalysts via surface plasmon resonances has the potential to dramatically improve catalytic reactions by photothermal heating and hot-electron transfer. This project investigates plasmonic light enhancement of the CO oxidation reaction over supported Au catalysts. Optimization of this reaction empowers removal of poisonous CO at room temperature which has the potential to improve human health. This reaction also features a negative activation energy which leads to a minimum in the temperature dependent conversion curve near 80 °C. Results show that catalytic activity around room temperature doubled under light and catalyst lifetimes increased by a factor of 5. From these results, an analysis of the relative magnitude of the photothermal catalytic enhancement and non-thermal catalytic enhancement effects were performed by utilizing the temperature dependent change from positive to negative activation energy. This demonstrated that the effect of photothermal heating is more substantial and that both effects enhance the reaction rate and improve catalytic lifetimes. From further experiments coupling light induced desorption of CO₂ to the regeneration of catalytic activity, a mechanism for light enhancement on gold catalysis is proposed. Light reactivates the catalyst by removing surface carbonates which otherwise act as poison, allowing for dramatically increased catalytic activity and lifetime to demonstrate a new path for highly active CO oxidation.

Here, we exploit the LSP resonance of a triangular Au nanoprim excited by an electron beam to drive CO disproportionation (2CO → C + CO₂), known as the Boudouard reaction that typically takes place between 300 °C to 600 °C, at room temperature, in an environmental scanning transmission electron microscope (ESTEM). Using in situ electron energy loss spectroscopy (EELS) mapping, combined with density functional theory (DFT) and electromagnetic boundary element method (BEM) calculations, we show that amorphous carbon deposits, resulting from the CO disproportionation reaction, occur only at selective sub-particle locations where preferred CO adsorption sites and plasmon modes antinodes are coincident. Low-loss and core-loss EELS are used to locate the maximum LSP resonance intensity excited by the electron beam and the adsorbed CO molecules, respectively, on a Au nanoprim. Amorphous carbon deposited on the cantilevered corner of a nanoprim, measured after CO is evacuated from the sample chamber, confirms that (a) CO molecules disproportionate at room temperature and (b) the location corresponds to where the CO adsorption probability and the intensity of dipolar LSP mode overlap. The combination of high energy and spatial resolution, along with simulations, provide an unprecedented insight that (a) CO molecules disproportionate at room temperature and (b) the location corresponds to where the CO adsorption probability and the intensity of dipolar LSP mode overlap. The combination of high energy and spatial resolution, along with simulations, provide an unprecedented insight into the catalytically active sites, for LSP induced chemical reactions.

Controlling Energy Flow in Plasmonic Photocatalysis Through the Design of Hybrid Plasmonic Nanostructures for Selective Catalysis Suljo Linic; University of Michigan, Ann Arbor, Michigan, United States.

It has been shown that photo-excitation of plasmonic metal nanoparticles (Au, Ag, and Cu) can induce direct photo-chemical reactions on the nanoparticles. However, the widespread application of this technology in catalysis has been limited by the relatively poor chemical reactivity of noble metal surfaces. In this presentation, we present our recent work in which we conceptualized and designed hybrid nanostructures in which a plasmonic metal harvests the energy of visible light photons and selectively channels that energy into catalytically active centers on the nanostructure. To accomplish this, we developed a synthetic protocol to deposit a few monolayers of Pt onto plasmonic Ag nanocubes. This model system allows us to conclusively separate the optical and catalytic functions of the hybrid nanomaterial and analyze the interaction between the two functions. Through experimental and theoretical studies of the optical properties of these nanostructures, we show that the flow of energy is strongly biased towards absorption (i.e. excitation of energetic charge carriers) in the thin Pt shell. We demonstrate the utility of these nanostructures for photo-catalytic chemical reactions in the preferential oxidation of CO in excess H₂. The reactor studies conclusively show that photo-excitation of these nanostructures results in photo-chemical reactions on the Pt surface. We describe the fundamental physical reasons for the observed directed flow of energy and discuss how these discoveries impact the field of plasmonic catalysis.

Rotational spectroscopy is introduced as a new in situ method for monitoring gas phase reactants and products during chemical reactions. Exploiting its unambiguous molecular recognition specificity and extraordinary detection sensitivity, rotational spectroscopy at terahertz frequencies was used to monitor the decomposition of carbonyl sulfide (OCS) over an aluminum nanocrystal (AlNC) plasmonic photocatalyst. The intrinsic surface oxide on AlNCs is discovered to have a large number of strongly basic sites that are effective for mediating OCS decomposition. The strength of rotational spectroscopy is witnessed through its ability to detect and distinguish isotopologues of the same mass from an unlabeled OCS precursor at concentrations <1 nanomole or partial pressures <10 mTorr. These attributes recommend rotational spectroscopy as a compelling approach for monitoring gas-phase chemical reactants and products in real time.

Sustainable Nanocatalysis—Plasmonic Silver Nanocubes and Cellulose Nanocrystals as Non-Innocent Support Audrey Moores; McGill University, Montreal, Quebec, Canada.

We explored the use of cellulose nanocrystals as a non-innocent support to generate metal/cellulose nanohybrids. We showed that, with Pd, we could afford active and enantioselective hydrogenation catalysts, while with Ru, extremely active and recyclable catalysts were accessed for the difficult reduction of aromes under mild conditions. These nanocrystals in suspension could allow the direct synthesis of silver nanoparticles without the use of any additional oxidizing or reducing chemical. Besides, we have employed silver nanocubes for hydrogen activation and hydrogenation of ketones and aldehydes via irradiation at 405 nm, corresponding to the position of the plasmon band of the nanocubes. Exposure to other wavelengths, or absence of light failed to provide activity thus proving the plasmonic effect. Compared to other catalytic systems, the plasmonically activated catalyst provides access to primary and secondary alcohols using milder conditions, in a highly atom economical fashion. Plasmonic catalysis of the oxidation of aldehyde to carboxylic acid was also demonstrated.

11:30 AM ET08.06.07
Efficient Ammonia Synthesis via Light-Driven Thermal Gradients in Fixed-Bed Catalytic Reactors Xueqian Li1, Jie Liu1 and Henry O. Everitt1,2; 1Chemistry, Duke University, Durham, North Carolina, United States; 2Physics, Duke University, Durham, North Carolina, United States; 3Army AMRDEC, Huntsville, Alabama, United States.

When the temperature of exothermic chemical reactions increases, thermodynamic equilibrium shifts away from producing products and towards retaining reactants. Unfortunately, for reactions with high activation barriers, the reaction rate can be extremely slow at the lower temperatures that favor products. Scalable industrial processes require both high reaction rates and high product yields and balancing these two represents the art of chemical engineering. A prominent example is the industrial Haber-Bosch process, which requires optimized catalysts, high temperatures, high pressures, and several recycling steps to achieve practical reaction rates and yields of ammonia, but at the cost of consuming up to 2% of the global energy produced annually. Here, we demonstrate how light-induced plasmonic heating can produce a controlled thermal gradient in a conventional Ru-based catalyst that simultaneously achieves both high reaction rates and high conversion yields in ammonia synthesis. Using continuous wave light emitting diodes, ammonia is copiously produced under ambient conditions without any external heating. Our results suggest that the optical control of thermal gradients in catalysts may become a universal strategy for simultaneously increasing reaction rates and conversion yields of many exothermic reactions.

11:45 AM ET08.06.08
Electrocatalytic CO2 Reduction at Functionalized Cu Surfaces—Structure-Reactivity Relationships Between Organic Modifiers and Product Selectivity Aya K. Buckley1,2, Francisca Maria Toma1,2, 1Joint Center for Artificial Photosynthesis, Berkeley, California, United States; 2Chemical Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

An efficient electrocatalyst for the reduction of CO2 (CO2R) would enable the conversion of a major contributor to global warming into valuable carbon-based products. Cu surfaces are unique in that they are the only single-metal system to catalyze the formation of multiconcat products from CO2. However, the lack of selectivity of these Cu surfaces necessitates investigation into how their catalytic behavior may be adjusted.

The complexity of the catalyst/electrolyte interface poses challenges in identifying how a change in an electrocatalyst affects the observed CO2R selectivity. Therefore, we employ a methodical experimental approach that focuses upon identifying which parameters play an important role in determining CO2R selectivity.

First, we examined the effect of a series of organic modifiers on the CO2R selectivity of Cu. Oxide-derived Cu surfaces were functionalized with molecular and polymeric modifiers featuring a wide variety of structural characteristics, including neutral and cationic species, protic and aprotic species, and species bearing various functional groups. The product distribution of these surfaces in the CO2R reaction was characterized at -0.7 V vs. RHE, focusing upon the selectivity between CO, formic acid and H2. This allowed classification of the organic structures based upon the promoted product. Finally, each class of modifiers was examined and key, common structural characteristics of the modifiers were identified.

Through this systematic study, we demonstrate that the CO2R selectivity of a non-precious metal catalyst may be improved for CO, formic acid or H2 by changing the organic modifier applied. Selectivities of up to 76% CO or 62% formic acid were observed, and H2 selectivity was tuned from 97% down to 2%. In this presentation, we describe the structural characteristics of these modifiers that are key to changing the observed selectivity. These common features offer insights into the mechanism by which organic modifiers influence CO2R selectivity at the metal surface. We expect that the identified structure-reactivity relationships will illuminate important design principles for novel, selective CO2R electrocatalysts and organic structures for CO2R devices.

**Quantitative Super-Resolution Imaging of Nanocatalysis** Peng Chen, Cornell University, Ithaca, New York, United States.

This talk will present our latest efforts in developing and using single-molecule super-resolution microscopy to map catalytic reactions on single nanoparticles at nanometer resolution and under operando conditions. Depending on available time, the topics may include: 1) cooperative communications within and between single nanocatalysts; 2) visualizing bimetallic effect within single nanocatalysts; and/or 3) mapping catalytic hotspots on plasmonic nanostructures.

2:00 PM  *ET08.07.02
**In Situ Characterization of Metal Surface Dynamics in Reaction Gas by Atomic Scale and Millisecond Resolution Environmental TEM** Seiji Takeda, Naoto Kamiuchi, Takehiro Tamaoka, Ryotaro Aso and Hideto Yoshida; Osaka Univ, Ibaraki, Japan.

Environmental transmission electron microscopy (ETEM) provides us with mostly static structural data of solid surfaces in reaction environments for a long time. However, given the recent advancement in TEM image detectors such as CMOS-based TEM cameras, the technique has started to progress in revealing the atomic dynamics that are correlated with catalytic reaction processes [1].

In this presentation, first we summarize the history of in-situ TEM in our research group briefly for the past decades. Second we show our recent time-resolved analyses with millisecond-resolution on the unexpected atomic dynamics on the surface of nanoporous gold (NPG) catalysts. The surface of NPG catalysts is structurally stabilized in pure oxygen environments, while the surface appears to be dynamically fluctuated with space and time in the reaction environment for the oxidation of CO at room temperature. Since the NPG catalysts inevitably include the residual impurity of Ag in addition to the majority of Au, it is concluded that the Ag atoms on the surface are oxidized to form stable Ag-O-Au atomic clusters in pure oxygen environment. It is also concluded that the self-activating atomic clusters are reduced and oxidized repeatedly in a reaction environment that, of course, includes both oxygen and CO. Hence, the catalytically active structure in the gold catalysts (supported Au nanoparticulate catalysts and NPG catalysts) can now be experimentally unified toward elucidating the fascinating catalysis mechanism of gold. We also show some recent challenges on the oxidation and reductions processes on the surfaces of related metals.

Though a chemical reaction is an extremely fast electronic phenomenon, the present study has clarified that the atomic dynamics occurring on the catalytically active surfaces can be observable by the advanced ETEM technique. Finally, to derive clearly the intrinsic natures of a specimen in a reaction environment by atomic scale and millisecond resolution ETEM, it is still indispensable to consider the influence of electron beam. We also discuss the related topics [2].

**Investigation of Gas-Solid Reaction in Confined Space by In Situ TEM and Synchrotron X-Ray** Yuzi Liu; Argonne National Laboratory, Lemont, Illinois, United States.

The reaction between gas and solid is a great interest for material science. In more specific, materials transformation, gas molecules adsorption/desorption and chemical reaction on the surface are the most attractive topics. Here we use both transmission electron microscope (TEM) and synchrotron x-ray to study the gas-solid reaction with the material in gas environment in confined space (tween two SiN membranes with gap ~500nm) which allow the high energy electron beam and x-ray penetrating the system. Firstly, the conventional and gas flow TEM were employed to study how the AgCl transformed to AgOx at different O2 partial pressure. It was found that the high energy electrons help to generate Cl vacancies which drive the AgCl reduction to Ag. The Ag was further oxidized to Ag2O due to the high O2 partial pressure. Secondly, the reaction between Cu2O and CO2 was studied by integrated imaging through combination of environmental TEM and synchrotron x-ray. The multi-beam and detectors were employed to study the same object at different length scales. A cross-platform holder was used to guarantee the same nanoparticle was investigated by electron beam and hard x-ray nanoprobe to ensure that we get the complimentary information. In addition to the study on the single particles, the investigation on the assembly of Cu2O particles by high resolution synchrotron x-ray powder diffraction (HRXRD) also indicates the charge transfer between Cu2O and gas molecules adsorbed on certain facets.

This work was performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, and supported by the U.S. Department of Energy, Office of Science, under Contract No. DE-AC02-06CH11357.

**Resolving the Atomic Details of Gas-solid Interfaces in Catalytic Materials Through In Situ Neutron Total Scattering** Daniel Olds, Jue Liu and Kate Page; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Nanostructured and porous materials have widespread industrial applications in adsorption and catalysis, but experimental studies providing atomistic data regarding gas-sorbent interactions under application-relevant conditions are limited. Current analytical methods give information about either the crystal structure or the macroscopic kinetics involved in these processes, but not their interplay.

We present a new sample environment for interrogating materials under precise gas-flow conditions using time-of-flight neutron scattering. This capability allows for simultaneous measurements of stroboscopic, isotope-contrast neutron total scattering and Steady-State Isotopic Transient Kinetic Analysis (SSITKA), thus providing material insight into both structural and kinetic details. We anticipate this sample environment will be useful in studies of gas-
solid interfaces, hierarchical structure, molecular sieves, nanomaterials catalysis, and more.

The results of a commissioning study on nitrogen adsorption in calcium exchanged zeolite X will be presented. Together with theoretical considerations from Grand Canonical Monte Carlo simulation, we identify the location of a heterogeneous distribution of adsorption sites under operational conditions (1 atm, 300°C). We also highlight recent upgrades to the sample environment allowing for high-temperature studies (up to 800°C) of materials under gas flow, which is demonstrated with an in situ redox reaction study on ceria nanorods. This sample environment is presently available in the general user program on the NOMAD beamline at the Spallation Neutron Source (ORNL).

Mechanisms of Photocatalytic H2 Evolution on Co-Catalyst Loaded Semiconductors in the UHV Constantin A. Walenta1,2, Sebastian Kollmannsberger1, Carla Couto12, Rui Nuno Pereira1, Martin Stutzmann1, Martin Tschurl1 and Ueli Heiz1; 1Chemistry Department & Catalysis Research Center, Technische Universität München, Garching, Germany; 2Department of Chemistry & Chemical Biology, Harvard University, Cambridge, Massachusetts, United States; 3Walter Schottky Institute & Physics Department, Technische Universität München, Garching, Germany.

Despite of intense research efforts in the last decade, photocatalytic processes for the generation of renewable fuels are still lacking the requirements for successful application on industrial scale. Research strategies have so far been focused on material screening due to the complexity of the underlying processes. However, a deep fundamental understanding will ultimately allow us to implement knowledge-based improvements towards enhanced photocatalytic efficiencies, selectivities and stabilities.

In this work, we examine the reaction mechanism of photocatalytic alcohol reforming on a model system (co-catalyst loaded rutile TiO2(110)). By judicious choice of surface preparation and catalyst loading, we are able to unravel the photochemical mechanism on an atomic scale. By changing the reaction conditions e.g. temperature, photochemical reaction steps of the isotopically labeled reactant can clearly be disentangled from chemical thermal reaction steps in the mechanisms. A detailed kinetic analysis reveals, that the photocatalytic reaction rate depends linearly on the photon flux, indicating that only one charge transfer of this two-step process is facilitated photochemically.

Ammonia Synthesis on the Fe(111) Surface—Reaction Mechanism and Kinetics Qi An1, Jin Qian2, Alessandro Fortunelli1,2, Robert Nielsen1 and William Goddard4; 1University of Nevada, Reno, Reno, Nevada, United States; 2Materials Science, Caltech, Pasadena, California, United States; 3Consiglio Nazionale delle Ricerche, Pisa, Italy; 4Chemistry, Caltech, Pasadena, California, United States.

The Haber-Bosch (HB) process converting nitrogen gas (N2) and hydrogen gas (H2) into the ammonia (NH3) consumes 1–2% of the world's energy supply and generates more than 300 million tons of carbon dioxide annually. It is essential to optimize the efficiency of HB process extensively to save energy and reduce CO2 production. However, the reaction mechanisms of HB process at industrial conditions are not fully understood. Here, we employed density functional theory to predict reaction mechanisms and kinetics for NH3 synthesis on Fe (111) surface which is more efficient for NH3 synthesis than other surfaces such as (100) and (110). First of all, the free energies of all steps are predicted under experimental condition of 673 K and 20 atm and industry condition of 730 K and 200 atm. Then we built the free energy diagrams into a kinetic Monte Carlo model to predict the steady state catalytic rates and compare with single-crystal experiments. We predicted a turnover frequency (TOF) of 17.7 s⁻¹ per 2 × 2 site (5.3 × 10⁻⁹ mol/cm²/sec) under condition of 673 K and 20 atm. This agrees very well with single crystal experiment of TOF = 10 s⁻¹ per site.

4:45 PM ET08.07.07
Spatial Tailoring of Dopant Position in Solids for Enhanced Visible Light Photocatalytic Performance Pragathi Darapaneni1, Natalia da Silva Moura1, Darrell Harry2 and James A. Dorman1; 1Louisiana State University, Baton Rouge, Louisiana, United States; 2Chemical Engineering, Southern University, Baton Rouge, Louisiana, United States.

Transition metal (TM) doped semiconductor materials are extensively employed for light harvesting and photocatalytic applications to increase the charge mobility for better performance. The position and site occupancy of the dopant dictate the physical properties of these materials such as light absorption, separation of charge carriers, and the surface reaction kinetics. Commonly used bulk characterization techniques are often indifferent to surface vs. bulk dopant occupancy. Therefore, this work addresses the phenomenon of spatially controlled dopant incorporation for controlled optical and photocatalytic properties.

In this work, highly doped TiO2: Ni²⁺ (15 mol%) nanoparticles are synthesized via sol-gel chemistry. The drying and annealing of the aged sol are shown to affect the segregation of NiO on the surface of TiO2. Specifically, it is possible to control the dopant position by varying the moisture exposure time, indicating that the ambient water layer on the surface of TiO2 plays an important role on surface energetics. The effect of moisture and annealing rate on the dopant position was systematically studied using steady-state and time-resolved methods (XRD, UV-Vis, Raman, TGA/DSC, and FTIR) to extract crystallization temperatures, optical absorption, bond formation, and surface hydroxyl concentration. XRD results show that the vacuum dried TiO2:Ni powders formed a doped anatase phase while the air dried powders formed segregated anatase and NiO phases upon annealing. Furthermore, rapid annealing of the air-dried TiO2:Ni powders formed a metastable anatase doped phase while slow annealing resulted in the segregation of NiO phase, which can also be observed in TGA/DSC. The annealing processes produce a shift from discrete peaks to a broad absorption based on the dopant position. The evolving local environment is probed via x-ray absorption spectroscopy (XAS) and High-Resolution TEM to elucidate the difference in the dopant local environment with photocatalytic performance using photoluminescence (PL) spectrometer. Moreover, the charge carrier recombination kinetics in these NPs can be investigated using time-resolved PL measurements to understand the modified reaction pathways. This ability to incorporate higher dopant concentrations while engineering the dopant position in nanostructures will assist in the development of improved photocatalytic devices. Finally, a similar trend of dopant segregation was observed with other first row TM doped TiO2 powders upon slow annealing, suggesting that the segregation of TM dopants in TiO2 is a function of the dopant size.
Selective Formation of Li₂O in a Lithium-Air Battery

Jelyn Lunger, Livvia Giordano and Yang Shao-Horn; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Although current electric vehicles rely on lithium-ion technology, lithium-ion batteries cannot provide a sufficiently far driving range at low cost [1]. Lithium-air batteries offer a promising alternative to conventional lithium-ion batteries due to their high theoretical energy density, close to that of gasoline. Although lithium peroxide is the discharge product typically observed in lithium-air batteries, lithium oxide is the preferred product with a specific capacity 1.3 times greater than that of lithium peroxide [2]. In addition, many electrolytes have been found to react significantly with lithium peroxide and with the superoxide ion, whereas lithium oxide is less reactive with the electrolyte [3]. Because the free energies of reaction for lithium oxide and lithium peroxide are similar (-561 kJ/mol and -571 kJ/mol respectively), it should be possible to design a catalyst that selectively forms lithium oxide at room temperature. Additionally, it is important that such a catalyst also reduces ORR/OER potential losses, which currently inhibit lithium-air battery efficiency.

To design a catalyst selective for lithium oxide formation, it is necessary to understand the reaction pathways for the growth of lithium oxide and lithium peroxide. While the reaction mechanism describing electrochemical growth of lithium peroxide has been well studied [4], much less is known about the initial nucleation of lithium peroxide or lithium oxide on the surface of a catalyst. In this study, the initial nucleation pathways for both lithium peroxide and lithium oxide are identified using the ruthenium dioxide (110) surface as a model catalyst. The lowest energy interfaces between lithium peroxide and lithium oxide and the ruthenium dioxide (110) surface are identified by employing a lattice matching algorithm. Density functional theory is then used to identify the charge and discharge pathways which offer the lowest overpotentials. Initial growth of lithium oxide on ruthenium dioxide (110) is found to have a discharge overpotential of 0.58 V, rate limited by adsorption of lithium ions. The removal of the final layer of lithium oxide on ruthenium dioxide (110) is found to have a charge overpotential of 0.44 V, rate limited by the desorption of oxygen. The effects on the charge/discharge overpotentials due to straining and doping the ruthenium dioxide (110) catalyst are studied to identify design principles for a catalyst that is both selective for lithium oxide formation and offers low ORR/OER overpotentials.

ET08.08.02
Computational High-Throughput and Screening of Catalytic Mass Activities of Tailored Pt Electro catalysts for the Oxygen Reduction Reaction
Marlon Rueck and Alessio Gagliardi; Department of Electrical and Computer Engineering, Technische Universität München, Munich, Germany.

Tailored Pt electrocatalysts harbor great potential to enhance the catalytic mass activity for the oxygen reduction reaction (ORR) in fuel cells [1]. Due to elaborate experimental synthesis and innumerable variations of nanostructures, computational high-throughput screening may highly promote the search for promising electrocatalysts. In our present work, we computationally screen through a plethora of distinct Pt nanostructures where an optimization algorithm tweaks the fine adjustment on the atomic-scale. Precise characterization of tailored electrocatalysts within feasible timescales is the critical step in high-throughput screenings. To this end, we employ our recently developed model [2] which rapidly predicts the catalytic mass activities of the screened nanostructures in absolute units of A mg⁻¹ Pt. Our study discloses nanostructures with high mass activities up to 3.86 A mg⁻¹ Pt. To further support experimental synthesis, we analyze the size dependence of the nanostructures on the catalytic mass activity. Summing up, our work comprises the crucial steps from screening and characterization to size dependence of tailored Pt electrocatalysts aiming at experimental and theoretical collaboration in nanoparticle synthesis.

Advanced Structural Characterisation of La-Doped Ceria Nanocubes for Enhanced Redox Ability
Colm O'Regan¹, Alberto Casu¹, Andrea Falqui¹, Danilo Loche², Lucy Morgan², Gavin Mountjoy² and Anna Corrias²; 1King Abdullah University of Science and Technology, Thuwal-Jeddah, Saudi Arabia; 2University of Kent, Canterbury, United Kingdom.

Ceria nanomaterials possess an exceptional reactivity due to the ability of the cerium ion to switch easily between 3+ and 4+ oxidation states, via the formation of oxygen vacancies within the ceria fluorite structure. This effect is enhanced at the nanoscale, and can be tailored by changing both the size and the shape of nanoparticles. In order to further enhance the ceria redox ability, doping of ceria with another element, such as lanthanum, has proved effective via an increased mobility of the oxygen vacancies.

With this aim, powder X-ray Diffraction (XRD), and transmission electron microscopy (TEM) techniques have been used to study the solid miscibility of La in samples of ceria nanocubes with nominal lanthanum doping up to 10 mol%, and to study the effect of doping on the morphology of the lanthanum-doped nanocubes.

Low-magnification TEM imaging shows lanthanum-doped ceria nanocubes have cubic morphologies, and a more regular cubic shape with sharper facets than pure CeO₂ nanoparticles. This suggests the beneficial role of La on maintaining a well-defined cubic shape during nanoparticle growth, via stabilization of the oxygen vacancies, and formation of highly reactive <100> terminated facets.

Additionally, XRD and aberration-corrected High Resolution TEM (HRTEM) imaging confirmed the cubic (Fm3m) fluorite single crystalline structure of the lanthanum-doped ceria nanocubes. In particular, the results of 2D-Fast Fourier Transform (2D-FFT) analysis conducted on HRTEM data were always consistent with the pure CeO₂ structure, confirming that the introduction of La did not give rise to the local formation of secondary phases. A shift in the peaks of the XRD patterns was observed with increasing La content up to approximately 7 mol%, suggesting the latter value is approximately the limit of the La solid solubility. Indeed, this was further confirmed by Energy Dispersive X-Ray Spectroscopy (EDS) spatially resolved chemical analysis, performed with subnanometer resolution by Scanning TEM (STEM). This revealed that the largest observed lanthanum concentration is equal to 7 mol%, in the sample with 10 mol% nominal lanthanum doping. Chemical mapping carried out using STEM-EDS also showed the La was homogeneously distributed throughout the CeO₂ nanocubes for all investigated samples, thus proving the formation of an evenly La-doped structure.

Further characterisation is in progress to confirm that these lanthanum-doped nanocubes do enhance redox ability.

ET08.08.04
NH\textsubscript{3} synthesis by the electrocatalytic N\textsubscript{2} reduction reaction (NRR) under ambient conditions is regarded as an appealing alternative to the industrial method that requires high temperature and pressure. Finding a material that can efficiently catalyze electrochemical N\textsubscript{2} fixation at ambient condition is a subject of considerable current interest. Atomically dispersed catalysts with mononuclear metal complexes or single metal atoms anchored on supports would be a promising candidate, because of their maximum atom efficiency, unique catalytic performances, and the similarity of the metal coordination environment to the ligand fields in molecular catalysts. A series of cost-effective and optimized atomically-dispersed electrocatalysts for NRR will be reported. Our results show that the catalysts are featured with high density of single metal atoms supported on hierarchically porous carbon frameworks. They exhibited remarkable selectivity of NH\textsubscript{3} formation and high NH\textsubscript{3} yield rate at low applied potentials at room temperature. Moreover, the catalysts show negligible activity decay in an N\textsubscript{2} electrolysis as long as 30,000 s. On the basis of our results and the previously reported work, a possible mechanism for NRR on the catalyst will be proposed to provide a fundamental insight into the high-efficiency NRR.

ET08.08.05
Efficient Photocatalytic and Photoelectrocatalytic Generation of Hydrogen Peroxide by Organic Semiconductor Catalysts

Shili Zheng and Yi Zhang; 1Institute of Process Engineering, Chinese Academy of Sciences, Beijing, China; 2Department of Chemical & Environmental Engineering, Yale University, New Haven, Connecticut, United States; 3University of Chinese Academy of Sciences, Beijing, China.

Recently, the market for hydrogen peroxide is expanding in various industrial applications, with the increasing importance of green chemistry. At present, hydrogen peroxide is synthesized by the so-called anthraquinone process on a large scale. The in-situ synthesis of H\textsubscript{2}O\textsubscript{2} based on advanced technologies is attracting much interest as a simple H\textsubscript{2}O\textsubscript{2} production method. Among them, electrochemical methods are environmentally-friendly and effective for the direct generation of hydrogen peroxide with high production rate and simple process.

Hydrogen peroxide can be electrochemically generated by the two-electron oxygen reduction reaction (ORR) on the surface of electrocatalysts. Considerable attempts have been made to prepare appropriate and cost-effective cathode materials to enhance the ORR activity and current efficiency for H\textsubscript{2}O\textsubscript{2} electro-generation. For this purpose, there are various materials reported including carbon-based materials (g-C\textsubscript{3}N\textsubscript{4}, graphite, carbon nanotubes, graphene, graphite felt and carbon cloth), transition metal oxides (Nb\textsubscript{2}O\textsubscript{5}, CeO\textsubscript{2}, Fe\textsubscript{2}O\textsubscript{3}, and Co\textsubscript{3}O\textsubscript{4}) and precious metal nanomaterials. Development of low-cost carbon-based metal-free catalyst with high ORR catalytic activity and low cost is emerged as an effective strategy for the replacement of precious metal.

As carbon-rich precursor, biomass has been used as raw material for the fabrication of carbon-based materials for a long time. With the choice of suitable activators, various works have reported that porous carbon derived from biomass can obtain well-defined micropore size distribution and an ultrahigh specific surface area. Activated carbon materials are applied as the development of catalyst in energy storage/conversion devices. Furthermore, considering the advantages of nitrogen doping for the enhancing of electrocatalytic activity, nitrogen-rich biomass and their derivatives have been recently chosen as promising precursors for nitrogen-doping carbon catalysts.

As a typical low-cost and easily obtained nitrogen-rich biomass resource, Ramie is widely distributed in the east and south of China as textile, feeding and paper raw materials. We developed nitrogen-doped powered activated carbon from Ramie biomass under appropriate temperature with high surface area from Ramie biomass as a highly efficient electrocatalyst for hydrogen peroxide production. Electrochemical characterizations revealed that the as-prepared catalyst showed superior ORR selectivity through a two-electron pathway and extraordinary long-term stability. The nitrogen atoms on the catalyst surface was derived from the biomass and decomolovated by XPS techniques, which is the important factor for the enhancement of photocatalytic electrocatalytic performance. The present work paves a way for the development of biomass-derived carbon material for electrochemical applications.
ET08.08.09
Mediated Photoelectrochemical Oxidation of Water on WO3 by Silver (II)  Tae-Hwa Jeon1, Damián Monllor-Satóca1,2, Gun-hee Moon1, Wooyul Kim1, Hyoun-il Kim1, Hyunwoong Park1 and Wonyoung Choi1; 1Division of Environmental Science and Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of); 2School of Environmental Engineering, Kyungpook National University, Daegu, Korea (the Republic of); 3School of Engineering, Universitat Rovira i Llo, Barcelona, Spain; 4Department of Civil and Environmental Engineering, Yonsei University, Seoul, Korea (the Republic of); 5Department of Chemical and Biological Engineering, Sookmyung Women's University, Seoul, Korea (the Republic of).

Ag(I) is a common electron scavenger used in photocatalysis for promoting oxidative pathways through photogenerated holes, preventing deleterious electron-hole recombination. Albeit its straightforward reduction to metallic state (i.e., Ag(0)), it can also capture holes to generate the highly reactive Ag(II) species, provided the proper reactive conditions are given. In this contribution, we demonstrate, for the first time, mediated photoelectrochemical oxidation of water and concurrent oxygen evolution by the Ag(I)/Ag(II) redox cycle with high efficiencies. In the presence of Ag(I), photoelectrochemical (PEC) performance of WO3 electrodes was enhanced (biased at 1.23 V vs. RHE) in a mild acidic nitrate medium (pH 5) in terms of steady-state photocurrent (>4-fold), and O2 evolution (>4-fold) and its Faradaic efficiency (40% without Ag(I) vs. 75% with Ag(II)). During the PEC reaction, the electrolyte solution acquires a brown color, caused by the formation of Ag(II)NO3 complexes. Upon turning both potential bias and light off, photocurrent drops to zero whereas O2 evolution continues over ~10 h (homogeneous water oxidation) leading to the overall Faraday efficiency of 100%, and simultaneously the electrolyte is gradually bleached. This confirms the Ag(II) complex-mediated water oxidation which occurs during the PEC and the unbiased dark periods. This phenomenon is found neither in the Ag(I)-free PEC reactions nor in the photocatalytic (i.e., bias-free) reactions with Ag(I). The various spectroscopic analyses (UV-Vis, XRD, XPS, SEM/EDS, HR-TEM/EELS, etc.) suggest that Ag0/Ag2O core-shell structure and AgNO3 complexes play the heterogeneous and homogeneous water oxidation reactions, respectively.

ET08.08.10
Loading Effect of Various Metal Oxide Colloids as an Electron Mediator on Visible-Light-Responsive Photocatalyst Particles in Photocatalyst Panels for Z-Scheme Water Splitting  Hiromasa Tokudome1,2, Sayuri Okunaka1,2, Shingo Oozu1,2, Qian Wang1, Takashi Hisatomi1 and Kazunari Domen1,3,4; 1TOTO Ltd, Chigasaki-city, Japan; 2Japan Technological Research Association of Artificial Photosynthetic Chemical Process (ARPChem), Chiyoda-ku, Japan; 3Department of Chemical System Engineering, School of Engineering, The University of Tokyo, Bunkyo-ku, Japan; 4Center for Energy & Environmental Science, Shinshu University, Nagano, Japan.

Photocatalytic water splitting utilizing abundant sunlight including visible light is an active area of research focused on providing a renewable hydrogen. In the past two decades, a lot of visible light responsive photocatalysts have been developed to oxidize and/or reduce water, but only a few were known to overall split water into H2 and O2 in the stoichiometric amount. On the other hand, Z-scheme system is known to realize overall water splitting using two kinds of visible light responsive photocatalyst particles, which were active for either H2 or O2 evolution, with/without appropriate mediators such as redox ions or conductive materials. We recently developed a Z-scheme-type photocatalyst panel consisting of mixed films of two visible-light-active photocatalysts (La, Rh-doped SrTiO3 and BiVO4 for H2 and O2 evolution) and a colloidal electron mediator (gold or indium-tin-oxide) on a glass substrate. It showed relatively high activity with a solar-to-hydrogen energy conversion efficiency of 0.1%–1.2%. In this study, we prepared a Z-scheme-type photocatalyst panel composed of BiVO4 and Rh-doped SrTiO3 loaded with various metal oxide colloids as a low-cost and scalable electron mediator and examined the water splitting activity.

Z-scheme-type photocatalyst panels were prepared by a screen-printing on borosilicate glass substrates using a viscous paste including Rh-doped SrTiO3 loaded with various metal oxide colloids by impregnation or adsorption method and BiVO4 particles. The panels produced hydrogen and oxygen from pure water in the stoichiometric ratio under visible light irradiation. The water splitting activity varied depending on the kind of the loaded metal oxide colloids. This result showed that the colloids acted as an electron mediator between the two photocatalysts.

ET08.08.11
Improvement of Z-Scheme Water Splitting Activity on Nano ITO-Mediated Printable Photocatalyst Panels by Loading Co-Catalyst Sayuri Okunaka1,2, Hiromasa Tokudome1,2, Qian Wang3, Takashi Hisatomi1 and Kazunari Domen1,3,4; 1TOTO Ltd, Chigasaki-city, Japan; 2Japan Technological Research Association of Artificial Photosynthetic Chemical Process (ARPChem), Chiyoda-ku, Japan; 3The University of Tokyo, Bunkyo-ku, Japan; 4Shinshu University, Nagano, Japan.

Photocatalytic water splitting has been widely investigated as a potential method to produce hydrogen from renewable solar energy. Although two types of semiconductor-based systems (heterogeneous system and photoelectrochemical system) have extensively been studied for photo-induced water splitting so far, it is necessary to develop a scalable, versatile and cost-effective system for the practical application. Photocatalyst panels, wherein semiconductor particles are fixed on substrates such as glass, have a potential to be employed as a cost-effective system on large scale. To utilize wide range of visible light, it is necessary to employ narrow bandgap materials and/or introducing Z-scheme mechanism. Recently, the authors’ group reported that the composite-type photocatalyst panels, which composed of La, Rh-codoped SrTiO3 as the hydrogen evolution photocatalyst (HEP), Mo-doped BiVO4 as the oxygen evolution photocatalyst (OEP) and gold (Au) indium-tin-oxide (ITO) nanocolloids as the electron mediator, for Z-scheme water splitting. These panels were prepared by using simple screen-printing method. The obtained printable panels evolved hydrogen and oxygen from pure water in the stoichiometric ratio under visible light irradiation and showed relatively high activity with a solar-to-hydrogen energy conversion efficiency (STH) of ca. 0.1%–1.2%.

In this study, we investigated the effect of co-catalyst loading on the photocatalytic water splitting activity of the printable ITO nanocolloids-mediated photocatalyst panels. The water splitting activity of these panels was changed by changing the metal species and loading amount of co-catalyst. By loading appropriate co-catalyst, the water splitting activity was greatly enhanced and achieving 0.4% STH, which is four times greater than photocatalyst panels without co-catalyst loading.

ET08.08.12
Real Time Imaging of Nucleation, Growth and Corrosion Behaviors of Electrocatalysts Hao Shan, Yanling Ma, Fenglei Shi, Tao Deng and Jianbo Wu; Shanghai Jiao Tong University, Shanghai, China.

The core-shell catalysts with atomic layered structure Pt through liquid phase atomic layer deposition has been proven to be one of the most promising oxygen reduction (ORR) electrocatalysts with high activity and low consume of Pt. It is important to directly observe how the atomic layers grow via in situ
spectrum and simultaneous hydrolysis catalyst (for nerve agent removal) and oxidation catalyst (for mustard removal) is fairly needed. In this work, an advancement forward of the current bounds of continuous hydrothermal synthesis for catalysts applications is reviewed.

Metal oxide nanoparticles have been studied at length for their catalytic properties in many industries including chemical manufacturing, energy-related applications and environmental remediation. Given these advances in their applications, the tunable synthesis is of great interest, especially regarding the re-deposition behaviors during the cyclic voltammetry in TEM. References:

ET08.03.13 A Double-Anionic Oxides Based Organic-Inorganic Hybrid Compound for Simultaneously Catalytically Oxidative and Hydrolytic Decontamination of Chemical Warfare Agent Simulants Jufang Hu1 2; 1Beijing Institute of Nanoenergy and Nanosystems, Academy of Sciences, Beijing, China; 2College of Optoelectronic Engineering, Shenzhen University, Shenzhen, China.

Rapid transformation of chemical warfare agents (CWAs) to environmentally benign products is a significant issue, and considerable efforts have been devoted to the catalytic removal of CWAs. Although many homogenous and heterogeneous catalysts for CWA removal have been developed, a broad-spectrum and simultaneous hydrolysis catalyst (for nerve agent removal) and oxidation catalyst (for mustard removal) is fairly needed. In this work, an organic-inorganic hybrid compound, $\text{(NH}_4 \text{CH}_3\text{O}_2\text{)}_2\text{V}_2\text{O}_5\text{(OH)}_2\text{Cl}_2\text{H}_2\text{O}$ (I), based on two different anionic oxide fragments (also known as polyoxometalates, primarily constituted by Mo, V, Nb centers and oxo ligands), was hydrothermally synthesized, structurally thoroughly characterized, and catalytically tested with the broad-spectrum reactivity in the decontamination of chemical warfare agents. Compound I crystallizes in the tetragonal I-4 space group and contains bicapped polyoxoniobate (PNb$_6$O$_{19}$(VO)$_3$) and tetranuclear polyoxovanadate, which are independent on each other, a complex scarcely seen in polyoxometalate chemistry. Interestingly, compound I effectively catalyzes both hydrolysis of the nerve agent simulant, diethyl cyanophosphonate (DECP), and selective oxidation of the sulfur mustard simulant, 2-chloroethyl ethyl sulfide (CEES) under mild conditions. In particular, in the oxidative decontamination system 100% CEES was transformed selectively to nontoxic 2-chloroethyl ethyl sulfoxide and vinyl ethyl sulfioxide using nearly stoichiometric 3% aqueous H$_2$O$_2$ with a turnover frequency (TOF) of 16000 h$^{-1}$. The catalytic performance is maintained even after ten runs and CEES is completely decontaminated in 3 mins without formation of the highly toxic sulfone by-product. The combination of polyoxoniobates and polyoxovanadates give this compound those noteworthy catalytic properties, and a three-step oxidative mechanism is proposed. References:

ET08.03.14 Continuous Hydrothermal Synthesis of Catalytic Metal Oxide Nanoparticles in Supercritical Water Elizabeth G. Rasmussen, Brian R. Pinkard, Justin Davis, John C. Kramlich, Per G. Reinhall and Igor V. Novosselov; Mechanical Engineering Department, University of Washington, Seattle, Washington, United States.

Metal oxide nanoparticles have been extensively studied, primarily to extend their catalytic properties in many industries including chemical manufacturing, energy-related applications and environmental remediation. Given these advances in their applications, the tunable synthesis is of great interest, especially regarding control of crystal structure. In this study iron oxide (Fe$_2$O$_3$) and zirconium oxide (ZrO$_2$) nanoparticles were synthesized using a continuous-flow supercritical water reactor. The products were characterized for both size and crystalline structure by transmission electron microscopy (TEM), scanning electron microscopy (SEM), and X-ray diffraction (XRD). Additionally, Raman spectra samples taken showed a decreased presence of the toxic organic solvent Dimethylformamide (DMF) showing advancement in completely eliminating such reagents in final products. Thus, the present product can be used for green and sustainable technology in a way that reduces the total environment load. The optimization of this technique is discussed and its advancement forward of the current bounds of continuous hydrothermal synthesis for catalysts applications is reviewed.

ET08.03.15 Intermetallic Pt-Mn/C Nanoparticles as ORR Electro catalysts Mahdi Ahmadi and Héctor D. Abrau; Cornell university, Ithaca, New York, United States.

The sluggish kinetics of the oxygen reduction reaction (ORR) at the cathode remains as one of the main challenges for commercial viability of alkaline exchange membrane fuel cells (AEMFCs). It is therefore, of great interest to explore the development of electrocatalysts with superior activity and stability relative to the conventional carbon supported Pt nanoparticles (NPs). In this work we have studied the effects and evolution of structure and surface composition of Pt-Mn NPs on their electrocatalytic activity for the ORR in alkaline media. Pt-Mn NPs were synthesized using solvothermal methods and were supported on C via impregnation. An ordered intermetallic phase was obtained by heat treatment. We have investigated the crystalline structure of these NPs using X-ray diffraction (XRD) and their size, morphology and composition using TEM/STEM, EELS and EDX. Cyclic voltammetry (CV) and rotating disk electrode (RDE) voltammetry were used to assess their...
electrocatalytic activity and stability. The Pt-Mn NPs were electrochemically dealloyed in acidic media, through potential cycling, leading to the formation of a ~1nm thick Pt shell on an ordered Pt-Mn core. Enhanced mass and specific activity resulted by such electrochemical dealloying. The stability of the electrocatalyst was tested after 4,000 potential cycles in alkaline media following the DOE protocol (0.6-1.0 V vs reversible hydrogen electrode). In alkaline media, Mn surface segregation ensued, leading to a lower electrocatalytic activity when compared to the freshly dealloyed catalyst.

Descriptors from scaling relations are at the forefront of theoretical studies in the search for effective catalyst design principles and in the prediction of catalytic activity from first principles. We propose an intuitive and widely applicable structural descriptor for transition metal oxides from first principles. We demonstrate that our descriptor can provide the bridge between the structural, the electronic, and the energetic properties for TMO surfaces. We then use it to accurately predict C-H activation energies with low deviations from DFT calculations. By building upon the compositional diversity of the perovskites, we further establish some descriptors to correlate with the key reaction steps of methane activation on the oxide surfaces. From the analysis of first and second C-H activation energies and their correlation with the hydrogen adsorption energy on a variety of ABO3 perovskites, general trends emerge that an optimal range of hydrogen adsorption energy strikes the right balance between easy first C-H activation and difficult second C-H activation energies to avoid further oxidation.

Descriptors for Transition-Metal Oxides and Implications in Selective Catalysis
Dechen Jiang; Department of Chemistry, University of California, Riverside, Riverside, California, United States.

Zeolites are nanoporous industrial catalysts (e.g. consisting of [AlO4] 4- and [SiO4] tetrahedra) with catalytically active sites located inside the channels and nano-cages, rendering them inaccessible for surface science measurements. Two-dimensional (2D) ultrathin (~0.5 nm) bilayer aluminosilicate films consisting of hexagonal prisms with acidic hydroxyl groups exposed on the surface have been synthesized on Ru(0001) surface as a zeolite model system to study gas molecule adsorption1 and chabazite (CHA)-based catalysts2,3. DFT studies were performed to investigate the dehydrogenation and monomolecular cracking of n-butane molecules over the acidic hydroxyl groups of aluminosilicate films. Intrinsic energy barriers of dehydrogenation, terminal and central C-C bond cracking on aluminosilicate films were found to be ~0.6 eV higher than those of the bulk CHA. We further investigated the effects of the zeolite channel and cage sizes on the n-butane adsorption and monomolecular cracking for six different 3D nanoporous zeolite frameworks (TON, MEI, VFI, FER, CHA, and MEL). We found that as the confinement of straight channels or nano-cages decreases, n-butane adsorption becomes weaker and intrinsic energy barrier for terminal C-C cracking increases. The 2D bilayer film surface, which may be considered as zeolite cages at the infinite cage size limit, has the smallest adsorption energy and highest intrinsic energy barrier. Comparison of the reaction pathway of n-butane terminal C-C cracking in 3D nano-cages and on bilayer aluminosilicate film surface revealed that the decrease of the intrinsic energy barriers in bulk zeolites is caused by the stabilization of the transition states in the 3D nano-cages.

Research is carried out in part at the Center for Functional Nanomaterials and the Scientific Data and Computing Center, a component of the Computational Science Initiative at Brookhaven National Laboratory, which is supported by the U.S. Department of Energy, Office of Basic Energy Sciences, under Contract No. DE-SC0012704. This research used resources of the NERSC, a DOE Office of Science User Facility supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

Exploring Non-Oxidative Dehydrogenation of Alcohols Using Reaction of Ethanol Over Transition Metals and Bimetallic Catalysts
Fatima Jalid1,2, Tuhin Suvra Khan1 and Mohammad A. Haider1; 1Department of Chemical Engineering, Indian Institute of Technology Delhi, Delhi, India; 2Department of Chemical Engineering, National Institute of Technology Srinagar, Srinagar, India.

The selective dehydrogenation of alcohols to carbonyl compounds is an important class of reaction as aldehydes and ketones produced are essential intermediates in the chemical process industry. The process can be made environmentally sustainable by integrating it with the renewable biomass-derived feedstock and employing a non-oxidative process, which prevents catalyst inhibition due to water formation and suppresses over-oxidation of products. To gain insights into the non-oxidative dehydrogenation (NODH) of biomass-derived alcohols over transition metal catalysts, a microkinetic model (MKM) using ethanol as a model molecule has been developed. Previously, a similar study has been conducted to understand the hydro-deoxygenation trends1. The NODH of ethanol was first demonstrated by Church and Joshi in 1951, wherein Cu catalyst was employed with Co and Cr as promoters2. Since then, catalysts mostly based on Cu have been utilized for NODH of alcohols. The NODH of ethanol may proceed via the initial C-H, O-H, C-O or C-C bond scission leading to the production of acetaldehyde, hydrogen, ethane, carbon monoxide, water and methane. For the production of aldehydes and ketones, the process should be made selective for acetaldehyde and hydrogen production. At the reaction conditions of 473K and 10% reactant conversion, the activity trend for acetaldehyde production from ethanol followed the order; Pt > Cu > Pd > Co > Ni > Ag > Au > Rh > Ru > Re. At these conditions, Pt showed the highest activity (TOF ~ 10^3 s^-1), followed by Cu (TOF ~ 10^4 s^-1). As Cu is the cheaper metal, therefore, it is widely used for this process. Followed by acetaldehyde, ethane was the other major product formed. However, all the metals except Au and Ag were selective towards aldehyde production. From the coverage analysis done in the MKM, it was determined that the surface of Cu was covered with the intermediate, CH2=CH2O whereas
most of the metal catalysts viz. Pt, Pd, Co, Ni, Rh, Ru, Re were covered with the intermediate CH3CO, suggesting difficult C-H bond activation of CH2CHO on it. Inspired from this fact, a bimetallic catalyst was proposed where Cu was combined with Ni in a monolayer having low C-H activation barrier (such as Ni, Pd, Pt, Rh). These bimetallic alloys were found to show higher reactivity (TOF > 10³ s⁻¹) as compared to Cu for aldehyde formation. Earlier experimental studies on ethanol NODH over the bimetallic NiCu measured lower activation barrier of 45 kJ/mol, than that of Cu catalyst (Ea = 70 kJ/mol) and increased catalyst stability owing to lesser Cu sintering in the presence of Ni²⁺.

**Nanoarray-Based Monolithic Catalysts for Propane Oxidation—Enhanced Activity by Copper Manganese Oxide and Co Dopant Effect**

With growing demands of fossil fuel, advanced technologies of exhaust treatment are getting more concern in order to control the deteriorating air pollution from vehicles and factories. A series of nanoarray-based manganese oxide catalysts were developed by one-pot hydrothermal synthesis to fabricate nanorod arrays on the cordierite honeycomb substrates. Compared to monolithic catalysts with a traditional alumina support, nanoarray-based monolith catalysts possess advantages, e.g., efficient open surfaces, reduced usage of porous supports, low pressure-drop, less agglomeration of nanoparticles. Copper manganese oxide (CuMn2O4) nanosheets were introduced to enhance the oxidative activity for hydrocarbons. The CuMn2O4 nanosheets coated nanoarray-based catalyst, NA-CuMn2O4, shows efficient 90% propane (C3H8) conversion at around 400 °C, which is 50 °C and 75 °C lower than CuMn2O4 wash-coated catalyst (WC-CuMn2O4) and Pd loaded catalyst (WC-Pd), respectively. The benefit of nanoarray morphology was demonstrated by correlating the variation of surface area to the reactivity. The incorporation of cobalt ions was found to increase the specific surface area and thus enhance C3H8 conversion of CuMn2O4. The CuMn2O4/MnO2 nanoarray-based monoliths are promising types of emission control devices.

**Selective CO Production by Photoelectrochemical Methane Oxidation on TiO2**

Da He, Wei Li and Dunwei Wang; Boston College, Chestnut Hill, Massachusetts, United States.

The inertness of the C–H bond in CH4 poses significant challenges to selective CH4 oxidation, which often proceeds all the way to CO2 once activated. Selective oxidation of CH4 to high-value industrial chemicals such as CO or CH3OH remains a challenge. Photocatalytic reactions hold great promise for practical applications but have been poorly studied. Existing demonstrations of photocatalytic CH4 oxidation exhibit limited control over the product selectivity, with CO2 as the most common product. The yield of CO or other hydrocarbons is too low to be of any practical value. In this work, we show that high selectivity production of CO by CH4 oxidation can be achieved by a photoelectrochemical (PEC) approach. Moreover, our results revealed that the selectivity toward CO also depends on the substrate types and applied potentials. Based on the experimental results, we proposed a reaction mechanism that involves synergistic effects by adjacent Ti on TiO2. Spectroscopic characterization and computational studies provide critical evidence to support the mechanism. Furthermore, the synergistic effect was found to parallel heterogeneous CO2 reduction mechanisms. Our results not only present a new route to selective CH4 oxidation, but also highlight the importance of mechanistic understandings in advancing heterogeneous catalysis.

**Novel Inverse Oxide/Metal Catalysts for Cl Chemistry**

Jose A. Rodriguez; 1Brookhaven National Laboratory, Upton, New York, United States; 2Chemistry, SUNY Stony Brook, Stony Brook, New York, United States.

Inverse oxide/metal catalysts have shown to be excellent systems for studying the role of the oxide and oxide-metal interface in catalytic reactions. These systems can have special structural and catalytic properties due to strong oxide-metal interactions difficult to attain when depositing a metal on a regular oxide support. Oxide phases which are not seen or are metastable in a bulk oxide can become stable in an oxide/metal system opening the possibility for new chemical properties. Using these systems it has been possible to explore fundamental properties of the metal-oxide interface (composition, structure, electronic state) which determine catalytic performance in the oxidation of methane, the water-gas shift, and the hydrogenation of CO2 to methanol. Systematic studies have been performed for the deposition of nanoparticles of CeO2, TiO2, FeOx and MgO on surfaces of late transition metals. The nature of the metal substrate has a large effect on the physical and chemical properties of the supported oxide. Recently, there has been a significant advance in the preparation of oxide/metal catalysts for technical or industrial applications. One goal is to identify methods able to control in a precise way the size of the deposited oxide particles and their structure on the metal substrate.

11:00 AM ET08.09.07
**Pt/Sn-Based Nanoparticles in Ionic Liquids as Nanocatalysts for the Selective Hydrogenation of Cinnamic Aldehyde**

Christine Dietrich and Silke Behrens; Karlsruhe Institute of Technology, Karlsruhe, Germany.

Bimetallic nanoparticles have attracted a lot of attention because they show multiple functionalities and prominent catalytic activity, selectivity as well as thermal and/or chemical stability over their monometallic counterparts. Due to synergistic effects, modified electronic and/or geometric surface structures, high catalytic activities and selectivities have been achieved for chemical reactions even if one of the constituents is less or even inactive. Although the controllable synthesis of nanoparticles has developed rapidly over the recent years, more accurate control over nucleation and growth stages is needed for bimetallic nanocrystals. Since bimetallic nanocrystals are composed of different metal atoms, the composition and atomic distribution not only influences the final nanoparticle architecture but also the catalytic properties. The catalytic performance is highly sensitive to the nature of atomic ordering (i.e., random alloy, intermetallic compound) even if the overall composition and stoichiometry are the same. Here, we address the synthesis of bimetallic Pt/Sn-based nanoparticles with tunable composition and structure by exploiting the beneficial properties of ionic liquids (ILs). Small nanoparticles are obtained in a one-pot synthesis by reducing the metal salt precursors with triethylborohydride in the IL. The weakly coordinating IL anions and cations directly control particle nucleation and growth processes enabling nanoparticle synthesis without addition of stabilizing additives or strongly coordinating capping molecules. The nanoparticles form sols of very high colloidal stability in the IL, which is particularly interesting in view of their use as quasi-homogeneous catalysts. The composition and structure of the nanoparticles is tailored by the nature of the metals salt precursors, their initial molar ratio and the nature of the IL. Investigations by X-ray diffraction, X-ray photoelectron spectroscopy and transmission electron microscopy reveal the formation of random-type alloy or intermetallic nanoparticles. The catalytic performance of the bimetallic nanoparticles is evaluated in hydrogenation reactions. The selective hydrogenation of cinnamaldehyde, for example, is used to probe the catalytic performance of the Pt/Sn nanoparticles, demonstrating the effect of tin alloying on the catalytic activity and selectivity to the α,β-unsaturated cinnamic alcohol. In general, the selective hydrogenation of α,β-unsaturated...
aldehydes is a critical step in the synthesis of various fine chemicals. As compared to their monometallic counterparts, both a higher catalytic activity and selectivity to the α,β-unsaturated cinnamic alcohol is achieved for the Pt/Sn-based nanoparticles.

11:15 AM ET08.09.08

Supported Transition Metal Catalysts for Methane to Methanol Oxidation Darinka Prime1,2, Julie Fornaciari1,2, Adam Z. Weber2 and Alexis T. Bell1,2; 1Department of Chemical and Biomolecular Engineering, University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Methane is a relatively inexpensive, abundant resource, and its partial transformation to chemicals and chemical fuels presents attractive pathways for its utilization. Conventional synthesis of methanol involve a multistep process, which requires high energy input and high cost [1]. Alternatively, methane oxidation using a catalyst in an electrochemical cell is a promising single-step approach to achieve a direct conversion of methane to methanol at lower temperatures and low cost [2].

Catalysts need to be developed for this energetically challenging process. There specific electrocatalysts play a dual role: the activation of the relatively inert C-H bond enabling oxidative hydroxylation of methane, and simultaneously inhibit further methanol oxidation. To date, a variety of the catalysts, including supported metals (Pd, Ru, Au, Ag) and metal oxides (V2O5, Fe2O3, CoO, Mn2O3, MoO3, CrO), have been tested in electrochemical cell and shown promise for the direct oxidation of methane [2]. However, further systematic studies are essential for understanding the mechanism for methane oxidation, enabling the rational design of the catalysts. In this regards single atom catalysts (SAC) are particulars interesting [3]. In addition of showing potential for high methane conversion and methanol selectivity, these catalysts are able to overcome the complicated multiple components and are regarded as ideal model catalysts to identify active sites and facilitate understanding of the reaction process at a molecular level. In spite of great interest; however, it still remains challenging to achieve atomically dispersed metals in high loadings for efficient catalysis. Moreover, for electrochemical methane-to-methanol conversion it is concurrently of importance to develop supported SAC which provide active sites along with hierarchical porosity enabling optimal mass/electron transport.

In this study, first-row transition metal oxides as well as single atom catalysts, supported on carbon supports, have been investigated. The catalysts are synthesized with a ligand-based approach and subsequently characterized for electrochemical methane-to-methanol oxidation. In-depth structural and chemical analyses of catalysts using a combination of various spectroscopy techniques is used to establish structure-property relationship. These insights will provide valuable basis for a scientific-guided approach toward new metal oxide and supported single-atom catalysts for this challenging process.

Bifunctional Catalysts Based on Colloidal Nanoparticles in the Single-Step Synthesis of Dimethyl Ether Manuel Gentzen, Joerg Sauer and Silke Behrens; Karlsruhe Institute of Technology, Karlsruhe, Germany.

The development of new routes to base chemicals and fuels from renewable resources has drawn much attention worldwide. Synthesis gas (CO + H2) derived from renewable sources (e.g., biomass) and its conversion to dimethyl ether (DME) provides one attractive option with respect to a wide range of applications (e.g. as liquefied petroleum gas, intermediate product for base chemicals or as clean diesel substitute). In the conventional two-step DME process, synthesis gas is converted to methanol over Cu-based catalysts in the first stage, which is subsequently dehydrated to DME over an acidic catalyst in the second stage. Alternatively, DME can be manufactured from synthesis gas in a single-step in the syngas-to-dimethylether (STD) process with methanol as an intermediate [1]. The STD process has many technical and economic advantages and allows for higher CO conversions. The design of efficient bifunctional STD catalysts with balanced methanol and dehydration functionalities and long term stability, however, remains a crucial issue. In this context, model systems derived from well-defined nanoparticles contribute to a more fundamental understanding of structure-performance relationships, enabling the future more rational design of highly efficient catalysts. Herein, we present the synthesis of small, uniform nanoparticles via ruct制服rilization. The colloidal nanoparticles are deposited on the dehydration catalyst (i.e., different types of solid acids), and in this way, serve as the key building blocks for the methanol active component in bifunctional STD catalysts [2,3,4]. This strategy provides us with a flexible nanoparticle toolbox which reduces the influence of the catalyst preparation history and ensures a high comparability. The catalytic properties of the nanoparticle-derived, bifunctional catalysts are investigated in a single continuous-flow reactor, using a simulated biomass-derived, CO-rich synthesis gas and different reaction parameters. The bifunctional catalysts revealed high CO conversions and DME selectivities. The effect of the materials characteristics of the two catalytically active components on the overall catalytic performance is elucidated. Long-term studies of selected bifunctional catalysts displayed outstanding stability under the reaction conditions.

The Addition of La Via Double Flame Spray Pyrolysis and Its Effect on Catalyst Activity and Selectivity Towards the Dry Reforming of Methane Jonathan Horlyck, Emma Lovell, Jason Scott and Rose Amal; University of New South Wales, Sydney, New South Wales, Australia.

The active and stable catalysis of methane dry reforming relies upon the ability of the material to inhibit carbon formation. Central to this is the ability of a catalyst support to remove oxygen from the acidic carbon dioxide gas, storing or transporting this oxygen, before releasing it to oxidise an adsorbed CHx intermediate species (Djinnovic et al., 2012). For the first time, an aerosol method was used to mix lanthanum with cobalt/alumina materials to improve support basicity. Double flame spray pyrolysis was used to synthesise heterogeneous mixtures of cobalt oxide, alumina and lanthanum oxide. Lanthanum loadings of up to 15 wt% were investigated at two separate nozzle distances (11 and 18cm). The lanthanum content in the materials and the nozzle distance separating the flames were both found to have a key influence over material composition and properties.

The structure of the supported cobalt catalysts was characterised by high-resolution transmission electron microscopy, X-ray diffraction, XANES, carbon dioxide temperature programmed desorption, X-ray photoelectron spectroscopy and hydrogen temperature programmed reduction. Catalytic activity and
stability for methane dry reforming was determined via testing in a fixed bed reactor over a temperature range of 500-800 °C, while catalyst activity was determined at a fixed temperature of 700 °C for 48 hours. The addition of La to the system gave rise to the substitution of La⁺ into the Al₂O₃ lattice, as shown by high-resolution transmission electron microscopy and XANES. Hydrogen temperature programmed reduction showed that doping with La and increasing the nozzle distance limited CoAl₂O₄ spinel formation and facilitated the production of readily reduced Co species. The addition of La also resulted in an increase in material basicity, independent of nozzle distance, lending the catalysts a strong resistance to carbon formation.

Methane conversion and catalyst stability at 700 °C were enhanced via the addition of La. Maximum methane conversions of 89-93% were observed for the two samples with the greatest (15 wt%). This remarkable conversion is very promising when compared to the other Co-based dry reforming catalysts. Additionally, the catalysts with 15 wt% La loading showed no sign of catalyst deactivation or carbon formation, indicating high selectivity towards the desired reaction.

The reactive metal-support interaction (RMSI) offers electronic, geometric and compositional effects that can be used to tune catalytic active sites. Generally, supports other than oxides are disregarded as candidates for RMSI. In this presentation, we will discuss an example of non-oxide based RMSI between Pt and Nb₂C₅ MXene, a recently developed, two-dimensional (2D) metal carbide. The surface functional groups of the 2D carbide can be reduced, and a Pt-Nb surface alloy is formed at a moderate temperature (350 °C). Such an alloy exhibits weaker CO adsorption than monometallic Pt.

Water-gas shift (WGS) reaction kinetics reveal that the RMSI stabilizes the nanoparticles and creates alloy-MXene interfaces with higher H₂O activation ability compared to a non-reducible support or a bulk niobium carbide. This RMSI between Pt and the niobium MXene support can be extended to other members of the MXene family and opens new avenues for the facile design and manipulation of functional bimetallic catalysts.
An electrode is a compound in which electrons serve as anions. Due to the weakly bound nature of the anionic electrons, electrodes exhibit a variety of interesting properties, such as long work function, which enables any few electron donation to materials with high work functions. Therefore, recently, these materials have been successfully employed as promoters to catalyze for ammonia synthesis [1]. Importantly, the reaction bottleneck was shifted from the sluggish N₂ dissociation to NH₃ formation, providing an alternative route to synthesize ammonia beyond the industrial Haber-Bosch process. However only a few electrodes have been discovered so far and most of them are chemically unstable in the presence of air and water, so the exploration of new electrodes and the concept of electrode are urgent issues for both chemical interests and catalytic applications in the materials society.

In the present presentation, we show that LaScSi (TM=Sc, Mn, Fe, Co, Ru) are new electrode candidates and show robust chemical stability in ambient conditions. LaScSi contains multiple types of symmetry-distinct interstitial voids accommodating tiered electron anions. When loaded with Ru, it shows outstanding activity for ammonia synthesis under mild conditions (0.1 MPa, 400°C), with its turnover frequency (TOF~0.1 s⁻¹) one order of magnitude higher than those of oxide-based Ru catalysts. When Sc is replaced by Mn, Fe, Co or Ru, the transition metal atoms become activation centers and the compounds show a self-promotion behavior with high catalytic activity without loading additional metals. As with other electrodes, these compounds show reversible hydrogen storage ability, and electron anions (H vacancies) exchange with H anions rapidly, providing many activated H for the catalytic reactions. Importantly, the transition metal atoms, implanted into the lattice, are activated and work effectively to cleave the N₂ triple bond and modify the rate-determining step from the N₂ dissociation to NH₃ formation. The good catalytic performance will be interpreted on a basis of the electrode concept and a “hot-atom” mechanism by combining the experimental observations and theoretical simulations.

2:45 PM ET08.10.05 Developing Fe-Based Electrocatalysts for Ambient Ammonia Synthesis Lin Hu, Jun Wang and Xiaofeng Feng; University of Central Florida, Orlando, Florida, United States.

Considering the limited supply of fossil fuels, there is an urgent need to use renewable energy to drive NH₃ production, as the current Haber-Bosch process for NH₃ synthesis is energy-intensive and consumes 3–5% of the world’s natural gas production. Electrochemical NH₃ synthesis may provide a promising strategy, which can enable sustainable, distributed production of NH₃ when powered by solar- or wind-generated electricity. However, the development of such a process has been impeded by the lack of efficient catalysts for the N₂ reduction reaction (N₂RR) under ambient conditions. Many catalysts show a Faradaic efficiency <1% for N₂RR under ambient conditions. Here, we report the development of Fe-based electrocatalysts for N₂RR with a Faradaic efficiency of up to 8.29%. An Fe/Fe₃O₄ sample was prepared by in situ reduction of a pre-oxidized Fe foil in 0.1 M phosphate buffer solution (PBS). The resulting Fe/Fe₃O₄ catalyst shows greatly enhanced activity and selectivity for N₂RR under ambient conditions than the original Fe foil, achieving a Faradaic efficiency of 8.29% for NH₃ production at ~0.3 V vs RHE in the 0.1 M PBS electrolyte, which is around 120 times higher than that of the Fe foil. The high selectivity is enabled by an enhancement of the intrinsic N₂RR activity as well as an effective suppression of the undesired hydrogen evolution reaction. Comparisons with Fe/Fe oxide samples prepared at different pre-oxidation temperatures indicate that the N₂RR activity may depend on the ratio between Fe and Fe oxide. In addition, the N₂RR selectivity of the Fe/Fe₃O₄ catalyst is superior to that of the Fe, Fe/Fe₂O₃ and Fe/Fe₃O₄ nanoparticles, which provides new insights into the understanding and development of efficient, cost-effective electrocatalysts for ambient NH₃ synthesis.

2:30 PM ET08.10.04 Electrode Concept in Intermetallic LaTMSi (TM=Sc,Fe,Co,Ru) for Catalytic Ammonia Synthesis Jiazhen Wu, Yutong Gong, Junjie Wang, Masaaki Kitano and Hideo Hosono; Tokyo Institute of Technology, Yokohama, Japan.

Fischer-Tropsch to olefins (FTO) synthesis has drawn significant attention due to the high demand of light olefins as building blocks for the chemical industry, the desire to reduce the dependence on petroleum cracking for these chemicals, and the need for improving environmental sustainability. Iron-based catalysts have emerged as promising FTO catalysts because of their low cost and excellent catalytic performances. We have designed a promising nanocatalyst of porous interconnected carbon nanosheets supported iron oxide nanoparticles for FTO synthesis. The catalysts demonstrate an extremely high iron time yield (FTY) of 1882 μmolCO/gFe₃ with 41% selectivity for light olefins and excellent stability (> 100 h on stream). Our FTY value is found to be one of the highest FTYs and in particular, is 50 to ~1300 times higher compared with those catalysts exhibiting similar light olefins selectivity reported in literature. Mössbauer characterization demonstrates the presence of catalytically active iron carbide species after FTO reaction. ex situ XAFS measurements reveal that the carbon nanosheets support stabilizes metallic iron during the initial catalyst reduction step, which leads to more carbon uptake.
under FTO reaction conditions to more efficiently form highly active iron carbide phase. In contrast, a control sample with carbon nanotubes as the catalyst support exhibits oxidized iron in the catalyst after removal from H₂ reduction pretreatment, suggesting nanostructurally reduced stabilizing effect of carbon nanotubes towards supported metallic iron nanoparticles. This results in inefficient formation of iron carbide species under FTO conditions. Additional EXAFS results further confirm the buildup of iron carbide phase as a function of time on stream in the carbon sheets supported catalysts, whereas a much smaller portion and negligible growth of iron carbide phase was observed in the carbon nanotube supported catalysts under the same reaction conditions.

4:15 PM ET08.10.08 Hydrocracking Catalyst Optimization for Upgrading Heavy, Polynuclear Oil Fractions Mark Kaminsky¹, Sarah Kobasiljà¹, Tatiana Pilyagina¹, Kareemuddin Shatkii², Lianhui Ding³ and Essam Al-Sayed³; ¹Aramco Services Co., Cambridge, Massachusetts, United States; ²Research and Development Center, Saudi Aramco, Dhahran, Saudi Arabia; ³Technical Services Dept., Aramco Services Co, Houston, Texas, United States.

Introduction
Changes in global supply and demand for fuels versus chemicals has increased the incentive to better control how much of each is produced from a barrel of crude oil. In addition, as the value of crude oil increases, there is incentive to improve the efficiency of upgrading a barrel of crude, in particular the bottom of the barrel resid. Such highly aromatic resid fractions, which used to end up in petroleum coke or asphalt, are being upgraded to more valuable products with new catalytic and process advances. This is partly driven by further restrictions on the burning of petroleum coke, which makes delayed coking less desirable. Hydrogen addition, via hydrocracking, avoids the production of such petroleum coke from the resid fractions, transforming them into more useful fuel and chemical products.

Discussion
This talk will describe two aspects of hydrocracking catalyst development to upgrade heavier crude oil fractions. In the first part, we will present results on the development of a multifunctional hydrocracking catalyst, comprising both homogeneous organometallic and heterogeneous zeolite components. The homogeneous components are oil soluble organometallic compounds of Mo or Fe that are designed to transform in situ into unsupported nanoparticle metal sulfides that hydrocrack the large asphalteneic molecules, which tend to foul heterogeneous zeolitic pores. The mesoporous zeolites will then more effectively hydrocrack the smaller products of the asphaltene salts and maltenes cracking, in order to make chemicals/fuels with less pore plugging. However, with time on stream, the nanoparticles might sinter and become less active. We will present results on the sintering rates of the Mo and Fe nanoparticles at various conditions in the presence of zeolites. Since the nanoparticles and zeolite crystals are both in the same hydrocracking reactor, it is important to understand their interaction under reaction conditions via characterization of the used catalytic materials. Such catalyst characterization will shed light on the interaction and deactivation mechanisms of these catalyst species.

In the second part of hydrocracking catalyst development we will present data on the synthesis of nano-sized Beta zeolite crystals and the effect of zeolite crystal size and shape on hydrocracking activity. Details of the synthesis method for preparation of the nano-sized Beta will be presented in addition to activity studies using a highly aromatic LCO (Light Cycle Oil) feedstock for the hydrocracking reaction.

4:30 PM ET08.10.09 Electroreduction of Oxygen at Nanostructured Methanol Tolerant Cathodes for Mixed-Reactant Direct Methanol Fuel Cells Juan C. Abrego¹, Youling Wang², Alonso Moreno-Zuría³, Francisco Cuevas-Muniz⁴, Luis G. Arriaga², Shuhui Sun¹ and Mohamed Mohamed³; ¹Energie, Materiaux et Telecomunications (EMT), Institut National de la Recherche Scientifique (INRS), Varennes, Quebec, Canada; ²Centro de Investigacion y Desarrollo Tecnologico en Electroquimica, Queretaro, Mexico.

Energy sources for all kind of electronic devices are under constant pressure to achieve higher efficiency levels by increasing the energy density and decreasing both volume and weight while reducing the cost of portable power sources at the same time [1]. Mixed-reactant microfluidic direct methanol fuel cells (MR-μDMFCs) represent a promising power supply alternative for electronic portable devices in the future, due to their simplicity of design, fabrication and operation. Theoretically, they can achieve higher energy density in comparison with other DMFCs. The main challenge arises from the need for selective electrocatalysts [2]. The synthesis of cathode materials with high mass specific activity towards the oxygen reduction reaction (ORR) and no activity towards the methanol oxidation reaction (MOR) is crucial for the development and commercialization of MR-μDMFC.

In the present work, we report a two-step synthesis by pulsed laser deposition (PLD) of two Pt-based catalysts having a layer onto layer structure. For the two catalysts, first an ultra-low loading Pt layer is deposited directly on carbon nanotubes and further coated with a porous Ag layer or a porous Mn₃O₄ layer, obtaining Ag/Pt/CNTs and Mn₃O₄/Pt/CNTs, respectively. According to the physicochemical characterization, these layers don’t present electronic interaction with each other. The resulting binary materials exhibit electrocatalytic activity similar to Pt towards the ORR in alkaline media. The RRDE studies reveal that the ORR on both Pt/CNTs and Mn₃O₄/Pt/CNTs, is carried out through a 3.9 electron transfer mechanism, while on Ag/Pt/CNTs, the transfer is about 3.7 electron. Interestingly, the bilayer cathodes show no activity for the MOR. Furthermore, those materials demonstrate to be tolerant to methanol concentration as high as 5 M. The results suggest that the superficial Ag and Mn₃O₄ components discriminate between the molecular volume of O₂ and MeOH. Lastly, in order to compare the performance of the methanol-tolerant cathodes in a fuel cell, the materials are tested in a passive, air-breathing MR-μDMFC in conditions close to real application.

4:45 PM ET08.10.10 Epitaxial and Atomically Thin Graphene—Metal Hybrid Catalyst Films—The Dual Role of Graphene as the Support and the Chemically-Transparent Protective Cap Ali Abdelhafiz and Faisal Alamgir; Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Commercialization of polymer electrolyte membrane (PEM) fuel cell materials has been of a great interest over the past decade. At the cathode side, the oxygen reduction reaction (ORR) is the key reaction where sluggish kinetics is present, for which Pt remains the catalyst of choice. In order to leapfrog the current limits to Pt use, three main objectives have to be achieved. First, is a reduction of Pt loading; second, is an enhancement of the mass activity per Pt atom; and third is an increase the catalyst durability. Herein, we demonstrate the dual role of single graphene layer, both as a growth template and as a protective cap for 2D Pt monolayers catalysts, where all three objectives can be achieved.

Using iterative under potential deposition (UPD), atomic layers of Pt catalyst are grown on top of a single layer graphene. X-ray absorption spectroscopic (XAS) and scanning transmission electron microscopy (STEM) analyses show that Pt growth is dictated by the graphene-templated epitaxy. Pt/graphene intimacy induces a localized compressive strain on Pt monolayers ranges 3-10%, owing to structural defects, with an overall compressive strain of 3.5% according to extended x-ray absorption fine structure (EXAFS) analysis. In addition, cyclic voltammetry (CV) analysis shows fully-wetted Pt monolayers coverage of graphene under-layer with only a ~1 nm ultra-thin layer of Pt, while ripening was suppressed as shown through STEM images. Atomic Force Microscopy (AFM) analysis demonstrates that Pt monolayers prefer to follow Frank-van der Merwe growth (i.e. layer-by-layer growth mode) rather than
Volmer-Weber growth (i.e. island growth mode), where root mean square (rms) of surface roughness remains quite similar while increasing Pt loading is increased.

Pt/graphene hybrid catalysts show superior catalytic activity for ORR relative to the graphene-free counterparts or state of the art Pt commercial catalyst. A combination of the graphene-imposed compressive strain and electron transfer, push the Pt d-band center up, lowering the overpotential needed for ORR to occur. Furthermore, the graphene/Pt cap hybrid shows the graphene protecting Pt MLs from both dissolution and from ripening, with almost no Pt loss after 5000 fuel cell operating cycles. Our demonstration of a graphene-Pt hybrid opens the door for graphene/metal or metal/graphene architectures with potential applications in, and not limited to, energy, thermo-electric and electronics field.

8:30 AM *ET09.01.01
Designing Lithium-Sulfur Batteries with Practically Necessary Parameters Arumugam Manthiram; The University of Texas at Austin, Austin, Texas, United States.

Sulfur has become appealing as a cathode in recent years as sulfur is abundant, is environmentally benign, and exhibits an order of magnitude higher charge-storage capacity than the currently used lithium-ion battery oxide cathodes. However, lithium-sulfur cells suffer from a few formidable challenges: (i) poor electronic and ionic conductivity of sulfur and its discharge product Li2S, (ii) dissolution in the liquid electrolyte of the polysulfide intermediates and their shuttling between the cathode and anode, (iii) large volume changes occurring during charge-discharge cycling, and (iv) lithium-metal degradation during cycling due to continuous solid-electrolyte interphase (SEI) formation and electrolyte consumption. Efforts to overcome these difficulties around the world have shown enormous improvements in cycle life, but a vast majority of the published work has been with low sulfur content, low sulfur loading, and a high amount of liquid electrolyte, which will drastically reduce the practical energy density and make the lithium-sulfur technology uncompetitive with the current lithium-ion technology.

This presentation will focus on designing lithium-sulfur cells with practically necessary parameters to be competitive with lithium-ion technology. Innovative sulfur cathode architectures and novel cell configurations will be presented to realize the practically necessary parameters. For instance, lithium-sulfur cells with a coaxial-graphene-coated cotton-carbon as a substrate for sulfur cathode that display high performance with simultaneously a high sulfur loading (~ 50 mg cm^-2), high sulfur content (75 wt. %), and a low electrolyte/sulfur ratio (4.2 μL mg^-1) will be presented. Such a cell exhibits remarkably a high areal capacity (31 mA h cm^-2), high sulfur content (75 wt. %), and a low electrolyte/sulfur ratio (4.2 μL mg^-1) will be presented. Such a cell exhibits remarkably a high areal capacity (31 mA h cm^-2) and areal energy density (66 mWh h cm^-2) with a capacity-retention of 68% over 200 cycles, exceeding the areal capacity (4 mAh cm^-2) and areal energy density (10 mWh h cm^-2) of commercial LiCoO2 cathode. Besides the challenging cycle life, lithium-sulfur cells also suffer from rapid self-discharge. With novel cell configurations, self-discharge data collected over an extended period of one year will be presented. Moreover, the roles of the porosity, electrical conductivity, and chemical interaction with sulfur of various carbons used in lithium-sulfur cells will be presented, which will help to choose the appropriate carbons. Finally, the areas that need to be addressed in the future to make the lithium-ion technology practically viable will also be presented. In addition, a comparison of the lithium-sulfur technology with other metal-sulfur batteries will also be provided.

9:00 AM *ET09.01.02

Taken advantage of a high theoretical energy density of 2567 Wh kg^-1, lithium sulfur batteries (LSBs) have been considered promising candidates for next-generation energy storage systems. Tremendous efforts have been devoted to improving the battery performance by preparing smart nanostructures. However, detailed reaction mechanisms and the principles of tailoring reaction paths at nanoscale remain unclear. In-situ transmission electron microscopy (TEM) is a powerful technique to probe the dynamic processes of electrochemical reactions at a high spatial resolution and in real-time. Through in-situ TEM study with a solid cell (using Li/Li2O as lithium source and electrolyte, respectively), we find that carbon nanofibers activated at 550 °C encapsulating sulfur particles (PCNF/A550/S) present a low volume expansion of <35% and integrated structure upon full lithiation. In contrast, PCNF/A750/S prepared from carbon fibers activated at 750 °C shows a larger volume expansion of 61 % and overflowing of Li2S, due to the weak
mechanical property and large pores of the carbon host, providing a testament to their different electrochemical performance. Further, we develop in-situ TEM techniques with a graphene-based liquid cell (GLC), where liquid electrolyte and TiN-C/S nanoparticles are encapsulated between two graphene sheets. When exposed to the electron beam, the liquid cells undergo chemical reactions, showing that sulfur particles disappear gradually and Li$_2$S particles nucleates and grows at the conductive and polar TiN substrate during lithiation. An interesting inward growth of Li$_2$S particles is observed in the TiN-C/S cathode. Now, we are trying to establish in-situ TEM with flow liquid cells undergoing electrochemical reactions. It is believed that in-situ microscopic investigation of sulfur cathodes would not only shed new light on understanding of reaction mechanisms but also provide fundamental guidelines to design better LSBs.

9:30 AM ET09.01.03
Sulfur Interaction with Porous Carbon Marie-Vanessa Cougel, Loic Gourmelen and Renaud Denoyel; CNRS-Aix Marseille Univ, Marseille, France.

Sulfur is the most puzzling element in the chalcogen family, in the liquid as well in the solid state. It is the element of the periodic table with the highest number of allotropes in the solid state [1]. At the melting point (Tim= 115°C), the liquid is essentially composed of S$\_8$ rings and has a low viscosity. Around 159°C, a reversible polymerization transition is observed and the chain formation leads to an increase in the viscosity of almost four orders of magnitude [2]. At 445°C, the sulfur sublimates into vapor consisting of S$_n$ molecules (n = 2 - 10) in proportions depending on temperature and pressure.

Within the last decade, Sulfur has been considered as a promising component of electrode material for the next generation of Li-ion batteries since it would permit to obtain high energy density rechargeable batteries [3]. However, the main drawbacks remains in the poor electrochemical cycle stability of the sulfur cathode because of the insulating nature of sulfur and the formation of highly soluble lithium polysulfides leading to the so-called shuttle effect.

One of the methodologies to avoid those problems consists in reducing the polysulfide dissolution using barrier materials. Among the proposed methods, confinement of the sulfur into porous carbon materials is seen as a promising technique since the pores could retain the polysulfides. Various hosts are considered ranging such as mesoporous carbon [4], microporous carbon [5] or carbon nanotubes [6].

Our objectives are to understand the interaction between sulfur and porous carbon and the influence of confinement of sulfur thermodynamic properties. The confinement is realized using commercial porous carbon structures that differ from their specific surface area and pore-size distribution. Various carbon-sulfur composites are synthetized using different impregnation temperatures in the liquid (before and after polymerization) and in the vapor states. It is shown that sulfur loading in the porous carbon hosts is related to the impregnation temperature and to the pore-size distribution. The evidence for sulfur incorporation into the pores is demonstrated owning energy measurements. Using immersion calorimetry, the interaction energy between sulfur and carbon is evaluated for both meso- and microporous carbons. These results could make it possible to propose new ways of synthesis of the Li-S batteries in order to improve their capacities.

Li-S batteries featuring high areal capacity and high current density have been developed based on functionalized free-standing carbon nanotubes (CNT). Each Li-S battery can potentially deliver high energy density and power, the critical problems such as high loadings of sulfur, polysulfide shuttle, and lithium dendrite formation still impede practical Li-S batteries. Furthermore, the state-of-the-art high-performance Li-S batteries use nanomaterials, which requires scalable synthesis processes and manufacturing processes with binders, which further hinder the commercial application of Li-S batteries.

This study reports free-standing self-assembled CNT electrodes activated by functional groups and embedded nanoparticles. The nano-structure provides polysulfide-philic surfaces in the cathode to alleviate the shuttle problem and lithiophilic surfaces in the anode to lower lithium nucleation potential. The activated CNT sponge electrode tackles most critical problems on cathode and anode of Li-S battery. The reduced interfacial resistance and charge transfer resistance at cathode and anode improved the reaction kinetics and lowered the overpotential. A binder-free CNT sponge can be manufactured with a commercially viable roll-to-roll process and directly used as electrodes. The 3D connected CNT network are flexible, ultra-light weight, highly conductive, porous and low-cost. The meso-scale structure such as porosity and tortuosity was tuned to facilitate optimal accommodation of active material as well as fast electron and mass transfer. The functionalized CNT sponge demonstrated not only performance improvement of Li-S batteries, but also provided a commercially viable solution of nanomaterials that can be utilized in energy storage and beyond.

SESSION ET09.02: Energy Conversion and Storage
Session Chairs: Seok-Jin Kim and Ju Li
Monday Afternoon, November 26, 2018
Hynes, Level 3, Room 301

1:30 PM *ET09.02.01
Advancing Li-S and Li-O2 Batteries Through New Electrolyte and Electrode Design Linda F. Nazar, Quan Pang, and Chun Xia; University of Waterloo, Waterloo, Ontario, Canada.

Li-S and Li-oxygen batteries are both promising as alternatives to conventional lithium-ion technology due to the high energy density of their theoretical redox couples. For Li-S, extended battery life times have been demonstrated, but two notable challenges still exist to realize its full potential: overcoming the undesired high electrolyte/sulfur (E/S) ratio required for the catholyte-type mechanism that governs most cell configurations, and inhibiting Li dendrite growth and its parasitic reaction with the electrolyte that results in cell degradation. In this presentation we demonstrate that by tuning the electrolyte structure, the challenges at both electrodes can be tackled simultaneously. The sulfur speciation pathway transforms from a dissolution-precipitation route to a quasi-solid-state conversion in the presence of lowered solvent activity and an extended electrolyte network structure, curtailing the need for high electrolyte volumes. With such an optimized structure, the Li plates dendrite-free and shows 20-fold reduction in parasitic reactions with Li, avoiding electrolyte consumption and greatly extending the lifetime of a low E/S (5 µl/mg) sulphur cell. A new advanced electrolyte/electrode design for the Li-oxygen cell will also be presented that demonstrates exceptional Coulombic efficiencies of close to 100% with good cycle life.

2:00 PM *ET09.02.02
"Solid Oxygen" Cathodes Ju Li; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

As the energy ceiling (~700Wh/kg) of conventional transition-metal oxide (LiMn2O4, M=Ni,Co,Mn) Li-intercalation cathodes has been approached, hybrid anion- and cation-redox (HAC) cathodes are being actively pursued, to compete with purely anion-redox Li-S and Li-O cathodes [Nature Energy 1 (2016) 16111] as candidates for the next-generation Li-ion battery. HAC cathode is a hybrid between traditional Li-ion (purely cation redox, intercalation-type) and Li-O (purely anion redox, conversion-type) cathodes. Here we show a scalable synthesis of new HAC material with energy density 858 Wh/kg at the end of the 100th cycle at 1C, compressed density 3.5 g/cm3, with very little oxygen release by differential electrochemical mass spectrometry and almost no voltage decay.

2:30 PM ET09.02.03
Neighboring Pt Atom Sites in 2D Ultrathin FePt Nanosheets as the High Performance Oxygen Reduction Reaction Electrocatalyst Wenlong Chen, Wenpei Gao, Hong Zhu, Tao Deng, Xiaoqing Pan, Hong Yang, and Jianbo Wu; 1Shanghai Jiao Tong University, Shanghai, China; 2University of California, Irvine, Irvine, California, United States; 3University of Illinois at Urbana–Champaign, Urbana, Illinois, United States.

The shape and morphology structure of catalyst can largely affect their reactive selectivity and activity. Recently, single atom catalyst and two-dimensional (2D) nanostructures have attracted much interests because of their optimized electronic structures and sufficient use of atoms. Generally, single atom catalysts show an improved cost efficiency because the abundant participate and exposure of the noble elements in the reaction. However, in some catalytic processes, such as the oxygen reduction reaction (ORR) in fuel cells, its fast four-electron reaction path usually required at least two neighboring Pt atomic sites to cooperate, which cannot be realized in the traditional isolated single Pt atoms catalysts. To this regard, the low loading of a single atom hinders the wide application in some catalytic reactions which need enough active sites for reactants or intermediates. The fabrication of densely dispersed single atom catalysts with adjacent atom sites available at the same time on a 2D metallic nanostructures matrix with a high surface area paves a feasible way but is still challenging and rarely studied. Here, we combined the advantages of 2D structure and single atom to fabricate 2D ultrathin FePt nanosheets (NSs) with 6.7 wt % neighboring Pt atomic dispersion. Different from the previous reported isolated Pt single atoms materials, these neighboring Pt sites in the ultrathin wrinkled FePt NSs showed a four-electron reduction pathway, a high electrochemical active surface area of 545.54 m² g⁻¹, and an improved 7 times mass activity than the commercial Pt/C in the ORR. The high performance to catalyze a fast ORR derived from the sufficient use and synergistically interaction of neighboring Pt atoms dispersed in a more packed spacing and exposed on the surface of ultrathin sheets. In conclusion, this “neighboring atom catalyst” not only reserves the advantages of the traditional single atom catalysts but also can synergistically cooperate to catalyze the reaction, which needs two or more nearby sites, contributing to a four-electron pathway of the ORR, which distinguished from the traditional isolated single Pt atom catalysts that usually showed a two-electron path to produce H₂O₂. Furthermore, we also proved its outstanding CO-tolerance performance in the ORR by the experiment and computational density functional theory (DFT) calculation method.

2:45 PM ET09.02.04

The need for inexpensive high-activity materials in electrocatalytic applications such as water splitting has driven substantial research into the surface chemistry of non-noble metal catalysts, especially metal oxides. Great progress has been achieved in optimization of oxide electroactivity by the use of
mixed metal oxides, which achieve the necessary physicochemical properties via controlled substitution of cation sites. Despite the obvious importance of the anionic partner in determining the catalyst electronic and surface structure, knowledge of the effects of anionic substitution in electrocatalysis is far less certain. We show that, by controlling the relative proportions of oxide and sulfide, the activity of cobalt oxysulfide nanoparticle electrocatalysts can be substantially increased. Cobalt oxide nanoparticles undergo anion exchange in the presence of ammonium sulfide at low temperatures, allowing access to thermodynamically unstable structures by preventing phase separation of immiscible oxides and sulfides. A lightly doped CoO,S0.18 prepared in this way exhibits a metastable, S-substituted CoO structure and is 2-3 times more active in the hydrogen evolution reaction than either end-member of the oxide-sulfide series. We explain this result using density functional theory calculations, which reveal that S-substitution of the CoO surface increases the bonding strength of H to the surface. This binding energy reaches an optimum value at a low doping level, consistent with our observations. These results show that mixed-anion catalysts are accessible under mild conditions and provide an important strategy for controlling the physicochemical properties of electrocatalyst surfaces.

3:00 PM BREAK

3:30 PM ET09.02.05
Efficient Anchoring of Polysulfides Using a Metal Oxide Interlayer in Li-S Rechargeable Batteries with High Mass Loading S-Cathodes Aninda J. Bhattacharyya and Subhra Gope; Indian Institute of Science, Bengaluru, India.

Over the last decade, there has been a paradigm shift towards usage of earth abundant and cost effective electrodes in rechargeable batteries. This strategy enhances the energy density by nearly one order of magnitude. The concept of sulfur as a positive electrode material was highlighted as early as 1962 by Herbet and Ulan. Sulfur delivers a high theoretical capacity of 1672 mAh g⁻¹, nearly one order higher compared to the intercalation oxide cathodes (IOC) used in conventional Li/Na-ion batteries. The high theoretical capacity originates from the possibility of two exchangeable Li-ions/Atom as compared to only one Li⁺ ion/formula unit of IOC. In addition to high storage, S is cheap, highly abundant and non-toxic in nature. Despite these advantages, the chemical reactions determining the mechanism and quantum of electrical energy storage in Li-S battery pose a formidable challenge mainly due to the various intermediate polysulfides formed during the reversible conversion of elemental S8 to Li2S. Bulk of the work related to Li-S rechargeable battery revolves around materials design strategies of a suitable carbon/non-carbon)-host matrix targeted towards the entrapment of S and prevention of leaching out of polysulfides into the electrolyte. This strategy however, limits the extent of S-loading and depending on the host may simultaneously increase the un-utilizable mass of S in the electrode. The presentation will discuss various hosts for the sulfur cathodes for rechargeable Li-S battery. Recently, usage of interlayers between conventional S/C composite cathode and separator has been demonstrated in Li-S batteries. This interlayer, mostly carbon or doped carbon, has been used to trap the polysulfides in between the interlayer and S-cathode. Instead of carbon, we demonstrate here an alternative and novel interlayer of metal oxide nanoparticles between cathode and separator to efficiently trap and arrest the polysulfides at the S-cathode. Oxide-based compounds exhibit superior ability to hold the lower order polysulfides towards the S-cathode by bonding interactions thereby, enhancing anode protection. In the presence of metal-oxide nanoparticle interlayer, an alternative pathway for S-reduction and oxidation takes place which simultaneously lead to a phenomenal reduction in the polysulfide shuttle effect, even at extremely high loadings of sulfur (up to 15 mg cm⁻²). The inhibition of the shuttle effect is studied by probing the battery separator and interlayer ex situ (cycled at various depths of discharge and charge). The conventional Li-S cell with S/C composite cathodes and metal oxide interlayers exhibits a remarkable improvement in cyclability and rate capability vis a vis the cell without any interlayer. The talk will also discuss some of our explorations in to other metal-sulfur chemistries viz. Na-S and Mg-S.

3:30 PM ET09.02.06
Modification of Back-Surface Contacts to Metal Chalcogenide Active Layers Using Carrier-Selective Thionated Perylene Derivatives Curtis W. Doiron, Alexander D. Carl, Emma Travassos and Ronald L. Grimm; Worcester Polytechnic Institute, Acton, Massachusetts, United States.

Sulfur-terminated organic functional layers were attached to TiO₂ surfaces through successive reactions of substrates with 3-aminopropyl triethoxysilane (APTES), perylene tetracarboxylic dianhydride (PTCDA), and Lawesson’s Reagent (LR). X-ray photoelectron spectroscopy (XPS) quantified coverages of APTES and thionated perylene species. IRRAS confirmed chemical attachment of PTCDA to the APTES surface through the formation of the imide, and thionation yields on the exposed anhydride group of PTCDA were estimated by C=O features and the presence of sulfur in the XPS. Throughout the surface modification process, UPS studies observed changes in the HOMO-LUMO levels of the organic species at the TiO₂surface that indicate the desired electron-transfer and hole-blocking characteristics for the modified perylene surface that could ultimately yield increased solar energy conversion efficiency in a tandem junction solar cell with deposited metal chalcogenides.

3:45 PM ET09.02.07
Encapsulation of Fe in 2D Fused Aromatic Networks as an Oxygen Reduction Electro catalyst Seok-Jin Kim¹, Javeed Mahmood¹, Changmin kim¹, Gao-Feng Han¹, Seong-Wook Kim¹, Sun-Min Jung¹, Guomin Zhu², James J. De Yoreo², Guntae Kim¹ and Jong-Beom Baek¹; ¹Energy Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); ²Physical Science Division, Pacific Northwest National Laboratory, Richland, Washington, United States.

For oxygen reduction reaction (ORR), nonprecious iron (Fe)-based materials, such as Fe–N–C and FeFe:C have gained considerable attention as electrocatalysts. However, the poor stability hindered their practical application because of the defective protection of unstable Fe nanoparticles. Here, a synthesis strategy of a stable iron-based electrode catalyst is introduced using a two-dimensional phenazine-based aromatic porous organic network (Aza-PON). The bifunctional Fe@Aza-PON catalyst exhibited promising electrocatalytic activity and practical performance in a hybrid Li–air battery cell. Moreover, the Fe@Aza-PON displayed void-free encapsulation of vulnerable metallic nanoparticles for improved stability and tolerance against contamination (methanol and CO poisoning). The new design and synthesis of indirect-contact catalysts is promising for various additional applications.
Alkaline electrolysis has been considered in commercial applications as a clean and efficient technology for the growing demand for hydrogen fuel in fuel cell technologies. To speed up the Hydrogen Evolution Reaction (HER), several matrices including precious metals with appropriate surface properties have been considered as catalyst. Difficulty in common synthesis of catalysts through chemical means with variations in morphology and higher economics brings the need for a more scalable and cost-effective approach. Natural molybdenum disulfide (MoS2) in the form of the crystalline Molybdenite has been extracted from mine waste tailings (Residue Impoundment Sludge) in FCF Minerals Corp, Nueva Viscaya, Philippines through Rougher-Cleaner route of Oil-Agglomeration Froth Flotation with 99.97% final recovery and final grade of 74.80% Mo from a low grade Mo source (1.052% Mo) with ultrafine particles with interference of organic matter and silicates, with SEM/EDX photomicrographs of probable fine and flaky molybdenite particles on a silicate matrix. MoS2, nanosheets were produced from exfoliation of Rougher (1st stage flotation) and Cleaner 2 (final stage flotation) concentrates in OAF flotation through high-shear milling in common household surfactant solution and the dispersion in varying concentrations of Ethanol (EtOH). Agglomeration due to the retained oil from OAF has no significant effect on particle size distribution of PBM Products (Head sample, Rougher concentrate, Cleaner 1 concentrate and Cleaner 2 concentrate) with average Cumulant diameters of 26.27±6.56 nm, 25.69±50.40 nm, 25.93±67.58 nm and 25.51±61.23 nm, respectively. Exfoliated and dispersed Rougher (50%EtOH) and Cleaner 2 (20%, 50% and 80% EtOH) products were drop-casted onto a conductive substrate (0.025cm² NiO film) to serve as a cathode of in an electrolytic cell with 1 M KOH as electrolyte, Pt counter electrode and sat’d Ag/AgCl as reference electrode. Voltage bias of 0.5V at 0.1V/s at a rate of -0.7 to 0.3V was applied to derive the Linear Sweep Voltammograms of each cathode at 4 trials. There was a significant difference between Rougher and Cleaner 2 (50%EtOH) cathodes with the former having a wider range of performance and instability with the progression of trials that may be due to the lower grade of Mo on the sample and unwanted reactions on the cathode surface. There was a significant difference in Cleaner 2 cathodes in varying EtOH concentrations. Best electrocatalytic performance among the three was found at 50%EtOH with the lowest average onset potential of -0.341V, while 20% and 80% EtOH having -0.354 and -0.352V, respectively. The higher onset potentials were due to the summative of either ineffective dispersion or lower MoS2 concentration. Results show that the dispersed MoS2 from OAF flotation of fine molybdenite from mine waste tailings is a viable source of HER electrocatalyst in alkaline medium.

**Synthesis and Determination of the Activity of Mesoporous Sulfoselenides for the Hydrogen Evolution Reaction**

Shayvin A. Cetegen¹, Biswanath Dutta² and Yang Wu¹;
¹Chemical Engineering, University of Connecticut, Storrs, Connecticut, United States; ²Chemistry, University of Connecticut, Storrs, Connecticut, United States.  

In this work, Lead oxide (PbO) was synthesized chemically at an elevated temperature from lead acetate and sodium hydroxide solution. As prepared powder was polycrystalline in nature having alpha phase tetragonal symmetry. The average crystallite size of 70nm with lattice constants a=3.97Å, b=3.97Å, and c=5.02Å was obtained from X-Ray Diffraction analysis. Direct band gap of the PbO powder was found to be 1.9 eV by Uv-visible spectral analysis. Raman analysis confirmed the presence of pure alpha phase. Photoactivity of the prepared PbO powder was studied by employing it as a photoelectrode in photoelectrochemical cell. Photocurrent density value of about 0.5mA/cm² could be achieved by photoactive microcrystallites in ferrocyanide electrolyte.

**ET09.03.03**

**Synthesis and Determination of the Activity of Mesoporous Sulfoselenides for the Hydrogen Evolution Reaction**

Shayvin A. Cetegen¹, Biswanath Dutta² and Yang Wu¹;
¹Chemical Engineering, University of Connecticut, Storrs, Connecticut, United States; ²Chemistry, University of Connecticut, Storrs, Connecticut, United States.  

Electrocatalysis of water provides a scalable and sustainable means of hydrogen (H₂) production. The drive for a clean energy future inspired us to develop a stable, readily producible, and highly active catalyst that can serve as a cheaper alternative to many pyrites. To achieve this, we adopt the approach of structural tuning by different metals/non-metals that has been found to be effective in several instances. We present one such effort by partial surface selenization of mesoporous metal sulfides produced by sulfurization of cobalt, iron, and nickel UCT-synthesized metal oxides. Using a variety of analytical techniques and electrochemical measurements, we analyze the morphology and demonstrate the enhanced electrochemical activity of these mesoporous sulfoselenides under acidic media, highlighting our catalysts superiority over most existing systems.

**ET09.03.04**

**Improving Performance of Facile Preparing Antimony Selenide Sensitized Solar Cells by Interface Modification**

Bowen Zhao, Xingzhao Liu and Chunyang Jia; University of Electronic Science and Technology of China, Chengdu, China.

Sb₂Se₃ has received great attention for photovoltaic cells recently due to its excellent optical property, superior stability and eco-friendly nature. Herein, an efficient Sb₂Se₃ sensitized solar cell (SSC) is prepared for the first time through a solution-based successive ionic layer adsorption and reaction (SILAR) procedure which is flexible, low-cost and easy to access. Aiming to further improve the device performance, a novel approach based on TiCl₄ treatment on mesoporous TiO₂ has been introduced, which is found to optimize the growth condition of Sb₂Se₃ nanoparticles and improve the interfacial surface state, resulting in the better band alignment and the controlled recombination losses in Sb₂Se₃ SSCs. The TiCl₄ treated devices achieve the best photovoltaic conversion efficiency of 1.22%, which is much higher than that of 0.46% for the solar cells without TiCl₄ treatment.

**ET09.03.05**

**La₉₋₆Ca₃MnO₉ as Model Catalyst System for the Oxygen Evolution Reaction**

Raika Oppeermann, Christoph Richter, David Kröck, Viet A. Chu, Bjørn Luerben and Juergen Janek; Institute of Physical Chemistry, Justus-Liebig-Universität Gießen, Gießen, Germany.

The catalysis of the oxygen evolution reaction (OER) represents a key challenge in (photo)electrochemical water splitting, fuel cells and metal-air batteries. In nature, the large overvoltage of the energy-intensive reaction is circumvented through a calcium-manganese complex in photosystem II, which draws the attention to manganese oxides as earth abundant alternatives to the state-of-the-art catalysts such as IrO₂ and RuO₂.

One main issue of binary manganese oxide catalysts is the insufficient activity in OER due to their poor electric conductivity. Ternary perovskite materials like CaMnO₃ have shown a possibility to overcome this problem. Controlled defect formation due to doping or careful post processing under varying oxygen partial pressures led to increased electrocatalytic activities in OER.²³

We have systematically investigated the perovskite system La₉₋₆Ca₃MnO₉ (LCMO) as model nonstoichiometric electrocatalyst for OER in alkaline media. Powder samples over the whole composition range have been prepared by citrate route as well as the corresponding thin films by pulsed laser deposition (PLD). By varying the lanthanum to calcium ratio we could adjust the manganese oxidation state and the nonstoichiometry from an oxygen deficient to an
Lithium-sulfur (Li-S) batteries have high theoretical specific energy for portable and stationary storage application. However, Li-S batteries have many challenging issues at the materials level. Here I will present our recent progress on: 1) Nanoscale design of host and interface for Li metal anodes; 2) Discovery of sulfur cathode phase behavior, leading to new guidance to materials design.

8:30 AM ET09.04.01
Nanoscale Design for Lithium-Sulfur Batteries Yi Cui; Stanford University, Stanford, California, United States.

Lithium sulfur (Li-S) batteries have high theoretical specific energy for portable and stationary storage application. However, Li-S batteries have many challenging issues at the materials level. Here I will present our recent progress on: 1) Nanoscale design of host and interface for Li metal anodes; 2) Discovery of sulfur cathode phase behavior, leading to new guidance to materials design.

9:00 AM ET09.04.02
Stable Li Anodes Enabled by Interfacial Functionalization for Li-S Batteries Donghai Wang; The Pennsylvania State University, University Park, Pennsylvania, United States.

Li-ion batteries are promising high-energy storage devices due to high theoretical capacities of both the sulfur cathode and lithium (Li) metal anode. Considerable efforts have been made to improve sulfur cathodes. However, the issues associated with Li anodes such as low Coulombic efficiency (CE) remain unsolved due to poor stability of solid-electrolyte interphase (SEI) associated with excessive SEI accumulation and exacerbation of Li dendrite growth, leading to poor capacity retention and short cycling life of Li-S batteries. In this talk, I will present a strategy to reinforce the SEI with desired properties including good tolerance to the Li-based material volume change and efficient surface passivation against electrolyte penetration. The strategy works via introducing multiple functional components bonded to the Li-based material surface into the SEI. The SEI reinforced shows much better stability than the SEI reinforced by electrolyte additive strategy, which is the current state-of-art and commercially used solution to SEI stability issue. The durable SEI layer can suppress dendritic Li growth, enhance Li plating/stripping CE, and in turn, enable Li-S batteries with long cycling life and good capacity retention. We also demonstrate the reinforced SEI can improve Li metal efficiency in a carbonate-based electrolyte for Li-metal oxide batteries. This study provides a promising route to address the issues associated with Li metal anodes and promote the development of high-energy rechargeable Li metal batteries.

9:30 AM ET09.04.03

The worldwide consciousness of the low-carbon economy and sustainable energy concept greatly promote the progress of chemical power sources such as batteries and fuel cells. With the rapid development of portable electronic devices and electric vehicles, the demand for research on advanced energy-storage and conversion systems with low cost, high power density, long cycle life and high energy density has significantly increased to optimize the traditional devices. Therefore, electrocatalytic layered materials and host materials, which success the task of separators in battery application, attracted great attention. Layered two-dimensional (2D) transition metal dichalcogenides (TMDCs) materials, like tungsten or molybdenum disulfide, are receiving increased interest due to their high specific surface area and versatile electronic structure. The direct bandgap of these monolayered materials is located in the visible light or near infrared range, which also make them promising for efficient solar energy conversion, water splitting applications as well as semiconductor utilization.

In this context, a new class of chalcogenide based transition metal single-source precursors of the formula [MIV(SEtN(Me)EtS)2] were designed in this work which enable a highly efficient approach towards crystalline 2D-structured transition metal disulfides (TMDSs). To synthesize mono- or few-layered WS2 and MoS2, volatile single-source precursors [W(SEtN(Me)EtS)2] and [Mo(SeN(Me)EtS)2] were prepared based on the reaction of the chelating pincer type (HSEt)3NMe-ligand with the tetravalent metals tungsten and molybdenum. Chemical vapor deposition (CVD) on various substrates including fibrous structures resulted in the formation of homogenous thin films, which were subjected to atomic scale imaging and x-ray analysis to confirm the synthesis of crystalline WS2 and MoS2 materials. The advantageous properties of WS2 and MoS2 combined with the flexible, controllable and sustainable synthetic route, developed in this work, is expected to be of significant interest for various energy storage and conversion applications including lithium-oxygen batteries and photochemical water-splitting.

9:45 AM ET09.04.04
Effect of the Solvate Electrolyte on Lithium-Sulfur Battery Performance and Reaction Mechanism Heng-Liang Wu; National Taiwan University, Taipei, Taiwan.

Solvate electrolytes such as acetoni-trile-based solvate electrolyte have been proposed to suppress the polysulfide dissolution and enhance the capacity retention of lithium-sulfur (Li-S) batteries.(1-3) In this study, we report on our use of in situ spectroscopy including Raman and X-ray spectroscopy (X-ray diffraction and X-ray absorption spectroscopy) to investigate sulfur reaction mechanism and the interaction between polysulfide and electrolyte. Raman spectroscopy and cyclic voltammetry obtained from sulfur-carbon cathodes in the conventional ether-based electrolyte show that long chain polysulfides (S2n2+) are formed in the first reduction process at ~2.4 V vs Li/Li+ and short chain polysulfides such as S2, S4, and S4O42- are observed with continued discharge at ~2.3 V vs Li/Li+ in the second reduction process.(4-5) The elemental sulfur changes from orthorhombic phase to monoclinic phase in the
conventional ether-based electrolyte during the first cycle. In acetonitrile-based solvate electrolyte, in situ spectroscopy results show that short chain polysulfides are formed at the early stage of discharge process and the formation of soluble long chain polysulfides is suppressed. Elemental sulfur with orthorhombic phase is reformed in acetonitrile-based solvate electrolyte during cycling. These results suggest that solvate electrolyte changes the sulfur reaction mechanism. The effect of solvate electrolyte on Li plating/stripping process was also studied. We next propose different solvate electrolytes with low polysulfide solubility and high stability toward Li metal to enhance the capacity retention of Li-S batteries.

From Insulating to Conductive, From Hard to Soft Materials—Sulfur and Chalcogenides (CuS, MoS2) in Metal-Sulfur and Solid-State Batteries Philippo Adelhelm1,2 1Institute of Technical Chemistry and Environmental Chemistry, Jena University, Jena, Germany; 2Center for Energy and Environmental Chemistry (CEEC Jena), Jena University, Jena, Germany.

Sulfur and chalcogenides are attractive materials for rechargeable batteries thanks to their generally high specific capacity. Other relevant properties such as conductivity, plasticity or volume expansion during lithiation/sodiation largely vary and depend on the specific compound of interest. Sulfur and the ideal discharge product Li2S or Na2S are insulating which requires a sophisticated electrode design with a porous carbon matrix. CuS, on the other hand, is both electronically and ionically conductive which generally benefits the reversibility of the cell reaction. Finally, MoS2 is very soft which may be of advantage considering the large volume expansion during lithiation/sodiation. In this presentation, we will discuss specific properties of sulfur in contact with a porous carbon matrix combined with results on room-temperature-sodium-sulfur cells. We also address the use of copper sulfide and molybdenum sulfide as electrode material for lithium/sodium solid state batteries which can show high capacity despite their large volume expansion during cell cycling.

11:00 AM ET09.04.06
Developing Air Cathodes Using ORR and OER Catalysts for Aqueous Lithium-Air Batteries Varun Rai and Daniel John Blackwood; National University of Singapore, Singapore, Singapore.

Lithium air batteries with aqueous acidic catholytes system have a high potential to attain theoretical energy density limits in energy storage devices because of high conductivity and solubility of discharge products along with low CO2 solubility [1,2]. Therefore, the role of low cost, active, durable and noble free ORR and OER catalysts are very critical in improving charging and discharging cycles followed to addressing the problem in achieving high energy density for practical storage applications. Catalysts suitability as efficient air cathodes are determined by its electronic conductivity, non-solubility in aqueous acidic catholyte, optimal porosity for fast oxygen diffusion and selective adjustments of hydrophobic in ORR and hydrophilic property in OER processes. Transition metal oxides [3] shows fairly low conductivity in comparison to noble metal however by introducing dopant centers and hetero atoms like N, S, F etc significantly improve electronic conductivity and favorable redistribution of positive charges in the lattice for oxygen ad-sorption than pristine oxides. We would be presenting carbon black supported catalyst for better ORR performance with high current. As Carbon black improves the electron transfer among substrate, catalyst and electrode tip.

Amorphous Superatom Molecular Cluster-Based Nanospheres for Electrochemical Energy Storage and Conversion Boyu Qie1, Andrew Pinkard2, Xavier Roy2 and Yuan Yang1; 1Applied Physics and Applied Chemistry, Columbia University, New York, New York, United States; 2Chemistry, Columbia University, New York, New York, United States.

Precisely tunable and programmable synthesis of materials that satisfy specific functions is one of the critical points of materials chemistry. One trend to design solid-state materials is using functional molecular clusters, so-called superatoms, to substitute single atoms in strategy design to create more applicable possibility like high porosity and novel nanomaterials. A rich library of different molecular clusters has been established in a variety of attractive properties, such as redox activity, large magnetic moments and luminescence. However, to our knowledge, there have been few attempts to use these building blocks to assemble new materials for energy purposes - alkali ion battery and water splitting. Here we report a new method to synthesize cobalt sulfides (CoSx) and selenides (CoSex) based on molecular cluster building blocks. The products presented amorphous micron-size spherical shape with high porosity and surface area (~360 m2/g of CoSx and ~130 m2/g of CoSex), considering which, they could provide more channels/rooms for ion transport, to have better kinetics and less volume change during battery cycling in high-capacity conversion reaction. We successfully utilized these micron-sized spheres into lithium and sodium-ion batteries with high specific capacities (~650 mAh/g for CoSx-Li-ion battery and ~450 mAh/g for CoSeS-Na-ion battery), impressive rate capability, and reasonable reversibility (17% lost for 300 cycles in Li-ion battery and 10% lost for 100 cycles in Na-ion battery). Moreover, we also found that the super-based materials are efficient catalysts for the hydrogen evolution reaction (HER) with reasonable overpotential (the highest -0.184V vs. SHE at 10 mA/cm2 in 0.5 M H2SO4 solution).
1:30 PM *ET09.05.01
High Capacity Cathodes Invoking Oxygen Redox Chemistry  
Peter Bruce; University of Oxford, Oxford, United Kingdom.

The energy stored by Li-ion batteries is limited by the cathode. State-of-the-art materials can deliver in the region of 180 mAh g\(^{-1}\) of charge storage capacity. Such materials, e.g. LiFePO\(_4\), are limited by storing electrons only on the transition metal ion (transition metal redox). It is now known that the oxide in so called lithium-rich transition metal oxides, e.g. Li\(_2\)Ni\(_{0.6}\)Mn\(_{0.2}\)O\(_{2}\) can store charge (oxygen redox). To harness the opportunity of increased charge storage that O-redox may offer it is important to understand the nature of O-redox processes and the factors that control them. O-redox in 3d transition metal oxides will be discussed, leading to a high capacity manganese based cathode that utilises the full capacity of the Mn as well as charge storage on oxygen.

2:00 PM *ET09.05.02
Catalyzing the Charging Process in Li-O\(_2\) Batteries Using Lithium Halides  
Graham Levericker, Michal Tulodziecki, Ryoichi Tatara, Shuting Feng and Yang Shao-Horn; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Non-aqueous Li-O\(_2\) batteries have been the subject of intense research interest over the past decade or two, owing to their very high theoretical gravimetric energy density; potentially up to three times that of state-of-the-art lithium ion batteries. Despite this widespread effort, lithium oxygen batteries still suffer from a number of significant issues, including high overpotential on charge and poor cycle life. Part of this poor charging performance can be attributed to the insulating nature of the Li\(_2\)O\(_2\) formed on discharge, which makes direct electrochemical oxidation challenging. While a number of approaches have been taken to try and catalyze the charging process of a Li-O\(_2\) battery, soluble lithium halides, such as lithium iodide and lithium bromide, in particular, have shown very promising performance. Despite this promise, there has been serious ambiguities in literature relating to the influence of lithium iodide on both the discharge and charge processes. In this talk, strategies for controlling the thermodynamics of the chemical oxidation of Li\(_2\)O\(_2\) during the charging progress are discussed, based on controlling solvation energy through solvent-ion interactions and the addition of water to the electrolyte, as well as through the formation of halide-complexes. This work shows promise that the charging process of a Li-O\(_2\) battery can be optimized for both energy efficiency and effective oxidation of Li\(_2\)O\(_2\) through systematic electrolyte and redox mediator design.

2:30 PM ET09.05.03
Systematic Design of Bifunctional Hybrid Electro catalysts Comprised of 1T’ MoS\(_2\) and Fe, Co, Ni-Based Compounds for Overall Water Splitting  
Haoyi Li and Xin Wang; Department of Chemistry, Tsinghua University, Beijing, China.

Driven by the exigent demand for sustainable and renewable energy sources, a huge effort has been devoted to the development of efficient and accessible energy conversion technologies. Electrochemical water splitting – an environmentally-friendly and cost-effective technology for hydrogen production from electricity – has attracted great attention as a promising pathway to decrease social dependence on fossil fuels. The development of low-cost, high-performance electrocatalysts is necessary to enable water splitting as a functional and practical technology. As a means of lowering the driving overpotential and increasing the efficiency of catalytic water splitting, first, enhancing the intrinsic activity of catalytic sites in electrocatalysts requires an optimization of the adsorption free energy of reactants to speed the rate-determining step of the overall reaction. Second, the enhanced conductivity of electrode materials contributes to fast charge transfer, a requirement for which metallic materials have demonstrated superior ability. Third, the optimization of mass transfer properties has a tremendous effect on the ultimate efficiency of electrocatalysts. Innovative nanoarray and porous two-dimensional architectures can facilitate the dissipation of as-formed gas bubbles from the electrode surface. Finally, the increased density of catalytic active sites in the electrode material allows for the maximization of limited electrode surface area – porous nanostructures have a proven ability to facilitate increased surface area.

Herein we prepared the hybrid nanostructures integrating metallic 1T’ MoS\(_2\) with Fe, Co, Ni-based compounds for water splitting via integrated compositional and geometric structural design. Metallic 1T’ MoS\(_2\) was employed for its excellent electrode kinetics, fast charge transfer, and remarkable intrinsic electrocatalytic HER activity. Fe, Co, Ni-based compounds were utilized for their inherent and adjustable OER reactivity (a result of synergistic effects between metal ions). Lastly, nanotube-array and porous two-dimensional architectures were exploited for their porosity, high surface area, and uneven surface characteristics – a way to maximize catalytic active site density and facilitate mass transfer. Notably, the hybrid nanostructures deliver a current density of 10 mACm\(^{-2}\) at an overpotential of 38 mV for the HER and 184 mV for the OER while demonstrating outstanding durability (200 mACm\(^{-2}\) for 80-hour continuous operation). The low Tafel slopes of 37.5 mVdec\(^{-1}\) and 49.9 mVdec\(^{-1}\) for HER and OER demonstrate the fast reaction kinetics. AES demonstrates that the predominant failure mechanism is film cracking and delamination, which originates from initial film heterogeneity.

**SESSION ET09.05: Catalysis in Energy Conversion and Storage**

*ET09.05.04*
Developing Photoelectrochemical Water-Splitting Anodes with Iridium Oxide-Based OER Catalysts  
Micha Ben-Naim\(^{1}\), Alaina L. Strickler\(^{1}\), David W. Palm\(^{1}\), Drew Higgins\(^{2}\), Laurie King\(^{1}\), Adam Nielen\(^{1}\) and Thomas F. Jaramillo\(^{1,2}\); \(^{1}\)Chemical Engineering, Stanford University, Stanford, California, United States; \(^{2}\)SUNCAT Center for Interface Science and Catalysis, SLAC National Accelerator Laboratory, Menlo Park, California, United States.

Photoelectrochemical (PEC) water-splitting is a promising technology that uses solar radiation to split water into hydrogen and oxygen, providing a storable form of chemical fuel to pair with intermittent renewable electricity sources\(^{1}\). Silicon shows promise as a small bandgap absorber material (1.1 eV) to use in tandem PEC devices\(^{1}\). However, pairing catalysts with semiconductorss has proven difficult due to poor energetic alignments and interfaces as well as stability concerns, which are especially limited in acid\(^{2}\).

Many catalyst deposition techniques require high temperatures and complicated processing and are incompatible with some photoabsorber materials. Thus, we developed a spin coating procedure due to its inherently simple and versatile nature to synthesize amorphous iridium oxide and biphasic strontium iridium oxide. Material structure is probed by SEM, XPS, AES, and XRD, while electrochemical performance was measured under illumination and in the dark by cyclic voltammetry, chronoanodometry, and electrochemical impedance spectroscopy.

The addition of strontium to the catalyst gives 550 mV of photovoltage, a 100 mV improvement upon iridium oxide. By probing a facile redox couple, we show that the strontium iridium catalyst forms a more beneficial electronic interface with silicon. A comparison of the as-prepared and post-test anodes via AES shows that the predominant failure mechanism is film cracking and delamination, which originates from initial film heterogeneity.
Designing simultaneous activity and stability of a catalyst during electrochemical water splitting is a significant challenge on the way to efficient energy storage. The development and deployment of these large electrolyzer stacks will cultivate the large-scale application of a variety of renewable energy sources. Due to their high conversion rate and efficiency, electrolyzers have been extensively investigated at Giner. Advanced catalysts have been developed to enhance the conversion rate and boost the process efficiency. For example, the electrochemical production of ammonia from nitrogen and water has thus led to tremendous energy savings compared to the conventional Haber-Bosch process. The produced ammonia can be used as low-cost energy carrier for fuel cells. Some of these advances have been applied in our electrolyzer products, from single cell lab hydrogen generators to large stacks. The performance and efficiency of our electrolyzers are thus tremendously improved. The development and deployment of these large electrolyzer stacks will cultivate the large-scale application of a variety of renewable energy. Due to their high density and reduced cost, the electrolysis technologies may become strongly competitive and complementary to rechargeable batteries for renewable energy storage.

3:40 PM ET09.05.07
Activation of Ultrathin SrTiO3 with Subsurface SrRuO3 for the Oxygen Evolution ReactionAndrew Akbashev1, 2, Liang Zhang3, J. Tyler Mefford1, 2, William Chuah1, 2 and Aleksandra Vojvodic3; 1Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 2Stanford Institute for Materials and Energy Sciences, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 3Department of Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Designing simultaneous activity and stability of a catalyst during electrochemical water splitting is a significant challenge on the way to efficient energy conversion. A dream material for the oxygen evolution reaction (OER) should evince sufficiently high activity and maintain stability of the active surface. Although oxide materials hold great promise for the electrocatalysis applications owing to their high OER activity, their efficient operation is often hindered by structural instability. A core-shell design, where an active core catalyst is covered with a stable nanometers-thick shell, is an attractive solution to the problem of catalyst instability that is commonly employed in metal nanoparticles. However, the interaction between the core and shell of oxide materials during electrocatalytic reactions is not well understood. We hypothesize that the core material can act as a subsurface activator for the shell by introducing spatially accessible electronic states. We validate this hypothesis by studying single-crystalline oxide heterostructures (epitaxial thin films) as model core-shell architectures.

A highly OER-active SrRuO3 undergoes rapid dissolution under OER conditions, which makes it an ideal material for a model active layer. On the contrary, SrTiO3 is OER-inert and chemically stable and can serve as a shell material. We employ atomically-precise deposition to fabricate ultrathin heterostructures composed of bottom SrRuO3 and capping SrTiO3 layers.

We demonstrate that inserting as little as one unit cell of an active material (SrRuO3) under a shell layer (SrTiO3) activates the inert shell, while only two unit cells (1 nm) of SrTiO3 is enough to fully protect the inherently unstable SrRuO3 against dissolution. Using density functional theory calculations, we unravel the mechanism for the subsurface activation in oxide systems. Burying an active material under an ultrathin shell layer introduces new electronic states in the system, changing the electronic hybridization between the adsorbates and the shell layer and facilitating an easy transfer to the adsorbed intermediates.

Ultrathin heterostructures serve as a rigorous platform for screening core/shell nanoparticle combinations and thicknesses. Our study provides an insight into the role of atomic-level modification of the surface and subsurface layers of oxide electrocatalysts, opening up a rich playground for further discovery and design of active and stable materials.

4:45 PM ET09.05.08
Hierarchical Titanium Nitride Nanostructures as Stable Catalyst Supports for Low-Pt Content Fuel Cell Cathodes Andrea Perego1, 2, Giorgio Giuffreda1, 2, Piero Mazzolini2, Rosaria Brescia1, Dinesh Sabarirajan3, Iryna Zenyuk4, Andrea Casalegno3 and Fabio Di Fonzo2; 1Department of Energy, Politecnico di Milano, Milan, Italy; 2Center for Nano Science and Technology @PolMi, Istituto Italiano di Tecnologia, Milan, Italy; 3Istituto Italiano di Tecnologia, Genova, Italy; 4Mechanical Engineering Department, Tufts University, Medford, Massachusetts, United States.
To overcome the high cost of the catalyst in Polymeric Electrolyte Fuel Cells (PEMFC) technology, research is moving towards the reduction in the Pt loading in the electrodes by increasing the electrochemical surface area through a proper catalyst support. To date, the state of the art of catalyst supports is dominated by mesoporous carbon, which shows high activity but suffers from stability issues especially on long term operation. As shown in various works in the literature, titanium nitride (TiN) has a metal-like conductivity with an outstanding chemical stability, making it a possible candidate to replace carbon.

In this contribution, we report about Pt-TiN catalysts support with self-assembled, hierarchical mesoporous nanostructure, grown by Pulsed Laser Deposition. This approach controls the gas dynamics of the nanoclusters-inseminated supersonic jet in order to differentiate the resulting impaction deposition, affecting the growth of the film. We demonstrate that with our technique, morphology can be controlled at the nanoscale to tune the pore size to a mesoporous range, already proven to be effective in fuel cell electrodes. Platinum catalyst is deposited on the tree-like structures either by electrodeposition and atomic layer deposition, tuning the process to achieve ultra-low Pt loading (~0.1 mg cm⁻²).

Electrochemical characterization towards ORR is carried out and shows it is possible to reach good value of the ECSA while controlling the porosity and the morphology of the material down to the nanoscale, reaching good current values. Stability of the scaffold is evaluated according to DOE Accelerated Stress Test (AST) standard protocols, and the ECSA loss is registered to be around only 7% with respect to the 40% goal. The thin films fabricated this way are then transferred by decal method to a Nafion® membrane, to demonstrate their applicability to a fuel cell cathode. Despite the currents are fairly low, further optimization, focused in particular towards a better ionomer contact in the electrode, will improve the cell performance in the future.

Our results show the potential of a PVD based technique that opens the doors of the nanoscale to the fabrication of highly stable electrodes whose morphological and electrochemical properties are easily tuned. This approach holds promises for a high platinum utilization and lower costs for PEMFC technology.

SESSION ET09.06: Poster Session II: Energy Storage

Hynes, Level 1, Hall B

ET09.06.01 Lithiated Metal Oxide Nanosheets Decorated Sulfur Microparticles for High-Performance Lithium-Sulfur Batteries Arnab Ghosh1, 2, Amlan Roy1, Manas R. Panda1, Mega Kar1, Douglas R. MacFarlane3 and Sagar Mitra1
1, 2Department of Chemical Engineering, Indian Institute of Technology Bombay, Mumbai, India. 3University of Victoria, Victoria, BC, Canada.

Due to its high capacity and high energy density, lithium-sulfur batteries are considered as promising alternative to conventional lithium-ion batteries. Combining lithium and sulfur could yield as much as 2600 Wh/kg. However, some serious issues like dissolution of active sulfur and polysulfides into the electrolyte and their shuffling between the anode and cathode impedes the practical realization of lithium-sulfur batteries. In this work, lithiated metal oxide (LMO) nanosheets (with an average size of 100 nm) were decorated on the surface of sulfur microparticles of 50-80 μm. The LMO decorated sulfur shows lower rate of dissolution of active material sulfur as well as intermediate polysulfides into the ether-based electrolyte, leading to a low self-discharge rate and high cycling stability. The lithiated metal oxide (LMO) facilitates the transport of Li⁺ ion throughout the cathode scaffold, resulting higher utilization of active material. At a current rate of 200 mA/g, the LMO decorated sulfur cathode delivers an initial reversible capacity of 788 mAh/g at second cycle and retains a capacity up to 657 mAh/g (83.4% of initial capacity) after 100 cycles. During the meeting discussion, I will elaborate the synthesis procedure and highlight the electrochemical performance of lithiated metal oxide decorated sulfur microparticles as cathode material in lithium-sulfur batteries.

ET09.06.02 MoSe₂ Anchored with N, P Dual Doped rGO for High-Performance Sodium-Ion Batteries Amlan Roy, Arnab Ghosh, Ajit Kumar and Sagar Mitra; IIT Bombay, Mumbai, India.

Although lithium-ion batteries excel for its sheer performance, sodium ion batteries have attracted more attention to the scientific community because of its low cost-per-storage and their vast abundance in the earth’s crust. There is an immense need for the battery farms to store renewable energy like wind energy and solar energy, therefore, a suitable host material specifically anode is required, which can integrate large size of sodium cation (0.108 nm vs. 0.078 nm of Li⁺) throughout the cycle. Graphite is a commercially available anode material for Li-ion batteries (LIB) but their limited capacity against sodium due to the discrepant interlayer distance between graphite layers because of the radius of Na⁺ ion. Another anode material based on transition metals (TMD) has the unique 2D structure with excellent electronic property and high energy density as compared to graphite. Another most commonly used conversion based anode material MoS₂ for SIB has the interlayer distance of 0.62 nm, but major issues with this material are the utilization of less conductive S after full conversion of MoS₂. MoSe₂, the analogous structure of MoS₂, have large interlayer distance (~ 0.64 nm) with higher conductivity as compared to MoS₂. The major drawbacks with this TMD’s are large volume expansion and layers agglomeration while cycling. Here, we improved cyclic performance as well as the stability of MoSe₂ by incorporating the heteroatom doped reduced graphene oxide (N, P doped rGO) in between the layers of MoSe₂ (denoted as MoSe₂/NPr) through single step method at the high temperature in the inert atmosphere. In MoSe₂/NPr, N and P dual dope boosts the conductivity of rGO sheets which improves the Na⁺ion transportation throughout the active material compare to bulk MoSe₂ electrode. The MoSe₂/NPr composite delivers 337 mA h g⁻¹ at a current rate of 0.1 A g⁻¹ and stable up to 100 cycles whereas MoSe₂ shows 63.2 mA h g⁻¹ after 100 cycles at the same current density. Lastly, Sodium storage mechanism also investigated by several ex-situ physical and microscopic studies.

ET09.06.03 Nickel-Based Sulfide/Phosphide Electrocatalysts for Rechargeable Lithium-Oxygen Batteries Bobae Ju, Hee Jo Song, Gwang-Hee Lee, Hyunseok Yoon and Dong-Wan Kim; Korea University, Seoul, Korea (the Republic of).

Lithium-oxygen batteries are considered as another potential alternative to lithium-ion technology due to their high theoretical energy density of 3505 W h kg⁻¹. However, in spite of their high energy density, lithium-oxygen batteries are still faced with many issues such as sluggish O₂ redox kinetics and inferior Li₂O₂/cathode contact interface on cathode, resulting in high oxygen reduction/evolution reaction (ORR/OER) overpotential, low round-trip efficiencies, short lifetimes, and poor rate capabilities. To overcome these obstacles, it is required to develop an effective electrocatalyst which is capable of inducing a reversible reaction between lithium-ion and O₂ at the cathode. So far, although carbon-based materials or carbon-supported noble metals, metal oxides are investigated as effective electrocatalysts, there still remain several unresolved drawbacks. Thus, it is necessary to develop the new efficient electrocatalyst for lithium-oxygen batteries. Transition metal sulfide/phosphide are known to be used as a hydrogen evolution reaction, oxygen...
evolution reaction electrocatalyst. However, the use of these materials has rarely been addressed as ORR/OER electrocatalysts for lithium-oxygen batteries in detail. In this study, therefore, we develop the nickel-based sulfide/phosphide electrocatalysts (NiS$_2$ and Ni$_3$P) for high-performance lithium-oxygen battery cathodes. Nanostreamed Ni(OH)$_2$ precursors are prepared via hydrothermal process, and then they are transformed to NiS$_2$ and Ni$_3$P via sulfidation/phosphidation process. Their microstructural and electrochemical activities are systematically investigated. Both NiS$_2$ and Ni$_3$P show the long-term cyclic stability over 200 and 150 cycles, respectively, at a current density of 500 mA g$^{-1}$ and a fixed capacity of 1000 mA h g$^{-1}$ in voltage range 2.0-4.8 V. Also, both electrocatalysts exhibit overpotential of 1.6 V even at the 100th cycle.

ET09.06.04

High-Capacity WS$_2$ Nanosheets Derived from WO$_3$ Nanocolloids for Lithium-Ion Battery Anodes

In this study, uniform WS$_2$ nanosheets derived from WO$_3$ nanocolloids are successfully synthesized via underwater electrical wire explosion and subsequent sulfidation process. Firstly, to prepare WO$_3$ nanocolloids, a tungsten wire was exploded in deionized water as a surrounding medium at 320V, and then the obtained nanocolloids were freeze-dried. Secondly, the dried WO$_3$ nanocolloids were placed in an alumina crucible and underwent sulfidation at various temperatures from 400 to 600 °C. Thin uniform WS$_2$ nanosheets were successfully prepared without any residual WO$_3$ phase. These nanosheets exhibited an excellent Li-ion electroactivity, delivering of over 700 mA h g$^{-1}$ at a current density of 50 mA g$^{-1}$.

Functional Energy Materials Based on Multifunctional Polymers and Carbon Nanomaterials

In this talk, I will present some of our rational concepts for the design and development of functional conjugated polymers and multidimensional carbon nanomaterials for various energy-related applications, including polymer solar cells containing graphene nanosheets for improving charge transport, fuel cells and metal-air batteries with carbon nanomaterials as multifunctional metal-free catalysts, and supercapacitors with nanotube/graphene hybrid electrodes for energy storage.

8:45 AM *ET09.07.02

Carbon-Rich Electrocatalysts by Design and Nanostructure Engineering

For universal utilization of hydrogen energy, development of high-efficiency, low cost and sustainable energy conversion technologies, especially fuel cells and electrochemical/photocatalytic water splitting devices, is of paramount significance. In order to enhance the energy conversion efficiency of water splitting and fuel cell systems, earth-abundant and stable electrocatalysts are essential for accelerating the sluggish kinetics of hydrogen and oxygen reactions. Up to now, noble metal (e. g., Pt, Ir and Ru)-based materials still remain as the benchmark hydrogen and oxygen electrocatalysts. Unfortunately, high cost and scarce reserve of such noble metals seriously hinder their large-scale applications. Recently, intensive study on active centers and nanostructures of carbon-based materials have greatly advanced the rapid development of new classes of carbon-rich electrocatalysts, featuring defined electronic structures of active sites, for example, metal-free carbons, atomic metal-doped carbons, metal-organic frameworks (MOFs), as well as conjugated porous polymers. To explore earth-abundant and efficient carbon-rich electrocatalysts, it is pivotal to rationally design their active sites, electronic properties and nanostructures that can offer optimal active sites, abundant accessible surface area, and fast mass transport during the electrochemical processes.

In this lecture, we will present our recent efforts on the design and synthesis of carbon-rich nanomaterials as metal-free or noble-metal-free electrocatalysts for hydrogen and oxygen reactions, particularly including template-directed synthesis of metal-free and noble metal-free carbons, 2D metal organic framework nanosheets and Cu surface-mediated fabrication of carbon-rich nanofibers. We will highlight the great potential by tailoring active sites and nanostructures as well as to address the fundamental relationships associated with these carbon-rich electrocatalysts.

9:15 AM ET09.07.03

Cu$_2$BaSn(S$_2$Se$_2$)$_3$-Based Photocathodes for Hydrogen Production

In this study, we develop the nickel-based sulfide/phosphide electrocatalysts (NiS$_2$ and Ni$_3$P) for high-performance lithium-oxygen battery cathodes. Nanostreamed Ni(OH)$_2$ precursors are prepared via hydrothermal process, and then they are transformed to NiS$_2$ and Ni$_3$P via sulfidation/phosphidation process. Their microstructural and electrochemical activities are systematically investigated. Both NiS$_2$ and Ni$_3$P show the long-term cyclic stability over 200 and 150 cycles, respectively, at a current density of 500 mA g$^{-1}$ and a fixed capacity of 1000 mA h g$^{-1}$ in voltage range 2.0-4.8 V. Also, both electrocatalysts exhibit overpotential of 1.6 V even at the 100th cycle.
Photoelectrocatalytic cells (PEC) provide a prospective sustainable and environmentally benign route towards the generation of hydrogen and oxygen from water. Various chalcogenides (Cu(In,Ga)(S,Se)2, CdTe, Cu2ZnSn(S,Se)4) have been adopted as a photocathode for hydrogen evolution but several concerns and material limitation remain regarding scarcity/toxicity (e.g., In and Ga/ Cd) and Cu-Zn anti-site disordering in earth-abundant Cu2ZnSn(S,Se)4 chalcogenides. Recently, the Cu2BaSn(S,Se)4 (CBTSSe) system has attracted attention as an emerging chalcogenide semiconductor with desirable properties for solar energy conversion applications. The current study investigates how the introduction of Se into the parent compound, CBTSSe, influences its electronic and optical properties and overall photoelectrocatalytic performance.

It was found that the photocurrent of vacuum-processed CBTSSe photocathode increases significantly with increasing Se concentration due to larger grain size, reduced grain boundaries, and improved light absorption. In addition, the use of TiO2/CdS protective overlayers creates a desirable band alignment for efficient charge extraction at the hetero-interfaces. This significantly improves the PEC performance of CBTSSe films, yielding a photocurrent of 12 mA/cm² at 0 V/RHE, the highest value reported for CBTSSe-based PEC devices, as well as stable hydrogen evolution for 10+ hours. Ultimately, the study demonstrates that similar level of performance is achieved with high purity CBTSSe films synthesized in solution using inexpensive and commercially available precursors. The present results highlight the potential of CBTSSe materials as efficient, stable and low-cost photocathodes for solar water splitting.

Effects of Electrochemical Potential on Aliovalent Dopant Segregation on Perovskite Oxides Through Elastic and Electrostatic Interactions Dongha Kim, Roland Blien and Bilge Yildiz, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

La-based perovskite oxides such as (La,Sr)CoO3 and (La,Sr)MnO3 have been extensively studied as cathodes in solid oxide fuel cells (SOFCs) due to their high oxygen reduction activity and good compatibility with the electrolyte materials. However, cathode performance is still regarded as one of the main bottlenecks in SOFC operation. In the case of perovskite cathodes, the activity for oxygen reduction and incorporation is impeded by the surface segregation of aliovalent dopants such as Sr. Our previous work assessed the role of temperature and oxygen pressure on segregation of dopants on perovskite oxide surfaces. The present study investigates the effect of electrochemical polarization on dopant segregation. This is important for electrochemical energy conversion applications because electrode material is under different electrochemical and oxygen chemical potentials when we run the system in electrolytic or fuel cell modes. In order to resolve the electrochemical potential effect systematically, we applied a potential gradient parallel to the surface of thin films, (La,D)MnO3 (D =
electron-beam evaporation, thus modifying the local bond strength of oxygen in the surface region. Similar doping has proven successful in a previous study on solution-based metal deposition on (La,Sr)CoO$_3$ \cite{6}. Here we demonstrate that this effect is not limited to one material and deposition method, but can be generalized to (La,Sr)MnO$_3$, an intrinsically different type of cathode material, modified using metal evaporation. Using in-situ ambient pressure photoelectron spectroscopy and X-ray absorption spectroscopy, we observe an improved stability under the influence of metals such as Hf and Ti. In combination with scanning probe microscopy and electrochemical performance measurements, we analyze the details of surface doping on structure and stability and explore its limitations. Identifying the nature of the surface phase and the changes due to metal deposition will provide a foundation for targeted approaches to inhibit segregation, facilitating the pathway towards higher long-term stability of doped perovskite oxide surfaces.

Highly active doped ternary oxides, including perovskites, are common functional materials in energy conversion, catalysis, and information processing applications \cite{1}. At elevated temperatures related to synthesis or operation, however, surface segregation of dopant cations is a common problem of state-of-the-art materials, such as the Sr-doped La-based transition metal perovskites (La$_{1-x}$Sr$_x$CoO$_3$), (La$_{1-x}$Sr$_x$FeO$_3$), and (La$_{1-x}$Sr$_x$MnO$_3$), used for example as solid oxide fuel cell cathodes. In these oxides, Sr segregation under operating conditions leads to degradation via the formation of an inactive surface oxide \cite{2,3}, blocking the oxygen reduction reaction \cite{4}. This dopant segregation occurs due to two driving forces: strain and electrostatics \cite{5}. While the size mismatch between Sr and La cations causes strain that can be released via segregation, the electrostatic driving force originates in the attraction of negatively charged dopants to the surface layer enriched in positively charged oxygen vacancies.

Here we relate the segregation in perovskite oxide cathodes to their surface properties, comparing the effects on surface structure and composition of as-grown thin films and metal-doped surfaces. We address the electrostatic driving force of segregation by depositing metals of different reducibility using electron-beam evaporation, thus modifying the local bond strength of oxygen in the surface region. Similar doping has proven successful in a previous study on solution-based metal deposition on (La,Sr)CoO$_3$ \cite{6}. Here we demonstrate that this effect is not limited to one material and deposition method, but can be generalized to (La$_{1-x}$Sr$_x$MnO$_3$, an intrinsically different type of cathode material, modified using metal evaporation. Using in-situ ambient pressure photoelectron spectroscopy and X-ray absorption spectroscopy, we observe an improved stability under the influence of metals such as Hf and Ti. In combination with scanning probe microscopy and electrochemical performance measurements, we analyze the details of surface doping on structure and stability and explore its limitations. Identifying the nature of the surface phase and the changes due to metal deposition will provide a foundation for targeted approaches to inhibit segregation, facilitating the pathway towards higher long-term stability of doped perovskite oxide surfaces.

Although intercalation and conversion battery chemistries have their own advantages in either gravimetric or volumetric energy densities, it is very challenging to achieve both simultaneously. Here, we develop an “intercalation+conversion” hybrid cathode by introducing electrochemically-active Chevrel-phase MoS\textsubscript{2} with fast lithium intercalation reactions and high tap density to hybrid with sulfur to achieve high full-cell gravimetric-and-volumetric-energy-density simultaneously. The mechanically “hard” MoS\textsubscript{2} with fast Li-ion transport, decent capacity contribution and the dramatically enhanced affinity for LiPS after lithium intercalation, is an ideal backbone to immobilize “soft” sulfur species and “unlock” their high gravimetric capacity. This material combination is akin to the relation between primer and TNT in explosives, one fast acting, the other with high gravimetric energy content. The cell using the hybrid cathode paired with Li metal anode delivers very high full-cell gravimetric and volumetric energy densities with good cycling stability, surpassing both Li-S and Li-ion batteries. Our approach demonstrates the potential for such hybrid cathodes for high energy density applications.

**SESSION ET09.08: Li-Sulfur Batteries: Design and Applications**

*Wednesday Afternoon, November 28, 2018*

Hynes, Level 3, Room 301

**3:30 PM ET09.08.03**

**Design of a High Energy Lithium-Sulfur Battery**

Ning Kang\textsuperscript{2}, Li Yang\textsuperscript{1} and Mei Cai\textsuperscript{1}; \textsuperscript{1}General Motors, Warren, Michigan, United States; \textsuperscript{2}Optimal CAE, Plymouth, Michigan, United States.

Li-S batteries have a theoretical energy density of 2510 Wh/kg and 2740 Wh/L, which is one of the most promising candidates for the next generation rechargeable batteries \textsuperscript{1}. Despite the great merits of the Li-S batteries such as high energy density and low cost, challenges, including polysulfide anions redox \textsuperscript{2} and low lithium cycling efficiency, hinder its commercialization. There has been great research effort devoted to the optimization of sulfur electrodes, the formulations of electrolytes as well as the ratios of electrolyte to sulfur. In this talk, we will address the impact of sulfur electrode porosity on the energy density of Li-S battery and the influence of electrolyte/sulfur ratio on the Li-S battery performance.

Based on our preliminary results, the total sulfur concentration [S] in the electrode increases exponentially with the decrease of the porosity. The [S] is 15 M at 70% porosity but increase to 30 M at 50% porosity, which may explain the reason for the 2nd discharge voltage plateau decay of the Li-S cells.

Rechargeable lithium-sulfur (Li-S) batteries with a theoretical specific energy of 2,500 Wh kg\textsuperscript{-1} are promising candidates to replace Li-ion batteries in many applications.\textsuperscript{1} Even though Li-S batteries possess a high theoretical specific energy, several major technical challenges must be overcome. Many of these challenges are closely related to the formation of soluble lithium polysulfide (LiPS) intermediates. For instance, the irreversible redistribution of LiPS inside the battery leads to degradation of sulfur cathodes and passivation of Li metal anode. The uncontrolled LiPS relocation further leads to severe active material loss and self-discharge behavior of the batteries.

Ultimately, the most critical question for Li-S batteries is whether their high theoretical energy density can be practically delivered. The practical specific energy of Li-S batteries greatly depends on the electrolyte/sulfur (E/S) ratio of the batteries. To increase the energy density of rechargeable Li-S batteries, the E/S ratio should be decreased as much as possible. However, when the E/S ratio is decreased, multiple issues arise that degrade battery performance such as discharge capacity, cycle life, and rate capability. Very importantly, our group has recently found that once the electrolyte becomes saturated with liquid phase high-order LiPS, the solid phase LiPS cannot be further reduced and consequently does not contribute to the capacity of the cells at normal discharge.
discharge rates. Therefore, the solubility of high-order LiPS can potentially lower the achievable specific energy of Li-S batteries to less than 500 Wh kg⁻¹, which becomes much less attractive for their commercialization.

To address the above mentioned challenges associated with conventional Li-S batteries, here we use the solid-state lower-order LiPS, i.e., Li₂S₄, as the cathode active material to construct a new type of Li-Li₂S₄ battery. By replacing the elemental sulfur with solid-state Li₂S₄ as the active cathode material, we avoid any solubility limitation previously encountered in the upper plateau of discharge. We found that in the lower plateau of discharge, the discharge capacity is not limited by the finite solubility of Li₂S₄ and much higher discharge capacity with a Li-Li₂S₄ cell is achieved under a higher sulfur content of 84% and a low E/S ratio of 4.4 ml g⁻¹. Moreover, the cyclability is also enhanced due to the reduced diffusion of high-order LiPS. We believe the reported results of our Li₂S₄ cathode open a new direction of cathode development for high energy density Li-S batteries.

4:15 PM ET09.08.05
Electrochemical Study of Novel MoTe2 Anode Based Lithium-Ion Full Cell Manas R. Panda1, 2, 3, Anish Raj K2, Arnab Ghosh2, Ajit Kumar2, Qiaoliang Bao1 and Sagar Mitra2; 1IITB Monash Research Academy, Mumbai, India; 2Energy Science & Engineering, IIT Bombay, Mumbai, India; 3Material Science and Engineering, Monash University, Melbourne, Victoria, Australia.

Lithium-ion batteries (LIBs) are capable power sources for the convenient power electronic device, electric vehicle and space applications during last few years. However, the specific power density at high rate electrochemical test is still too poor to satisfy the industry needs. Hence, the development of high-performance rechargeable lithium-ion batteries becomes increasingly important. Transition metal dichalcogenides (TMDs) are considered as a promising anode for high-performance lithium-ion batteries due to their availability, low-cost, structural stability and layered structure for easy movement of lithium-ion into the host structure. Among TMDs, layered molybdenum ditelluride (MoTe₂) has the highest interlayer spacing and electronic conductivity which are the two key factors to provide more Li-ion storage property. However, their comprehensive study in lithium batteries is limited. Henceforth in the present study, the polycrystalline MoTe₂ powder has been prepared by a simple solid-state synthesis and characterized using XRD, FESEM, EDS, and HRTEM techniques. The physiochemical characterizations of the material prove the phase purity and crystallinity of the material. When the same material used as a working electrode for lithium battery, it gives a high reversible specific discharge capacity ~280 mA h g⁻¹ in the potential window of 0.1 V–2.8 V at a current density of 1.0 A g⁻¹. The above results stimulated us to construct a lithium-ion full cell using our synthesized anode against commercial LCO cathode for the first time. The electrochemical analysis of the MoTe₂/ LCO full cell shows a competitive discharge capacity of ~140 mA h g⁻¹ at a current density of 500 mA g⁻¹ in the potential range of 1.75-3.75 V. The excellent cyclability of the full cell without capacity fading over 50 cycles was achieved with the coulombic efficiency ~100%. The obtained results positively open up the possibility of scaling up the technology for energy-storage applications.

8:00 AM ET10.01.01
Complexes with Redox Non-Innocent Ligands for Flow Battery Energy Storage Kathryn Toghill, Ross Hogue and Craig Armstrong; Lancaster University, Lancaster, United Kingdom.

Redox flow batteries (RFBs) are energy storage devices where solutions of electroactive materials are pumped to/from external tanks to the electrode interface for charging/discharging. As energy is stored externally in solution, capacity can be increased independently of the battery power, thus making RFBs promising candidates for grid-scale energy storage. Established RFBs utilise aqueous electrolyte solutions; however the voltage output is limited by the narrow (~1.5 V) electrochemical window of water. Instead, the development of non-aqueous RFBs, which use organic solvents with wide
Redox flow batteries (RFBs) are expected to play a critical role in the grid energy storage by facilitating the widespread adoption of intermittent renewable energy sources like wind and solar. However, the worldwide market penetration of RFB systems is still limited due to technical and economic challenges. A key advantage of transitioning from aqueous to non-aqueous systems is the possibility of achieving higher energy density through the wider windows of electrochemical stability associated with organic solvents. Despite this promise, non-aqueous flow batteries are a nascent concept and, to date, no redox chemistry has proven competitive due to a combination of low solubility and stability for redox couples and a lack of selective membranes/ separators.

When building energy dense RFBs, the solubility of redox couples in the neutral and oxidized/reduced form is critical as active species must remain soluble across all states-of-charge. Notably, recent reports have highlighted redox active compounds that are highly soluble in their neutral state but haltingly soluble in their charged form, frustrating practical implementation. To this end, we have been developing a series of phenothiazine derivatives to achieve a high solubility at their neutral as well as charged states (radical cation and dication) through simple and easy molecular engineering strategies. This presentation will focus on the synthesis of highly soluble radical cations/dications with strategic substituents on phenothiazine, their solubility in non-aqueous solvents, spectroscopic, and electrochemical analysis of the radical cation salts.

Recent progress in performance enhancement of high-stability mushroom-derived non-aqueous redox flow batteries.

Acetylpyridinium and cyclopropenium salts have recently been identified as promising catholyte and anolyte candidates for non-aqueous redox flow batteries (RFBs). Most early work on these systems focused on independently cycling the anolytes and catholytes in static electrochemical cells. In this work, we demonstrate the cycling of these molecules together in a laboratory-scale redox flow battery. Cyclic voltammetry experiments indicate that the two molecules should be compatible in a flow battery. However, initial cycling experiments showed a significant capacity fade resulting from a combination of both (1) crossover of these molecules through the membrane and (2) degradation of the anolyte in presence of the catholyte. This presentation will describe our work on the molecular tailoring of both the anolyte/catholyte structures as well as the membrane in order to address both of these challenges.

We recently reported a bio-inspired strategy that leverages biological evolution as a toolkit to address the problem of redox-couple instability that impedes commercialization of NRB.The approach led us to investigate Amavadin, a redox-active vanadium-containing-biometabolite found in mushrooms, for application as a stable NRB-active-material. An analogue of Amavadin, known as vanadium bis-hydroxyiminodiacetate (VBH), has been selected as a molecular scaffold as a new NRB active material due to its exceptional stability, redox reversibility and ease of synthesis. We will present the recent progress in performance enhancement of mushroom-derived NRBs. Fundamental and technical factors underpinning high area-specific resistance and low capacity fade during extended cycling are elucidated using in-situ and ex-situ electrochemical and spectro-electrochemical diagnostic techniques. The results of these analyses will be discussed for various operating conditions and flow cell components.

Therefore, it is essential to understand any mechanisms for molecular degradation in these systems. The performance of a quinone flow battery system is the stability of the quinone molecules, which is an important factor of overall battery calendar life. For renewable energy sources such as solar, wind, and hydroelectric to be effectively used in the grid of the future, flexible and scalable energy-storage solutions are necessary to mitigate output fluctuations. For systems that are intended for both domestic and large-scale use, safety and cost must be taken into account as well as energy density and capacity, particularly regarding long-term access to metal resources, which places limits on the lithium-ion-based and vanadium-based RFB development. Here we describe an affordable, safe, and scalable battery system, which uses organic polymers as the charge-storage material in combination with inexpensive dialysis membranes, which separate the anode and the cathode by the retention of the non-metallic, active (macro-molecular) species, and an aqueous sodium chloride solution as the electrolyte. In parallel, printable solid-state polymer batteries were developed allowing a new generation of metal-free batteries (e.g. with application possibilities for smart labels, internet of things or smart clothes).

Aqueous organic redox flow batteries (AORFBs) have emerged as an attractive alternative RFB technology because redox active organic molecule materials are synthetically tunable, sustainable, and potentially low cost. We have previously showed that positively charged viologen molecules are a class of viable anolyte materials for pH neutral anion exchange AORFBs with water soluble ferrocene and TEMPO catholytes. The presentation will cover our recent research efforts in developing sulfonate functionalized viologen molecules as anolyte materials for cation exchange AORFBs with low cost ferrocyanide and halide catholytes. The viologen based cation exchange AORFBs demonstrated outstanding battery performance including capacity retention up to 99.99% per cycle, energy efficiency up to 72% at 60 mA/cm², and a power density up to 120 mW/cm². Particularly, the presentation emphasizes that fundamental understandings of redox active electrolytes at molecular level are crucial to develop new generations of redox flow batteries for large scale and dispatchable renewable energy storage.

Redox flow battery is considered as a powerful technology for grid-scale energy storage because of the excellent scalability and design flexibility to meet the requirements for diverse grid applications. Inorganic-based flow batteries are the state-of-the-arts, but generally suffer from limited energy density and high chemical costs. Instead, redox-active organic compounds have demonstrated encouraging physico-chemical properties and electrochemical performance as attractive alternative materials for flow batteries, suggesting a promising avenue for developing next-generation flow batteries. Despite the current progress of organic flow battery materials, further improvements in energy density and cycle life are still urgently needed to demonstrate their potential for practical grid applications.

In this contribution, we will introduce the newly developed organic diquat herbicide materials for aqueous organic flow batteries. A series of diquat derivatives were designed and evaluated in flow cells to investigate the structural effects on the flow battery-relevant properties including solubility, redox potential, and chemical stability. A combination of electrochemical analysis, density functional theory (DFT) simulations and electron paramagnetic resonance (EPR) studies were performed to reveal important structure-property-activity insights to the diquat family, which also suggests further developmental needs for performance improvement. The diquat-based flow cell was capable of long cycling with low capacity fading.

Among the technologies available for large-scale storage of electrical energy, flow batteries have recently gained considerable interest. They are suitable for longer-duration storage because their energy capacity and power ratings are decoupled. With the aim of minimizing storage costs, researchers have designed electrolytes with synthetic redox-active organic molecules made from inexpensive and earth abundant materials. Quinones in alkaline solution have proved to be promising candidates. Various quinone derivatives have been reported with different substituents. One key criteria of evaluating the performance of a quinone flow battery system is the stability of the quinone molecules, which is an important factor of overall battery calendar life. Therefore, it is essential to understand any mechanisms for molecular degradation in these systems.
Using 2,6-dihydroxyanthraquinone (DHAQ) as the model system, we here present an analysis of the chemical stability and decomposition mechanism of this quinone in alkaline solution during cycling. High resolution LC-MS and advanced NMR techniques were used in elucidating the degradation pathway of DHAQ. This degradation pathway is independent of substituent groups on the anthraquinone, but the rate can depend on the substituent groups. We draw important implications for the rational design of more stable quinone molecules for alkaline flow battery systems.

Development of redox flow batteries (RFBs) for fast growing grid-scale energy storage is supported in part by the Advanced Research Projects Agency (ARPA-E), which funds high risk, high reward transformational research to reduce energy related emissions, reduce imports of energy from foreign sources, improve energy efficiency across all economic sectors, and ensure US technological lead in advanced energy technologies. Exergy flow batteries are attractive for grid energy storage, because the amount of stored energy can be scaled up or down for rated power depending on the customer’s need and also potentially low cost. The cost reduction, which is the major driver in current RFB development, can be achieved by increasing power density (decreasing the stack cost) and using inexpensive active materials and electrolytes (decreasing energy cost). The former approach was funded via GRIDS program and led to development of high power cells based on traditional vanadium chemistry and their transfer to a commercial product. The latter approach was funded via OPEN projects and focused on low cost materials for aqueous RFBs. All-iron RFB uses one of the cheapest and most abundant active materials. However, the cell chemistry includes iron electroplating accompanied by hydrogen evolution side reaction. It required the development of cell rebalancing techniques, which were successfully demonstrated. Iron electroplating was realized on stationary (hybrid RFB) and movable (true RFB) electrodes. Another group of potentially inexpensive active materials is redox active, water soluble organic compounds. Redox potential and solubility of such compounds can be tuned by targeted substitution to increase RFB energy density. Trade-off between these parameters and the active materials cost and membrane crossover will be discussed.

Development of novel ion-selective membranes for RFBs is also being funded via IONICS program. Future ARPA-E program targeting the long duration energy storage will be also discussed.

A redox flow battery (RFB) can store large amounts of energy with relatively high efficiency and low cost. We have shown in the past that membrane-less lead flow batteries can operate with ultra long cycle life, enabled by simple additives. Recently, we reported that riboflavin derivatives, such as alloxazine and the sodium salt of flavin mononucleotide (FMN), can be relatively stable active materials for RFBs. Side reactions, such as the base-catalyzed hydrolysis and dimerization of flavins, however, are problematic. I will discuss on a few effective ways to maintain a highly stable FMN-based RFB enabled by the use of complexing agents. While the cycling performance at high efficiency could be further improved, other challenges regarding redox flow batteries will be discussed.

Considering the great system scalability and operation flexibility, redox flow batteries create their own niche for the large-scale energy storage application. Unlike other rivals like lithium ion and lead-acid batteries, the redox flow battery stores energy in flowable liquid electrolytes other than in immobile solid electrode materials. One of the main obstacles of conventional redox flow batteries is the low energy density (~40 Wh/L) as a result of the limited solubility of redox species in electrolytes, which adds onto system footprint and capital cost. To exploit the high energy density of lithium ion battery in flow systems, various redox-targeting based flow batteries have been developed recently. The energy density of those systems is no longer associated with the concentration of redox molecules but the amount of solid materials stored in the tanks. Thus, by increasing the loading of solid energy storage materials in the tanks, a markedly increased energy density can be achieved without sacrificing the merits of the flow battery. However, most reported redox-targeting reactions resort to multiple redox mediators and rely on lithium ion as the charge balancing and host ion. The potential mismatch of the multi-mediator system would result in undesirable complexity and low voltage efficiency. In addition, the scarcity of lithium relative to other elements may one day be a barrier for large-scale applications. Here, with the single molecule redox targeting reaction, a sodium ion-based redox flow battery with high energy density (up to 259 Wh/L) is developed to address the above issues. With a NASICON-type (Na3V2(PO4)3) both as the anodic and cathodic energy storage materials, an all-organic redox targeting system is demonstrated. In addition, to further reduce the system cost and improve the power capability, aqueous flow systems using open-framework materials are explored for practical applications. In light of operando spectroscopic measurements, the factors dictating the operation of the system at high power are unambiguously disclosed and investigated.

Reference:
The ability to store large amounts of electrical energy is of increasing importance with the growing fraction of electricity generation from intermittent renewable energy sources such as wind and solar. Wide-scale utilization of flow batteries is limited by the cost of redox-active metals such as vanadium or precious metal electrocatalysts. We have developed high performance flow batteries based on the aqueous redox behavior of small organic and organometallic molecules, e.g. [1-8]. These redox active materials can be very inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling both low cost and large-scale energy storage at greatly reduced cost. We have developed new protocols for measuring capacity fade rates and have discovered that the capacity fade rate is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed [7]. We will report the performance of the very few chemistries with long enough calendar life for practical application in stationary storage.

3:30 PM ET10.03.05 Aqueous Redox Flow Battery with Novel Organic Electrolyte Alolika Mukhopadhyay, Jonathan Hamel and Hongli Zhu; Northeastern University, Boston, Massachusetts, United States.

Renevable energy sources such as wind and solar can supply a significant amount of electrical energy in the United States and all over the world. However, only a very efficient and consistent energy storage system can fully utilize the potential of the renewable energy sources because of their sporadic nature. Another critical aspect of electrical power storage is to reduce the power surges and balance overload to improve the robustness and efficency of the grid. The discharge time at peak power is too short for solid-electrode batteries to regulate the grid or solar power output fully. In contrast, flow batteries permit more economical long-duration discharge than solid-electrode batteries by using liquid electrolytes stored outside of the battery. Currently, commercialized flow batteries use precious transition metal ions in acidic solution, which impose challenges with cost, abundance, and environmental impacts. Herein, for the first time, we propose Lignin, the second most abundant nature derived biopolymer surpassed only by cellulose, as an anolyte for the aqueous flow battery. Lignosulfonate, a water-soluble derivative of Lignin, is environmentally benign, non-flammable and very inexpensive as it is the main component in the liquid waste of the chemical pulping and biofuel production process. Lignosulfonate utilizes the redox chemistry of quinone moiety to store energy and undergoes a fast two proton two electron reversible redox reaction. In this work, Lignosulfonate was paired with Br2/Br-, and the full flowcell runs efficiently with high power density. Also, the large and complex molecular structure of lignin considerably reduces the electrolytic crossover, which ensures very high capacity retention over several cycles. The promising results obtained from this economical organic-inorganic redox combination could be a breakthrough in grid-scale energy storage.

3:45 PM ET10.03.06 Two Electron Transfer TPA-Based Catholyte by Molecular Engineering for a Zinc Redox Flow Battery Xiaowei Wang1, Wei Tang2 and Kian Ping Loh3; 1NUS Graduate School of Integrative Science and Engineering, National University of Singapore, Singapore, Singapore; 2Electronic Materials (ELE) Department, Institute of Materials Research and Engineering, A-star, Singapore, Singapore; 3Department of Chemistry, National University of Singapore, Singapore, Singapore.

Redox flow battery (RFB) has been increasingly popular for grid-scale energy storage to meet high power demand due to the high capability and designable power. Nowadays, RFB has moved to the milestone of aqueous systems based on organic redox-active materials, in order to achieve sustainability (organic compounds), safety (aqueous electrolyte) and high energy density (redox with more electron transfer). However, possibly organic molecules are insoluble in water and their redox are irreversible in water. Therefore, apart from water solubility, it is important to engineer organic species with stable redox in aqueous ambiance by decoding the mechanism that attributes to redox instability. Triphenylamine (TPA) readily undergoes anodic oxidation to form TPA radical cation whose stability depends markedly on para-substitution due to radical transfer from N atom to C atom, leading to a dimerization in non-aqueous phase and radical quenching in aqueous system. Herein, we found that para-substitution by methoxy groups generates 4, 4′, 4′-trimethoxytriphenylamine (S3), which exhibits a reversible redox couple of 0.5/0.45 V (vs Ag/AgCl) with one-electron transfer in aqueous system. Moreover, an extremely rapid and reversible two-electron transfer reaction system 4, 4′, 4′-trihydroxytriphenylamine (P3) was also prepared with redox potential at 0.46±0.02 V and 0.53±0.01 V (vs Ag/AgCl), boasting a high kinetic rate constant of 1.1×107 cm2 s−1. The enol/keto redox couple of P3 exhibits fast and reversible kinetics as catholyte when paired with zinc negative electrode in aqueous RFB, yielding a high working voltage of 1.3 V with good cycling behaviour. This work aims to transform irreversible redox-active organic molecules into reversible ones by molecular engineering to broaden more possibility of redox-active materials for organic redox flow battery.

4:00 PM ET10.03.07 Benzothiadiazoles—Energy-Rich Anolyte Materials for Non-Aqueous Redox Flow Batteries Jingjing Zhang1, Jinhua Huang1, Lily A. Robertson2, Rajeev S. Assary1, Ilya A. Shkrob and Lu Zhang1; 1Argonne National Laboratory, Lemont, Illinois, United States; 2University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.
Redox flow batteries (RFBs) are among the most promising electrochemical storage technologies for grid electricity. Aqueous systems, which are currently making significant inroads into the commercial market, often display compromised cell voltages in typical aqueous solutions. Non-aqueous RFBs (NRFBs) enable a wider electrochemical window than the aqueous counterparts, but require high stability of redox-active organic materials (ROMs) in solution when charged. This is truly a difficult requirement to meet since charged ROMs exist as radical ions in solution. 2,1,3-Benzothiadiazoles (BzNSNs) that combine low redox potentials, high electrochemical stability, and excellent chemical accessibility are an exceptional class of analyte materials for NRFBs. Systematic investigations were conducted to elucidate the substitution effects on key properties including redox potentials, and stability of corresponding radical anions, and solubility. In terms of cyclability in RFBs, parasitic reactions that involve the sulfur loss and the oligomer formations were shown to restrict the long-term stability of these radical anions, yet the BzNSN molecules are among the leading energy-dense ROMs in performance found to-day.

4:15 PM ET10.03.08
Electrodes Modified with Redox Mediators for Improved Charge Transfer in Redox Flow Batteries Robert K. Emmett; Chemical Engineering, Clemson University, Clemson, South Carolina, United States.

Electrochemical performance of Iron RFBs was improved through incorporating iron redox mediators into the electrodes. Iron nanoparticles in the electrode create “hotspots” for faradaic charge transfer that reduces losses associated with kinetical, ohmic, and mass transfer resistances. Carbon nanotube electrodes are activated using cyclic voltammetry to initiate interactions between redox electrolytes and iron nanoparticles in the electrode. Modified electrodes experienced 152% increase in power density and a 50% increase in energy density in coin cell configurations. Economic value and ready availability of iron paired with enhanced performance makes iron RFBs a viable option for future RFB research. The highest peak power density reported for all-iron RFBs to the author’s awareness was accomplished at 178 mW cm\(^{-2}\) with iron-modified electrodes.

SESSION ET10.04: Electrode

Tuesday Morning, November 27, 2018
Hynes, Level 3, Room 309

8:00 AM ET10.04.01
Designing and Fabricating Engineered Electrodes and Flow Fields in Redox Flow Batteries Shohji Tsushima1, Takahiro Suzuki, Hidetoshi Matsumoto2, Kentaro Yaji1, Shintaro Yamasaki1 and Kikuo Fujita1; 1Osaka University, Suita, Japan; 2Tokyo Institute of Technology, Tokyo, Japan.

For further implementation of redox flow batteries for large scale electrical energy storage, high current density operation with less overpotentials is of great importance, leading to reduction of the system cost. In this talk, we will discuss minimizing energy loss by designing and fabricating porous electrodes and flow fields. We will present an approach to explore optimal material properties of carbon fiber electrodes, e.g. porosity, fiber diameter, thickness, etc. 2D or 3D cell simulations indicate renewed material properties to be fabricated to achieve high performance redox flow batteries [1,2]. We will show our recent progress on engineered porous electrodes fabricated for reduced fiber diameter and surface modification with emphasis on characterization of electrode, i.e. reaction kinetics and transport properties [3,4]. We also present an optimization of flow fields in redox flow batteries. We will discuss a potential of topology optimization for designing flow fields to achieve better cell performance with less pressure drop [5].

8:30 AM ET10.04.02
Unveiling the Redox Reaction Between Vanadium Electrolyte and Electrode via Electrochemical Analysis and Computational Method Chan Yong Choi, Hyungjun Noh, Soohyun Kim, Riyl Kim, Juhyuk Lee, Jiyoung Heo and Hee-Tak Kim; KAIST, Daejeon, Korea (the Republic of).

To enhance the performance of vanadium redox flow batteries (VRFB) and design the durable electrode, it is quite important to understand the redox reaction mechanism of vanadium electrolyte exactly. In spite of its importance, the redox reaction mechanism between vanadium electrolyte and electrode has not fully been unveiled yet.

Here, we report the electrochemical impedance spectroscopy analysis of symmetric positive and negative single cells to understand the mechanism. The symmetric cell analysis allows the individual investigation of the positive and negative redox reaction in a practical single cell structure without any perturbation from crossover and any use of problematic reference electrode. The comparisons of charge transfer resistance \(R_c\) for heat-treated/un-treated carbon felt electrode and positive/negative symmetric cell elucidated the feature of the redox reactions.

In addition, we demonstrated the hydration structure between the vanadium ion and the water molecule by molecular dynamics (MD) simulation, enabling a deeper understanding on the redox mechanism. We believe that the contribution provides an important insight on electrode material design and can motivate further research on study of vanadium electrolyte and redox reaction mechanism.

8:45 AM ET10.04.03
Conductive Polymer Electrodes for Controlled Energy Conversion Processes in Redox Flow Systems Erin L. Ratcliff; University of Arizona, Tucson, Arizona, United States.

Intermittent sunlight necessitates the storage of electricity, ideally in controlled chemical reactions analogous to photosynthesis. Many efforts have focused on the oxidation of water at metal oxide semiconductor surfaces, although light-driven electrochemical reactions at photoelectrodes continue to suffer from
sluggish half reactions. Alternatively, redox couples such as ferrocene and quinones used in redox flow systems offer more control over electrochemical kinetics through synthesis, with rates of electron transfer being several orders of magnitude larger than water splitting for improved storage capacity. This talk will focus on alternative electrodes for charge transfer to anolytes and catholytes in redox flow systems. The ideal electrode material should be low cost, compatible with industrial printing methods, and most critically, have predictable kinetics to maximize energy conversion processes in the context of convection and diffusion processes found in redox flow systems. The challenge with inorganic semiconductors continues to be the ability to control interfacial mid-gap states that undergo band bending when interfaced with the electrolyte. Conductive polymer electrodes offer the possibility to control redox properties through synthesis and processing, if critical structure-property relationships are understood. Importantly, these semiconductors demonstrate a hybrid electronic-ionic conduction mechanism, and thus, have unique electrochemical behaviors relative to classical inorganic semiconductor electrodes. This talk will provide new insights into the mechanism of charge transfer at conductive polymer/liquid interfaces. A mathematical framework will be demonstrated using a modified Marcus-Gerisher model that enables prediction of rate constants from simple film properties. Experimental evaluation of potential-dependent rate constants will be demonstrated. Results will be contextualized in electrochemical devices, with consideration to transport and nanoscale phenomena.

9:00 AM ET10.04.04
Biomass-Derived Electrodes for Vanadium Redox Flow Batteries
Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; Department of Civil and Environmental Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Redox flow batteries (RFBs) offer a promising pathway towards the goal of widespread, commercially viable energy storage capable of meeting increasing energy demands, seamlessly integrating renewable energy sources into the electric grid, and improving overall grid reliability and resilience. A critical shortcoming of the state-of-the-art all-vanadium redox flow battery (VRFB) that must be addressed is the inherently sluggish kinetics of involved vanadium redox couples, which significantly reduces cell efficiency. This has spurred research and development of novel electrode materials that outperform current materials, achieved by surface treatments or other means[31]. In addition to superior electrochemical performance, it is desirable that these surface-modified materials can be produced using low-cost methods that are both environmentally-friendly and sustainable.

In this work, we demonstrate that biomass can be used to obtain potentially lower-cost, sustainable electrodes that also enhance vanadium kinetics through the introduction of surface functionalities imparted by the choice of biomass precursor. Unlike fossil-derived carbon precursors (i.e. polyacrylonitrile), the biochemical constituents of biomass (e.g. proteins, carbohydrates, lipids) enable the manufacturing of electrodes with chemical functionalities that are uncommon in current generation carbon electrode materials, while using a low-value, renewable carbon source. Activated carbon (AC) with a hierarchical porosity and high surface area is produced by first stabilizing the biomass via hydrothermal processing at 200-300 °C for 6 h to obtain hydrochar, which is subsequently converted into AC by thermal activation at 850 °C in an inert environment. Evaluation of the electrochemical properties via ex-situ cyclic voltammetry and impedance spectroscopy of the biomass-derived activated carbons compared to carbon black (Vulcan XC-72) reveals that the ACs are not only conductive and electrochemically active, but also are, in some cases, more active than carbon black. Furthermore, XPS (and other compositional characterization techniques) suggest that increasing N-containing content reduces charge-transfer resistance and improves activity. The revealed correlation between electrode elemental composition and function will aid in the design of next-generation electrode materials.

9:15 AM ET10.04.05
Functional Construction of the Carbon Fiber Electrode Used in the Vanadium Flow Battery
Xinzhuan Fan, Haoran Jiang, Jing Sun and Tianshou Zhao, Department of Mechanical and Aerospace Engineering, HKUST Energy Institute, Hong Kong, Hong Kong.

Vanadium flow battery (VFB) is a liquid energy storage battery based on VO$_2$/VO$^+$ and V$^{3+}$/V$^2$ pairs, whose energy is stored in the electrolyte. Compared with other energy storage technologies, VFB has lots of outstanding advantages such as the long cycle life, large scale, high safety and reliability. So VFB has become one of the preferred technologies for scale energy storage. VFB is composed of the bipolar plate, electrode, separator and electrolyte. As the place where electrode reactions occur in VFB, the electrode is one of the key materials that determines the battery performance and cycle life. In general, The electrode portion near the membrane side often refers to “catalyst layer”, which requires high electrochemical activity and good mass transfer property. While the electrode portion near the bi-polar plate side often names as “conductive layer”, which not only needs good conductivity, but also a large contact area to reduce the contact resistance between the electrode and bipolar plate. The function of the electrodes in different regions is different, so it is unreasonable to use the traditional homogenous electrode directly as the electrode of VFB, which also greatly affects the corresponding battery performance. In response to this problem, we have constructed a functional carbon fiber electrode for VFB. Firstly, the active layer needs an excellent electrochemical activity and preferable pore structure, so we should produced electrop spun fibers with smaller fiber density and fiber diameters between 1 and 4 μm. The smaller density and larger diameter determine that the electrode has a good electrolyte transmission channel; then the electrop spun fibers are pre-oxidized and carbonized to ensure that the electrode has rich oxygen-containing groups, and these oxygen-containing groups can not only ensure the hydrophilicity of electrode, but also provide good electrocatalytic activity. Secondly, the conductive layer needs excellent conductivity and large contact area, so we made electrop spun fibers with larger densities and smaller diameters between 200-800 nm. The larger density and smaller diameter determine the electrode has a larger contact area; then the electrop spun fibers are graphitized to ensure a higher conductivity. Finally, the conductive layer and the catalytic layer are stacked together as a functional composite electrode, and it could be used as a freestanding electrode of VFB. The functional carbon fiber electrode for VFB constructed by the above method not only solves the contradiction between the electrode activity and conductivity of the conventional electrode, but also effectively improves the mass transfer process of electrode, and greatly reduces the contact resistance between the electrode and bipolar plate.

The work described in this paper was fully supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. T23-601/17-R).

With the increasing penetration of variable renewable generation, energy storage is now becoming one of the hottest topics in the utility industry. The
commercial success of energy storage applications will depend on aligning the cost of a project with the benefits of the technology. Research on materials
and devices has increased cost effectiveness, cycle life and safety of these systems. Besides Li-ion batteries, flywheels, flow batteries, and advanced lead-
carbon batteries are being deployed. The presentation will discuss research on flow batteries as an example of consistent, device driven reduction in cost.
Markets are now gradually taking shape as changes in the regulatory framework result in more equitable valuation of storage benefits. The presentation will
discuss diverse monetized and unmonetized benefit streams, using multi-megawatt applications of a variety of energy storage technologies and highlight
outcomes and objectives of DOE supported energy storage deployments in California, Massachusetts, Washington, Oregon, and Vermont. As major
players begin deploying more storage projects, operators are recognizing their value for ancillary services. In particular, smoothing and ramping of wind
and solar PV are being addressed. Emergency preparedness through storage microgrids is another important development. There are now over 1700 storage
projects close to 200GW capacity listed in the Global Energy Storage Data Base, but with the continuation of the California mandate for 1.3MW of storage
and new emphasis in other states, we can expect an exciting upsurge in storage research and many new projects to be realized.

In this presentation, we will describe appropriate porous electrode theory and boundary conditions to estimate overpotential and current distribution within
physical and electrical properties of a slurry electrode to performance, and will explore effects of cell dimensions and flow operating conditions, such as
mechanisms of electronic conductivity. Finally, we will discuss some of the practical problems we have encountered in scaling-up a slurry iron flow battery
incorporated into a full flow cell and undergone flow cell optimization. An exemplary candidate, when coupled with the benchmark ferri/ferrocyanide
catholyte, delivers an OCV of 1.35 V at 50% SOC and achieves stable cycling over extended periods. References: 1. Zhang, M.; Moore, M.; Watson, J.S.;

Grid-scale battery storage devices have garnered increased attention for their ability to balance the intermittency of ever-expanding renewable energy
deployment and to mediate periods of peak power demand. The redox flow battery has emerged as a viable alternative to traditional solid state batteries.
With decoupled electrode and electrolyte storage vessels, the redox flow battery offers design flexibility where capacity and power may be independently
tuned. The current state-of-the-art flow battery systems utilize vanadium-based electrolytes, however, the high cost of vanadium has hindered wide-scale
deployment. The use of organic molecules as electrolyte materials has emerged as a potentially lower cost alternative. Presented will be our recent
efforts in developing aqueous-soluble phenazine derivatives as anolyte materials for redox flow batteries. The phenazine core structure has undergone
rational design to affect solubility and redox potential via the introduction of varying substituents on the parent molecule. Promising candidates have been
incorporated into a full cell form and undergone flow cell optimization. An exemplary candidate, when coupled with the benchmark ferri/ferrocyanide
catholyte, delivers an OCV of 1.35 V at 50% SOC and achieves stable cycling over extended periods. References: 1. Zhang, M.; Moore, M.; Watson, J.S.;

Slurry electrodes have many advantages in electrochemical devices and systems. They can be used to de-couple power and energy in energy storage, such
as with flow capacitors and with flow batteries involving deposition reactions. Examples are an iron flow battery with a slurry electrode and flow electrochemical capacitors. Slurry electrodes also have high active surface area for enhancing interfacial mass transfer and reaction kinetics making them applicable for recovering metals from dilute streams, for chemical synthesis, and for other electrochemical processes. Slurry electrodes can also be used as sacrificial electrodes and for mechanical regeneration of electrode materials.

In this presentation, we will describe appropriate porous electrode theory and boundary conditions to estimate overpotential and current distribution within
the slurry electrode, and describe predictions of electrode materials utilization, and electrode performance. The analysis will demonstrate the importance of
physical and electrical properties of a slurry electrode to performance, and will explore effects of cell dimensions and flow operating conditions, such as
flow rate. The presentation will address models of the effective electronic conductivity of a slurry electrode, and discuss our perspective about the
mechanisms of electronic conductivity. Finally, we will discuss some of the practical problems we have encountered in scaling-up a slurry iron flow battery
such as flow blockages caused by slurry solidification, and describe means found to mitigate, or at least reduce the effects of these problems.

New Materials to Accelerate the Commercialization of Redox Flow Batteries Mike L. Perry; UTRC, Glastonbury, Connecticut, United States.

A Redox Flow Battery (RFB) possesses several key advantages that make this technology potentially well suited for large-scale energy-storage applications. This is especially true of applications that require high energy-to-power requirements (i.e., multiple-hour discharge times at rated power) since the energy capacity can be increased by simply adding reactant solution without necessarily requiring (or negatively impacting) the power-delivery components. Despite this inherent scaling-factor advantage relative to conventional battery systems, the initial capital cost of flow batteries has been the major barrier to commercialization of RFB technology. Capital cost targets for grid-scale energy storage are challenging; battery systems for major grid-scale applications must cost less on a normalized basis (i.e., $/kWh) than those currently used for portable or transportation applications. One attractive path to cost reduction is the development of RFB cells with substantially higher power densities than conventional RFB cells, which UTRC has developed and demonstrated in complete all-vanadium RFB Systems, including 0.5-MW/3-MWh systems built by Vionx Energy. The focus of this talk will be on new materials that can potentially enable additional RFB-system cost reductions while maintaining the high performance levels required to be commercially-viable. This includes advanced cell materials (e.g., electrodes, separators/membranes) that can further improve the performance RFB cells, as well advanced RFB active materials. A brief review of the state-of-the-art of each of these major RFB components, along with future targets, will be presented. Some of the latest results developed by UTRC and our partners as part of an ongoing ARPA-E IONICS Program project will also be included. The major goal of this presentation is to help material developers identify potential opportunities to substantially improve RFB technology.

Portions of the work described here was supported by the U.S. Department of Energy (DOE), which includes these projects: ARPA-E’s Flow Batteries—New Designs, Chemistries and Cost Models (DE-AR0000149) and ARPA-E’s IONICS Program (DE-AR0001478), and the Joint Center for Energy Storage Research (JCESR), Office of Science, Basic Energy Sciences (DE-AC02-06CH11357).
Vanadium redox flow batteries (VRFBs) are promising energy storage devices for the integration of renewable energy sources in grid-scale stationary applications, compensating the intermittent nature of renewable energy sources such as, wind and solar. The key advantage of these systems is that power generation and energy storage capacity are decoupled. While the volume of electrolyte and the energy rating can be changed to obtain the required capacity, the size of the cell dictates power rating, providing flexibility and modularity. Despite these benefits, there are problems related to the long-term cycling of these batteries which limit the cycle life and affect the overall performance of the system. One of the main issues associated with the prolonged cycling is faradaic imbalance which is described as the shift of the average oxidation state of the battery from the ideal case of V^{3.5+}. Faradaic imbalance happens as a result of irreversible side reactions (e.g., hydrogen evolution). The side reactions seen in VRFB operation often cause a positive shift to the average oxidation state of the electrolyte, which results in the equilibrium potential of the positive half-cell to increase. This potential shift increases the possibility of exceeding the critical polarization potential at the positive half-cell, consequently leading to CO and CO₂ evolution, and related electrode/bipolar plate corrosion. Despite their importance, the issues of faradaic imbalance and corrosion of electrode/bipolar plate have not been widely recognized in the community. These issues not only restrict the performance of the battery, but also can lead to a significant damage to the flow battery system.

This study investigates the effects of faradaic imbalance and related electrode corrosion on the overall performance of a VRFB by conducting two experimental case studies: one with prepared imbalanced electrolytes with different imbalance ratios, and the other one with corroded positive electrode, prepared through an accelerated electrochemical corrosion process. We will separately demonstrate the performance characteristics of the flow battery for both mentioned cases, using various electrochemical characterization techniques such as charge-discharge cycling, polarization curve, and EIS measurements. Additionally, the correlation between the material characteristics of the cell components and the system performance will be discussed.
Development of electrochemical capacitors focuses today on the improvement of their energy density (or specific energy) and cyclability. The energy density might be improved by capacitance enhancement and operating voltage increase. To some extent, the relation between capacitance and voltage and their impact on the energy output reflects an interfacial character of charge storage mechanisms in capacitors; capacitance is intimately linked with the electrode material whereas the operating voltage is governed by the electrolyte applied. Of course, they cannot be considered separately, since the final performance is always a combination of various factors (e.g., electrode porosity – electrolyte viscosity, wettability, etc.). The electrolyte-related issues create an interesting pathway for investigations aiming at maximum voltage increase and energy density enhancement. Undoubtedly, organic media (based on acetonitrile or propylene carbonate) and ionic liquids are the optimal electrolytic solutions in terms of performance is always a combination of various factors (e.g., electrode porosity – electrolyte viscosity, wettability, etc.). The electrolyte-related issues create an interesting pathway for investigations aiming at maximum voltage increase and energy density enhancement. Although the neutral electrolytes might demonstrate a significant decomposition overpotential once applied to porous carbon electrodes and thus provide the operating voltage up to 1.8 V, the performance of water-based capacitors is still not satisfactory enough for a broad application.

Since the significant disadvantage of water-based solutions is attributed to the solvent decomposition, in our recent study, we decided to decrease the amount of water in aqueous electrolytes to the minimal level. Since the primary study has been done on LiTFSI salt, in our study, we have focused on the conventional inorganic salts, based on the well-known anions like NO₃⁻ or SO₄²⁻.

The paper will discuss the correlation between the pore size distribution of carbon electrodes, electrolyte viscosity, and capacitor performance. Elucidation of the energy/power characteristics as well as cyclability at various temperatures will give a novel insight into ‘water’-based electrolytes.

Synthesis of Mesoporous β-Ni(OH)₂ Modified CdS Nano-Heterojunction Networks Showing High Visible-Light Photocatalytic H₂ Production Activity
Ioannis Vamvakasakis and Gerasimos S. Armatas; Materials Science and Technology, University of Crete, Heraklion, Greece.

Over the last years, photocatalytic hydrogen production through water splitting has attracted immense attention as a potential method for low-cost conversion of solar energy into chemical fuels. However, despite tremendous efforts on the development of various semiconductor-type catalysts, key challenges of obtaining catalysts with high activity and long-term stability still remain. Recently, the synthesis of highly crystalline mesoporous semiconductors has been the focus in the field of photo- and electrocatalysis. These materials combine the high reactivity of semiconductor nanocrystals (NCs) with mesoporous structure, offering new perspectives in designing novel photocatalysts with improved efficiency and reliability. Unlike to bulk-like microstructures and individual nanoparticles, 3D mesoporous networks of connected NCs can benefit from the large and accessible surface area within the assembled structure and enhanced light-harvesting efficiency arising from multiple scattering of light inside the pores.

Herein, we present the synthesis of 3D mesoporous β-Ni(OH)₂-decorated CdS nanocrystal assemblies (NCAs) and demonstrate their excellent performance for the visible-light photocatalytic H₂ production. XRD, high-resolution TEM, XPS, and N₂ porosimetry characterization results corroborate that the resulting materials consist of a porous network of linked β-Ni(OH)₂ and CdS nanoparticles (ca. 4–5 nm in size) and exhibit large internal surface areas (164–207 m² g⁻¹) and narrow distribution of pore sizes (ca. 6 nm). Catalytic studies along with UV–vis/NIR optical absorption, photoluminescence and electrochemical impedance spectroscopy measurements suggest that the p-type β-Ni(OH)₂ behaves as the oxidation active sites (hole collector), promoting efficient charge transfer and separation across the β-Ni(OH)₂/CdS nano-heterojunctions. Consequently, the Ni-modified CdS NCAs catalyst containing 5 wt % Ni reached an outstanding photocatalytic H₂-evolution rate of 1.4 mmol h⁻¹ with an apparent QY of 72% at 420 nm, while demonstrating good stability for at least 20 h in alkaline (5 M NaOH) ethanol solution (10% v/v). This work not only demonstrates the potential of the present p-n β-Ni(OH)₂/CdS photocatalytic system for sustainable hydrogen production, but also opens up new opportunities for the design and in-depth understanding of noble metal-free photocatalysts for efficient solar-to-chemical energy conversion.

Carbon Nanotube/Carbon Nanofiber Hierarchical Composites with Cobalt-Manganese Layered Double Oxide for High-Performance Flexible Membrane Capacitive Deionization Electrodes Meng Ding, Shaohuan Huang and Hui Ying Yang; Singapore University of Technology and Design, Singapore, Singapore.

In this work, our freestanding carbon nanotube/carbon nanofiber (CNT/CNF) composites are prepared from the electrospun nanofibers. After the electrospinning process, the obtained CNFs were coated with Co-Mn layered double hydroxides (LDHs) as the precursors for CNTs. By pyrolysis, hierarchical CNTs are able to grow on the surface of CNFs. And the LDH precursors were converted to Co-Mn layered double oxides (LDOs). The obtained CNT/CNFs are of benefit from the great electrical conductivity of CNTs and high surface area of CNFs. The Co-Mn LDOs provide good chemical reactivity. The prepared composites exhibited excellent desalination performance in long-term operation. The carbon substrates improve the mechanical strength, good conductivity and cycling stability. The combination of CNT/CNF/LDO composites is a promising method for preparing flexible membrane capacitive deionization electrodes with enhanced desalination performance.

Thermochemical CO2-Splitting at High Conversion Efficiency Using Doped-Ferrites Jimmy Rojas, Shang Zhai, Nadia Ahlborg, Kipil Lim, Arunava Majumdar and William Chueh; Stanford University, Stanford, California, United States.

Two-step thermochemical CO2 splitting (TCDS) cycle has been long pursued for CO2 mitigation, but the need for high operating temperature (>1400°C) makes it incompatible with the chemical industry infrastructure. Moreover, low CO2-to-CO conversion makes such cycles far from economical. We designed and synthesized a new class of doped-ferrites and experimentally demonstrated O2 evolution at 1300°C followed by 7 mL-CO evolution per gram of ferrite at 700°C with CO2/CO = 100:1 (balance Ar) in purge gas, indicating high conversion efficiency. The mechanism of oxygen exchange is illustrated through various characterizations: Ex situ x-ray diffraction on quenched samples illustrates the phase transition behavior of doped-ferrites while resonant x-ray diffraction sheds light on cation distribution. Furthermore, Fe is shown to be redox active by ex situ x-ray near edge structure. The high CO2-to-CO conversion efficiency achieved by innovative doped-ferrites opens new opportunities of thermochemical redox chemistry.

Polydopamine-Graphene Oxide Derived 3D Nitrogen Doped Graphene@Ni2P for Efficient Oxygen Evolution Electrocatalysis Huizhu Xu and Dianxue Cao; Harbin Engineering University, Harbin, China.

The composite catalysts which has large specific surface areas, growing uniform particles and high activity are particular important for oxygen evolution reaction. Here we report a three dimensional(3D), nitrogen doped graphene aerogel with abundant Ni2P nanoparticles in suit. The approach used dopamine undergoes self-polymerization that can functionalize the graphene surface and produce a large volume of graphene hydrogel (PDA/rGO). The PDA/rGO is immersed in an aqueous solution of nickel acetate, which adsorbs nickel ions. The nitrogen doped graphene aerogel with Ni2P (NGA@Ni2P) is produced by freeze-drying, 1173K carbonization, 623K phosphatization. The NGA@Ni2P has a low applied external potential of 1.68 V at 10 mA cm-2 and the Tafel slope of 78 mV dec-1.

Polydopamine has the properties of reducing, adhesiveness and adsorption of metal ions. Introduce polydopamine in graphene, which not only increased the volume of graphene aerogel, added to the favorable nitrogen species, but the abundant hydroxyl and amino groups in polydopamine, allowing metal ions can be uniformly long on the graphene. In this case, we use polydopamine to adsorb Ni2P nanoparticles. Ni2P nanoparticles have metallic quality, so it has better oxygen evolution performance. The unique 3D structure, high surface areas, favorable nitrogen species and uniformly grown nanoparticles of NGA-Ni2P have good performance as electrode material for oxygen evolution reaction. This paper is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.

Natural Selection as a Molecular Design Toolkit—Bio-Inspired Flow Battery Active Materials Shyam Pahari1, Tugba Caren Gokoglan2, Andrew Hamel3, Ertan Agar2 and Patrick J. Capelliing4; 1Chemistry and Biochemistry, University of Massachusetts Dartmouth, North Dartmouth, Massachusetts, United States; 2Mechanical Engineering, University of Massachusetts Lowell, Lowell, Massachusetts, United States.

Modern electrical grids, especially those comprising energy from intermittent, renewable sources such as wind and solar, require storage. Non-aqueous redox flow batteries (NRFB) are a promising technology to meet this growing need. They have the potential to greatly exceed the energy density of their aqueous counterparts while maintaining key advantages over Li-ion systems. These advantages include decoupled power and energy ratings, thermal stability, benign chemical nature and the capability of long-duration storage (months or even years).

Despite the promise of NRFB, fundamental technical obstacles limit their application:
- active-material instability (low cyclability)
- active-material insolubility (low energy density)
- poor electrochemical performance (low power, low open-circuit voltage)

We will present a bio-inspired approach that addresses each of these problems using a family of molecules that is naturally occurring and produced biologically. These compounds are analogues of Amavadin, which is found in mushrooms of the *Amanita* genus. Biosynthesis of this molecule evolved over countless generations to bind vanadium selectively and with the highest stability ever reported, using a unique tetratdentate, bis-carboxylato-η5-hydroxyimino- binding motif. Ligand-substitution is suppressed, shutting down a major mechanism of decomposition. In this way, natural selection serves as a toolkit for molecular design, elucidating a scaffold for optimized NRFB active materials. We will present a suite of electrochemical and spectroelectrochemical data demonstrating that this Amavadin analogue, which we call VBH, is stable even in the presence of water, is oxygen tolerant and that bulk oxidation and reduction is tightly coupled to formation of the vanadium(v) and vanadium(iv) species, respectively.

Further, we will discuss the key thermodynamic factors used to improve VBH solubility and present recent progress, including stable electrolyte solutions with > 1 M active material and > 2 M supporting electrolyte in organic solvent.

Finally, we will present a detailed computational investigation of the effect of covalent modification of VBH on its open-circuit voltage and its chemical stability in all oxidation states, along with progress on the synthesis of these derivatives.

ET10.07.06
A Stable and Long-Lasting Concentration Cell Based on Reduced Graphene Oxide Membrane and Redox Electrolyte Zhe Wang1, Yi He2,3, Jing Zhang' and Lei Wei1; 1School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore, Singapore; 2National University of Singapore, Singapore, Singapore; 3School of Defence Science & Technology, Southwest University of Science and Technology, Mianyang, China.
Concentration cell is a promising solution in developing sustainable energy device. Most of the reported concentration cells employed an ion-selective membrane to separate two half-cells with different solution concentration. Thus, the voltage will be generated because of the concentration gradient which follows Nernst equation. However, the concentration gradient is easily decreased due to continuous diffusion, resulting in short lifetime and low output voltage. Although graphene oxide membrane (GOM) has been developed for providing the two-dimensional confinement of electrolytes to reduce the diffusion, the drawback of the reverse electrodialysis still exists. Moreover, GOM is unstable in water and can easily disintegrate, which further limit its application area in energy conversion. Therefore, we demonstrate a long-lasting concentration cell based on natural source, humic acid (HA), and water-stable reduced graphene oxide (RGO) membrane. This cell develops a new mechanism based on redox electrolyte and reaches a high voltage of 0.21 V for more than 210 h, provides a new solution for long-lasting concentration cell.

GO dispersion with a concentration of 0.9 mg/mL is prepared by modified Hummer’s method. 50 mL GO dispersion is transfer into a glass petri dish and then dried under 323 K for 24 h. After that, GO membrane will be formed at the bottom of the dish. Then 10 mL hydriodic acid (HI) is used to reduce the GO membrane to RGO membrane under 373 K for 1 h. Freestanding RGO membrane is obtained by washed with deionized water and dried under 353 K. SEM images show that the thickness of the RGO membrane is ~4 micrometer with a layer distance of 0.36 nm. The FTIR spectroscopy of GO film and RGO film illustrate that the oxygen-containing groups are removed after reduction process. To fabricate concentration cell, the RGO membrane is fixed between two plastic tubes. Thus, one side of RGO membrane is exposed to 20 mL HA solution (1 mg/mL), while the other side is exposed to deionized water, forming a concentration gradient. An open circuit voltage of 0.21 V is measured which last for more than 210 h, indicating its long lifetime. After measuring the cell’s performance with different electrolytes, including KCl, Na2CO3, and HA, we find that good performance can only be achieved using HA as the electrolyte, indicating that this cell is based on redox reaction and the RGO membrane has no ion selectivity. At last, the cyclic voltammogram (CV) curves for HA solution is measured. Experimental result shows that HA is oxidized at the anode side while O2 is reduced to H2O at the cathode side. Thus, the redox reactions on both electrodes are clarified. This work reveals its promising application prospect in energy conversion area.

The Role of Carbon Surface on the Quinone-Based Molecular Electrochemistry for Energy Applications

Grazia C. Sedenho1, 2, Diana D. Porcellini2, Yan Jing1, Emily Kerr1, Roy G. Gordon1, 2, Frank N. Crespi1, 2 and Michael J. Aziz2, 3

1 São Carlos Institute of Chemistry, University of São Paulo (USP), São Carlos, Brazil; 2School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States; 3Department of Chemistry and Chemical Biology, Harvard University, Cambridge, Massachusetts, United States.

Growing global energy demand has motivated interest in new technologies for energy conversion and storage, such as aqueous organic redox flow batteries (AORFB). Quinones are promising as redox-active molecules in AORFB. Many of these molecules are composed entirely by Earth-abundant elements and are nontoxic, nonflammable, and safe for use in energy storage systems. The performance of a quinone-based AORFB depends directly on quinone properties such as redox potential, solubility in water and stability. The number of aromatic rings and the positions and types of side groups affect the redox potential and solubility; this opens a new opportunity in molecular engineering. The electrochemical redox kinetics can also be very important, and the electrode surface can play a decisive role in battery performance. Here, we show that the electrochemical kinetics can be significantly affected by the presence of functional groups on quinone-based molecules. We pay special attention to carbon-based electrodes because they are widely employed in flow batteries due to high electron conductivity and low cost. Based on half-cell experiments, we propose that some candidates for active redox molecules may have their electrochemical kinetics improved or worsened according to the electronegativity of the crystallinity of the carbon electrode. This is shown for alizarin red S, which shows two redox couples that are dependent on the structure of the carbon electrode material. We also evaluated some benzoquinones, which are candidates for the positive electrolyte: commercially available BQDS (1,2-dihydroxybenzene-3,5-disulfonic acid), and several newly-synthesized functionalized benzoquinones. We have observed sluggish kinetics with amorphous carbon and glassy-like carbon electrodes for these molecules. In contrast, graphite electrodes with a high density of plane edges on the surface exhibited a nearly reversible redox response. Based on these results, it is possible to propose new carbon electrode materials based on graphic structures to be used in AORFB.

Quaternized poly(arylene ether benzonitrile) Membranes for Vanadium Redox Flow Batteries

Eun Joo Park, Sandip Maurya, Yu Seung Kim and Ragachary Mukundan; MPA-11, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Development of membrane separators is important to enhance efficiency and durability of vanadium redox flow batteries (VRFB). Desired properties of the membranes for the VRFB application include (a) selective ion permeability, (b) high conductivity and (c) good chemical and mechanical stability in acidic-oxidative environment. Our approach to satisfy these criteria is synthesizing cation-functionalized nitrile-containing polyamorastics, poly(arylene ether benzonitrile)s, for membrane separators for VRFB. A series of high molecular weight poly(arylene ether benzonitrile)s with pendant quaternary ammonium groups were synthesized via aromatic nucleophile substitution polycondensation. The chemical structures of the polymers were characterized by 1H NMR and FT-IR spectroscopy. The polymers were cast as transparent and flexible membranes, and the ion exchange capacity was varied from 1.8 to 3.1 meq/g. The presence of highly polar nitrile groups, incorporated in the polymer chain enhances the dimensional stability of the membranes. The VRFB single cell performance of the quaternized membranes was measured and compared to standard Nafion membranes. In this presentation, the membrane properties and the electrochemical performance of quaternized poly(arylene ether benzonitrile)s in terms of cycling efficiencies, vanadium permeation and membrane durability will be discussed.

Electrodeposition of Redox Active Layered Double Hydroxides for Energy Applications

Erika Scavetta, Isacco Gualandi and Domenica Tonelli; Univ of Bologna, Bologna, Italy.

At present, there is an increasing demand in the development of new highly efficient and low cost catalytic systems in the field of global energy issues. Layered double hydroxides (LDHs) are lamellar compounds whose structure consists of positively charged brucite-like layers with interlayer anions balancing the positive charge. LDHs containing transition metals are redox active and are very promising materials for several applications due to their versatility, tunable properties, wide range of compositions and low cost. Recently, these compounds are attracting much interest in the area of electrochemistry for applications such as batteries, supercapacitors, sensors, fuel cells and as efficient electrocatalysts for oxygen evolution reaction (OER). For all these applications, the active material must be well adherent to the conductive support, thus guarantying the formation of a mechanically stable coating.

Our group has proposed and optimized an electrochemical approach to coat any kind of conductive supports, of any shape and dimension, with LDH films. The synthesis is based on the electrochemical generation of hydroxides by cathodic reduction of nitrate ions and its optimization was achieved through a detailed study and understanding of the sequence of reactions involved. The features of the deposited LDH (amount, thickness and composition) depend on the applied potential, the length of cathodic pulse and the composition of the electrolytic solution; the adhesion of the coating to the surface can be enhanced through a proper pretreatment of the electrode support (1).
This contribution is aimed to describe the outstanding results obtained by our research group on the performance of LDH films containing Cobalt or Nickel as bivalent cation and Iron and Aluminum as the trivalent one for two important energy applications, i.e., as supercapacitors and as electrocatalysts for OER. In particular, our results show that LDHs containing Co as the bivalent metal can be considered a good candidate for supercapacitors development, especially when the trivalent metal is Fe: actually for Co/Fe LDH the redox process significantly involves also the inner surface of the LDH, giving a peculiar electrochemical behaviour, where the capacitance has both Faradaic and charge separation origin. This guarantees a wider window than the one displayed by the Al based LDH, making that material even more suitable for supercapacitor development.

As to OER electrocatalysts are concerned the best performances in terms of onset potential, current density at a fixed potential and turnover frequency (TOF) were obtained for iron-based LDHs both containing Ni or Co as the bivalent metal. Our results show that the presence of iron is crucial to significantly enhance the OER performances of LDHs.

Investigating the Decomposition of Acylpyridinium Salts as Anolytes in a Redox Flow Battery Anuska Shrestha and Melanie Sanford; University of Michigan, Ann Arbor, Michigan, United States.

Acylpyridinium (AcPy) salts had been identified as promising anolytes for redox flow battery applications. These materials are extremely stable towards bulk electrolysis cycling as well as to cycling in a symmetrical flow cell (with AcPy on both sides of the cell). However, flow cell cycling of AcPy anolytes in combination with cyclopropenium or ferrocenium catholytes results in >50% fade in capacity over 72 h of cycling. A close examination of the solutions after the battery experiment showed that anolyte decomposition in presence of the catholyte is one of the major causes of the capacity fade. 1H NMR spectroscopic analysis of the spent solutions revealed that the anolyte is degrading into two products. The structures of these products as well as the degradation pathways leading to their formation will be described in detail.

Effect of Non-Uniformity of Functionalized Surface on the Two-Dimensional Transition Metal Carbides for the Hydrogen Evolution Reaction Fun Seob Sim and Yong-Chae Chung; Division of Materials Science and Engineering, Hanyang University, Seoul, Korea (the Republic of).

The MXenes, which are two-dimensional form of MAX phases, have been introduced as a potential candidate for hydrogen evolution reaction (HER) catalyst due to their high surface area and thermostability. Recent studies of MXenes as an HER catalyst have focused on interaction between hydrogen and the uniformly functionalized surface. However, synthesizing MXenes with uniformly functionalized surface is still remained as a main challenge in this field, which induces gap between experimental and theoretical results. In this study, to evaluate the activity of the HER, the adsorption properties of a hydrogen atom on the non-uniformly functionalized surfaces of Ti2C-based MXene were investigated using density functional theory (DFT). On the surface where fluorine and oxygen functional groups coexist, a hydrogen atom was turned out to be adsorbed on the top of oxygen functional group with slightly larger adsorption energy than the case on the uniformly oxygen functionalized surface. At the vicinity of oxygen vacancy, compared with adsorption energy of a hydrogen atom on the uniformly functionalized surface, much larger adsorption energy was obtained when a hydrogen atom interacted with the exposed transition metal while slightly smaller adsorption energy for the on top site of nearest oxygen from vacancy. The change of adsorption energy of a hydrogen atom affects Gibbs free energy difference of hydrogen, which was derived from ab-initio thermodynamics. Through these results, it could be inferred that non-uniformly functionalized surface condition influenced the HER activity of Ti2C-based MXenes. Therefore, this theoretical study will provide further insight into the design of MXenes as a catalyst for HER.

Membranes for Redox Flow Batteries Dirk Henkensmeier1,2, Sangwon Kim3, Ruiyong Chen4 and Yongchai Kwon4; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2Energy & Environment Technology, University of Science and Technology, Seoul, Korea (the Republic of); 3KIST Europe, Saarbruecken, Germany; 4Seoultech, Seoul, Korea (the Republic of).

Membranes need to balance a low resistance and a low crossover of redox-active species, and they have to be chemically stable in the electrolyte. For vanadium redox flow batteries, this implies stability against sulfurous acid and stability against VO2+ ions. For many years, the latter criteria strongly limited the choice of membrane materials, and perfluorinated Nafion membranes became the state of the art.[1]

A very recent development is the use of polybenzimidazole membranes, which do not conduct ions in the pure form, but become proton conductive in contact with the sulfurous acid containing electrolyte. The positive charge on the protonated polymer backbone and the narrow size of the electrolyte filled voids between the polymer chains successfully repels vanadium ions in ex-situ permeability measurements. Most interestingly, we observed that both voltage efficiency and coulomb efficiency increase when the membrane thickness decreases. This probably is related to the average charging potential, which increases with the membrane thickness and thus a) enhances migration in the electric field, providing some vanadium ions with the energy to pass the energy barrier which hinders them from entering the membrane, and b) possibly enhances side reactions.

This result suggests that cells with thin PBI films would be very efficient in terms of both voltage and coulomb efficiency; the thinner, the better.[2]

Building up on this finding, we prepared porous Nafion membranes coated with a thin PBI layer[3] and porous PVDF membranes coated with a thin PBI layer.

Another way to improve the voltage efficiency of PBI membranes is to blend them with anion exchange ionomers.[4, 5] By alkyllating PBI membranes, a permanent charge can be fixed on the PBI backbone, turning the membranes into anion exchange membranes with a high IEC.[6] While the alkyl groups may be s starting point for degradation by VO2+, this type of anion exchange membranes can be used well in other types of
flow batteries.[7]

Diversity-Oriented Approaches for Pairing Redoxmers and Porous Polymer Membranes for Long-Lasting Redox-Flow Cells
Brett A. Helms; Lawrence Berkeley National Lab, Berkeley, California, United States.

Here I will discuss emerging strategies for realizing multi-hour energy storage using redox-flow batteries. In particular, I will address design considerations and constraints in active materials, electrolytes, and membranes, which together in the flow cell constitute a highly interactive chemical system. With this new perspective, it becomes possible to design each component to respond to the others when the cell is driven to different states of charge. This collective behavior by the system can be used to prevent active-material degradation, capacity loss due to precipitation, and active-material crossover, all of which compromise the efficiency and integrity of the cell long-term. These insights elevate the prospects for macromolecular design to overcome longstanding challenges to flow-cell development, toward reliable solutions for grid stabilization.

Graphene Oxide Frameworks with Size-Modulated Pore Structure as Ion-Selective Layers on Hydrocarbon Membranes for Vanadium Redox Flow Batteries
Soohyun Kim, Junghoon Choi and Hee-Tak Kim; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

The laminated structure of graphene oxide (GO) membranes provides exceptional ion separation properties, due to the regular interlayer spacing between laminate layers. However, a larger effective pore size of the laminate immersed in water (~1.1 Å) than the hydrated diameter of vanadium ions (> 6.0 Å) prevents its use in vanadium redox flow battery (VRFB). In this work, we report an ion-selective graphene oxide framework (GOF) whose size is tuned by cross-linking the GO nanosheets. Its effective pore size (~5.9 Å) excludes vanadium ions by size but allows proton conduction. The GOF membrane is employed as a protective layer to address the poor chemical stability of sulfonated poly(arylene ether sulfone) (SPEA) membranes against VO₂⁺ in VRFB. By effectively blocking vanadium ions, the GOF/SPEA membrane exhibits 4.2 times lower vanadium ion permeability and five times longer durability compared with the pristine SPEA membrane. Moreover, the VRFB with the GOF/SPEA membrane achieves an energy efficiency of 89% at 80 mA cm⁻² and a capacity retention of 88% even after 400 cycles, far exceeding Nafion 115, and demonstrating its practical applicability for VRFB.

Flexible Ceramic Membranes for Low-Cost Flow Batteries
Gregory Newbloom; Membrion, Inc., Seattle, Washington, United States.

Grid-scale power storage remains one of the largest challenges to wide-spread adoption of clean energy technologies with intermittent energy sources (e.g., solar, wind and tidal). Redox flow batteries (RFB) are an environmentally friendly and scalable technology with the potential to meet this need. However, ion exchange membranes that are crucial to battery performance are expensive, lack chemical stability in a strong oxidizing environment, and/or have poor ion selectivity which leads to electrolyte diffusion across the membrane and performance instability. These issues have limited commercial flow battery manufacturers to two options: 1) perfluorosulfonic acid membranes - which are chemically robust and moderately ion selective but very expensive, or 2) separators - which are cheap but chemically degrade over time and have poor ion selectivity. In this paper, we discuss the design and scale-up of a novel, nanoporous ceramic flow battery membrane that is chemically robust, ion selective and inexpensive enough to reduce the total production cost of commercial flow batteries by > 15%.

In this work, we investigate the use of a primarily inorganic membrane created using sol-gel processing of silicates without calcination or sintering. Silica is an advantageous material for membranes because of its excellent chemical stability and extremely low cost. Furthermore, the gelation process can be utilized to tune the pore size for effective size exclusion of electrolytes (i.e., good ion selectivity). In this study, small angle x-ray scattering (SAXS) was utilized to characterize the membrane pore structure. Model fitting can be utilized to extract the porosity as well as pore shape, size and size distribution. By varying the gelation conditions, average pore radii were found to be in the range of 0.4 – 2 nm. This pore structure is nearly ideal for vanadium-based RFBs given that pores must be able to effectively transport protons (radius of 0.25 nm) but not vanadium ions (radius of 0.5 nm).

Proton conductivity and vanadium permeability were also determined and shown to be identical to an industry standard perfluorosulfonic acid membrane membrane is employed as a protective layer to address the poor chemical stability of sulfonated poly(arylene ether sulfone) (SPEA) membranes against VO₂⁺ in VRFB. By effectively blocking vanadium ions, the GOF/SPEA membrane achieves 4.2 times lower vanadium ion permeability and five times longer durability compared with the pristine SPEA membrane. Moreover, the VRFB with the GOF/SPEA membrane achieves an energy efficiency of 89% at 80 mA cm⁻² and a capacity retention of 88% even after 400 cycles, far exceeding Nafion 115, and demonstrating its practical applicability for VRFB.

Scaling the Water Cluster Size of Nafion Membrane and Its Application for High Performance Zn/Br Redox Flow Battery
Riyul Kim, Seongmin Yuk, Juhuyak Lee, Changyong Choi, Soohyun Kim, Ijjun Heo and Hee-Tak Kim; KAIST, Daejeon, Korea (the Republic of).

Nafion membranes have been widely used in many electrochemical device as a typical cation exchange membrane. However, it have been considered unsuitable for Zn/Br redox flow batteries (ZBBs) due to its cation selective transport ability. This work shows that pre-hydration treatment can scale the water cluster size of Nafion membrane, which leads to not only high ionic conductivity but also bi-ionic transport property. With increasing the pre-hydration temperature, the water clusters expanded, resulting in the increase of water uptake, ionic conductivity and anion transference number. The bi-ionic transport and low area specific resistance induced by the pre-hydration enable successful operation of ZBB with NRE-212 membrane. As we confirmed that properly pretreated Nafion can be used in ZBB, we present a void-free 16 μm-thick Nafion-filled porous membrane for ZBBs to lessen the cost issue of Nafion. As a result, the ZBB based on the Nafion/PP membrane exhibits a higher energy efficiency, demonstrating that ion exchange membrane can outperform the conventional porous membrane by reducing the membrane thickness with inexpensive porous substrate.

Mechanically Robust Poly(Ethylene Oxide) Sodium-Ion Conducting Membranes for Redox Flow Batteries

Guang Yang1, Rose Ruther2, Michelle Lehmann3, Ethan C. Steel1, Zhijiang Tang1, Chelsey Chen1, Frank Delsnick1, Thomas A. Zawodzinski1, Tomonori Saito1 and Jagjit Nanda2
1Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Energy and Transportation Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3Chemical Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The advancement of sodium-based energy storage systems relies on the development of high performance sodium ion conducting electrolytes and membranes, which must meet several stringent requirements including high ionic conductivity, chemical and electrochemical stability over a wide voltage window, selectivity to minimize crossover, mechanical robustness, and processability. Poly(ethylene oxide) (PEO) based polymer is one of the most commonly used polymer electrolytes. However, simultaneously improving the mechanical properties and ionic conductivity is the major challenge in PEO based membrane or any polymer electrolytes. We will present two strategies to develop sodium-ion conducting membranes that address this challenge. A crosslinked PEO based electrolyte was developed that demonstrates high ionic conductivity, as well as excellent mechanical and thermal stability. The role of ethylene oxide (EO) complexation with sodium triflate (NaTf) salt and its effect on polymer segmental dynamics and ionic conductivity is elucidated with and without tetraethylene glycol dimethyl ether (TEGDME) as a plasticizer. Ionic conductivities up to 2.0 x 10^{-4} S/cm at 20 °C and 7.1 x 10^{-4} S/cm at 70 °C were achieved for the plasticized membrane, four orders of magnitude greater than that of the non-plasticized membrane. The storage modulus of the membrane was maintained at ~1 MPa from -20 °C to 180 °C even with the addition of plasticizer.

The second method involves the use of TEGDME to plasticize linear high molecular weight PEO based membranes to increase the ionic conductivity. The conductivity of plasticized PEO membranes containing NaTf is about 2 orders of magnitude higher compared to non-plasticized PEO membranes. Vibrational spectroscopy and differential scanning calorimetry (DSC) describe the coordination chemistry in these materials and elucidate the mechanisms behind the increased conductivity. The mechanical properties of the plasticized membranes is significantly improved through the reinforcement with carboxymethyl cellulose (CMC). Importantly, all the materials selected for the membrane (PEO, NaTFS, TEGDME, and CMC) are highly stable at very negative voltages (near Na/Na+), and therefore compatible with sodium metal anodes or strongly reducing redox couples. Such a membrane can enable high voltage, high energy density batteries for grid storage applications.

Redox Processes and Design Strategies for High-Energy-Density Redox-Flow Batteries

Yi-Chun Lu; Chinese University of Hong Kong, Shatin, China.

Energy storage system is a critical enabling factor for deploying unstable and intermittent renewable power sources such as solar and wind power sources. Redox flow batteries (RFBs) offer unique advantages of high efficiency, low cost, scalability and rapid response for grid energy storage. One of the most critical bottlenecks of RFBs is their low energy density, which is strongly related to the cell voltage and the solubility of the active materials. In this presentation, we will discuss strategies to improve the energy density of aqueous and nonaqueous RFBs and spectroscopic investigation on the redox processes involved in these RFB systems. Design strategies including redox complexing agent (e.g. lithium iodide, lithium bromide), semi-solid approach (e.g. sulfur/C and organic molecules) and highly-concentrated organic molecules (e.g. ferrocene-based) will be discussed. The influence of flow rate and current density on the electrochemical performance under continuous/intermittent flow modes as well as the synergistic interplay between solvent and redox-active materials in solid and liquid phases will be discussed.

Zinc Based Flow Battery for Stationary Energy Storage

Hongzhang Zhang and Xianfeng Li; Dalian Institute of Chemical Physics, Chinese Academy of Science, Dalian, China.

Zn2+/Zn redox couple attracts more and more attention in flow battery due to its characteristics of high solubility, electrochemical reversibility and environmental friendly. Moreover, in aqueous electrolyte, a negative potential together with the abundant reverse in earth crust enable zinc-based flow battery with low cost and high energy density. Until now, many zinc based flow battery systems such as zinc-bromine2, zinc-nickle and zinc-iron2,3 etc. have been investigated, which have very promising prospect to be used in power grid, large energy storage, emergency power supply and other fields. Among them, zinc-bromine is one of the most successfully example of zinc based flow battery system, while zinc nickel and zinc iron systems have obtained tremendous developments recently. Many new zinc based systems such as zinc iodine have been proposed and demonstrated great advantages in some aspects such as energy density. However, secondary batteries that use zinc electrodes typically exhibit short lifetimes, because of problems with undesirable zinc morphology especially zinc dendrites, that form during charge. Hence, the challenge is to deposit a compact, uniform and free of dendrite layer that ensure a long cycle secondary negative electrode. Therefore, in this presentation we will introduce the research and development status of zinc based flow batteries at DICP.

Highly Efficient Monolithically Integrated Solar Flow Battery

Wenjie Li1, Hui-Chun Fu2, Yuzhou Zhao1, J-Hau He2 and Song Jin1
1University of Wisconsin-Madison, Madison, Wisconsin, United States; 2Electrical and Mathematical Sciences and Engineering, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

The practical utilization of solar energy demands not only efficient energy conversion but also inexpensive large scale energy storage. Building on mature regenerative solar cells and emerging electrochemical redox flow batteries (RFBs), more efficient, scalable, compact and cost-effective hybrid energy systems are being developed. The core of our strategy is the monolithic integration of a redox flow battery with a coplanar plate solar cell. This hybrid device is able to achieve high efficiency due to the extended active material volume, where the electrodes are directly coated on the absorber layer of the solar cell. Consequently, the performance is improved, the material yield is optimized, and the overall device is simplified. In this presentation, we will introduce the key results achieved so far, such as the improved efficiency and stability of the device.
conversion and storage devices could be realized. Here we present an integrated solar energy conversion and electrochemical storage device by integrating regenerative solar cells in aqueous electrolytes with RFBs using the same pair of organic redox couples. In such an integrated solar flow battery (SFB) device, solar energy is absorbed by semiconductor electrodes and photoexcited carriers are collected at the semiconductor-liquid electrolyte interface and used to convert the redox couples in the RFB to fully charge up the battery (i.e. store the solar energy into the redox couples). When electricity is needed, the charged up redox couples will be discharged on the surface of carbon felt electrodes as one would do in the discharge of a RFB to generate the electricity. We demonstrated that such an integrated SFB device can be charged under solar illumination without external electric bias and deliver a high discharging capacity comparable with state of the art RFBs over many cycles. This integrated device can utilize solar energy efficiently — an overall direct solar-to-output electricity efficiency (SOEE) of 14% has been achieved with advanced performance optimization. With comprehensive mechanism study and deeper understanding of the operation principles of SFBs, we also propose a set of design principles for highly efficient integrated SFB devices.

The water-energy nexus presents new opportunities for redox flow systems to make a large impact on our energy economy. Current efforts to make redox flow batteries commercially viable have traditionally focused on lowering capital costs; an alternative strategy is to increase the revenues associated with battery operation by creating a valuable product like desalinated water. By placing one or more intervening water chambers, bounded by ion-selective membranes, between the anode and cathode of a traditional flow battery, the system becomes capable of simultaneous water desalination and electrical energy storage. A symmetric flow cell that uses the same redox couple at both electrodes is no longer able to store electrical energy, but enables lowered specific energy consumption for salt removal, as well as greatly lowered reactant capital costs relative to the storage mode. Certain cell designs can additionally be switched reversibly between both operating modes, thereby allowing the stack to be utilized even when a conventional flow battery would normally be idled. We present several examples of devices that use flow battery architectures to perform redox water desalination for energy storage applications as well as nontraditional novel applications with large energy savings.

1:30 PM ET10.10.01

Hydrogen generation from water splitting is reaching a tipping point, with large scale electrolyzer systems being deployed for fueling and energy applications, and a growing number of projects under development. Still, the overall lifecycle cost makes widespread application challenging, due to both capital cost and operating cost of electricity. The oxygen evolution electrode is a significant driver in both capex and opex, since the high voltage and overpotential result in limited material choices for stable performance. Proton OnSite and Pacific Northwest National Laboratory have been developing a versatile electrochemical device capable of serving roles in large scale energy capture and conversion as well as fuel production. The concept involves replacing the high overpotential oxygen evolution electrode in a water electrolyzer cell with a more facile and lower voltage redox couple, enabling the system to operate at significantly higher efficiency. The system can operate in two modes: 1) as a pseudo-electrolyzer, it produces renewable H2 gas for industrial or energy applications including vehicle fueling and 2) as a hydrogen-redox flow cell, it is capable of high efficiency and low-cost grid scale energy storage. This talk will focus on the progress realized in this project, including materials and electrolyte development, incorporation of 30 bar hydrogen pressure into the system, and synergies and learnings that are applicable to water electrolysis.

2:00 PM ET10.10.02
Photocatalytic Oxidation of Formic Acid Using BiFeO3—Stability and Reproducibility Wegdan Ramadan1, Ralf Dillert2 and Detlef Bahnemann2, 3; 1Physics Department-Faculty of Science, Alexandria University, Alexandria, Egypt; 2Institut für Technische Chemie, Leibniz Universität Hannover, Hannover, Germany; 3Laboratory “Photoactive Nanocomposite Materials”, Saint Petersburg State University, Saint Petersburg, Russian Federation.

Iron based compounds are tempting; they are cost effective and introduce interesting physical properties like magnetism but could have stability issues as well. In this context, BiFeO3 (BFO) is a multiferroic that has a band gap ~2.3 eV enabling it to absorb light in the visible region. The conduction and valence band are located at 0.46 eV and 2.68 eV with respect to NHE making it a good candidate for water oxidation and oxidation of other organic pollutants like Formic acid (HCOOH). Under solar illumination and in the presence of BFO, as photocatalyst, redox reaction should take place such that holes created in the VB oxidize HCOOH to CO2 and protons (H+) and electrons in the CB should reduce H+ into H2. The CB position is more positive than the value required for H2 reduction. Mass spectrometer showed the formation of CO2 and less H2. Hence, what is the fate of the electrons if they are not consumed in protons reduction? To further elucidate this point, XRD and XPS were carried out for the photocatalyst before and after reaction with Formic acid. XRD of BFO after reaction with Formic acid, showed bleaching of most impurity peaks, Fe3O4, Bi2Fe4O9 and Bi25FeO40 and relief of the strained crystal lattice. The removal of the impurities under illumination is essentially a photocatalytic process requiring the presence of an electron donor like HCOOH as concluded from results obtained in absence of HCOOH. XPS showed the d/doublets of Bi 4f5/2 and 4f7/2 with 5.20 eV separation, indicating the formation of Bi-O bonds. On the other hand, Fe doublets, 2p1/2, and 2p3/2, could not be fitted to a single oxidation state but rather to mixture of Fe2+ and Fe3+ such that 14% of Fe is Fe2+ and 86% is Fe3+. These contents change such that Fe2+ increases to 36% and Fe3+ decreases 64% after reaction. To maintain charge balance in the system, electrons are transferred to H2O to form HO2. To further elucidate the effect of the observed changes of the BFO on its photocatalytic performance, BFO powder obtained after a first photocatalytic run was employed in a second run performed under the same experimental conditions.

The ratio between CO2 evolved in the second run to the first experimental run was found to be 0.87. The respective ratio for the amounts of H2 was calculated to be 0.46. This decrease in the evolved CO2 by 13% indicates a decrease of the activity of the photocatalyst. These results indicate that under the adopted experimental conditions BFO deviates from the standard definition of a photocatalyst and suffers some changes during the photocatalytic reaction. It is essential to ensure stability of photocatalyst, especially iron-based ones, if we are seeking long term stability and reproducibility.
Flow battery technologies (e.g., vanadium flow battery, iron-chromium, and zinc-bromide flow batteries) are being commercialized into the application of stationary electrical energy storage. However, the electrolyte materials of vanadium, chromium, and bromine are considered costly and more toxic. H_{2}/Fe \text{ (HyFe) flow battery has captured the great attention of the scientific community because it takes the advantages of low cost and environmental-friendly materials, high energy efficiency of > 90%, fast kinetics of hydrogen evolution/oxidation and facile Fe^{2+}/Fe^{3+} redox pair. However, the main problem of low power density of HyFe flow battery impedes the implementation of this battery technology. Our study demonstrates that the electronic conductivity of electrolyte solution, complex ligands of iron ions and iron ions diffusion kinetics are the dominant factors to affect the power densities of HyFe flow battery. The temperature effects on electronic conductivities of electrolyte solution, iron ion diffusion kinetics and electrochemical performance of HyFe flow battery are also investigated. The maximum power density of 375 mW/cm² was achieved in our HyFe flow battery.

Redox flow batteries are one of the most suitable electrochemical systems for large scale energy storage. The All Vanadium Redox Flow Battery (VRFB) technology invented at UNSW is being utilised on a global scale for stationary applications, but its low energy density is currently limiting its use in mobile systems. One promising approach to increasing energy density is the use of the oxygen reduction process for the positive half-cell. This forms the basis for the new Vanadium Oxygen Fuel Cell (VOFC) which eliminates the need for the positive vanadium electrolyte and removes the constraints associated with solubility limits of V(V) at elevated temperatures. Increasing the vanadium concentration from 2M to 4M for the negative electrolyte and the use of the oxygen reduction process for the positive half-cell can theoretically quadruple the specific energy density of the current VRFB from 25 Wh/kg to 100 Wh/kg allowing potential application in new transportation systems.

For long-term operation of the VOFC an important aspect is the regeneration of vanadium (II). The regeneration of V(II) can be performed externally to the cell, for example, at a recharging station for electric vehicles. In the present development project of the VOFC at UNSW, a separate regeneration cell has been designed and used to regenerate the vanadium (II) electrolyte. It is critical that the supporting electrolyte for the VOFC be carefully selected so as to avoid the potential generation of hazardous gas at the positive electrode during re-charge. This limits the use of halide-based supporting electrolytes such as HCl that could potentially be used to enhance vanadium ion solubility. The use of electrolyte stabilising agents has therefore been evaluated to allow the use of vanadium electrolytes with concentrations greater than 3 M at elevated temperature. Alternate non-noble metal electrocatalysts have also been studied to improve the performance of the oxygen reduction process without using platinum based catalysts that could potentially catalyse the evolution of hydrogen in the negative half-cell electrolyte. The design of single and multi-cell VOFC systems will be described together with details on the fabrication of membrane electrode assemblies that are utilised in this hybrid system.

Redox flow batteries (RFBs) are promising energy devices for grid-level applications due to their extraordinarily long cycle life (resulting from the use of highly reversible redox couples) and the ability to independently scale their energy and power densities. It may be worthwhile to mention that at present most of the research advances in the area of redox flow batteries has been incremental due to the extraordinarily long cycle life (resulting from the use of highly reversible redox couples) and the ability to independently scale their energy and power densities. collectors.

Recently, alkali metal and ammonium thiocyanates (SCN-) aqueous solutions have been successfully applied as electrolytes to ECs. The comparative study on the effect of salt concentrations depending on the type of current collectors has been presented. The cell operating with gold current collectors revealed a limited effect on charge propagation resulting from its high conductivity.

In this work, the addition of various nanoparticles (Au, Ag, carbon nanotubes) at extremely low concentrations to potassium thiocyanate solution (KSCN) is presented as an attractive way for electrolyte modification. Our previous work has shown that especially gold has a positive influence on SCN- based systems performance – better charge propagation, fast redox response and lower resistance has been observed. Furthermore, together with Au nanoparticles, these species could form complexes such as [Au(SCN)2]- and [Au(SCN)4]- and the redox equilibrium Au(I)/Au(III) might be established in the solution.

The investigated ECs were manufactured with 7 mol/L KSCN solution with gold nanoparticles and carbon electrodes made of high surface area carbon black, providing a suitable micro-to-meso pore volume ratio. The electrolyte solution displayed very high conductivity (372 mS/cm) and neutral pH (7.5). The systems with potassium thiocyanate and gold nanoparticles were characterized by a high operational voltage (1.6 V) and high capacitance, namely 168 F/g (@1 A/g). Moreover, high energy density has been retained at the whole range of applied current densities: 15 Wh/kg (@1 A/g) and 13.7 Wh/kg (@20 A/g).

The electrochemical characterization will be supported by several operando techniques - Raman spectroscopy, Quartz Crystal Microbalance and Scanning Electrochemical Microscopy, in order to provide a full picture of the interfacial phenomena.

Functionalised Graphene as High Surface Area ORR Electrodes in PEM Fuel Cells Theo Suter1, Noelia Rubio2, Mike Whiteley1, Milo Shaffer2 and Daniel J. Brett2; 1Department of Chemical Engineering, Electrochemical Innovation Laboratory, University College London, London, United Kingdom; 2Department of Chemistry, Imperial College London, London, United Kingdom.

Fuel cells are one of the keystones of the hydrogen economy but costs remain high, partly due to the high cost of the catalyst system.1, 2 Typically commercial electrodes are still based on platinum on a carbon black support.1, 2 Significant research has focused on developing new catalyst systems, with costs and scalability being two of the most important factors for success. Graphene has great potential as an catalyst support material due to its potential to be high surface area and carbon corrosion resistance replacement for carbon black.3, 4 Functionalising this graphene enables reduced platinum nanoparticle size and increased activity, thus reducing cost without comprising power output. However achieving this without damage and in a scalable manner is an active research area.

In this work we explore a scalable synthesis of functionalised graphenes and their use as high surface area ORR catalyst in fuel cells. The graphene was synthesised by a scalable method utilising layer charging with sodium naphthalene to allow exfoliation, allowing functionalisation of the resultant material. By reacting the charged graphene with particular functional groups/polymers we were able to develop a highly active graphene based electrode. This was characterised via SEM, TEM and XPS, as well as being tested for ORR activity in RDE and fuel cell systems showing improved performance.

Highly Flexible Perovskite Solar Cells with Low Cost Electrodes and Charge Selective Materials Peng Li and Zijian Zheng; The Hong Kong Polytechnic University, Hong Kong, China.

The organic-inorganic halide perovskite solar cells (PSCs) have witnessed efficiency soar from initial 3.8% to current-record 22.7% in the past less than ten years, representing one of the most promising active photo absorbent candidates to reduce the materials cost in the photovoltaic devices. It is however often overlooked that the majority of the materials cost in the PSCs come from transparent electrodes (e.g. ITO, FTO, etc), charge-selective carriers (e.g. PTAA, Spiro-MeOTAD) or metal contacts (e.g. Au, Ag), instead of the perovskite photo absorber itself. On the other hand, sufficiently thin perovskite film spontaneously inspires tremendous research interests and efforts in flexible application scenario in the emerging era of wearable electronics, imposing foldable, stretchable and even squeezeable photovoltaic devices in huge demand.

To tackle this, we propose a perovskite solar cell system employing ultrathin substrate, low-cost copper front and back electrodes as well as inexpensive metal oxides charge-selective materials to enable highly flexible PSCs. All the materials can either be prepared with affordable synthesis cost on avalanche quantity basis or readily obtained in the commercial market. To be more specific, Cu mesh hybridized with doped PH1000 serving as bottom transparent electrode replaces costly transparent conductive oxides while top Cu electrode further reduces metal cost. N-doped graphene as the hole transporting layer eliminates the use of expensive polymer PTAA yet maintains comparable high open-circuit voltage. Inorganic ZrO has partially and in principle could completely fulfill the role of fullerene type electron transporting material of PCBM. As such, the whole PSC system embraces dramatically reduced material cost in corresponding components by several order of magnitudes. More interestingly, the ultrathin polymeric substrate endows the perovskite solar cells with terrific flexibility and accordingly robust application potentials.

Flexible Crystalline Silicon Photovoltaics with Vertically Aligned Microwires Inchan Hwang, Han-Don Um and Kwanyong Seo; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Flexible photovoltaics (FPVs) are one of the most promising research fields in the solar energy industry because they can be utilized as a continuous power source for wearable and portable electronic devices. Thin crystalline silicon (c-Si) has attracted much attention as a potential means for FPVs because of its excellent flexibility while retaining the advantages of c-Si FPVs of high efficiency and stability. For highly efficient thin c-Si FPVs, it is important to maximize light absorption while maintaining the flexibility characteristics. In general, the conventional c-Si photovoltaics have increased light absorption by applying surface structures. However, the surface structures without consideration of the flexibility would limit the flexibility of the FPVs because induced stress during bending cannot be uniformly dispersed. In this study, vertically aligned microwires (MWs) on a 50 μm-thick thin c-Si substrate are designed for novel FPVs. Increasing the length of the MWs enhances the optical properties of the thin c-Si without affecting its flexibility. To maximize the efficiency of the thin c-Si FPVs with MWs, tapered MWs and a localized back-contact structure are devised. This device shows a maximum efficiency of 18.9%. In addition, the proposed thin c-Si FPV with MWs shows high stability without any change in efficiency, even with 1000 bending cycles with a bending radius of 12 mm. Thus, we successfully demonstrate battery-free flexible electronic devices integrated with our thin c-Si FPVs with MWs.

9:00 AM ET11.01.03
BIPV—A Bad Idea or Tomorrow's Mainstream Application? Sarah R. Kurtz; University of California, Merced, Merced, California, United States.

In 1994, PowerLight introduced a building-integrated photovoltaic (BIPV) product, touting it as saving money (avoiding the cost of installing a conventional roof) while introducing PV into an attractive roof. At the time it was introduced, the mainstream opinion was that the future of PV would be building integrated and that utility-scale applications were a non starter. Today, utility-scale PV accounts for more than half of the world PV installations and BIPV is a niche market (with most rooftop systems being “building applied” rather than “building integrated.”) Was BIPV a bad idea?, or was BIPV an idea whose time had/has not come? Many things have changed since 1994; could BIPV be poised to become a mainstream application? Tesla and other companies are introducing BIPV products today. Will they be more successful? The talk will review many things that have changed (including power electronics, products with lower temperature coefficients, demonstration of PV as an accepted technology so that it’s not such a risk to builders, the value of generating solar electricity near load centers, etc.), suggesting that there may be a new opportunity for BIPV. Then, the talk will review how a shift back to a goal of large-scale deployment of BIPV and related products changes the research agenda.

9:30 AM ET11.01.04
All Dielectric Light Trapping Scheme for Enhancing the Efficiency of Ultrathin Flexible Gr/Si Solar Cell Sonali Das1, Mohammad Jobayer Hossain1, Kristopher Davi2,3, and Tania Roy1,2,4,5; 1NanoScience Technology Center, University of Central Florida, Orlando, Florida, United States; 2The College of Optics and Photonics, University of Central Florida, Orlando, Florida, United States; 3Department of Materials Science and Engineering, University of Central Florida, Orlando, Florida, United States; 4Department of Electrical and Computer Engineering, University of Central Florida, Orlando, Florida, United States.

Graphene/silicon (Gr/Si) Schottky junction solar cells have attracted much attention due to the ease and low cost of fabrication, along with the lucrative properties of high electron mobility, transparency and mechanical flexibility of graphene as a transparent conducting electrode. Utilizing its inherent mechanical flexibility, graphene can be integrated with thin flexible crystalline Si substrates opening up a new regime of applications in flexible and wearable electronics. Reducing Si absorber thickness below 50 um offers advantages of reduced material cost, along with mechanical flexibility and light weight. But Si at such thicknesses suffers from low photon absorption in the solar spectrum. To compensate for the low light absorption in such thin substrates, light management schemes become essential. Light trapping in Gr/Si solar cells is enabled by engineering the Si surface to form nanopillars, nanowires etc., which decreases the reflection loss and allows more light to couple in to the Si substrate. The structured Si absorber increases surface area and surface recombination, which is detrimental to the solar cell efficiency. Thus, it is imperative to use a light trapping scheme devoid of Si structuring to enhance the photoconversion efficiency.

We present an all-dielectric light-trapping scheme on planar Gr/Si Schottky junction solar cells with the use of bottom layer of titania spheres and top layer of silica spheres. An optimal Si thickness coupled with an optimized light trapping scheme leads to efficient electron-photon harvesting. The photoconversion efficiency of a 20um thick nanosphere-decorated Gr/Si solar cell improves to 9%, which is 1.3x higher than the pristine cell’s PCE of 7%. FDTD simulations are performed for optimizing the diameter of nanoparticles in each of the layers. The ratio of size of nanoparticles in the top to bottom layer plays a crucial role in advanced light management. An optimized structure of silica spheres, having diameter larger than that of titania spheres, suppresses reflection over wide angles of incidence and increases absorption in active Si layer over AM1.5G solar spectrum. The non-absorbing dielectric spheres can be easily realized by the well-known Steber technique. Additionally, the photovoltaic characteristic of the laminated solar cell shows negligible change after several bending cycles having bend radius ranging from 5 mm to 10 mm. After continuous bending and straightening, the ultra-thin solar cell can retain its performance, revealing the excellent stability and flexibility of the device. Such simple, low-cost light trapping schemes are universal in nature, devoid of recombination losses and are potentially viable for any solar cell technology.
the rear side can theoretically exceed 50% conversion efficiency owing to an increase in absorption and improved carrier collection in nanowire structures. III-V-on-Si multijunction solar cells using 1.75 eV GaAsP nanowires on the front side of bulk Si solar cell and 0.5 eV InGaAs nanowires on the backside. The resulting device configurations combine Si and III-V materials to allow flexible and cheaply encapsulated modules and high voltage (and current) material devices for monolithically integrated PEC-PV concepts. The results of various types of devices will be presented: a-Si:H/CIGS 2-junctions, a-Si:H/OPV 2-junctions, and a-Si:H/a-Si:H/OPV 3-junctions, nc-Si:H/c-Si 2-junctions and a-Si:H/c-Si 3-junctions. The general design rules of these hybrid PV devices to accomplish high conversion efficiencies are discussed, like tackling the crucial electrical and optical loss mechanism. First, a detailed study on a wide variety of tunnel-recombination junctions for hybrid devices will be presented. Secondly, to realize conditions close to current matching a wide variety of light management concepts are discussed, like: modulated surface textured substrates and interfaces to establish a compromise between ideal light trapping and processing of high quality PV materials; bi-functional intermediate layers that act as reflector layers and tunnel recombination junctions; and minimizing the parasitic absorption losses of supporting layers. The current state-of-the-art hybrid PV devices will be presented. Finally, examples of the application of these multi-junction devices in solar-to-fuel and water purification applications will be presented.

What Can Nano Really Do for Solar? Erik Garnett1,2, 1AMOLF, Amsterdam, Netherlands; 2University of Amsterdam, Amsterdam, Netherlands.

Over the past decade there has been extensive research into using nanostructures for solar cells. Although many interesting optical and electrical phenomena have been observed, nanostructured solar cells still have not exceeded (or even reached) the same efficiency level as their bulk counterparts. The goal of this talk is to describe the ways in which nanoscience can theoretically improve solar cells and outline the remaining fundamental and applied research necessary to realize such theoretical gains in practice.

The talk will consist of two parts. First, ways in which nanoscience can help reach the standard Shockley-Queisser efficiency limit (34%) will be discussed. In particular, new methods for making a variety of relevant monocrystalline nanomaterials will be presented along with the accompanying nanophotonic concepts. The results of various types of devices will be presented: a-Si:H/CIGS 2-junctions, a-Si:H/OPV 2-junctions, and a-Si:H/a-Si:H/OPV 3-junctions, nc-Si:H/c-Si 2-junctions and a-Si:H/c-Si 3-junctions. The general design rules of these hybrid PV devices to accomplish high conversion efficiencies are discussed, like tackling the crucial electrical and optical loss mechanism. First, a detailed study on a wide variety of tunnel-recombination junctions for hybrid devices will be presented. Secondly, to realize conditions close to current matching a wide variety of light management concepts are discussed, like: modulated surface textured substrates and interfaces to establish a compromise between ideal light trapping and processing of high quality PV materials; bi-functional intermediate layers that act as reflector layers and tunnel recombination junctions; and minimizing the parasitic absorption losses of supporting layers. The current state-of-the-art hybrid PV devices will be presented. Finally, examples of the application of these multi-junction devices in solar-to-fuel and water purification applications will be presented.

11:00 AM ET11.02.02
Design and Simulation of Bifacial III-V Nanowire Arrays on Silicon Anastasia Fedorenko, Mohadeshe A. Baboli, Parsian Mohseni and Seth Hubbard; Rochester Institute of Technology, Rochester, New York, United States.

Cost-competitive Si-based hybrid photovoltaic systems featuring high photocurrent conversion efficiency can be realized through multijunction designs by combining Si and III-V materials. The manufacturing cost of III-V-on-Si solar cells can be further reduced by transitioning from thin-film to nanowire-based devices. III-V-on-Si multijunction solar cells using 1.75 eV GaAsP nanowires on the front side of bulk Si solar cell and 0.5 eV InGaAs nanowires on the rear side can theoretically exceed 50% conversion efficiency owing to an increase in absorption and improved carrier collection in nanowire structures compared to the planar devices. Wide-bandgap GaAsP top nanowire array, however, can suffer from low short-circuit current density lowering the overall efficiency of the multijunction cell. Thus, an optimization of the dimensions of nanowires relatively to their spatial distribution in the arrays is the key to achieving absorption enhancement providing high short-circuit current output to promote current matching between the subcells. Finite-difference time-domain (FDTD) simulation was used to model the absorption in periodic arrays of GaAsP nanowires on Si substrates dependent on the diameter, length, and spacing (center-to-center distance, or pitch) of the nanowires. Based on this study, the highest ultimate efficiency of 26% of the top 1.5 μm-thick nanowire array was achieved for the array with the nanowire diameter of 300 nm and pitch of 500 nm, thus showing an enhancement by about 5% compared to the planar GaAsP absorber with the same thickness. The peak total absorption of the arrays with different pitch was found to be associated with the diameter-to-pitch ratio of 0.6. Distinct resonance modes were resolved in the low-dimension nanowires. Additionally, front-side nanowires were shown to exhibit waveguiding properties in the absorption range of the underlying cSiPV. The final presentation will include physics-based simulation of
Germanium is one of the promising semiconductors for photovoltaic applications such as solar cells, due to its high electron and hole mobility [1], and its high absorption in the infrared region. Several researchers have demonstrated Ge-based solar cells [2], in fact, Germanium-based solar cells already account for more than 80% of satellite applications [3]. Recently, good quality Ge-on-Si films fabricated using RF-PECVD (atT=600 °C) were demonstrated [4]-[6], paving the way for their use in photovoltaic applications. From optical perspective, Ge has a high refraction index and 60% normal incidence reflection which leads to high surface reflection and hinder its use in solar cells which leads to high anti-reflective coatings (ARC). The use of metal nanoparticles, such as silver, is a low-cost and viable alternative to other ARC materials to improve the optical and electrical properties of Ge-on-Si films for solar cell applications. Metal nanoparticles are strong scatterers of light at wavelengths near their resonant frequency [7]. This work studies the effect of spin coating of 40nm silver nanoparticle films on 700nm of Ge-on-Si films grown using RF-PECVD. The optical and electrical properties of the films after spin coating with 10ml and 20ml of 40nm silver nanoparticle colloidal solution are studied and compared to the film properties with no nanoparticles present. The concentration of silver nanoparticles in the aqueous buffer solution is 0.02mg/ml, provided by Sigma-Aldrich.

In this work, Ossila Spin coater was used for spinning 40nm silver nanoparticles on RF-PECVD deposited 700nm Ge-on-Si films [4]-[6], where the spinning was performed for 45 seconds at 2000rpm. Three samples of Ge films were used, one sample is left as a reference sample and the other two are coated with 10ml and 20ml of the silver nanoparticles colloidal solution, respectively, which was dispersed using a pipette. Using ImageJ software for image analysis the spinning led to the deposition of 480 nanoparticles/mm² (0.047%) surface coverage and 3280 nanoparticles/mm² (0.328%) coverage, the samples were then characterized for optical reflectance and sheet resistance.

The optical and electrical properties of Ge-on-Si films with and without silver nanoparticles were analyzed. The reflectance was measured using LAMBDA1050UV/Vis/NIR Spectrometer. Results showed that presence of nanoparticles reduced the amount of the reflected light due to plasmon effect which enhances the light absorption in the near-infrared region. The sample with no nanoparticles had the highest sheet resistance (200Ω/Sq) whereas the sample with 480 and 3280 nanoparticles/mm² appeared to have lower sheet resistance of 60 and 1.5Ω/Sq, respectively, which is >95% less than the reference sample, showing promising film properties for device applications. Moreover, this finding validates the potential of using spin coated nanoparticles as a low-cost alternative to conventional ARC layers for photovoltaic applications.

Greenhouse Effect in Photovoltaic Cells to Enhance Efficiency Beyond the Shockley-Queisser Limit

Andrei Sergeev, Harry Hier, Kimberly Sablon and Christopher M. Waits; Army Research Laboratory, Adelphi, Maryland, United States.

The fundamental Shockley - Queisser (S-Q) model assumes chemical equilibrium between photocarriers and emitted photons (the same chemical potentials) and establishes a maximum solar conversion efficiency, which is limited by endoreversible thermodynamics. In this work we propose and investigate a new converter design, which mimics the greenhouse operation and increases the conversion efficiency, potentially above the Shockley - Queisser (S-Q) limit, due to suppression of radiative emission.

To overcome the S-Q limit, at least one of the conditions (i-v) that lead to the S-Q limit should be modified: (i) All above-bandgap photons are absorbed; (ii) All below-bandgap photons are absorbed; (iii) Every above-bandgap photon excites one electron-hole pair; (iv) All photocarriers reach thermal equilibrium with the lattice; (v) Photocarriers and emitted photons reach the chemical equilibrium. While various solar cell concepts related to (ii) – (iv) conditions have been actively studied (intermediate band cell, multi-exciton generation, hot carrier solar cell), the PV devices with chemical nonequilibrium between photocarriers and emitted photons (condition (v)) were not considered yet.

The proposed photonic-enhanced PV converter device mimics the greenhouse effect. The converter has a reflective interference “greenhouse” filter placed in front of a semiconductor cell and a reflective mirror on the back of the cell. The front filter is transparent for high energy photons, but traps low energy photons emitted by photocarriers accumulated near the semiconductor bandgap. Thus, the high energy band-edge of the greenhouse filter establishes the photonic bandgap above the semiconductor bandgap. The photons with energy above the photonic bandgap are absorbed and create electron – hole pairs. Most of the excess energy is gained by the photoelectron, while the hole has energy close to the edge of the valence band. For this reason, the kinetics of photoelectrons is more manageable than the kinetics of photo-generated holes. To optimize the kinetics of photoelectrons, the semiconductor PV cell should be the n-p single junction diode with a p-doped base. In the optimized operating regime of the greenhouse converter, the chemical potential of photoelectrons near semiconductor bandgap can substantially exceed the chemical potential of photoelectrons established by the filter. Such chemical nonequilibrium may be realized due to strong interaction of photoelectrons with holes. As a result, the photoelectrons de populate the states with energies above the photonic bandgap. Reduced photoelectron population of states above the photonic bandgap reduces the emission and improves conversion efficiency above the S-Q limit, up to 44%.

The work was supported by U.S. Army Research Laboratory.

SiGeSn as a Candidate Material System for use in Thin-Film Multi-Junction Solar Cells

Phoebe Pearce1, Nicholas Ekins-Daukes2, 1 and Andrew Johnson1; 1Department of Physics, Imperial College London, London, United Kingdom; 2School of Photovoltaic and Renewable Energy Engineering, University of New South Wales, Sydney, New South Wales, Australia; 1QE, Cardiff, United Kingdom.

Materials with a circa-1 eV bandgap are necessary in the optimal design of multi-junction solar cells, with one of the optimal bandgaps in many designs for two, three and four junction cells being close to 1 eV. The lack of suitable high-quality photovoltaic absorbers with a circa-1 eV bandgap and lattice constant matching that of Ge, InGaAs and In,Ga,AIP, commonly used in multi-junction solar cells, has meant recent research interest in various candidate material systems which can meet these requirements, including dilute nitrides, antimonides and bismides. A novel material system for use for a 1 eV absorber is the ternary Group IV alloy silicon-germanium-tin (SiGe,Sn). By adding relatively small amounts of Si and Sn to Ge, both the bandgap and lattice constant can be tuned. With an Sn:Si composition of around 3.7:1, the lattice constant of the resulting alloy remains equal to that of Ge, while the bandgap can be tuned by varying the Sn and Si fractions in this ratio. It is possible to achieve a circa-1 eV direct transition at relatively low (x < 0.1) Si and Sn fractions. At these compositions, the material remains slightly indirect, with its indirect bandgap around 0.8 eV. It is expected that the Voc of solar cells incorporating SiGeSn will be reduced compared to a material with a fundamental direct gap at 1 eV, since carriers can thermalize to the lowest available band edge; however, current-matching considerations mean it is still beneficial to absorb primarily across the 1 eV transition, which also allows thin layers to be used. Single and triple-junction InGaP (1.9 eV)/InGaAs (1.4 eV)/SiGeSn (≈ 1 eV) devices incorporating SiGeSn have previously been
Optical upconversion that turns infrared light into visible light could improve the efficiency of solar cells by capturing sub-bandgap photons. A solid-state and reaction (SILAR) have not reached high solar energy conversion efficiencies hitherto, and have primarily been studied as sensitizers for photovoltaic applications.

Efficient Solid-State Infrared-to-Visible Upconversion Integrated in a Microcavity

Mengfei Wu, Ting-An Lin, Michelle C. Sherrott, Vladimir Bulović and Marc Baldo; Energy Frontier Research Center for Excitonics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Optical upconversion that turns infrared light into visible light could improve the efficiency of solar cells by capturing sub-bandgap photons. A solid-state
device consisting of a monolayer of lead sulfide colloidal nanocrystals and a thin film of rubrene with a luminescent dopant can convert infrared photons at $\lambda = 1 \, \mu m$ into visible photons at $\lambda = 610 \, nm$ via sensitized triplet-triplet annihilation [1]. Such a bilayer device, limited by low infrared absorption in the nanocrystals, requires 12 W cm$^{-2}$ of incident intensity at $\lambda = 808 \, nm$ to attain maximum upconversion efficiency [1]. Depositing a silver back reflector with an optical spacer on top of the active bilayer enhances the optical field, and hence absorption, in the nanocrystal layer due to interference, boosting the upconverted emission by an order of magnitude and lowering the threshold intensity to $1.1 \, W \, cm^{-2}$ when pumped at $\lambda = 980 \, nm$ [2]. Here, to further increase the optical field, we deposit the above interference-enhanced device on top of a distributed Bragg reflector (DBR). Such a structure places the nanocrystal layer in a microcavity whose resonance can be tuned to the pump wavelength by adjusting the thicknesses of the DBR layers and the optical spacer. We observe another order-of-magnitude increase in the upconverted emission, and a threshold intensity as low as $20 \, mW \, cm^{-2}$ at $\lambda = 980 \, nm$, similar to the flux available in the AM1.5 solar spectrum. The microcavity-integrated device demonstrates the possibility of efficient solid-state upconversion under sunlight and its application to solar cells.

High-performance polymer solar cells (PSCs) with thick active layers are essential for large-scale production. Polymer semiconductors exhibiting temperature-dependent aggregation property offer great advantages towards this purpose. In this study, three difluorobenzoxadiazole (PffBX)-based donor polymers, PffBX-T, PffBX-TT, and PffBX-DTT, were synthesized, which contain thiophene (T), thieno[3,2-b]thiophene (TT), and dithieno[3,2-b:2′,3′-d]thiophene (DTT) as the n-spacers, respectively. Temperature-dependent absorption spectra reveal that the aggregation strength increases in the order of PffBX-T, PffBX-TT, and PffBX-DTT as the n-spacer becomes larger. PffBX-TT with the intermediate aggregation strength enables well controlled disorder-order transition in the casting process of blend film, thus leading to the best film morphology and the highest performance in PSCs. Thick-film PSC with an average power conversion efficiency (PCE) of 8.91% and the maximum value of 9.10% is achieved using PffBX-TT:PC(61)BM active layer with a thickness of 250 nm. The neat film of PffBX-TT also shows a high hole mobility of 1.09 cm^2 V^{-1} s^{-1} in organic thin-film transistors. When PffBX-DTT and PffBX-T are incorporated into PSCs utilizing PC(61)BM as the electron acceptor, the average PCE decreases to 6.54% and 1.33%, respectively. The performance drop mainly comes from reduced short-circuit current, as a result of non-optimal blend film morphology caused by a less well controlled film formation process. A similar trend was also observed in non-fullerene type thick-film PSCs using IT-4F as the electron acceptor. These results show the significance of polymer aggregation strength tuning towards optimal bulk heterojunction film morphology using PffBX-based polymer model system. The study demonstrates that adjusting n-spacer is an effective method, in combination with other important approaches such as alkyl chain optimization, to generate high-performance thick-film PSCs which are critical for practical applications.

In this work, we report a multilayer cascade device architecture which increases Voc through the insertion of discontinuous interlayers between electron donor (D) and electron acceptor (A). We systematically study the influence of adding various interlayers in a sequentially deposited α-6T/interlayer/SubNc/SubPc cascade OSC, resulting in a Voc which increases from 0.98 V to 1.16 V. We show that this remarkable Voc increase of 0.18 V is due to the suppression of non-radiative recombination, as a consequence of a reduced physical contact between α-6T (D) and SubNc (A). The EQE of electroluminescence (EQE_{EL}) of 0.9 E-4 for our highest voltage device is one of the highest for OSCs and corresponds to non-radiative losses of 0.23 eV, which are the lowest reported for OSCs. Hence, we achieve Voc of 0.58 eV from the optical gap (E_{gap}) to Voc and 0.61 eV energy losses from the low energy peak of the EQE spectrum to Voc. Most importantly, the low energy (700 nm) EQE peak remains high at 79%, despite a minimal driving force for charge transfer of less than 10 meV.

Our work shows that low E_{gap} can be efficiently combined with a high EQE in organic photovoltaic devices.

**2D Material-Based Layer Transfer to Revolutionize Photovoltaic Energy Generation**

Jeewhan Kim, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Because of substantially low cost of Si wafers, Si-based photovoltaics (PV) has been dominating although maximum power conversion efficiency of III-V solar cells is substantially higher than that of Si solar cells. To address this issue, wafer-reusing technique has been developed for the past few decades. However, the cost of recycling process has been much higher than that of the wafer. Thus, the room to improve levelized cost of energy has been limited. In today’s talk, I will introduce MIT’s novel wafer-reusing technique, so called a 2D material- based layer transfer process. We discovered that single-crystalline III-V PV layers can be epitaxially grown on graphene-coated III-V substrates, where the graphene is sufficiently thin such that crystalline orientation of III-V films can be guided by the substrate beneath graphene. The slippery graphene surface allows the III-V PV layers to be released from the substrate while the III-V substrate can be constantly reused. I will discuss how this technology revolutionizes photovoltaic technology by maximizing efficiency of solar cells while maintaining the production cost.

**Improved Light Harvesting with a Printed Light Guiding Nano-Structure to Increase the Performance of Flexible CZTS-Monograin Photovoltaic Modules**

Martin Ursprung, Lukas Plessing, Dieter Neess, Dirk Bontnick and Dieter Meissner, Crystalsol GmbH, Vienna, Austria; Materials, Institut für Surface Technologies and Photonics, Joanneum Research Forschungsgesellschaft mbH, Weiz, Austria; Allnex, Drogenbos, Belgium; Materials and Environmental Technology, TTÜ, Tallinn, Estonia.

Crystalsol has developed a novel PV-module structure and a manufacturing process for both, the semiconductor powder as well as the PV-modules. The core innovations are a light absorbing layer made of single-crystalline semiconductor powder and a low-cost and scalable roll-to-roll production process. The crystals are made of copper, zinc, tin, sulfur and selenium (CZTS) and are manufactured separately before module production. This unique technology combines the advantage of a single crystalline absorber with a vacuum free low cost printing process.

The weight of the membrane is about 0.5 kg/square meter up to 1 kg/square meter depending on the encapsulation used. It can be rolled with a radius of less than 5 cm and tailored to the customer’s needs. As a result of intense research an efficiency of 9.5 % has been reached. The crystalsol membrane layout is based on semiconductor grains, which are deposited as a monolayer. The photoactive material - the grains - covers about 80 % of the provided area thus incident light falling into the gaps between the grains, is not utilized.
In this paper a light-guiding structure is presented, which deflects the light towards the CZTS-grains enabling a higher share of incident light absorption and therefore an increase in photocurrent of up to 6.7 % which results in a 6.7 % gain in module performance. The foil deflects roughly 40 % of the incident light perpendicular to the line structure, whereby longer wavelengths show a wider deflection angle than shorter wavelengths. This structure was developed within the framework of the project Nano_Outside by JR (roll-to-roll-UV-nanoimprint lithography – R2R-UV-NIL), alkynes (UV-curable resins) and crystalsol (flexible PV-modules). The project is funded by the Austrian Research Promotion Agency (FFG). The concept was first tested with printed nanostructures and developed further by using R2R-UV-imprinting on a self-adhesive PET foil, which could easily be applied to the crystalsol modules. The UV-imprint-resin is based on urethane acrylates and designed to meet the requirements of the R2R-UV-NIL processes being strong adhesion to polymer substrates, high curing speed and imprint fidelity as well as excellent outdoor – i.e. abrasion and weathering – stability for the application on PV-modules.

The optimization of the nanostructure manufacturing, its impact on the PV-performance, as well as an outdoor stability assessment of the structure will be demonstrated.

9:15 AM ET11.05.03
Thermo-Mechanical Lift-Off of Thin-Film Photovoltaics—High Specific Power, Low Cost Deborah McGott1, 2, Mike Kempe2, Stephen Glynn2, Nick Bosco2, Colin A. Wolden1 and Matthew O. Reese2, 1Colorado School of Mines, Golden, Colorado, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Thin-film photovoltaics (PV), such as cadmium telluride (CdTe) and CuInxGa1-xSe2 (CIGS), offer extremely low manufacturing costs (< $0.50/Wp) and have achieved device and module efficiencies that rival multi-crystalline silicon. However, despite being comprised of just a few microns of active material, thin-film modules are among the heaviest due to their double glass construction. This increases costs and prohibits their use in applications where flexibility and specific power (power-to-weight ratio) are critical factors. One approach to overcome this issue is to synthesize the solar cells directly on flexible substrates such as stainless-steel foils or polyimide. While success has been obtained using this approach, it can often introduce additional weight (stainless steel) and/or processing steps (polyimide).

Here, we describe an innovative technique to lift off thin-film solar cells that are grown under standard processing conditions from their glass substrates in a reproducible manner. In this two-step process, we first laminate a commercially available polymeric backsheet to the solar cell, then submerge the stack in a cold bath (T ≤ -30°C) to thermally shock the system. This causes the polymer to contract quickly and pull the polycrystalline film cleanly off of a clean, reproducible manner. In this two-step process, we first laminate a commercially available polymeric backsheet to the solar cell, then submerge the stack in a cold bath (T ≤ -30°C) to thermally shock the system. This causes the polymer to contract quickly and pull the polycrystalline film cleanly off of its substrate at an interface that is weakened by a monolayer accumulation of 2-D material (CdCl2 in CdTe and MoS2 in CIGS). To enable clean lift-off of diverse thin-film architectures, a theoretical framework is developed and key process control parameters are identified. Focusing on CdTe devices, we show that the lamination temperature and device architecture control the quality of lift-off, while the rate at which the film stack is removed is controlled by the temperature of the cold bath.

Crack-free CdTe devices are removed and successfully re-contacted, recovering up to 80% of the original device efficiency. The areal density of these devices is ~0.4 kg m-2, a reduction of over an order of magnitude relative to their initial weight on glass. The broader applicability of this technique is then demonstrated by lifting off large areas (>50 cm2) of CIGS solar cells. The ability to lift these two major thin-film technologies off post-growth will allow for pre-existing high-volume manufacturing lines and their cost-structure to be leveraged, thus providing an alternative pathway toward inexpensive, flexible PV with high specific power.

9:30 AM ET11.05.04
Ligand Exchange of Copper Indium Gallium Sulfide Nanoparticles for Minimization of Carbonaceous Impurities in High Efficiency Solution Processed Photovoltaics Ryan Ellis, Jacob Fields and Rakesh Agrawal; Purdue University, West Lafayette, Indiana, United States.

Solution processing is an attractive method of producing high efficiency copper indium gallium sulfoselenide (CIGSSe) photovoltaics with significantly lower manufacturing costs, higher throughput, and greater large scale uniformity compared to traditional vacuum-based deposition technologies. A relatively benign colloidal nanoparticle route has shown great promise, reaching power conversion efficiencies up to 15%. However, further improvements are hindered by carbonaceous impurities originating from high boiling point organic ligands commonly used in nanoparticle synthesis. These ligands are difficult to remove via thermal treatment and often leave carbonaceous impurities in the final photovoltaic device as a distinct “fine grain layer” which can increase series resistance and could contribute to interfacial recombination. As such, the exchange of native ligands with volatile and non-contaminating ligands is of great interest to reduce carbonaceous impurities. For a successful ligand exchange for photovoltaic device fabrication, the exchange must remove the majority of native ligands, be thermally labile and not leave impurity elements, retain the stoichiometry of the as-synthesized nanoparticles, exhibit excellent colloidal stability at high mass concentrations, and not inhibit lead selenium assisted sintering of the absorber layer. In this work, we screen a wide variety of ligand exchange reactions for removal of native oleylamine ligands on copper indium gallium sulfide nanoparticles using a variety of amines, thiols, pyridines, and inorganic sulfide ligands to simultaneously meet the aforementioned criteria necessary for photovoltaic device fabrication. The screening revealed that alkylamines preferentially etched indium and gallium from the nanoparticles, thiols and functionalized pyridines were not readily thermally labile, and inorganic sulfides and pyridine were individually unable to remove the entirety of native ligands. Using these observations, a novel two-step ligand exchange was developed in which an initial microwave-assisted solvothermal ligand exchange was performed with pyridine to remove the bulk of native ligands, followed by an inorganic sulfide exchange to remove pyridine, additional native ligands, and to significantly enhance the colloidal stability of the nanoparticles in a variety of polar solvents. The two-step approach was uniquely able to meet all of the aforementioned criteria necessary for successful photovoltaic device fabrication. Along with the careful selection of solvents for ink formulation, ligand exchanged inks were employed for the fabrication of solution processed absorber layers, demonstrating high efficiency, fine grain free CIGSSe photovoltaics using a highly scalable and benign ink. The novel ligand exchange and subsequent photovoltaic device fabrication methods used hold wide applicability for the removal of carbonaceous impurities in nanoparticle based solution processed chalcogenide photovoltaics.

9:45 AM ET11.05.05
Effect of Solution pH and Post-Annealing on the Optical Bandgap of the Copper Oxide Thin Films Grown by SILAR Method Farhad Syed1, Alauddin Hossain2, Md. Abdul Majed Patwary3, Rumana Akter2, Nazmul Islam Tanvir4, Shanta Majumder2, Muhammad Shahriar Bashar4 and Mohammad Farhad Syed1, 1Department of Chemistry, Comilla University, Comilla, Bangladesh; 2College of Science and Advanced Technology, Dhaka University, Dhaka, Bangladesh; 3Optoelectronics Laboratory, Department of Science and Advanced Technology, Saga University, Saga, Japan; 4Institute of Fuel Research and Development (IFRD), Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh.

Copper oxide is one of the most studied p-type materials for solar cell and other optoelectronic devices due to its direct band gap, high optical absorption in the visible region and suitable band alignment with its n-type counterpart materials such as ZnO, TiO2 etc. Cuprous oxide (Cu2O) thin films have been grown on both microscope glass slides and Fluorine-doped Tin Oxide (FTO) substrates by SILAR technique. The pH level of the bath solution and concentration of NaOH solution were systematically varied. The films were deposited in the pH range 3.45 - 7.35 as well as 1M and 2M NaOH solution to control the texturing and phase purity of the as-deposited films. The effect of post-annealing treatments (75-350 °C) on the as-deposited films was also demonstrated.
studied and found to be crucial to control the optical band gap and electrical properties of the films. The XRD measurement showed that the as-deposited films were single phase Cu$_2$O with (111) preferred orientation and found to be changing with increasing pH and annealing temperature. The (111) texturing of the annealed Cu$_2$O films were found to be increasing and stable phase up to 200 °C and completely converted to cupric oxide (CuO) phases when the temperature reached to 350 °C. The optical band gap and the sheet resistivity of the as-deposited and annealed samples were found to be in the range (2.35 – 1.43) eV and (154.22 –393.9) × 10$^4$ Ω/square respectively. The prepared film shows fiber-like and dense grain surface morphology observed from their SEM images. The performance of copper oxide films was tested by estimating LED modulated ON/OFF ratio into a photoelectrochemical cell and was found to be reasonable to integrate them into optoelectronic devices.

Bio-Inspired Metallic Networks as Flexible Transparent Conductors—From Lab to Pilot Scale Jinwei Gao¹, Jun-Ming Liu¹ and Krzysztof Kempa¹; ¹South China Normal Univ, Guangzhou, China; ²Nanjing University, Nanjing, China; ³Boston College, Chestnut Hill, Massachusetts, United States.

Transparent conductors (TC) are critical materials for modern optoelectronic applications ranging from light emitting diodes, to displays (including touch-screen and flexible), to solar cells, to wearable electronics. In lighting and solar applications TC must be highly conducting in order to lower the ohmic losses. In display applications, microscopic transparency and lack of haze is required, as well as there is a need for mechanical flexibility in the case of flexible displays and wearable electronics. A chemical stability is also a must. These new requirements put pressure on the current standard material, indium tin oxide (ITO), which has overall good electro-optic performance and chemical stability, but is resistive, brittle and quite expensive. Recently, a new generation of TC materials emerged as a possible replacement for ITO, which can be tailored to satisfy all the above requirements. This talk will review such materials including our metallic networks, which have been inspired by nature. In one example, we developed the quasi-fractal hierarchical TC based on the self-cracking network combined with nanowires. This network TC has record high conductivity and simultaneously excellent transparency, and thus is ideal for lighting and solar applications. We have shown, that it is the plasmonic refraction of nanowires, which allows for the network increased transparency beyond the classic, shading limit. In addition, this network TC is mechanically flexible, and can be made inexpensively with wet chemical processing only. A version of this network can be used in displays, due to its low haze and low network visibility. We have very recently developed a roll-to-roll pilot production line of the self-cracking network on flexible plastic substrates with width of ~400 mm.

11:00 AM ET11.06.02
Exciton Binding Energy and Dielectric Effect in Small Molecular and Polymeric Photovoltaic Materials Ho-Wa Li, Liu Taili and Sai-Wing Tsang; City University of Hong Kong, Hong Kong, Hong Kong.

Owing to the low dielectric constant of organic materials, organic photovoltaic (OPV) is regarded as an excitonic solar cell that excitons are generated upon photo-excitation. Such intrinsic small dielectric constant ($\varepsilon$) in organic materials results in large exciton binding energy ($E_b$). That becomes a key detrimental factor limiting the further improvement in organic photovoltaic cells. Increasing the material dielectric constant seems to be a straight-forward strategy to reduce the strong coulombic attraction of the photo-generated electron-hole pairs. Despite the matter of importance, there are limited reports in measuring the $E_b$ and $\varepsilon$ in organic photovoltaic materials and the correlation between the dielectric constant and the exciton binding energy is unclear. Here, we extend our demonstration by using quantum efficiency measurement [1] and electro-absorption to access the transporting gap and exciton binding energy in pristine organic photovoltaic materials for polymeric donor, fullerene and non-fullerene small molecular acceptors. It is found that $E_b$ varies from 0.3 eV to 1.2 eV in those prototypical materials and it apparently follows a second power law with the inverse of the dielectric constant of the materials, i.e. $E_b \propto 1/\varepsilon^2$. Instead of widely assumed first-order dependence, this second order dependent relationship is firstly reported. Interestingly, we have also found that the binding energy is more dependent on the molecular-molecular interaction rather than the intrinsic properties of single molecule. In this presentation, we will also demonstrate how the higher dielectric material benefits the exciton dissociation at donor/acceptor interface.

11:15 AM ET11.06.03
Improving the Photovoltaic Performance and Mechanical Stability of Flexible All-Polymer Solar Cells via Tailoring Intermolecular Interactions Minjun Kim; Hong Il Kim, Seung Un Ryu, Cheol Woong Park and Taiho Park; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Naphthalene diimide (NDI)-based polymers are significantly promising electron accepting materials in all-polymer solar cells (all-PSCs) due to strong light absorption at the near infrared region and high electron mobility. Most NDI-based polymers have a large crystal structure through thermodynamically self-assembled aggregates, which lead to the low intermixing with polymer donor, resulting in large-scale phase separation in all-polymer blend films. The undesirable all-polymer blend morphologies cause inefficient exciton dissociation and charge transport between polymer donor and polymer acceptor, limiting the photovoltaic performance as well as mechanical resilience in all-PSCs. The low crystalline polymer acceptor with highly interconnected networks can provide an effective approach to high electron mobility and finely phase-separated blend morphology. Herein, we introduced a copolymer of NDI and (F)$\pi$-(3-fluorothiphen-2-yl)ethene (FTVT) (PNDI-FTVT) as a polymer acceptor with a low crystalline structure and high electron mobility ($\mu_e$). The blend film incorporating PNDI-FTVT exhibits well-mixed morphology without a large-scale phase separation. Moreover, PNDI-FTVT forms inter-junctions between polymer donor and polymer acceptor through strong $\pi-\pi$ stacking via fluorine induced dipole-dipole intermolecular interactions, improving the chain interconnectivity to construct better charge transport pathway. PNDI-FTVT based flexible all-PSC exhibited increased photovoltaic performance compared to PNDI-FTVT based flexible all-PSC (3.86% → 5.90%) and excellent mechanical stability in the flexible all-PSC, maintaining 72% of its initial performances (5.90% → 4.26%). This is the highest efficiency in the field of flexible all-PSCs and the first demonstration of the photovoltaic
Hybridised silicon nanospheres formed by simplified plasma-enhanced chemical vapour deposition (PECVD), without seed particle injection or microwave plasma, are fabricated in a variety of dimensions and with differing physicochemical properties, such as selective doping, via a modified Multi-Layer PECVD technique. Although the nanospheres can be directly incorporated onto a suitable substrate and within a dielectric during deposition, ex-situ processes have shown additional purpose can be ascribed to the nanosphere surface. By reducing the necessity of colloidal suspension or centrifugation steps, the nanospheres can be produced in functionalised states, for wavelength selection, light trapping and nanoscale dopant inclusion without negatively compromising the conductivity or passivation of the underlying structure. This can be attributed to the homogeneous H-Si distribution with no evidence for surface or bulk aggregation.

Suspension in poly-vinyl alcohol or ethyl acetate was utilised first for liquid phase analysis, then subsequently, for printing onto a selection of substrates, including crystalline silicon (c-Si) and semiconductor polymer. For silicon, monocrystalline with both planar and lightly textured surfaces were utilised. Semiconducting polymers based on naphthobisoxadiazole (PNOz4T), and Benzo[1,2-b:4,5-b’]dithiophene (BTD) incorporating thiene[3,4-c]pyrrole-4,6-dione (TPD) as a main chain and oligo(thiénylenevinylene) side chain were tested.

Non-peripherally alkyl-substituted phthalocyanines like octahexylphthalocyanine (C6PcH2) were examined as a top-layer for their higher carrier mobility compared to a-Si:H layers, and present a suitable matrix for allocation of the nanospheres, due to its hexagonal disordered columnar mesophase at approximately 170°C. An amorphous In2O3 front contact layer comprised of a transparent conducting oxide (TCO) and transparent oxide semiconductor (TOS) are shown to be effective in enhancing the short circuit current density of the assembled device.

When incorporated into the polymer-silicon membrane, the hybridised silicon nanospheres provide a solution to non-brittle light trapping or wavelength selection for flexible photovoltaic devices.
Flexible and Light Weight GaAs Solar Cells with Micro-Pattern and Back Reflectors

Kamran Forghani, David Rowell, Chris Stender and Raaqib Tatavarti; MicroLink Devices Inc., Niles, Illinois, United States.

Session Chairs: Jeehwan Kim and Kyle Montgomery
Tuesday Afternoon, November 27, 2018
Hynes, Level 3, Room 304

For large-scale implementation of photovoltaics, further improvement in the power-conversion efficiency is needed. Conventional silicon solar cells lose a large part of incident sunlight energy via thermalization of excited charge carriers. Singlet fission, a spin-allowed charge-carrier multiplication process which converts one singlet exciton into two triplet excitons is a promising way to reduce such thermalization losses. One way to harvest triplet excitons is by transfer of their energy into quantum dots that then emit photons into the silicon solar cell underneath. Thereby, the efficiency of the silicon solar cell can be increased by modulating the broadband solar spectrum.

We develop a model to simulate such a “photon multiplier”, and how it enhances silicon solar cells under realistic conditions. This model includes the relevant physical parameters such as the energy of the singlet and triplet exciton, the full width at half-maximum of the quantum dot emission, and losses due to parasitic absorption and non-perfect wave guiding of the emitted photons. We simulate the performance potential of a photon multiplier in comparison to an optimized perovskite/silicon tandem solar cell under realistic conditions. We find that the photon multiplier is more stable against changes in the solar spectrum than tandem solar cells. We furthermore find that the better the silicon base cell, the lower the efficiency gain of a tandem solar cell compared to the silicon solar cell alone, while the efficiency gain of a photon multiplier increases with increasing efficiency of the silicon solar cell. For current record silicon solar cells, the photon multiplier can boost the efficiency by up to 4.2% absolute under realistic conditions.

2:30 PM ET11.07.04
Flexible and Light Weight GaAs Solar Cells with Micro-Pattern and Back Reflectors

Kamran Forghani, David Rowell, Chris Stender and Raaqib Tatavarti; MicroLink Devices Inc., Niles, Illinois, United States.

III-V multijunction solar cells have the highest record efficiency for any type of photovoltaic devices: E.g. about 38% for AM1.5 1-sun and 33% for AM1.5 1-sun, as reported for 3 junction cells utilizing epitaxial-lift-off (ELO) [1]. Application of backside reflecting mirror for solar cells will enhance the performance by multiple photo-recycling events. The increase in optical absorption, not only helps to boost the performance but also helps to thin the cell, making them radiation-hard for space applications. We present our finding on back patterned GaAs solar cells. Single junction GaAs solar cells with two different configurations of up-right on rigid n-type substrate, as well as inverted flexible ELO cells were investigated. Several different patterns were applied and their effect on the overall cell short circuit current (Jsc) and quantum efficiency was studied. A more than 4% increase of the Jsc was observed in the backside patterned devices. The Jsc as function of light incident angle will also be presented, indicating an improved photo-response at smaller incident angles as compared to the planar control samples.

2:45 PM ET11.07.05
Epitaxial Growth of SiGe on Si Substrate by Printing and Firing of Al-Ge Mixed Paste

Shogo Fukami1, Yoshihiko Nakagawa1, Kazuhiro Gotoh1, Yasuyoshi Kurokawa1, Masahiro Nakahara2, Marwan Dhamrin2 and Noritaka Usami2; 1Nagoya University, Nagoya, Japan; 2Toyo Aluminium KK, Gamo-Gun, Japan.

The germanium substrate used for the bottom cell of tandem III-V solar cells is one of the most expensive components of this device structure. To make these devices cost-competitive with silicon, it is necessary to find an alternative material having a narrow gap which is suitable for the bottom cell. Silicon-germanium (SiGe) has a lattice constant and band gap close to Ge while also being relatively low cost and environmentally friendly. Also, because SiGe is an all-proportional solid solution whose composition can be freely controlled, its lattice constant and bandgap can be precisely controlled. However, conventional SiGe fabrication methods such as solid phase crystallization or chemical vapor deposition require long growth times or toxic gases. Thus, we focus on liquid phase epitaxial (LPE) growth utilizing the melting point depression phenomena of Ge and Si by Al [1]. In this paper, we investigated methods for LPE growth of SiGe on Si(100) substrate by printing and firing Al-Ge mixed paste and the influence of epitaxial growth by heat treatment under various conditions. We applied Al-Ge mixed paste which its thickness is about 30 µm on Si(100) substrate by screen printing and dried. LPE was performed using an Al-Ge mixed paste screen-printed on a Si (100) substrate and then annealing above Al-Ge eutectic temperature (420 °C) in the air or the Ar atmosphere. We annealed at 700, 800 and 900 °C to investigate the influence of annealing temperature on the growth of SiGe. After annealing, the residue at the top of the Si substrate surface was etched with a solution of phosphoric acid (H3PO4: CH3COOH: HNO3: H2O=16:1:1:2). The obtained SiGe was characterized by X-ray diffraction reciprocal space mapping (XRD-RSM), Scanning Electron Micrographs (SEM) and energy dispersive X-ray spectroscopy (EDX). From the SEM and EDX images, in case of annealing at 800 °C in the air, wave-like oxide film was confirmed at SiGe/Si interface. It is assumed that the oxide film interfered with the growth of SiGe. On the other hand, at 800 °C in the Ar atmosphere, we succeeded in forming abrupt heterointerface with thick SiGe. The results of XRD-RSM indicated that only the Si peak was observed before annealing. After annealing, a peak derived from SiGe appeared in addition to the Si peak. The SiGe peak shape was widely distributed since the composition distribution of SiGe occurred. The peak obtained from XRD-RSM by annealing at 700 °C in the Ar atmosphere showed that Ge fraction in SiGe was 7.56 %, which is higher than at 800 and 900 °C. It is assumed that Ge fraction in SiGe decreased by annealing at higher temperature due to more dissolution of Si substrate. These results suggest that the average composition and composition distribution in the SiGe can be controlled by changing paste composition and heat treatment history.

3:00 PM BREAK
and perovskite, but also on III-V compounds that have been made into flexible solar cells with potential for high efficiency and record power to mass ratio. As it turns, higher performance for solar cells goes with high power processing per unit volume, provided that absorption of incoming light is kept high. This is seen for instance in concentrated PV, but can also be done by reducing the thickness of the active material, provided efficient light management schemes are developed, such as the multi-resonant approach.

The presentation will highlight recent results obtained with high efficiency approaches to flexible solar cells, starting with thin film technologies and aiming at ultimate efficiencies such as III-V and Hot Carrier solar cells.

4:00 PM ET11.08.02
Investigation into the Selenization of Solution Processed Silver Zin Tin Selenide (Ag₂ZnSnSe₄) Thin-Film Solar Cells

Xianyi Hu, Dana Sulas, Steve Johnston, Darius Kuciauskas, Carol A. Handwerker, and Rakesh Agrawal.

Materials Engineering, Purdue University, West Lafayette, Indiana, United States; Chemical Engineering, Purdue University, West Lafayette, Indiana, United States; National Renewable Energy Laboratory, Golden, Colorado, United States.

Although CZTS solar cells have been fabricated with a maximum power conversion efficiency (PCE) of 12.6%, no further improvement has been demonstrated since 2013 due to intrinsic defects. It has been proven that the high density of Cu₂ZnSn(S,Se)₄ anti-site defects limits performance. These defects create band tails and dramatically decrease the open circuit voltage ($V_{oc}$) of devices. To eliminate these intrinsic defects, Ag has been used to substitute for Cu, which increases the formation energy of anti-site defects due to its larger radius and single valence. Our group did partial substitution of Cu with Ag and showed improved minority carrier life time. Gershon et al. developed photovoltaic devices based on an n-type Ag₂ZnSnSe₄(AZTSe) absorber layer by co-evaporation and achieved ~ 5% PCE, suggesting the potential of this material.

To establish a more cost-effective method for large-scale fabrication of AZTSe, compared with vacuum deposition, solution-processing is needed. Here, we report a systematic investigation into the selenization process from mixed AZT and ZnS nanoparticle films into large grain selenide films. We study key factors, such as selenization time, temperature, heating rate as well as Se vapor pressure utilizing a rapid thermal processor. Our results demonstrate that AZTSe has a narrow processing window to obtain phase-pure films with uniform composition and few pin-holes. We find that the heating rate plays an essential role in eliminating the formation of SnSe₂. Due to the fast sintering rate of the Ag-contained sulfide nanoparticles, selenization temperature and time have to be balanced to fabricate uniform, continuous, large grains. In addition, Se vapor condenses on the surface of nanoparticle film to enhance liquid-phase assisted grain growth of AZTSe films. To achieve a more uniform microstructure of AZTSe films and better adhesion between films and substrate, we deposit an intermediate layer on the surface of the film. We demonstrate that this layer helps with nucleation at the beginning of the selenization. We characterize the AZTSe films with photoluminescence and show a single, sharp peak at 1.3 eV was not a defect emission shoulder in contrast to CZTSe.

We propose a selenization mechanism based on the microstructure evolution and phase transformations that we observed and compared with CZTS. Ultimately, we establish a strategy to obtain AZTSe films consisting of continuous grains with uniform composition and few pin-holes, which is essential for the future production of AZTSe solar cells.

An Insight into the Effect of Band Alignment at Grain Boundaries on Photovoltaic Performance in CIGS and CZTS Thin-Film Solar Cells

Wenjie Li; Shenzhen Institute of Advanced Technology, Shenzhen, China.

The efficiency of CZTS solar cells is still not so high compared with other thin films such as CIGS. The underlying mechanism for the difference is a long-standing question that has remained elusive in spite of tremendous research efforts in the past. For polycrystalline thin film semiconductor, highly populated grain boundaries in the material will certainly have big influences on the photo-generated electron-holes. In this work, a conducting probe atomic force microscopy has been applied to study the electronic structure of CIGS and CZTS thin films with capability of nm-scale resolution. To exclude the surface effect, grain boundaries in the bulk were examined through cross-sectional SPM measurements and compared for both CIGS and CZTS. Different electronic structure of the grain-interior (GI) and grain boundary (GB) have been identified in both CIGS and CZTS thin films. We find that the band alignment of GI and GB in CIGS and CZTS is different, which can well explain the different device performance in two type of solar cells. With good Schottky contact between the AFM tip and semiconductor, a local electrical and photovoltaic performance can be measured and the conduction band overlap between GB and neighboring GI can be obtained. In CIGS, it is found that the conduction band has a larger overlap than in CZTS, which is consistent with the results of others. In CZTS, it is found that the conduction band has a smaller overlap than in CIGS, which is also consistent with the results of others. In CZTS, the GB and GI in CIGS behaves like a type-I hetero-structure that will trap both electron and hole inside the GB to produce strong recombinations.

Many experiments had demonstrated that air annealing process can improve the CZTS device efficiency with increased open-circuit voltage and fill factor. Our experiments of cross-sectional SPM measurements revealed that, for grain boundaries in the bulk, after air annealing, the downward bending valence band of GB turned to be upward bending, while the conduction band of GB turned from downward bending to upward bending. This resulted in the formation of electron and hole barrier at GBs which reduced the recombination, which can well explain the increased efficiency. However, the air annealing induced GB states behaved as barriers which can block the transport of electron and holes. Better GB passivation techniques are still in need.

4:30 PM ET11.08.04
Improved Voc Deficit in Kesterite Cu₂ZnSn(S,Se)₄ Solar Cells via Grain Boundary Passivation at the p-n Junction Interfaces

Cheng-Ying Chen, Naili Saidatin, Chih-Yang Huang, Ruei-San Chen, Jih-Shang Hwang, Kuei-Hsien Chen, and Li-Chyong Li.

Materials Engineering, Purdue University, West Lafayette, Indiana, United States; National Taiwan Ocean University, Keelung, Taiwan, Keelung, Taiwan; Graduate Institute of Applied Science and Technology National Taiwan University of Science and Technology, Taipei, Taiwan; Institute of Optoelectronic Sciences, National Taiwan Ocean University, Keelung, Taiwan, Keelung, Taiwan.

Kesterite-based Cu₂ZnSn(S,Se)₄ (CZTSSe) have emerged as potential alternatives for CdTe and CIGSSe absorbers due to the use of non-toxic and earth-abundant elements and providing desirable optoelectronic properties similar to those of CIGSSe. To raise the performance of CZTSSe based solar cells, much effort has been applied to improving the quality of absorbers, band alignments/passivation at p-n junction, front and back interfaces/contacts. [1,2,3,4]

The present investigation mainly addresses the open circuit voltage (Voc) issue in kesterites based Cu₂ZnSn(S,Se)₄ solar cells by simply introducing an interfacial alkaline earth fluoride (several nm MgF₂) between the absorber (i.e., CZTSSe) and the buffer layer (i.e., CdS) after sulfo-selenization processes without post-annealing. In statistical studies (10 cells), the alkaline earth fluoride increases power conversion efficiency ($V_{oc}$) from 7.5% to 8.8%, short circuit current density ($J_{sc}$) from 30.7 mA cm⁻² to 32.6 mA cm⁻² and from 440 mV to 470 mV, possibly resulting from the MgF₂ induced electric field passivation at grain boundaries. [2] Finally, a 9.4% efficient CZTSSe solar cell with $V_{oc}$ of 470 mV, $J_{sc}$ of 32.96 mA cm⁻² and fill factor (FF) of 60.7% was obtained.
Two-dimensional transition metal dichalcogenides (2D TMDs) are promising candidates for ultrathin photovoltaics because they have direct bandgaps that lie in the visible range, their absorption coefficients are one to two orders of magnitude higher than conventional semiconductors, and their interlayer van der Waals interaction eliminates the constraint of lattice matching in heterostructure design. Our group has demonstrated high internal quantum efficiency in 2D TMD photovoltaics (1), high open-circuit voltage remains a challenge (2). Here, we study open-circuit voltage in 2D TMD photovoltaics by fabricating both vertical and lateral photovoltaic devices with monolayer TMD absorber layers and contacts with asymmetric work functions (e.g. silver and platinum). In both vertical and lateral geometries, we compare the effects of transferred and directly evaporated metal contacts on the device’s open-circuit voltage. To transfer metal contacts, we modify a procedure that has been shown to create contacts to 2D materials with atomically smooth interfaces and no Fermi level pinning (3). Metals are patterned onto a smooth sacrificial substrate (i.e. silicon dioxide) using photolithography, peeled off that substrate using polyvinyl alcohol (PVA), and transferred onto a TMD device using a viscoelastic stamp. The devices are characterized, then passivated by immersion in solutions of the superacid bis(trifluoromethanesulfonimide) in acetonitrile to achieve near-unity photoluminescence quantum yield, as previously reported (4,5). Using photoluminescence mapping, photocurrent spectroscopy, and Kelvin probe force microscopy, we characterize these devices to analyze the effects of 1) vertical vs. lateral device geometry, 2) superacid-treated vs. untreated absorber layers, and 3) transferred vs. evaporated metal contacts on the open-circuit voltage of our photovoltaic devices. Our results demonstrate a pathway towards high open-circuit voltage in 2D TMD photovoltaics, and we outline specific design considerations for future high-efficiency devices.

Metalorganic Vapor Phase Epitaxy of Large CdTe Grains on 2D Substrates through Chemical and van der Waals Mixed Interactions
Xi Sun1, Dibhajyoti Mohanty1, Zonghua Lu2, Yu Xiang3, Yiping Wang4, Lihua Zhang5, Kim Kisslinger6, Jian Shi1, Lei Gao3, Morris Washington1, Gwo-Ching Jahelka1, Deep M. Jariwala1,2, Joseph S. DuChene1 and Harry A. Atwater1; 1California Institute of Technology, Pasadena, California, United States; 2University of Pennsylvania, Philadelphia, Pennsylvania, United States.

High-quality heteroepitaxy of CdTe is challenging due to lattice mismatches of CdTe with many substrates. Herein, we demonstrate the epitaxial growth of single crystalline CdTe films on mica using metalorganic chemical vapor deposition, regardless of large in-plane lattice mismatch between CdTe(111) and mica. X-ray and electron diffractions suggest that CdTe is epitaxially aligned with mica: out-of-plane CdTe[111]/mica[001] and in-plane CdTe [-12-1]/mica [010]. Full-width-at-half-maximum (FWHM) of X-ray rocking curve and FWHM of X-ray azimuthal in-plane angular dispersion of CdTe are shown to be 0.11° and 0.38°, respectively, better than most CdTe films reported. Electron backscattering diffraction shows that CdTe grains are tens of μm in size and, if twin boundaries are excluded, in excess of 250 μm in size. In contrast to the belief that overlayer growth on mica is purely through van der Waals interaction, our first-principles calculations unveil that van der Waals interaction only contributes to 20% of the total interfacial energy, and 80% of the interfacial energy comes from chemical interaction. Furthermore, we demonstrate that epitaxial CdTe films can be achieved on other 2D substrates, such as graphene. Compared to on mica, however, the films grown on graphene are characterized with larger orientation dispersions along out-of-plane and in-plane directions and smaller grains. Our first-principles calculations indicate a van der Waals interaction dominating interface between CdTe and graphene. We thus conclude that the nature of interface interactions dictates crystal quality of CdTe films on different 2D substrates. The demonstrated epitaxy of II-VI semiconductors on 2D van der Waals substrates suggests potential for flexible optoelectronic devices.

8:45 AM ET11.09.02
Effect of Stacking Disorder and Metastable Polymorph on Charge Conduction in Earth-Abundant Cu2ZnSn(S, Se)4-Based Solar Cells
Ji-Sang Park, Sunghyun Kim and Aron Walsh; Imperial College London, London, United Kingdom.

Cu2ZnSn(S, Se)4-based solar cells have attracted a much attention in achieving terra-watt scale photovoltaics. The solar conversion efficiency of Cu2ZnSn(S, Se)4 solar cells, however, is generally lower than CuIn, GaSe2 solar cells because of low open-circuit voltage, usually termed as the open-circuit voltage deficit. While the problem has not been solved yet, the spatial fluctuations of band edge have been suggested as the culprit which results in the band tailing and the lower efficiency. The spatial fluctuations can be caused by the formation of anti-site defect pairs which form electrostatic dipoles, or lower bandgap
Indeed the formation of the lower bandgap polymorph (e.g. stannite) can be understood as the periodic formation of anti-site defect complexes. In multication materials such as Cu$_2$ZnSn(S,Se)$_4$, the octet rule can be satisfied when anti-site defects are formed on two-dimensional planes in certain ways. Metastable polymorphs can be obtained from kesterite crystal structure by applying such operations globally, and the metastable polymorphs are shown to have lower band gap from the hybrid density functional theory (DFT) calculations [1]. If the operation is locally applied, then it results in the formation of so-called anti-site domain boundaries, and their formation has been experimentally proven in Cu$_2$ZnSnS$_4$ nanocrystal. In this work, we performed hybrid DFT calculations and found that these defects in Cu$_2$ZnSn(S,Se)$_4$ lower the conduction band locally, and thus act as electron donors [1].

On the other hand, studies of other solar cell absorber materials show that stacking faults are formed abundantly in zinc-blende-derived materials. We calculated the formation energy of the stacking faults (e.g. intrinsic stacking faults) and analyzed their effect on the electronic structure as well. We found that Stacking fault defects in Cu$_2$ZnSn(S,Se)$_4$ are more easily formed than the anti-site domain boundaries [2]. In contrast to the anti-site domain boundaries, the stacking faults increase the conduction band and thus electron barriers are locally formed, hamper the electron conduction.

Nanowires for Tandem Junction Solar Cells Magnus Borgström; Lund University, Lund, Sweden.

Semiconducting nanowires have been recognized as promising materials for high-performance electronics and optics where optical and electrical properties can be tuned individually, where the nanowires due to excellent light absorbing properties [1] have been suggested for future high efficiency solar cells [2, 3]. Especially, the geometrical shape of the NWs offers excellent light absorption. In order to further optimize the performance of NWPV, and integrate them on Si in a tandem junction configuration, nanowires with dimensions corresponding to optimal light harvesting capability are necessary. We developed nano imprint lithography for patterning of catalytic metal particles with a diameter of 200 nm in a hexagonal pitch of 500 nm, for which synthesis was redeveloped since the metal particles were found to move during annealing, destroying pattern fidelity before nucleation. By use of electron beam induced current measurements we learn how to improve the photocurrent generation profile in the nanowires by reducing native defects incorporated during synthesis, either by tuning the V/III ratio or by compensation doping, resulting in a certified efficiency of 15 % for a 12 % surface coverage of nanowires. We intend to transfer these grown nanowires to a Si platform (existing PV), either by direct growth on Si PV, or by nanowire peel off in polymer, followed by transfer and electrical contacting, or by aerotaxy and alignment for transfer to Si. The optimal band gap in combination with Si is about 1.7 eV, where we identify GaInP and GaAsP as materials for development of nanowire pn junctions by doping, the heart in a solar cell.

Tailoring the Defect Properties of Chalcohalide Systems for Photovoltaic Applications John Buckeridge, Alex M. Ganose and David O. Scanlon; University College London, London, United Kingdom.

Bismuth chalcohalides are promising new candidates for cheap, nontoxic and highly effective solar absorber layers in photovoltaic systems. The majority of those studied so far, however, have shown poor efficiencies well below industry standards. We investigate the suitability of these materials for solar energy applications using relativistic first-principles computational techniques, focusing on two of the most promising systems: BiSI and BiSeI. We find that both compounds possess desirable optoelectronic properties, with band gaps well within the visible range combined with strong optical absorption, resulting in high predicted device performance. Our analysis of their defect chemistry indicates that deep traps are likely to form, which may account for the observed poor performance of the materials. Nevertheless, we show that, by varying the experimentally accessible synthesis conditions, it is possible to avoid the formation of such killer defects, which would allow much higher efficiencies to be achieved. Furthermore, we apply similar analysis to study other III- (and V-) chalcohalides and determine their suitability for photovoltaic applications, building up a family of promising mixed-anion materials with similar optoelectronic properties.

9:45 AM ET11.09.05
Development of New High-Band Gap Photoabsorbers for Low-Cost Tandem Solar Cells with Different Thermal Budgets Andrea Crovetto, Brian J. Seger, Ole Hansen, Peter Vesborg and Ib Chorkendorff; Technical University of Denmark, Kgs. Lyngby, Denmark.

One of the current key challenges in both photovoltaics and solar-driven water splitting is to identify an efficient, stable, and low-cost material to be used as a high-band gap (1.6-2.0 eV) photoabsorber in tandem device configurations. In this contribution, we will report on our group’s development of three different emerging, inorganic, high-band gap solar absorbers with thermal budgets from 150°C to 1000°C, which may satisfy different applications. The first material is Bi$_3$I$_6$ (thermal budget of 150°C, record efficiency 1.0 %), which is straightforward to make and may be used for tandem solar cells on flexible plastic substrates [1]. The second material in Cu$_2$BaSnS$_4$ (thermal budget of 550°C, record efficiency 2.0 %), which is a promising alternative to the more extensively studied Cu$_2$ZnSnS$_4$, due to its more appropriate band gap for tandem solar cell applications and to its lower density of tail states [2]. The third material is La$_2$YS$_3$ (thermal budget of 1000°C, no efficiency reports). To our knowledge, La$_2$YS$_3$ the first chalcogenide perovskite to have been synthesized in thin film form, as well as one of the first photoabsorbers discovered by computational screening that were actually synthesized [3]. Those three materials are currently being investigated in our group. They share the following favorable optoelectronic properties: 1) appropriate band gap (1.7-2.0 eV) as a top absorber in a tandem solar cell; 2) strong photoluminescence, and 3) small shift between band gap energy and photoluminescence peak energy. We will present our results on alternative growth methods for the two previously synthesized absorbers (sodalization of metallic Bi for Bi$_3$I$_6$; sulfuration of...
oxide films for Cu$_2$BaSnS$_4$, as well as the main optoelectronic properties of the novel LaYS$_2$ absorber. Finally, we will discuss the solar cell performance obtained from the three absorber materials, with particular emphasis on the different device architecture limitations arising from the different thermal budgets of the three materials.

10:00 AM BREAK

10:30 AM *ET11.10.01 Interface-Enhanced Bulk Photovoltaic Effect in Metal Oxides Yun Liu; The Australian National University, Canberra, Australian Capital Territory, Australia.

Photovoltaic (PV) is a process converting light energy to electrical energy. A high efficient PV effect relies on two factors: (i) a high photocurrent and (ii) a built-in electric field enabling the separation of the photogenerated electrons and holes. In traditional PV devices, electron-hole pairs are generated by light absorption in narrow bandgap semiconductors, and then separated through the depletion field in the heterojunction. The maximum voltage of these devices, however, equals to their bandgap, and thus the power conversion efficiency is restricted by Shockley–Queisser limitation. To break this limitation and obtain higher voltage, ferroelectric (FE) materials, due to their non-centrosymmetric structures that can induce stable depolarization electric fields and generate much higher photovoltage than their bandgap (named as bulk PV effect), have received a renewed attention in the PV application. Despite the high voltage the FE materials can exhibit, the photocurrent of most of the FE materials is really low because of their wide bandgaps resulting in the low conductivity and the deficient absorption of the solar energy. In this talk, we will present several strategies to improve bulk PV effect of materials, especially focusing on structurally distorted and chemically varied narrow bandgap metal oxide semiconductors, in which high performance ferroelectric properties are achieved without significantly changing their intrinsic electronic and photoelectronic properties. It is found that such a very thin (<10nm) functional metal oxide layer, deposited on a strain layer, shows an excellent bulk photovoltaic effect with a photocurrent 10$^3$–10$^4$ times higher than that of conventional ferroelectric materials and comparable to state-of-the-art multilayered multiferroics.

11:00 AM ET11.10.02 Optimizing the Properties of Transparent Electrodes Based on Silver Nanowire Networks for Integration into Organic Solar Cells Joao A. Resende1, Thomas Sannicolo1, Afzal Khan2, Nicolas Charvin3, Ali Nourdine1, Dorina Papanastrausi1, Viethuong Nguyen1, 1, Sara Aghazadehchors1, 4, David Munoz-Rojas1, Carmen Jimenez2, Ngoc Duy Nguyen1, Lionel Flaudin1 and Daniel Beller1; 1LMGP, Grenoble, France; 2Department of Physics, Univ. of Peshawar, Peshawar, Pakistan; 3Univ. Grenoble Alpes, Université Savoie Mont Blanc, CNRS, Grenoble INP, LEPHI, Grenoble, France; 4Univ. de Liege; CESAM/Q-MAT, Liege, Belgium; 5Centre d’Etudes et de Recherche en Chimie Analysée et Moléculaire (CERMAC), Univ. of Peshawar, Peshawar, Pakistan.

The demand for low-cost and flexible photovoltaic systems is rapidly increasing, creating a need for a new generation of transparent electrodes. In the specific case of organic photovoltaics (OPV), flexible transparent electrode materials would allow the wide-spread of large-scale OPV, offering a technology with non-toxic, low-weight and flexible modules available in different shapes and colors. Although indium-tin-oxide (ITO) constitutes the state-of-the-art transparent conductive material for solar cells, it exhibits drawbacks such as brittleness, thus preventing its application in flexible devices. To replace ITO, metal-based nanowire networks have been considered as a promising alternative solution that exhibits high conductivity and the deficient absorption of the solar energy. In this talk, we will present several strategies to improve bulk PV effect of materials, especially focusing on structurally distorted and chemically varied narrow bandgap metal oxide semiconductors, in which high performance ferroelectric properties are achieved without significantly changing their intrinsic electronic and photoelectronic properties. It is found that such a very thin (<10nm) functional metal oxide layer, deposited on a strain layer, shows an excellent bulk photovoltaic effect with a photocurrent 10$^3$–10$^4$ times higher than that of conventional ferroelectric materials and comparable to state-of-the-art multilayered multiferroics.

11:15 AM ET11.10.03 Head-to-Head Linkage Containing 4-alkoxy-5-(3-alkylthiophen-2-yl)thiazole-Based Polymeric Semiconductors for Polymer Solar Cells with Small Voltage Loss Xin Zhou, Chen Peng, Jianwei Yu, Han Guo and Xugang Guo; Southern University of Science and Technology, Shenzhen, China.

Head-to-head linked bithiophene-type unit with advantages of good solubility and high planarity has been proven as a successful building block for polymeric semiconductors. However, since the strong electron-donating nature of alkoxy chain, bithiophene-based polymers suffer from elevated frontier molecular orbitals (FMOs), which are unfavorable to stability of semiconductors and lead to small open-circuit voltages ($V_{oc}$) in polymer solar cells (PSCs). Herein, we report the design, synthesis and characterization of a new head-to-head linked building block 4-alkoxy-5-(3-alkylthiophen-2-yl)thiazole
(TRTzOR). Compared to our previous work, 3-alkoxy-3'-alkyl-2,2'-bi thiophene (TRTzOR). TRTzOR retains high planarity through the intramolecular noncovalent S–O interaction, while its FMOs have been considerably lowered for the substitution of electron-deficient thiazole for the electron-rich thiophene. Copolymerized with the benzothiadiazole and its fluorinated derivatives, TRTzOR-based polymer showed a wider absorption range extending to 950 nm and tune FMOs down by 0.2–0.3 eV, versus TRTzOR-based analogous polymers. Thus, TRTzOR-based polymeric donor enlargers the $V_{oc}$ of polymer solar cells by 0.1 eV. Moreover, a much smaller energy loss as low as 0.61 eV was realized. Our study demonstrates thiazole substitution is an effective approach to tuning energy levels for higher open-circuit voltages in PSCs. The exceptional small energy loss indicates that head-to-head linkage TRTzOR motif is a promising building block for organic semiconductor.

11:30 AM ET11.10.04
IMPULSE–OPV—Integrated Molecular Plasmon Upconverter for Low-Cost, Scalable and Efficient Organic Photovoltaics Jonas S. Lissau and Morten Madsen; SDU NanoSYD, Mads Clausen Institute, University of Southern Denmark, Sønderborg, Denmark.

Upconversion of low-energy photons transmitted by traditional single-threshold solar cells is a promising approach to overcome their theoretical efficiency limit. Due to their relatively high-energy absorption threshold organic solar cells have a particular high loss of low-energy photons and consequently a high potential for improvement by photon upconversion.

In IMPULSE-OPV, we apply photon upconversion via triplet fusion in organic molecules to improve the efficiency of organic solar cells. This approach can be synthetically tuned to match the spectral requirements of the solar cell technology. In addition, molecular photon upconversion benefits from spin-allowed broadband absorbing transitions, which facilitates reasonable upconversion efficiency under solar flux [1].

Specifically, we investigate in this work systems based on palladium(II) 1,4,8,11,15,18,22,25-octabutoxyphthalocyanine as a triplet sensitizer and rubrene as a triplet-triplet annihilator. After light absorption and intersystem crossing the resulting triplet state is transferred to rubrene. The molecular upconverter is embedded in a polyurethane matrix which allows for efficient triplet energy migration via molecular diffusion. Two rubrene triplet states can annihilate (triplet fusion) to produce a high-energy singlet state which decays by emission of an (upconverted) high-energy photon.

To further boost the photon upconversion efficiency, metal nanostructures tailored for plasmon resonance at the absorption band of the upconverter are integrated. This work therefore provides a route for production of low-cost, scalable, and efficient organic solar cells via photon upconversion.

11:45 AM ET11.10.05
Metal Decorated Nano-Composite Effects to Enhance the Performance of Inverted Thin-Film Organic Solar Cells Genene T. Mola; University of KwaZulu-Natal, Pietermaritzburg, South Africa.

The efficient generation and transportation of charge carriers are the major factors that influence the performance of thin film organic solar cells (TFOSC). We have successfully synthesized and employed tri-metallic nanocomposite (Ag:Zn:Ni) in the preparations of TFOSC with the view to address some of the challenges with respect to charge generation and transportation. The nanocomposites were dispersed in the solution phase of the photoactive layer of the solar cells. As a consequence, notable influence of the nanocomposite was evident on the power conversion efficiency of the devices due to local surface plasmon resonance (LPSR). Several synthesis methods have been employed in the preparations of various bi and tri-metallic nanoparticles which include chemical, physical and biosynthesis methods such as chemical reduction, microwave and laser ablation [1,2,3,4,5]. Among these techniques, the chemical reduction method is the most preferred one because of its simplicity and low cost preparation. Moreover, the chemical reduction method offers the ability to control size and distribution of the nanoparticles by optimizing the experimental parameters. In this work, we have synthesized and characterized of silver:zinc:nickel (Ag:Zn: Ni) tri-metallic nanoparticles which are eventually explored for first time to influence the photovoltaic performance of bulk-heterojunction organic solar cells. The synthesis of the nanocomposite, device preparation and characterization are discussed in terms of changes in optical, electrical and morphological properties.

Interfacial Solar Steam Generations—Materials, Structures and Applications Jia Zhu; Nanjing University, Nanjing, China.

Nanomaterials with carefully tailored properties can be used to manipulate the flow of phonons, electrons and photons, to enable unconventional solution for solar energy conversion. In this talk, I will present our recent progress in interfacial solar steam generations.
We report a plasmon-enhanced solar desalination device. This most efficient and broad-band plasmonic absorber is fabricated through self-assembly of metallic nanoparticles onto a nanoporous template by one step deposition process. Because of its efficient light absorption and strong field enhancement, it can enable very efficient and effective solar desalination by using low cost aluminum nanoparticles. Inspired by the transpiration process in plants, we report an artificial transpiration device with a unique design of two dimensional water path. With efficient two dimensional water supply and suppressed heat loss, it can enable an efficient (80% under one-sun illumination) and effective (four orders salinity decrement) solar desalination device. The energy transfer efficiency of this artificial transpiration device is independent of water quantity and can be achieved without extra optical or thermal supporting systems, therefore significantly improve the scalability and feasibility of this technology. In addition, interfacial solar steam generations can enable effective sterilization and efficient generations of electricity.

2:00 PM ET11.11.02
Synthesis and Characterization of c-Axis Oriented Zinc Oxide Thin Films and Its Use for the Subsequent Hydrothermal Growth of Zinc Oxide Nanorods
Farhad Syed1, Nazmul Islam Tanvir1, Muhammad Shahriar Bashar2 and Munira Sultana3; 1Solar Energy Conversion and Storage Research Section, Industrial Physics Division, BCSIR Labs, Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh; 2Institute of Fuel Research and Development (IFRD), Bangladesh Council of Scientific and Industrial Research (BCSIR), Dhaka, Bangladesh.

Oriented ZnO seed layers were deposited by simple drop casting of zinc acetate dihydrate(ZAD) solution on glass substrates at room temperature followed by a post-heating treatment at 250 °C. X-ray diffraction (XRD) analyses revealed that ZAD solutions with concentration 0.0025 – 0.0100 M produced amorphous type thin films, whereas 0.020 M ZAD solutions produced ZnO seed layers with a preferential c-axis texturing. The Scanning Electron Microscopy (SEM) analysis evident that the morphology of ZnO seed layer surface is compact and coherently carpets the underlying glass substrate. ZnO nanorods were then grown by hydrothermal method atop the oriented ZnO seeded and non-seeded substrates. The presence of ZnO seeding layers was found to significantly affect the surface morphology and crystallographic orientation of the resultant ZnO NRs films. The optical band gap of ZnO seed and ZnO NR were estimated to be in the range of 3.40 – 3.95 eV and 3.20 – 3.25 eV respectively by using UV–VIS–NIR diffuse reflection spectroscopy. The room temperature photoluminescence analyses revealed that nanostructured ZnO films exhibit a sharp near-band-edge luminescence peak at ~380 nm consistent with the estimated optical band gap and the ZnO nanorod arrays are notably free from defect-related green-yellow emission peaks.

2:15 PM ET11.11.03
Slow Transient Photoconductivity in ZnO Explained from Light-Induced Trap Filling
Jason A. Rohr1, 2, Mohamed Abdelkhalik1, Liam Appelson1, Anna Cieslak1, Janusz Lewinski1, 3, Jacinto Sa1, 2 and Steven Konezny1, 2; 1Department of Chemistry, Yale University, New Haven, Connecticut, United States; 2Energy Sciences Institute, Yale University, West Haven, Connecticut, United States; 3Department of Chemistry, Uppsala University, Uppsala, Sweden; 4Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland; 5Faculty of Chemistry, Warsaw University of Technology, Warsaw, Poland.

Zinc oxide (ZnO) nanoparticles have been studied extensively as gas sensors, as an alternative electronic transport material to titanium dioxide in dye-sensitized solar cells, and as a potential photocatalyst for solar driven water splitting. This is primarily due to their low cost, material abundance, potentially large surface area as mesoporous films, low toxicity, relatively large charge-carrier mobilities, and their capability to be doped either n- or p-type. However, important fundamental mechanistic questions remain unanswered. The chemical nature of charge-carrier traps, and the observed transient behavior of the conductivity of ZnO thin films after UV light exposure, also known as persistent photoconductivity, are still as much the subject of debate as it has been over the last three decades. We offer new insight based on a combination of temperature-dependent conductivity measurements, in the 8 to 310 K range, and mid-infra-red transient absorption spectroscopy measurements. Using these techniques we are able to isolate the effects from light and temperature. At low temperature, the conductivity increases as transport tends from being trap limited to trap filled when exposed to UV light as the fraction of filled traps increases. At higher temperatures, the dark current, post UV exposure, slowly decreases as it returns to trap-limited behavior as charge carriers are reemitted from the traps. At practical device temperatures and light conditions, the observed conductivity is governed by both trapping and detrapping kinetics that establish an equilibrium density of occupied trap levels. We show that the conductivity can be modeled within this framework by assuming a combination of inter-particle tunneling, light induced trap filling and temperature-dependent detrapping kinetics. This model can be used to extract the trap depths, which can be assigned to the defects limiting the transport. Our findings not only give insight into the conduction mechanism of ZnO particle films, but into any conduction mechanism exhibiting persistent photoconductivity, such as other nanostructured metal oxides and amorphous metal chalcogenides.

3:30 PM ET11.11.04
Optical Properties of Magnesium-Zinc-Oxide for Thin-Film Photovoltaics Applications
Mohammed Razaeqi, Prakash Koirala, Adam Phillip, Geethika K. Liyanage, Michael Heben and Robert W. Collins; Department of Physics and Astronomy, and Wright Center for Photovoltaics Innovation and Commercialization, The University of Toledo, Toledo, Ohio, United States.

Magnesium-zinc oxide (MgZn1-xO; MZO) is a window layer material of great interest in thin film photovoltaics technologies such as CdTe and CuIn(x)Ga(2-x)Se2. Recent numerical modelling and experimental data have shown that replacing the CdS window layer in CdTe devices with an MZO layer improves the band alignment at the front contact, which in turn reduces recombination [1,2] and leads to improved solar cell open circuit voltage and fill factor [3]. Although the window layer performance is critically dependent on its optical properties, such characterization of MZO films after the various steps throughout device fabrication has not been reported to date. Specifically, information is lacking on the evolution of the optical properties as a function of time during thermal treatments in different environments. Whereas the SnO2 high resistivity transparent (HRT) layer traditionally used in CdTe devices is known to be thermally stable, it is not clear the extent to which the properties of as-deposited MZO are affected by subsequent device processing. Here, we use spectroscopic ellipsometry (SE) to determine the optical properties of the MZO at various stages of CdTe device processing and apply this information to guide device fabrication. In these experiments, MgZn1-xO films with Mg contents from x = 0 to x = 0.25 were sputtered at room temperature on soda lime glass (SLG). This provides a range in the MZO bandgap energy from Eg = 3.3 eV to Eg = 3.7 eV, respectively. The room temperature complex dielectric functions of the MZO films on SLG were measured immediately after deposition and again after heating for 4 hours at 250 °C, the same thermal cycle used for sputtering an overlying CdTe film. In subsequent studies, the optical properties of the annealed SLG/MgZn1-xO/CdTe. The capabilities of SE are explored in particular for determining the magnesium content x simultaneously with the film structure for correlations of both composition and thickness with the device performance.

Photon management can be used in III-V solar cells to increase absorption in the active region of the device. This can allow addition of low bandgap nanostuctures such as quantum wells, without the need for excessive strain balancing. It can also be used to harden space cells against high-energy, damaging particles. In this work, a model was first developed integrating simulations from electromagnetics and device physics software packages to evaluate absorption enhancement in, and performance of, III-V solar cells with both flat and textured back surface reflectors as well as front side scattering structures. Models predicted that a nanostructured GaAs cell with a pyramid-textured back surface reflector (BSR) could enhance absorption of in the nanostuctures by about 30% compared to a conventional upright design of the same thickness. The model also found that integrated light management could be used to radiation harden InGaP/GaAs/Ge space cells by thinning the GaAs subcell to less than half of the conventional thickness. In addition, simulation was compared to experiment focusing on the GaAs middle cell using combinations of textured back reflectors as well as partially reflective epitaxial DBR mirrors. For epitaxial DBR mirrors, internal and external quantum efficiency, as well as performance under 1-sun illumination shows nearly complete recovery of performance to optically thick conditions, while using half the thickness of GaAs absorber. As well, pyramidal and random back surface texturing has shown that optical path lengths much greater than 2 can be realized in practice. These results have been used to verify and refine the developed simulations and as well predict realistic end of life enhancements for typical space radiation conditions.

ZIF-67 Derived Nanostructures of Co/CoO and Co@N-Doped Graphitic Carbon as Counter Electrode for Highly Efficient Dye-Sensitized Solar Cells
Hongyu Jing, Suzhen Ren, Yantao Shi, Xuedan Song, Yonglin An and Ce Hao; State Key Laboratory of Fine Chemicals, Dalian University of Technology, Dalian, China.

Here we present a facile one-step approach of using ZIF-67 as a sacrificial template for the synthesis of counter electrode (CE) catalyst of dye-sensitized solar cells (DSCs). Via controlling the carbonization temperature under N2 atmosphere, porous nanocomposites of Co, CoO and N-doped graphitic carbon are synthesized. Structural characterizations indicate that some cobalt nanoparticles are well embedded in an N-doped graphitic carbon matrix (a core-shell structure named as Co@NGC) while the other cobalt and cobalt oxide nanoparticles are exposed on the external surface (named as Co/CoO). Especially, the nanostructure of Co@NGC is more chemically stable than Co/CoO against etching of strong acid, for example, hydrochloric acid (HCl, 0.1 M). The performance of DSC using ZIF-67-850 (pyrolyzed at 850 °C) as CE yields a photoelectric conversion efficiency (PCE) of 7.92%, which is close to that of Pt CE (8.18%) in the liquid I3-/I- redox couple electrolyte. The excellent performance of ZIF-67-850 can be ascribed to the synergetic effects between the Co and CoO coupled with the nitrogen doped graphitic carbon. The cost-effective porous Co/CoO and Co@NGC nanocomposites show great potential for application in the field of high performance CE in solar cells.

Effect of Solvent and Substrate on the Surface Binding Mode of Carboxylate-Functionalized Aromatic Molecules
Janna Domenico1, Michael E. Foster2, Erik D. Spoerke2, Mark Allendorf3 and Karl Sohlberg1; 1Department of Chemistry, Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Materials Physics, Sandia National Laboratories, Livermore, California, United States; 3Department of Electronic, Optical, and Nano Materials, Sandia National Laboratories, Albuquerque, New Mexico, United States; 4Department of Energy and Transportation Technology Center, Sandia National Laboratories, Livermore, California, United States.

The efficiency of dye-sensitized solar cells (DSSCs) is strongly influenced by dye molecule orientation and interactions with the substrate. Therefore, understanding the factors controlling the surface orientation of sensitizing organic molecules will aid in the improvement of both traditional DSSCs and other devices that integrate molecular linkers at interfaces. Herein, we employ DFT calculations and ab initio molecular dynamics simulations to investigate the effect of substrate, solvent, and protonation state on the orientation of linker molecules relevant to DSSCs. In the absence of solvent, we predict that most carboxylic acid-functionalized molecules prefer to lie flat (parallel) on the surface, due to van der Waals interactions, as opposed to binding at a tilted orientation with respect to the surface that is favored by covalent bonding of the carboxylic acid group to the substrate. Once solvation effects are considered, however, most molecules are predicted to orient perpendicular to the surface. This approach can be extended to help understand and guide the orientation of metal–organic framework (MOF) thin-film growth on various metal–oxide substrates. Finally, a two-part analytical model is developed that predicts the binding energy of a molecule by chemical and dispersion forces on rutile and anatase TiO2 surfaces, and quantifies the dye solvation energy for two solvents. The model is in good agreement with the DFT calculations and enables rapid prediction of dye molecule and MOF linker binding preference on the basis of the size of the adsorbing molecule, identity of the surface, and the solvent environment. Results suggest that linker orientation can be controlled by choice of adsorbate, substrate, and solvent; this novel approach can be used to achieve a desired linker orientation and, by extension, MOF growth orientation in a MOF-based DSSC.

Solar Cell Degradation Due to Corrosion of Glass Substrates
Yuriy Kudriavtsev, Angelica Hernandez, Rene Asomoza-Palacio, Miguel Avendaño and Marcela Guerrero; CINVESTAV, Mexico City, Mexico.

Thin film solar cells meet a great interest because of their low price and a relatively high efficiency. Many technologists use glass substrates to deposit thin films forming a photo-diode structure. In the most popular configuration of solar cells, photons transmit through the glass substrate and a special transparent ohmic contact before arriving in a p-n junction region. It is evident that glasses with a highest possible transparency coefficient are necessary.
for the higher solar cell efficiency and the transmittance should be saved for the time of life of the cells. Borosilicate (b-s) and soda-lime (s-l) glasses are most popular substrates because of the mentioned reasons. In our previous studies, we demonstrated that interaction of atmospheric water vapor with silicate glasses results to their corrosion. A radical difference in the corrosion mechanisms was observed for s-l and b-s glasses. Hydration of a near surface layer occurs in s-l glasses, whereas hydrogenation - in b-s glasses. Both the hydration and the hydrogenation processes are stimulated strongly by the temperature. Typical solar cells work at elevated temperatures, which can reach 90-100°C in a sunny day, so the glass substrate corrosion for a working solar cell due to such glass surface corrosion looks very possible. We realized an experimental hydration of s-l and b-s glasses in a 100% water vapor atmosphere at 90°C for two months to simulate the glass substrate corrosion. Experimental samples were cut from commercial polished substrates. SIMS depth profiling analysis was performed to define the thickness of hydrated and hydrogenated layers, formed in the s-l and b-s glass samples, respectively. Optical transmittance coefficients were measured for the hydrated samples in comparison with the original ones. We concluded a radical decrease of the transmittance of the s-l glasses, caused by hydrated layer formation. An insignificant decrease of the transmittance coefficient was observed for b-s glass. We concluded that a special study should be realized directly to those of the glass substrates used for solar cell fabrication to avoid cells degradation due to glass surface corrosion.

**Coumarin-Based Europium Complexes for Luminescent Solar Concentrators**

Ahmad Alsaleh, Anita C. Jones and Neil Robertson; University of Edinburgh, Edinburgh, United Kingdom.

Solar energy is the most promising source to address the growing energy needs of the planet. Luminescent solar concentrators (LSCs) can collect light over a large area and concentrate it onto a small area of solar cells in order to enhance the performance of the solar cells. The light is absorbed by a transparent sheet containing luminescent dyes and the emission is transported by total internal reflection to the edge of the plate where photovoltaic cells are positioned. β-diketonate-based Europium (III) complexes are promising candidates for use as dyes in LSCs due to their high quantum yields, extended absorption window, minimal overlap between the absorption and emission spectra, and narrow emission band. We will report a study of β-diketonate coumarin-based Lanthanide complexes aimed at optimising their luminescence characteristics by ligand design. Coumarins are well-known organic dyes that have served as antennae for LSC applications. We will report the preparation and photophysical properties of two Europium complexes, [Eu(L)_3X_2] where, X=DPEPO, L=7-methoxy or 7-diethylamine coumarin derivative, and investigation of their incorporation in several polymer films.

**Acknowledgment**

We are grateful to Dr. álvaro Cañete M. (Pontificia Universidad Católica de Chile) for the gift of the coumarin ligands.

**Fast Hall™—A New Method for Measuring Low Mobility Thin-Film Materials**

Jeffrey R. Lindemuth; Lake Shore Cryotronics, Inc., Westerville, Ohio, United States.

The Hall effect is the primary method to measure carrier density, mobility and carrier type in materials. The most common method for measuring the Hall effect in semiconductors uses a DC magnetic field. The community has developed a well-defined protocol for removing spurious voltages in the measurement. Reversing the magnetic field and subtracting the measured voltages will remove any voltage that does not depend on the magnetic field. As research interest in studies of the transport mechanisms expands beyond semiconductors, with moderate to high mobility, the standard DC field method reaches its limit of applicability. We present a new measurement protocol based on the reverse-field reciprocity theorem. The reverse-field reciprocity theorem considers a four port network with current inputs and voltage measurements and an applied magnetic field. If a current is applied to two of the inputs (say 1 and 3) and a positive field B a voltage (V) is measured on terminals 2 and 4. This voltage can depend of the magnetic field V(B). If the current and voltage leads are interchanged, current on terminals 2 and 4, voltage measured between 1 and 3, V(1) and V(2). The theorem states that V(2) = V(1) - V(B). This is a very general result; the only requirement of the material is that it is electrically linear. This means that thermoelectric voltages require special treatment. In the above example, V(2) = V(1) - V(B) removes the offset voltage without physically reversing the magnetic field. Measurements using the Fast Hall™ method on InAs, IGZO, ZnO, pyrite, Graphene and GaAsSb have demonstrated excellent agreement between measurements using DC or AC field hall and Fast Hall. The Fast Hall method can preform up to 100 Hall measurements per second. The high speed of the measurements greatly reduces the
effects of thermal drift and self-heating of the sample during the measurement. Thermal drift is one of the major contributions to noise in hall measurements of low mobility and thin film samples. The Fast Hall method increases measurement speed, extends the range of mobility that can be measured using DC field methods. The method is applicable to both single carrier materials and multi-carrier materials.

Air-Processed Defect-Free ZnO Nano-Particles for Solution Processed Photovoltaic Cells **Yuhui Ma**, Xiwen Xu, Yuemin Xie, Menglin Li and Sai-Wing Tsang; Department of Materials Science and Engineering, City University of Hong Kong, Hong Kong, Hong Kong.

Solution-processed ZnO nanoparticles (ZnO-NPs) have been widely used as electron transporting layer (ETL) in developing high efficiency organic photovoltaic (OPVs) cells. However, the ZnO-NPs are known to be sensitive to oxygen and moisture in air with strong trap emission in the visible (400-700nm) region. Consequently, those reported high efficiency OPVs with ZnO ETL were fabricated in inert environment. This limits the large-scale industrial implementation of low-cost and high-efficiency photovoltaic cells. Here, we will demonstrate an approach to achieve defect-free ZnO NPs thin film processable in ambient air. It is found that the trap states in ZnO are rapidly induced by oxygen and moisture within a few seconds exposure in air. Interesting, this trap developing process is complete with the ultra-violet (UV) irradiation. There exists an operation widow that the trap states can be drastically reduced in very short period of UV irradiation time with less than 10s. However, they start growing gradually with continuous irradiation in longer time for more than 1min. Using the air-processed ZnO-NPs ETL with short time UV irradiation, it is found that different donor:acceptor OPVs can achieve high efficiencies comparable with those fabricated in inert environment. By eliminating the trap states, it mainly reduces the interfacial recombination with enhanced fill-factor and prolonged device lifetime. The un-encapsulated devices stored in ambient air can retain more than 80% of the initial efficiency.

Synthesis and Characterization of SnO2 and TiO2 Nanoparticles Doped with Li or Ni and Hybrid Composites **Antonio Vázquez**, María Taeño, David Maestre, Julio Ramírez-Castellanos and Ana Cremades; Física de Materiales, Facultad de CC. Físicas, Universidad Complutense de Madrid, Madrid, Spain; 1Química Inorgánica I, Facultad de CC. Químicas, Madrid, Spain.

Wide bandgap semiconducting oxides, such as SnO2 and TiO2, have demonstrated potential applicability in numerous fields such as optoelectronic devices, catalysis, gas sensing or energy storage, which can be improved by controlling the dimensions, morphology, doping and composition of these materials. Moreover, hybrid composites combining advantages of inorganic and organic compounds are emerging as low cost materials with promising application in photovoltaic and energy storage devices [1]. These hybrid composites can retain the advantages of their organic and inorganic counterparts and even exhibit new synergetic properties, hence gaining increasing research attention in the last years.

In this work, rutile SnO2 and anatase TiO2 nanoparticles have been synthesized by a co-precipitation method based on hydrolysis, using SnCl2·2H2O or Ti(OBu)4, respectively, as precursors. For the synthesis of Ni or Li doped nanoparticles, stoichiometric amounts of NiCl2·6H2O or LiCl, respectively, were added as precursors. Large amounts of nanoparticles with high crystallinity, good homogeneity and dimensions ranging from 8 to 10 nm are obtained with this method. These nanoparticles have been initially characterized by x-ray diffraction (XRD), transmission electron microscopy (TEM), energy dispersive x-ray spectroscopy (EDS), Raman spectroscopy, X-ray absorption spectroscopy (XAS), photoluminescence (PL), and cathodoluminescence (CL). The presence of dopants induces changes in the dimensions of the nanoparticles, and in their structure of defects and optical and electronic properties. In this work, nanoparticles with reduced dimensions were achieved by Ni doping, while Li doping induces an enhancement of the luminescence, both for SnO2 and TiO2. Moreover, changes in the Raman signal, mainly in the Eg modes associated with O-Ti-O symmetric stretching vibrations in anatase TiO2, and vibrations of O anions along the c axis in SnO2 were observed.

In this work hybrid compounds made with PEDOT:PSS functionalized with the undoped or doped SnO2 or TiO2 nanoparticles, synthesized by hydrolysis, were deposited onto Si substrates at room temperature by spin-coating, thus involving low cost and rapidity, as compared with the commonly used vacuum-based techniques. The thickness of the composite layers fabricated in this work is around 120 nm, as measured by atomic force microscopy (AFM). The presence of inorganic SnO2 or TiO2 nanoparticles could add functionality to the hybrid composite and broaden its related applicability in photovoltaic devices [1], photocatalysis, optoelectronics and bioapplications, as some examples, due to charge transfer and variations in the local electronic structure of the hybrid material which can lead to improved performance.

Improving Charge Extraction from Bismuth Oxyiodide Photovoltaics with 2D Metal Dichalcogenide Transport Layers **Tahmida N. Huq**, Rosie Baines, Robert L. Hoyer, Pin-chun Shen and Judith L. MacManus-Driscoll; 1Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 2Cavendish Laboratory, University of Cambridge, Cambridge, United Kingdom; 3EPSRC Centre for Doctoral Training in Graphene Technology, University of Cambridge, Cambridge, United Kingdom; 4Research Lab of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Bismuth oxyiodide (BiOI) has recently been shown to be a promising lead-free alternative to halide perovskites for photovoltaics. BiOI replicates the electronic structure of halide perovskites, and is predicted to show tolerance towards anti-site and vacancy defects. Notably, BiOI thin films have been found to be at least two orders of magnitude more air-stable than methylammonium lead iodide. Although record external quantum efficiencies of 90% have been achieved, the power conversion efficiency (1.8%) is limited by inefficient hole extraction in an ITO|BiOI|ZnO|Au device stack. This is due to downwards band-bending of BiOI at the BiOI|ZnO interface caused by poor energetic matching of the BiOI (work function of 5.1 eV) with NiOx (work function of 4.8 eV). Higher work function materials are required to overcome this barrier. In this work, 2d molybdenum sulphide (MoS2) is investigated as an alternative hole transport layer due to its work function tunability. Through plasma treatment, the work function is increased to >5.1 eV. We use photoemission spectroscopy to probe the MoS2|BiOI interface, and our detailed studies reveal an upwards band-bending which can enable improved hole extraction. We explore the modification of chemical vapour transport BiOI growth conditions required as a result of the change in surface chemistry at the new hole transport layer interface. SEM microscopy and X-ray diffraction reveal that these modifications lead to an improvement in orientation and morphology (i.e. more compact and pinhole free) of the BiOI films, essential for shunt-free devices. Through these optimisations and subsequent characterisation, we are able to increase our understanding of the interfaces in the device stack which is crucial for achieving at least 4% efficient devices.

Tomographic Imaging of PbSe Quantum Dot Superlattices for PV Applications **Xiaolei Chu**, Hamed Heidari, Alex Abelson, Caroline Y. Qian, Matt Law and Adam J. Moulé; University of California, Davis, Davis, California, United States; 2University of California, Irvine, Irvine, California, United States; 3University of California, Irvine, California, United States; 4University of California, Irvine, Irvine, California, United States; 5University of California, Davis, Davis, California, United States; 6University of California, Irvine, Irvine, California, United States; 7University of California, Los Angeles, Los Angeles, California, United States; 8University of California, Los Angeles, Los Angeles, California, United States; 9University of California, Irvine, Irvine, California, United States; 10University of California, Los Angeles, Los Angeles, California, United States; 11University of California, Irvine, Irvine, California, United States; 12University of California, Los Angeles, Los Angeles, California, United States.
Ordered PbS and PbSe quantum dot (QD) arrays have demonstrated multiple exciton generation in response to photo excitation by high energy photons. This inherently quantum material demonstrates a pathway to photovoltaic efficiency above the Shockley limit if ordered and defect free super-lattices of these QDs can be fabricated. Here we use high-resolution tomographic imaging of PbSe super-lattices to study the material order resulting from self-assembly and ligand exchange. Quantum dots are synthesized using long chain ligands to ensure a narrow size distribution. Superlattice arrays of long-chain ligand QDs self-assemble at liquid-liquid interfaces into ordered superlattice films with hexagonal packing. After the film has formed, in-situ ligand exchange is used to reduce the distance between QDs, leading to recrystallization of the super-lattice to a distorted simple cubic array. This array has structural defects including twinning between domains, point defects, and bridging between some neighboring QDs, that leads to a heterogeneous energy landscape. The super-lattice order, seen at the top interface of the film, is accessible using SEM imaging and is often very different from the arrangement of particles in the center of self-assembled films. We use tomographic reconstruction of STEM images to determine the position of QDs with nm precision and bridging between particles. We show how defects in the superlattice structure effects the charge localization.

Layered Hexagonal Oxycarbides, M_{n=1}AO_{2}X_{n} (M=Sc, Y, La, Cr and Mo, A=Ca, X=C)—Novel Photovoltaic Ceramics
Zhenu Wang, Xin Chen and Chunming Niu; School of Electrical Engineering, Xi’an Jiaotong University, Xi’an, China.

Solar energy is increasingly becoming an integrated part in energy spectra worldwide and promises to greatly relieve the world from the shackles of fossil fuels. Development of high performance solar cells depends on the discovery of new photovoltaic materials. The search for the new photovoltaic (PV) materials has been intensified since the invention of the perovskite solar cells. 1 The rapid development of computational methods and tools deepens our understanding of existing materials and provides an insightful guide for experiments. 2 And most importantly, it also makes more and more feasible to discover novel materials via computer simulations, such as solid state electrolytes, electrocatalytic materials, two-dimensional (2D) semiconductors, and perovskite solar cell materials.

In the recent years, advanced functional ceramics attract broad interests due to its outstanding mechanical properties, such as high strength and hardness, excellent wear resistance and good frictional behavior. 3 Given excellent dimensional stability as well as the ability to withstand corrosive environments, the applications of functional ceramics in the semiconductor industry is desirable.

A family of layered hexagonal oxycarbides and oxynitrides with the general formula, M_{n=1}AO_{2}X_{n} (MAOX) is discovered using first-principles DFT calculations, where \( n=1\), \( M \) is an early transition metal, \( A \) is an alkaline earth metal in Group IIA or a late transition metal in Groups IB and IIB, \( X \) is C and/or N. 4 The family can be divided into three sub-groups of 2121, 3122 and 4123 with \( n=1, 2 \) and 3, respectively. Thermodynamically, the MAOX phases are very stable. Tuning the composition, MAOX can be metals, semimetals or semiconductors. In this report, we discuss five 2121 oxycarbide MAOX semiconductors, \( M \) is Sc, Y, La, Cr and Mo. Their band gaps are from 0.39 to 1.14 eV. They have superior PV properties and their theoretical solar cell efficiencies are on par with GaAs. Particularly, the efficiency of \( Cr_{2}CaO_{4}C \) reaches 27.7% that is above 90% of the Shockley-Queisser (SQ) limit. Furthermore, amazingly, the five MAOX semiconductors possess outstanding strength and machinability, e.g., their Young’s moduli are comparable to ceramics and MAX phases, and Poisson’s ratios higher than MAX and even comparable to metals. MAOX semiconductors are promising multifunctional ceramics. The unique combination of the photovoltaic and mechanical properties suggests great potentials for advanced solar cell applications.

*Improve the Photo-Stability of Polymer Solar Cells by Controlling the Chemical Structure of Photoactive Materials* Rasool Shafke1, 2, Vu Van Doan1, 2, Chang Eun Song1, 2, Hang Kun Lee1 and Won Suk Shin1, 2; 1Energy Materials Research Center, Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Advanced Materials and Chemical Engineering, University of Science and Technology, Daejeon, Korea (the Republic of).

To commercialize the polymer solar cells many conditions should be satisfied such as efficiency, process and stability. Recently many scientists are interested in the stability of the polymer solar cells, but most of the researches are hovering at thermal stability. But real challenges are in photo-stability and the burn-in loss during exposed on the sun light is one of the biggest challenges to go to the market. Lost more than 40% of their initial efficiency in just 24 hours after exposing to 1 sun condition is common for polymer solar cell devices. This burn-in loss does not come from the decomposition of the photoactive materials but rather caused by the electro- and physical-properties of the photoactive materials. To overcome the burn-in loss, we tried two approaches. First one is inserting an appropriate interlayer for inverted solar cells. Second approach is design new photoactive materials which reduce the burn-in loss. Here we present the improved photo-stability results by applying elaborately designed photoactive materials.

**ET11.12.16**

*Hydrogen Motility at Reduced-Dimension Interfaces in Proximity to Near Semiconductor-Metal Boundaries and Dislocations* Jonathon Mitchell; National Institute of Advanced Industrial Science and Technology, Koriyama, Japan.

Understanding of the fundamental physical processes underlying key material properties in electronically active interfaces has increased importance with reduced-dimension devices like FET, MOS and photovoltaics. As in many of these devices, the inclusion of non-natives like Hydrogen, Nitrogen and Oxygen, are known to strongly affect the electronic and structural properties of many materials and have particular importance in semiconductors for binding defects, enhancement or suppression of electrical activity, long-term stability and operation. Acting as an isolated interstitial impurity, amphoteric hydrogen occupies different lattice sites and can counter the conductivity of extrinsic dopants. Nitrogen is largely impeded by an anomalous optical saturation effect, and similarly Oxygen can be impacted by variable voltage influencing dielectric permittivity and charge separation. However, the mechanisms involved are more complex than the simple application of a single hydrogen, nitrogen or oxygen to the semiconductor bond. Although tracking individual particles through the sub-lattice interface remains difficult, previous theoretical and simulation study of these interfaces has provided additional information which resolves current experimental observations. Utilising an adaptive moving-mesh in Eulerian space with Lagrangian point-aggregation for a large 904 site interface surface with bookkeeping in z-space, our model has compared the smoother particle hydrodynamics with real-time and cumulative particle transport solids. Essentially rendering a recursive output for predictive yield of electron charge transport at or near semiconductor-metal interfaces.

In this work we evaluated planar and also surfaces with sharp discontinuities from manufacture and handling, comparing the simulation to the intermediate and long-term interface properties. Non-Gaussian distribution agreed with the observed preferential diffusion probabilities and pseudo-sparse motilities according to discontinuities including mecha-mechanical shearing, grain orientation, and chemical orientation of defect alignment. New information is obtained concerning the intergranular properties thermal characteristics, as well as the presence of distinct profiles seemingly dependent to some extent on the binding algorithm of the semiconductor between the bulk and extending through the interface. For MOS-like devices (including photovoltaic), oxygen and hydrogen both introduced long-term parasitic conductivity, while the response for nitrogen and hydrogen was suppressed. This describes the suitability of nitrogen based environment during the semiconductor fabrication prior to encapsulation on the long-term performance and reliability of thin, flexible devices.

*Exploring γ-In$_2$(Se$_{1-x}$Te$_x$)$_3$ Alloys as Photovoltaic Materials* Wei Li, Tianshi Wang and Anderson Janotti; Materials Science and Engineering, University of Delaware, Newark, Delaware, United States.

γ-In$_2$Se$_3$ (hexagonal crystal structure, space group P6$_3$) has a direct band gap of ~1.8 eV with high absorption coefficients near the band edge. Alloying with Te could allow for tuning the band gap, widening the wavelength range in the absorption spectra, adding great flexibility to device design. Using density functional theory with the HSE06 hybrid functional, we investigate the electronic and optical properties of γ-In$_2$Se$_3$ and γ-In$_2$(Se$_{1-x}$Te$_x$)$_3$ alloys. The calculated band gap of 1.84 eV for γ-In$_2$Se$_3$ is in good agreement experimental data, and the absorption coefficient is found to be as high as that in direct gap III-V semiconductors. We also find that incorporation of Te, forming γ-In$_2$(Se$_{1-x}$Te$_x$)$_3$ alloys, is an effective way to tune the band gap from 1.84 eV down to 1.23 eV, thus covering the optimal band gap for single layer solar cells. We determined the band alignments between γ-In$_2$Se$_3$ and γ-In$_2$(Se$_{1-x}$Te$_x$)$_3$, and their band edge positions with respect to vacuum level. Our results indicate that γ-In$_2$Se$_3$ has a tendency for displaying n-type conductivity.

Titova2, Muhammad N. Huda1 and Pratap M. Rao; 1Department of Physics, The University of Texas at Arlington, Arlington, Texas, United States; 2Department of Physics, Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 3Department of Mechanical Engineering, Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Metal oxide semiconductors with moderate band gaps are highly desired for high-efficiency, low-cost, stable, and environmentally-friendly solar cells. CuBiW$_2$O$_8$ (CBTO) has been predicted by density functional theory (DFT) to be a promising metal oxide light absorber with band gap of 1.43 eV. However, this semiconductor has not been experimentally synthesized so far, and the optical and transport properties have not been measured. Here, CBTO was successfully synthesized for the first time by solid-state reaction in a Cu-rich environment, and identified by X-ray diffraction. The light absorption spectrum of CBTO was measured, and a light absorption edge of 820 nm (~1.5 eV) with absorption coefficient of 10$^4$ cm$^{-1}$ at 700 nm, was observed. Electron mobility in CBTO (~200 cm$^2$ V$^{-1}$ s$^{-1}$) was determined by time-resolved THz spectroscopy. This CBTO showed promising performance as a photocathode for photoelectrochemical water reduction. However, the photovoltaic performance of the CBTO solar cell is still limited by granular CBTO film quality and impurities introduced by inter-diffusion between CBTO and other layers in the cell. By modifying the synthesis methods, we believe CBTO with ~1.5 eV band gap and promising charge mobility can achieve higher efficiency than Cu$_2$O, which is the best-performing metal oxide photovoltaic absorber to date.

Silver (Ag) has been incorporated at the copper sub-lattice sites in the quaternary compound Cu$_2$ZnSnS$_4$ (CZTS) which is being under intense investigation as an absorber material for the photovoltaic application. Thin films of the resulting quaternary compound (Ag$_x$Cu$_{1-x}$)$_2$ZnSnS$_4$ (0 ≤ x ≤ 1) show remarkable changes in their microstructure and electronic properties. With the increasing Ag content, the grain size increased from 0.13 to 2 μm which could be attributed to the liquid assisted grain growth mechanism. While the observed increase in the optical band gap from 1.5 to 2.0 eV could be attributed to the influence of d-orbitals of Ag atoms on the valence band edge of the CZTS compound. The charge carrier density decreased by two orders of magnitude with only 4 atomic % Ag (x = 0.04) incorporated in the films which indicate the strong influence of Ag$_{32}$ on the density of Cu$_{32}$ and V$_{Cu}$ point defects which are the major acceptors in CZTS. The reduction of these intrinsic point defects is also being reflected in the observed decrease in the Urbach energy from 336 meV (for x = 0.00) to 230 meV (for x = 0.21). This has been further correlated with the ordering-disordering detected by the near-resonant Raman scattering. These observed changes with increasing Ag content could possibly be used for tailoring the properties of CZTS for the better performance of CZTS based solar photo voltaics.

ET11.12.20 Structural and Electronic Properties of the Pentenary Compound (Ag$_x$Cu$_{1-x}$)$_2$ZnSnS$_4$ Synthesized via Solution Route Jitendra Kumar and Sarang Ingole; Indian Institute of Technology Kanpur, Kanpur, India.

ET11.12.21 Band Alignment at the Back Contact of CdTe Devices—What Bands Need to Align? Adam Phillips, Geethika K. Liyanage, Fadhil K. Alfadhiili, Randy Ellingson and Michael J. Heben; University of Toledo, Toledo, Ohio, United States.

The deep valence band position of CdTe (~5.9 eV) makes it difficult to form an Ohmic back contact in CdTe devices. Back contact formation typically results in significant downward band bending in the CdTe that forms an energetic barrier to hole transport. Historically, the addition of Cu at the back of CdTe results in a doped interface region in which the width of the band bending is limited, effectively reducing the barrier. In addition to limiting hole transport, the band bending in the conduction band affects electrons to the interface. While the Cu doping reduces the width of the band bending, the achievable doping levels do nothing to repel the electrons from this interface. Addition of semiconducting buffer layers with a conduction band higher than that of CdTe have been incorporated into devices to prevent the electrons from recombining in the back contact and are often referred to as electron reflectors. Recent numerical modeling of CdTe devices has shown that band alignment of the conduction band at the front contact is critically important to device performance. In this case, the a modest 0.1-0.2 eV “spike” at the emitter/CdTe interface results in the best device performance even though, energetically, it would appear to restrict electron flow. Recently, we used numerical modeling to understand how the band alignment at the back contact affects device performance. We showed that in an ideal case, one in which the CdTe/semiconductor buffer interface is outside the depletion regions, band alignment of the valence bands plays a significantly larger role than band alignment of the conduction bands, and, in fact, the overall device efficiency is independent of the conduction band offsets at the back of the device. In this presentation, we will discuss these generalized results and how to apply these results to real world applications.

ET11.12.22 Modeling PV/TPV Devices Based on Exact Analytical Solution of the Generalized Shockley-Queisser Model Andrei Sergeev, Sunny Karnani and Christopher M. Waits; Army Research Laboratory, Adelphi, Maryland, United States.

Currently, interplay of electron and photon processes in the open-circuit regime is understood substantially better than that in the regime with optimal conversion of electromagnetic power. First, the open-circuit regime is well described by classical thermodynamics. Second, there is exact analytical solution for the open-circuit voltage as a function of photon flux characteristics. This analytical solution has been generalized to include other losses due to nonradiative recombination processes in terms of luminescence quantum yield. Therefore, analysis of the open circuit regime is very often employed for optimization of electron and photon processes related to PV conversion. The Shockley-Queisser limit is described by the endoreversible thermodynamics, which includes irreversible processes and entropy generation due to thermal energy transfer from the radiation source to the solar cell. Despite extensive theoretical research, the analytical expression for the maximal efficiency as a function of photon flux characteristics and electronic properties has not been reported yet.

For advanced modeling of PV/TPV devices with sophisticated photon management we obtained exact solution of the generalized Shockley – Queisser model and developed original modeling tool. Our modelling takes into account spectral absorption/emission characteristics, nonradiative recombination processes, and photon management. For noninteracting electrons and for electrons interacting via Auger processes we obtained exact analytical solution for photovoltaic efficiency, output power, and all other PV characteristics. The obtained solution provides mathematical base of PV conversion and endoreversible thermodynamics controlled by the chemical potential. We derive exact equations for useful energy, emission losses, and total thermal losses (electron-phonon relaxation and nonradiative recombination) per absorbed photon. The developed formalism is very convenient for analysis of analysis of photocarrier kinetics. In particular, we derived the universal relation between the optimal photocarrier collection time and the photogenerated electron lifetime with respect to all radiative and nonradiative processes. Let us highlight that due to the short photocarrier collection time with respect to the photocarrier lifetime, the photocarrier kinetic and transport processes in the optimal power regime may differ from the processes in the open circuit regime. Our preliminary analysis also shows that in traditional devices without photon management, it is not possible to realize simultaneously both high absorption and fast photocarrier collection, which is required by the optimal collection rate. In PV/TPV devices with enhanced photon trapping and recycling, the thickness of the base may be reduced below the characteristic value, at which the diffusion processes do not limit the optimal photocarrier collection.

ET11.12.23 Solution-Processed Vanadium Oxide as an Efficient Hole Injection Layer for Phosphorescent Organic Light-Emitting Diodes Deepak K. Dubey, Yu C. Lo, Rohit Ashok Kumar Yadav, Sujith Sudheendran Swamyprabha and Jwo-Huei Jou; Department of Materials Science and Engineering, National Tsing Hua University, Hsinchu City, Taiwan.

Organic light-emitting diodes (OLEDs) have attracted significant attention in both industry and academic research because of the increasing demand of flat panel displays for televisions, smartphones and tablets, etc., and solid-state lighting applications. With the development of highly efficient materials, innovative fabrication and out-coupling techniques, the power efficacy of OLEDs can reach as high as, >100 lm/W, meeting the requirements for flat panel display and lighting applications. Nevertheless, most OLEDs with high efficiency are fabricated by thermal evaporation, which is suffering from the high manufacturing cost and difficulties to realize large area devices. To address these issues, all or partly solution-processed OLEDs offer an opportunity to
significantly lower the fabrication cost and also enable the application of large area devices and flexible substrates, thanks to its compatibility to roll-to-roll processing. However, relatively low efficiency is often a challenge for solution-processed OLEDs. To achieve high efficiency, hole injection/transport layers (HIL/HTL) and the charge blocking layers are usually incorporated to maintain charge balance and to confine the excitons in the emitting layer. Most solution processed OLEDs use PEDOT: PSS (polyethylene dioxythiophene :polystyrenesulfonate) as a hole injection material because of its high transparency, high work-function and high conductivity. However, PEDOT: PSS exhibits an acidic and hygroscopic nature, which induces the corrosion of ITO electrodes, resulting in the decrease of device performance lifetime. Therefore, much effort has been devoted to finding a new substitute for PEDOT: PSS. In this work, we develop a solution processed vanadium pentoxide (V2O5) as an alternative. The proposed approach can be easily processed under the simple conditions of room temperature and a water-free and solution-based process, which distinguish this approach from vacuum thermal evaporation or temperature annealing processes. OLEDs fabricated with V2O5 HIL exhibit a current efficiency of 64.3 cd/A, a power efficiency of 57.4 lm/W and an external quantum efficiency of 19.2% at the brightness of 100 cd/m², which are respectively 21, 23 and 31% higher to those fabricated with a conventional PEDOT: PSS HIL. Moreover, by substituting the problematic PEDOT: PSS with the inorganic V2O5, the operating voltage and maximum luminance of the OLEDs is also substantially improved. Our study demonstrates that the presented new approach can serve as a new and simple route for the emerging technologies of low-cost and large-scale organic optoelectronic devices.

Solar Photo-Crystallization in the Production of Thin-Film Solar Cells
Jesus Canistran Martínez, Laura Guerrero Martínez, Perla Yoloxóchitl García Ayala, Alessandra Beauregard León, M.T. Sanhanta Murri Nair and P. Karunakaran Nair; Universidad Nacional Autonoma de Mexico, Temixco, Mexico.

We present an innovative method of crystallization under concentrated sunlight of antimony sulfide selenide thin films in solar cell structure: F-doped SnO2 (FTO)/CdS/Sb2S3-Se3-x/C. Here, CdS n-window thin film of 90 nm in thickness, as well as the p-absorbers of Sb2S3-Se3-x thin films of 300 nm in thickness are produced by chemical deposition at 80 °C. Colloidal graphite paste is applied on the absorber films so as to define cell areas of ~0.25 – 1 cm². The absorber films require heating at 250 – 300 °C to transform them to crystalline phase, which till now required heating in a vacuum oven under nitrogen atmosphere. We report that under clear-sky condition, concentrated sunlight (115 – 215 suns) directed toward the absorber film by a glass lens 8.5 cm in diameter helps achieve this crystallization. The approach has the added advantage that it is a rapid thermal processing technique as well, which minimizes loss of volatile components of the absorber film (S and Se) when heated in conventional way. The absorption of concentrated sunlight at the absorber-electrode interface helps increase the temperature toward the crystallization temperature. The acrylic-based graphite paint also encapsulates the cell, thereby eliminating the need for a vacuum environment to prevent degradation of the cell through oxidation. Solar cell produced this way has open circuit voltage of 0.46 V, short circuit current density of 16 mA/cm² and conversion efficiency of 3 % at this stage. The deposition technique as well as the cell processing described here are low-capital intensive. Hence it offers an accessible alternative in the preparation of this type of solar cells.

ET11.12.25
Functional Prototype Modules of Chemically Deposited Antimony Sulfide Selenide Thin Films
Laura Guerrero Martínez, Perla Yoloxóchitl García Ayala, José Diego Gonzaga Sánchez, Alessandra Beauregard León, M.T. Sanhanta Murri Nair and P. Karunakaran Nair; Universidad Nacional Autonoma de Mexico, Temixco, Mexico.

Functional photovoltaic modules of 7 cm² in active area and open circuit voltage 3.3 V and 20 mW power capable of lighting blue-light emitting diode (LED) were prepared by chemical deposition. For this R & D, first a chemically deposited CdS thin film of 100 nm in thickness was prepared on a commercial F-doped tin oxide coated glass (FTO) of sheet resistance 7 Ω. On this, a thin film (300-350 nm) of antimony sulfide selenide was prepared by chemical deposition at 80 °C in two successive depositions lasting 7-8 h from solution containing potassium antimony tartrate, triethanolamine, ammonia (aq), thiourea, thiourea and selenourea. Graphite paste in acrylic base was painted on area 1 cm²; a total of 7 such area painted on each FTO-coated glass cut to 2.5 cm x 7.5 cm. Antimony chalcogenide thin films obtained from chemical deposition are amorphous in nature and they require heating at 270 – 310°C to crystallize them. In this work the heating was done at 300°C during 30 min in nitrogen ambient at 20 Torr. After these, the FTO coating was scribed using carbonic acid point; and the cells were demarked by etching. Colloidal silver paint was applied on the graphite electrode and on the FTO coating along the periphery. Current-voltage characteristics of the cells were measured using solar simulator under standard conditions as well as under the sun (925 W/m²) near mid-day at 24 °C. Average values of the cell parameters are presented: Voc= 0.47 V; Jsc= 18 mA/cm² and conversion efficiency, 3.9%.

Spray-Deposited CdS/PbS Solar Cell
Nagendra Dhakal1, Seth Calhoun1, Robert E. Peale1, Saiful Khondaker1 and Isaiah Oladeji2; 1University of Central Florida, Orlando, Florida, United States; 2Siism Thinfilms LLC, Orlando, Florida, United States.

We demonstrate photovoltaic action for a thin-film CdS/PbS heterojunction solar cell fabricated by aqueous spray deposition using earth-abundant elements as a potentially flexible, low-cost solar-cell technology. The structure comprises borofloat glass substrate, fluorine-doped tin oxide as transparent current collector, CdS window layer, and PbS absorber layer. Gold is deposited as ohmic contact to the PbS and light is incident through the substrate. The current-voltage curves in the dark are diode like with threshold voltage ~0.6 V. Under 1 sun illumination with 1.5 air-mass filter, the short circuit current density is ~ 4 microAmp/mm², the open circuit voltage is 0.14 V, the maximum power is ~ 150 nW/mm², and the fill factor is ~30%. The efficiency of these unoptimized first cells is ~0.01%.

ET11.12.27
Green Route Synthesized Copper-Zinc-Tin-Sulphide Nanocrystals for Heterojunction Solar Cells on Silicon Platform
Sudarshan Singh1, Ajit K. Katiyar1, Arup Ghoria2, Anupam Midya, Dipak K. Goswami1 and Samit K. Ray1, 2; 1Indian Institute of Technology Kharagpur, Kharagpur, India; 2’S. N. Bose National Centre for Basic Sciences, Kolkata, India.

Recently, the kesterite Cu2ZnSnS3 (CZTS), comprising earth-abundant and environmental-friendly elements, has been widely considered as the most promising material among the chalcogenide-based semiconductors for thin films photovoltaic (PV) applications. The colloidal CZTS quantum dots and nanocrystals (NCs) are potentially attractive candidates for low-cost PV cells and modules owing to their compatibility with solution processing techniques [1]. A novel, facile and environment-friendly synthesis route, at a relatively low temperature, has been developed to synthesize the CZTS nanocrystals. Natural, edible olive oil containing mainly oleic acid has been utilized as a solvent, which also acts as a capping agent to control the growth of nanocrystals. The synthesis of CZTS NCs inks were prepared at various centrifugation speeds obtained using ultrasonic techniques, and studied by means of their structural and optical characteristics. For the device demonstration, the quaternary nanocrystals ink prepared with different sized NCs have been integrated on n-silicon substrates by spin coating to fabricate the CZTS NCs/Si heterojunctions. The photovoltaic characteristics of the fabricated p-CZTS/n-Si heterojunctions using the synthesized colloidal quaternary NCs are demonstrated in detail. The study reveals that the CZTS nanocrystals having smaller diameter exhibits higher power conversion efficiency in comparison to the nanocrystals having the larger diameter. An improved minority carrier lifetime has been observed in open circuit voltage decay measurement for the CZTS/Si heterojunctions fabricated with smaller sized nanocrystals. Optical reflectance measurements show that the enhanced light scattering in smaller nanocrystals plays an important role in improved power conversion efficiency.
The one-step environmental friendly procedure for the production of CZTS NCs along with the demonstration of CZTS/Si photovoltaic cells implying the potential of earth-abundant and non-toxic CZTS in the nanostructured form integrated with the existing Si solar cell technology.

**Large-Area Flexible Perovskite Solar Cells with Outstanding Mechanical Durability**

Gunhee Lee1, Min-cheol Kim1, Yong Whan Choi2, Namyoung Ahn1, Daeshik Kang1, Hyun Suk Jung2 and Mansoo Choi1; 1Seoul National University, Seoul, Korea (the Republic of); 2Sungkyunkwan University, Suwon, Korea (the Republic of); 3Ajou university, Suwon, Korea (the Republic of).

With the development of wearable electronic devices, the importance of portable power sources has been highlighted. Recently, perovskite solar cells have become promising candidates for portable power sources due to their high power density, lightweight features and low temperature processing. However, there still exist problems in terms of performance and flexibility of large-area device, prior to practical uses of perovskite solar cells as a portable power sources. To improve flexibility of perovskite solar cells, many studies have previously been conducted to replace the brittle transparent conducting oxide (TCO) like indium tin oxide (ITO), but there was no deep understanding about the mechanical properties of perovskite materials themselves. In this work, we experimentally investigated their own mechanical properties and flexibility from cyclic bending test of perovskite-coated film, in which the applied stress is controlled depending on different thickness of the substrate and bending radius. By finding crack-free region of perovskite films, we successfully demonstrated flexible perovskite solar cells with high efficiency (17.03%) and the unprecedented flexibility, sustaining its initial power conversion efficiency (PCE) after 10,000 cycles of bending at 0.5 mm bending radius. Finally, we fabricated large-area flexible perovskite solar cells without TCO, leading to the best PCE of 13.6% (cell size, 1.2 cm²). The large-area device showed outstanding flexibility as well.

**Bringing III-V Photovoltaics Down to Earth with Dynamic-Hydride Vapor Phase Epitaxy**

III-V semiconductors are the gold standard of photovoltaic materials. They have the highest demonstrated conversion efficiencies, and they can be very light, thin, and flexible. III-V devices are also straightforwardly extendable to multijunction structures for even higher efficiencies. What III-Vs are not, however, is cheap. Much of the cost of III-V deposition comes from the expensive precursors used in the incumbent metalorganic vapor phase epitaxy (MOVPE) process, the inefficiency with which they’re used, and the low-throughput of traditional batch-style growth reactors. This leads to costly devices that are only prevalent in somewhat niche markets, including space power.

Here, we describe our recent development of dynamic hydride vapor phase epitaxy (D-HVPE), an extension of the standard HVPE process that has been known for decades, but unlike traditional HVPE allows for the deposition of relatively complex heterostructures and devices. HVPE uses much less expensive elemental source material, lower hydride overpressures, and lends itself to high-throughput, in-line deposition. These features project to make III-V deposition costs by D-HVPE much lower than is possible today.

The challenge is to use this low-cost growth platform to create III-V devices that rival the excellent performance of MOVPE-grown solar cells. There is little point in cheap III-V devices if they don’t maintain the conversion efficiency advantage that makes them so attractive in emerging markets such as electric vehicles, device charging, and other space-constrained applications. Fortunately, D-HVPE produces bulk material and interface quality that is nearly identical to MOVPE-grown material. We will give a general overview of the D-HVPE development of single-junction GaAs and GaInP devices, tunnel-junction interconnects, and the world’s first HVPE-grown multijunction solar cells. We will also describe the next steps for this technology as we attempt to bring photovoltaics that are largely constrained to space applications down to Earth.

9:00 AM ET11.13.01

**Engineering Light Absorption, Carrier Collection and Recombination in Atomically-Thin Photovoltaics**

Joeson Wong1, Deep M. Jariwala1,2, Artur Davoyan1, Giulia Tagliabue1, Michael Kelzenberg1, Joseph S. DuChene1, Matthias H. Richter1, Kevin Tat1, Michelle Sherrott1,2, Alexandra Welch1, Wei-Hsiang Lin1 and Harry A. Atwater2; 1California Institute of Technology, Pasadena, California, United States; 2Electrical Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The class of layered van der Waals (vdW) materials, materials where their weakly-bonded layered structure provides intrinsically passivated surfaces along the basal plane, allows one to mechanically cleave these materials to produce a single monolayer of atoms. Graphene, cleaved from graphite, was the first member discovered in this layered two-dimensional (2D) family. The group of layered vdW materials now span nearly every material class imaginable, from insulators and semiconductors to superconductors and topological insulators. Furthermore, because of their weak out-of-plane van der Waals interaction, they can be mechanically stacked to form a high-quality heterostructure between the most disparate materials, allowing one to design arbitrary heterostructures with a vast array of unexplored properties and applications.

An interesting member of this 2D family for photovoltaic applications is the semiconducting transition-metal dichalcogenides (TMDCs), compounds of the form MX₂, where M is a transition metal and X is a chalcogen (e.g. sulfur, selenium, or tellurium). TMDCs have some of the highest absorption coefficients of photovoltaic materials, and in their monolayer form, can be passivated in a way to reach nearly perfect radiative efficiency. Moreover, they offer a wide range of bandgaps (~1.1 – 2.0 eV), which can be tuned through quantum confinement effects and chemical alloying. Combined with their inherent stability and use of earth-abundant metals, vdW heterostructures of TMDCs are therefore attractive candidates for photovoltaic applications.

A conventional photovoltaic device that has high efficiency must maximize three figures of merit: optical absorption, subsequent carrier collection, and high photovoltage. Through proper nanophotonic engineering and device design, we show that atomically-thin vdW materials can achieve these three...
First, we experimentally show that in ultrathin (~10 nm) transition metal dichalcogenides (TMDs), it’s possible to achieve near-unity (>90%) broadband absorption in the visible spectrum. We therefore utilize this optical geometry along with an optimized carrier collection scheme (IQE > 70%) to create a device with record photocurrent density (EQE > 50%) in these materials. Second, we modified the recombination dynamics in these materials through the use of carrier selective contacts, leading to record values of open circuit voltage (Voc > 700 mV). Lastly, we present an outlook for large-area integration and schemes to further enhance the efficiency in these atomically-thin devices.

Microscopy Reveals the Role of Boundaries in Single-Crystalline-Like GaAs Solar Cells Grown on Flexible Metal Substrates Jonathan Pohlawsky\(^1\), Pavel Dutta\(^2\), Wei Guo\(^3\), Harvey Guthrey\(^4\), Monika Rath\(^5\), Devendra Khattawar\(^6\), Carlos Favela\(^7\), Sicorn Sun\(^2\), Chuanze Zhang\(^2\), Bo Yu\(^2\) and Venkat Selvamanickam\(^2\); \(^1\)Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; \(^2\)University of Houston, Houston, Texas, United States; \(^3\)National Renewable Energy Laboratory, Golden, Colorado, United States.

Photovoltaic (PV) devices based on single-crystalline GaAs semiconductors hold the world record for the highest efficiency for a homojunction solar cell. However, the substrates used for these materials are expensive making GaAs based solar cells cost-prohibitive for mainstream terrestrial use, which limits the device applications. A unique method to grow GaAs devices has been developed using roll-to-roll processing on a flexible metal substrate. In addition to decreasing costs, this method allows for GaAs devices to be flexible, which is of interest when considering transportability. In addition to solar cells, GaAs devices made using this process can be used for many other applications. The power conversion efficiencies (PCE) of the flexible GaAs solar cells were measured to be approximately 10%. Although a 10% PCE is about three times less than the world record GaAs solar cell, this is a good preliminary device using roll-to-roll processing. To better understand the efficiency limits, films and devices with different doping concentrations were tested using a suite of microscopy techniques including electron backscatter diffraction (EBSD), electron beam induced current (EBIC), probe tomography (APT), and cathodoluminescence (CL). The films showed a unique property in that the mobility increases with increasing dopant concentration, which has been better understood after the microscopy experiments. The EBSD results show that the GaAs films are highly oriented in the [001] direction, however, there is evidence of slight orientation deviations (<1°) between ~1 μm-sized features. The degree of orientation deviation and the presence of twin boundaries between grains has been shown to increase with dopant concentration. Correlative EBSD and EBIC cross-sectional measurements show a decreased EBIC signal in the grain boundary (GB) regions. Higher rotational angles (still <1°) have been correlated to a lower EBIC signal, which is indicative of recombination centers that are detrimental to the device performance. CL measurements corroborate the EBSD results showing defect emission in the GB regions. APT has shown C accumulation in the GB regions, which is potentially responsible for recombination in these regions. Overall, the results suggest that the low angle GBs (<1°) do not benefit the device and may be detrimental in their current state. Post-deposition heat treatments (HT), such as the CdCl\(_2\) HT for CdTe based solar cells, have been shown to significantly improve other solar cell technologies by passivating or activating GBs. The microscopy results suggest that a GB passivating treatment needs to be developed for these flexible GaAs solar cells to significantly increase their efficiency. A process that removes carbon from the GBs may be a good starting point for improving these devices. This research was supported by ORNL’s Center for Nanophase Materials Sciences (CNMS), which is a U.S. DOE Office of Science User Facility.

9:30 AM ET11.13.03
Epitaxy-Free GaAs Nanowire Photovoltaics Phillip Jabelka, Wen-Hui Cheng, Rebecca Glaudell and Harry A. Atwater; California Institute of Technology, Pasadena, California, United States.

We report on an unconventional, epitaxy-free GaAs photovoltaic cell process, designed to enable scalable manufacturing of III-V solar cells. Scalability places constraints on both the overall cost per Watt at the cell level, and the fraction of cost that related to capital equipment expense (capex), which must be minimized for large-scale production. Thin-film III-V compound semiconductors are promising for next generation photovoltaics because of their ideal bandgaps, high radiative efficiencies and mature development. However, almost all previously proposed III-V photovoltaics utilize epitaxial growth to define the cell and the high capital equipment and supply costs of epitaxy currently preclude the economic viability of these cells. In order to leverage the mature development of III-V devices without incurring the capex penalty of epitaxial growth, we have developed epitaxy-free processes for synthesis of GaAs solar cells where III-V nanostack arrays are etched using liquid-phase anisotropic etching, and mechanically exfoliated from a bulk III-V crystal, enabling many cells to be generated from a bulk crystal source material. Electron and hole selective contacts and passivation materials are then grown using low-temperature, non-epitaxial techniques.

Because low cost, epitaxy-free designs do not permit use of standard epitaxially-grown III-V heterojunctions and window layers, we first developed a coupled optoelectronic model to understand the design space of the proposed solar cell using nontraditional heterojunction carrier-selective contacts. Using this model, we determined the optimal design to be a radial junction and discovered the absolute necessity of wide-bandgap carrier selective contacts due to the high density of photogenerated carriers throughout the nanowire. Simulations indicate the potential for an optimized GaAs nanowire solar cell using SnO\(_2\) and CuSCN heterojunction contacts to operate as a single junction cell with 32% efficiency with Voc = 1.13 V and Jsc = 32.3 mA/cm\(^2\).

We have also performed proof-of-principle experiments for each fabrication step of our epitaxy-free cell processes. For GaAs cells, we have developed a metal-free wet chemical etch for defining nanostructures, and have also exfoliated them from a host wafer in a polymer handle. In addition, we have demonstrated very high quality passivation of planar 100 GaAs, with external radiative efficiencies implying a planar Voc of 970 mV, near the theoretical limit of bulk GaAs.

We have also taken first steps to extend this approach to synthesis of epitaxy-free In\(_n\)P solar cells. Highlights to date for In\(_n\)P include developing a plasma etching recipe for defining In\(_n\)P nanowires and successful exfoliation and fabrication of complete nanowire cells from their substrates by embedding them in a polymer handle. In addition, a nanowire-on-wafer In\(_n\)PTiO\(_x\)heterojunction cell exhibits a 70% increase in photocurrent over its planar counterpart.

9:45 AM ET11.13.04
Interfacial Misfit Growth of GaSb on GaAs by MOCVD for Multijunction Photovoltaics Stephen Polly, Emily Kessler, George Nelson and Seth Hubbard; Rochester Institute of Technology, Rochester, New York, United States.

The long-standing leader in multijunction photovoltaic technology consists of a three junctions made from InGaP, (In)GaAs, and Ge all grown lattice matched to germanium. While convenient due to the relative ease of growth, the bandgaps of these materials are not ideally matched based on the detailed balance for absorption from the solar spectrum which can be improved through the use of a wider band gap bottom cell. One method of realizing a higher band gap material based on the III-V material design spaces through thick metamorphic grading from the Ge lattice constant to 1 eV InGaAs, which must be grown inverted to limit the effects of the inevitable higher threading dislocation density created by this method. In this work, an alternate method is used relying on the large lattice mismatch between GaAs and GaSb (7.8%) to induce an interfacial misfit array, locking 90° dislocations in a thin layer which do
not propagate in the growth direction. This method allows for direct heteroepitaxy of GaSb and related direct bandgap materials on GaAs and InGaP heterostructures without the need for a thick grading buffer, enabling a wider range of more cost-effective inverted multijunction photovoltaic devices. Solar cells were grown and fabricated investigating the growth of GaSb single junction solar cells on GaAs substrates using the IMF technique as a function of growth conditions including metalorganic precursor type. Device results including 1-sun light-IV, quantum efficiency, and minority carrier lifetime will be discussed and compared against GaSb homoepitaxial devices, as well as the integration and performance of multijunction devices using this method.

Demonstrating the Hot Carrier Solar Cell—The Ultimate Thin Photovoltaic Device Nicholas Ekins-Daukes1, James Dimmock2, Paul Stavrinou3, Huiyun Liu3, Mattias Kauer4 and Jiang Wu4; 1School of Photovoltaic & Renewable Energy Engineering, University of New South Wales, Sydney, New South Wales, Australia; 2Sharp Laboratory Europe, Oxford, United Kingdom; 3University of Oxford, Oxford, United Kingdom; 4University College London, London, United Kingdom.

The hot carrier solar cell has the potential for high efficiency and has recently been demonstrated experimentally in using both semiconductor and metallic absorbers. The latter is particularly interesting from the viewpoint of thin solar cells since a metal layer of only a few tens on nanometers can almost completely absorb broadband sunlight. Experimental hot carrier IV data has been measured from a chromium absorber deposited onto a GaAs based tunnel diode. Importantly the data confirm that the photo current arises from a hot carrier population as opposed to internal photoemission; the distinction being important since only a hot carrier device can attain high power conversion efficiency. The prospects for the technology as a realistic PV device will be discussed together with alternative applications such as photon energy resolving photodetection.

11:00 AM ET11.14.02
High Efficiency Infrared PbS Colloidal Quantum Dot Solar Cells with 50% EQE at 1.55 μm Haibin Wang1, Shoichiro Nakao1, Takaya Kubo1, Hidenori Saito2, Shinichi Magaino2, Katsuhiko Takagi2, Tetsuya Hasegawa1, Jotaro Nakazaki1 and Hiroshi Segawa1; 1The University of Tokyo, Tokyo, Japan; 2Kanagawa Institute of Industrial Science and Technology, Kawasaki, Japan.

Colloidal quantum dots (CQDs) have attracted much attention as light absorbers and carrier transporters for next-generation solar cells because mainly of QD-size dependent bandgap tunability, solution process compatibility and so on. Among various types of CQD solar cells, hetero-junction CQD solar cells constructed by combining PbS CQDs and ZnO have been widely studied, and the record high efficiency of 12% was reported [1]. Fundamental studies on CQD solar cells based on a new concept such as multiple exciton generation, hot-carrier concept, and multi-junction concept are also carried out to overcome the single junction efficiency limit (~30% under one-sun illumination). In fact, III-V semiconductors based multi-junction solar cells only have achieved a power conversion efficiency well over the single-junction limit. However, the solar cells rely heavily on high cost solar cell technology, which makes it difficult for the solar cells to be susceptible of wider application. While the size-dependent bandgap tunability and solution process compatibility unique to CQDs are suitable properties to construct low-cost multi-junction solar cells.

Here we constructed PbS colloidal quantum dot/ZnO nanowire solar cells, with the aim of developing solution-processed bottom subcells for multi-junction solar cells. Spatially-separated carrier pathways formed by ZnO nanowires together with highly infrared-transparent conductive oxide (Ta-doped SnO2; TTO) electrodes were successfully used to enhance the spectral sensitivity in the infrared region [2, 3]. Junction solar cells. The TTO-solar cells reached an even higher EQE of 50% at 1.55 μm due mainly to high infrared-transparency of the TTO electrode. This EQE value is, to the best of our knowledge, the highest value ever reported on the solution-processed solar cells. The results that we have obtained indicate that the solution-processed PbS CQD/ZnO NW solar cells are one of the promising candidates for the bottom subcells to construct flexible, low-cost multi-junction solar cells.

11:15 AM ET11.14.03

Colloidal quantum dots are promising materials for flexible solar cells because they have a large absorption coefficient ranging from visible to infrared wavelengths, a band gap that can be tuned across the solar spectrum, and compatibility with solution processing. However, the performance of flexible solar cells can be degraded by the loss of charge carriers due to recombination pathways that exist at a junction interface as well as the strained interface of the semiconducting layers. Therefore, fundamental strategies for actively controlling the junction properties are required to boost charge extraction and reduce the recombination of photo-generated charges. In this regard, the modulation of charge carrier transport using the piezoelectric effect is one of the effective ways to resolve the inherent material and structural defects. Towards this end, we have employed a porous piezoelectric poly(vinylidenefluoride-trifluoroethylene), PVDF-TrFE) polymer layer between a zinc oxide (ZnO) ETL and a PbS QD heterojunction in a flexible QDSC. Through the active control of strain/stress of the flexible form factors, the inserted porous PVDF-TrFE layer generates a piezoelectric potential which modulates the junction properties and consequently changes the behavior of the charge carriers. As a result of the modulated electric field at the junction, the photo-generated charges are effectively extracted along with reduced radiative recombination, which results in a 38% increase in the current density and a concomitant increase of 37% in the power conversion efficiency of the flexible QDSC.

11:30 AM ET11.14.04
The cadmium telluride (CdTe) thin film solar cells have attained over 20% efficiency with low-cost fabrication. However, the high efficiency CdTe devices have been achieved by increasing the photo-generated current by changing the traditional window layer (CdS) of CdTe to a wider bandgap material with better band alignment. The open circuit voltage ($V_{oc}$) remains below the theoretical limit due to the barrier at the back of the device due to the deep valence band edge of CdTe (~5.7 eV). $V_{oc}$ can be increased by adding a buffer layer between CdTe and the back electrode due to a decrease in band banding and reducing carrier recombination at the back surface. Previous modelling work shows that adding a Tellurium (Te) layer at the back contact of CdTe reduces band banding, which leads to higher performance CdTe thin film solar cells. Recently, we developed a way to form a Te layer at the back surface of CdTe by interacting the surface of CdTe sample with methylammonium iodide (CH$_3$NH$_3$I, MAI) solution followed by a mild thermal treatment. The MAI treatment is more effective than evaporated Te at the back of CdTe due to reducing the interface defect states between CdTe and the Te buffer layer. This leads to increasing the efficiency up to 10% compared to standard Cu/Au back contact. To further reduce the carrier recombination at the back surface, we need to increase the barrier for minority carrier (electrons) and reduce the barrier for majority carrier (holes) at the back surface. This can be achieved by adding a higher bandgap layer to act as an electron reflector (ER). Here, we demonstrate the use of Zinc Telluride (ZnTe) as an electron reflector at the back surface of CdTe devices with a Te layer between CdTe/ZnTe and ZnTe/metal interfaces to break down the large Schottky barrier at the CdTe/metal interface into four smaller ones. We show that this is an effective method to reduce the carrier recombination at the back surface despite not using Cu. The $V_{oc}$ of Cu-free devices with Te/ZnTe/Au back contact are notably higher than the CdTe device fabricated with standard Cu/Au back contact.

**SESSION ET11.15: Organic Photovoltaics III**

**A Novel Approach to Multi-Junctions—The Heterojunction Bipolar Transistor Solar Cell**

*Elisa Antolin, Pablo García-Linares, Marius Zehender and Antonio Martí*

**Instituto de Energía Solar, Universidad Politécnica de Madrid, Madrid, Spain.**

Conventional multi-junction solar cells achieve unparalleled efficiencies at the price of a complex structure, high fabrication cost and low spectral tolerance. Recently a new device has been proposed called three-terminal heterojunction bipolar transistor solar cell (HBTSC) which has the same efficiency limit of a double-junction solar cell but consists of a much simpler structure with no tunnel-junctions or isolating layers. Being a three-terminal device, it enables higher spectral tolerance than series-connected multi-junction cells through the engineering of module interconnection.

The HBTSC comprises only three main active layers. These layers may be called emitter, base and collector since they resemble the structure of an npn (or pnp) transistor. However, the operation of this device is antagonistic to the operation of a transistor. In the HBTSC the emitter and base terminals form the top sub-cell and the base and collector terminals form the bottom sub-cell. For the device to achieve a high efficiency it is necessary that the voltage of the top sub-cell exceeds the voltage of the bottom sub-cell even though they share the base layer. In this talk we will present the theoretical model of the device and will show how that situation can be realized if the emitter injection efficiency approaches zero. One of the most interesting aspects of the HBTSC model is that biasing one sub-cell can improve the conversion efficiency of the other sub-cell. We will analyze the impact of the base layer design on the HBTSC operation and its effect on how the sub-cell efficiencies are interrelated.

We have produced proof-of-concept HBTSC prototypes based on epitaxial AlGaAs/GaAs structures. We will show experimental proof that the two sub-cells can be operated at their respective maximum power points, with the voltage of the top sub-cell exceeding the voltage of the bottom sub-cell. The operation of five HBTSC assembled in a prototype module with two-terminal output will also be demonstrated.

Finally, we will describe possible architectures to implement the HBTSC concept with low-cost technologies. These proposals will include a design comprising a perovskite absorber and another one based on the use of nanowires.

**Enhancing the Performance of Polymer Bulk Heterojunction Solar Cells by Large Sized Gold Nanoparticles via Near- And Far-Field Plasmonic Coupling**

*Min Seok Lee, Dong Hyun Kim, Justin Jessuraj Periyayagam, Hassan Hafeez and Seung Yoon Ryu*  

**Korea University, Sejong city, Korea (the Republic of).**

Nobel metal nanoparticles are well-known to unveil plasmonic coupling with molecular excitons to enhance the performances of opto-electronic devices especially light emitting diodes and solar cells. The higher momentum associated with metal surface plasmons can alter the lifetime of molecular excitons, thereby the efficiency increased in respective devices. However, this kind of coupling is stronger within the near-field of surface plasmons and is highly dependent on distance between metal surface to exciton and also on the size of metal nanoparticles.

In this scenario, we have investigated the effect of incorporating large size gold nanoparticles (AuNPs) in polymer bulk hetero junction (BHJ) solar cells. In addition, we exclusively studied the near- (Localized surface plasmonic resonance; LSPR) and far-field (scattering) interaction of AuNPs plasmons with BHJ excitons through theoretical and experimental tools. To clearly understand the efficiency improvement tactics, we have fabricated three BHJ solar cells containing three different donor active materials with [6,6]-phenyl-C$_{61}$,1,3-butyric acid methyl ester (PC$_{61}$BM). AuNPs have been incorporated in BHJ solar cells through the poly(3,4-ethylenedioxithiophene):poly(styrene sulfonate) (PEDOT:PS) solution as hole injection layer (HIL). To understand size dependent behaviors, AuNPs with sizes 71, 80, 87, 103 nm were inserted in PEDOT:PS and employed as HIL for the two polymer solar cells containing PBDTT-T:C$_{60}$,PC$_{61}$BM and PTB7:PC$_{61}$BM. Interestingly, smaller size AuNPs (equal or less than 80 nm) very active in establishing near-field interaction with excitons, whereas bigger size (~80 nm) particles were found to produce superior far-field scattering. By monitoring the lifetime of the excitons through time resolved photoluminescence found to be beneficial to identify the near- and far-field coupling. In other words, the AuNPs (<87 nm) showing lifetime lesser than the reference were considered to demonstrate near-field (LSPR) effect and AuNPs (>87 nm) revealed longer lifetimes indicating far-field (scattering) effect. At 87 nm, AuNPs yielded a fair combination of near-field coupling along with far-field scattering resulting in enhanced absorption and dissociation of photons in BHJ. Therefore, 87 nm found to be an optimum (maximum) size for AuNP to attain superior efficiency in BHJ solar cells through the cultivation of near- and far-field interactions. Further, full-
wave simulation (COMSOL) investigations were employed to reveal the plasmonic interaction and electric field distribution of AuNPs respectively. These findings are coincided with the experimental results of BHJ solar cell performances.

Side Chain Engineering of Polymer Donors and Non-Fullerene Small Molecule Acceptors for Organic Photovoltaics Micaela Matta, Tobin J. Marks and George Schatz; Chemistry, Northwestern University, Evanston, Illinois, United States.

Organic bulk-heterojunction (BHJ) solar cells made of polymeric donors and small molecule non-fullerene acceptors (NFA) have been the subject of interest due to their record-high efficiencies.[1] Tremendous effort is being directed at the development of novel donor and acceptor building blocks, and the optimization of energetics and morphology of donor/acceptor systems.

In order to make these highly conjugated materials soluble and thus processable at low cost, the presence of side alkyl chains is fundamental. However, their role in determining key morphological and structural properties in both donors and acceptors has been often overlooked by the organic photovoltaics (OPV) community.

Our work investigates how the length of alkyl side chains influences the properties of some of the best performing donors and NFAs available to date. The polymer donor PBTZF4[2] was characterized using a combination of molecular dynamics (MD) simulations, X-ray scattering and spectroscopic techniques. MD provided a rationalization for the observed trends among a series of PBTZF4-R devices with alkyl chains R of different length, elucidating the subtle equilibrium between the conjugated backbone rigidity and the folding enhancement provided by longer alkyl chain substituents. The results established a relationship between the single polymer chain behavior, its aggregation in solution and the subsequent formation of domains in the BHJ.[3] This study shows how side chain engineering can be used to fine tune the BHJ morphology without significantly changing the HOMO-LUMO levels of polymer backbone.

Moreover, a series of ITIC-derived[4] NFA having alkyl chain substituents of different length[6] was also investigated by means of quantum chemical calculations, MD simulations, X-Ray diffraction and other spectroscopic measurements. It emerges that the alkyl chain length has a dramatic effect on OPV performances. Side chains effectively mediate intermolecular interactions by preventing excessive aggregation and crystallization of the acceptor while allowing efficient π-stacking in the amorphous and semi-crystalline domains.

In summary, this work highlights the importance of side chain engineering as a strategic tool for OPV morphology control, where MD simulations have been instrumental in providing a correlation between molecular-scale properties and device performances.

Enhanced Photovoltage and Short Circuit Current Density for the Polymer:Fullerene Solar Cells Using Individual Bis-PCBM Isomers Xueyan Hou1,2, Jun Yan1, Xingyuan Shi3, James McGregor1, Jenny Nelson2 and T. John S. Dennis1; 1School of Physics and Astronomy, Queen Mary University of London, London, United Kingdom; 2Physics and Centre for Plastic Electronics, Imperial College London, London, United Kingdom; 3SPECIFIC, Swansea University, Swansea, United Kingdom.

It has been a longstanding goal to enhance the power conversion efficiency (PCE) of polymer donor: fullerene solar cells by tuning the acceptor energy levels to raise the open-circuit voltage ($V_{oc}$). Previous work showed that replacing the most commonly used fullerene acceptor, [6,6]-phenyl-C61-butyric acid methyl ester (PCBM), with its bis-adduct raised the $V_{oc}$ of poly(3-hexylthiophene-2,5-diyl) (P3HT):fullerene solar cells by ~100 mV and increased the PCE. The increased $V_{oc}$ was assigned to the higher lying LUMO energy of the bis adduct. However, when combined with other polymers, higher fullerene adducts tend to reduce PCE via losses in short-circuit current density ($J_{sc}$) and fill factor (FF) due to poor electronic properties. This is assigned to a combination of (i) energetic disorder, which results from varying frontier orbital levels of the individual isomers in the mixture that is normally produced; (ii) poor molecular packing leading to lower electron mobility. Recently, we separated all 19 bis-PCBM isomers from the as-produced mixture by peak-recycling HPLC and identified their structures by a combination of 13C NMR, UV-Vis spectroscopy and HPLC retention time analysis. LUMOs of all isomers lie above that of PCBM, with the highest lying about 100 meV higher than that of the mixture and 200 meV above PCBM. The pure isomers should contain much reduced disorder due to the absence of multiple isomers and be capable of crystallising. Therefore, improved electronic properties and solar cell PCE may be expected.

In this work, I will present a comprehensive analysis of the solution- and film-based energy levels, solubility and crystallinity of different bis-PCBM isomers. I will present the performance of devices when blended with different polymer donors of different crystallinity together with an analysis of the $V_{oc}$, $J_{sc}$ and transport properties. For example, $V_{oc}$ as high as 1.13 V was observed for some isomers along with a net increase in PCE. The pure isomer with a certain molecular structure can help us understand the intrinsic electronic properties of the higher fullerene adducts more clearly without the disorder of an isomer mix. Finally, I will give some suggestions for the synthetic routes to achieve particular higher adduct fullerenes whilst avoiding the disorder due to multiple isomerism.

backsheet product produced through an alternative process to the traditional lamination process, which uses adhesives and solvents in the production of multi-layer backsheets. Instead, they use coextrusion technology to produce their novel multilayer polymeric backsheet. Their current product, PhotoMark®Reflections™, is a 5-layer film that does not contain PET or fluoropolymers, but rather a proprietary polyamide-ionomer alloy coupled with polyolefin and amide layers. The primary purpose of this research was to compare the performance of Tomark-Worthen’s coextruded backsheet films with the current industry standard films and determine modes of failure. Infrared spectroscopy (FTIR) and Scanning Electron Microscopy (SEM) were used in order to: assess the severity of degradation and determine the mechanism degradation after extensive exposure to damp heat and ultraviolet (UV) radiation. Spectroscopy and microscopy results indicate high stability of PhotoMark®Reflections™after exposure to these severe accelerated weathering conditions. Since the layers of the backsheet are adhered in the coextrusion process as opposed to the traditional use of adhesives, the interlayer bond strength of various backsheet samples was tested via ASTM D903-98. The results obtained from ASTM D903-98 show that Tomark-Worthen’s PhotoMark®Reflections™coextruded films have an interlayer adhesion strength 6.5 times greater than that of the current industry standard. Additionally, several backsheet samples were exposed to harsh hydrolysis conditions in a Highly Accelerated Stress Test (HAST) common to the solar industry. Current industry standard and competitive films experienced dramatic degradation and loss in tensile properties as a result of the HAST, while Tomark-Worthen’s PhotoMark®Reflections™showed minimal degradation.

This tutorial will be divided into two parts. In the first part, the instructor will introduce advanced synchrotron X-ray techniques, focusing on latest developments in coherent X-ray scattering to image defects in solids. In the second part, the instructor will introduce electronic-structure methods, focusing primarily on the latest advances in Quantum Monte-Carlo techniques, with concrete examples on computing different types of properties in solids, relevant for energy materials.

1:30 PM
Advances in Coherent X-Ray Scattering Techniques Dillon D. Fong; Argonne National Laboratory

Synchrotron X-ray methods allow observation of the structure and behavior of materials in their native environment or while undergoing transitions. The continuing advances in X-ray sources are leading to considerable improvements in the coherence of the beam and will eventually enable direct imaging of a material in a non-destructive fashion with atomic-scale resolution. In this tutorial, we will discuss the application of different synchrotron X-ray techniques to the study of materials, with a focus on imaging defects and investigating real-time defect behavior. Examples of current and future experiments exploiting coherence will be provided.

3:00 PM BREAK

3:30 PM
Advances in Quantum Monte Carlo Methods for Solids Luke Shulenburger; Sandia National Laboratory

Predicting properties of materials for energy applications, such as batteries, fuel-cells and photovoltaics, often stresses the capabilities of current electronic structure techniques, such as Density Functional Theory. This tutorial will initially give a broad overview of electronic-structure methods that are used to compute such properties, focusing on their strengths and weaknesses. It will then give a deep dive into the state-of-the-art of Quantum Monte-Carlo techniques as applied to the condensed phase. Concrete examples will be shown from recent calculations pertaining to the properties of functional materials.

1:30 PM *ET12.01.01
The Versatility of Mesoscopic Solar Cells Anders Hagfeldt; ISIC, EPFL, Lausanne, Switzerland.

In our work on solid-state dye-sensitized solar cells (ssDSC) we have recently shown that copper phenanthroline complexes can act as an efficient hole transporting material. We prepared ssDSCs with a novel organic dye WS-72 and \([\text{Cu(tmbpy)}]_{2}^{2+}\) as redox system and achieved record power conversion efficiencies for ssDSCs of 11.7%. Our best DSC efficiency of 13.1% for a liquid Cu-complex electrolyte is achieved by the discovery that the PEDOT-based counter electrode can be directly contacted with the dye/TiO₂ photoanode. Thus, there is no space between the two electrodes minimizing diffusion limitations and fill factors up to 0.8 is achieved.

In our work on perovskite solar cells (PSC) we have achieved efficiencies above 22% with a mixed composition of iodide/bromide and organic and inorganic cations. With the use of SnO₂ compact underlayers as electron acceptor contacts we have constructed planar perovskite solar cells with a hysteresis free efficiency above 20%. Through the compositional engineering larger perovskite grains grown in a monolithic manner are observed and reproducibility and device stability are improved. With regards to lifetime testing, we have shown a promising stability at 85 °C for 500 h under full solar illumination and maximum power point tracking (95% of the initial performance was retained). Recently, we have also commented on the standardization of PSC aging tests.

2:00 PM ET12.01.02
Active Materials and Interfaces for Stable Perovskite Solar Cells Antonio Abate; Helmholtz Berlin, Berlin, Germany.

Halide perovskites are quickly overrunning research activities in new materials for cost-effective and high-efficiency photovoltaic technologies. Since the first demonstration from Kojima and co-workers in 2009, several perovskite-based solar cells have been reported and certified with rapidly improving power conversion efficiency. Recent reports demonstrate that perovskites can compete with the most efficient inorganic materials, while they still allow processing from solution as a potential advantage to deliver a cost-effective solar technology. Compare to the impressive progress in power conversion efficiency; stability studies are rather weak and often controversial. An intrinsic complication comes from the fact that the stability of perovskite solar cells is strongly affected by any small difference in the device architecture, preparation procedure, materials composition and testing procedure. In the present talk, we will focus on the stability of perovskite solar cells in working condition. We will discuss a measuring protocol to extract reliable and reproducible ageing data. We will present new materials and preparation procedures, which improve the device lifetime without giving up on high power conversion efficiency.

2:15 PM *ET12.01.03
Role of Functional Defects in Cu₂ZnSnS₄ Solar Cells Sai Gautam Gopalakrishnan, Kuang Yu and Emily A. Carter; Princeton University, Princeton, New Jersey, United States.

Cu₂ZnSnS₄ (CZTS)-based solar cells, which are based on the kesterite structure of CZTS, constitute an inexpensive, beyond-Si photovoltaic (PV) technology. However, practical CZTS cells often suffer from low open-circuit voltage and poor efficiency. In the first part of the talk, we explain the fundamental origins of poor performance in CZTS, namely disorder in the Cu and Zn sub-lattices caused by anti-site defects. Based on a cluster expansion model built on density functional theory (DFT) calculations, we find that a significant amount of lattice disorder can accumulate within the kesterite structure under typical synthesis conditions. Additionally, we find that Cu-vacancies can beneficially improve performance by reducing band gap fluctuations within bulk CZTS.

One pathway to reduce anti-site defect formation in CZTS is to employ isovalent dopants, such as Cd²⁺ and Ag⁺ for Zn²⁺ and Cu⁺, respectively, as suggested by previous experimental studies. Hence, in the second part of the talk, we focus on the effects of Cd- and Ag-doping within CZTS cells, based on our evaluation of the bulk stability, defect (and surface) energetics, and the electronic structure of doped CZTS using DFT-based simulations. Importantly, we find that Cd and Ag can increase efficiencies via contrasting mechanisms, depending on the dopant concentration and Cu-content available during synthesis. For example, we predict that Cd (Ag) stabilizes the lower (higher) band gap stannite (kesterite) structure at high concentrations. Similarly, we find that Cd does not influence the surface energetics of kesterite-CZTS, while Ag decreases the surface energies significantly, which would favor smaller particle sizes. Finally, we suggest the exploration of alternate abundant, non-toxic, isovalent dopants to improve the performance of CZTS.

2:45 PM ET12.01.04
Assessing the Role of Hydrogen in Fermi-Level Pinning in Chalcopyrite and Kesterite Solar Absorbers from First-Principles Calculations Joel B. Varley¹, Tadashi Ogitsu¹, Vincenzo Lordi¹, Kimberly Horsley², Alex DeAngelis² and Nicolas Gaillard²; ¹Lawrence Livermore National Laboratory, Livermore, California, United States; ²University of Hawaii, Honolulu, Hawaii, United States.

Understanding the impact of impurities in solar absorbers is critical to engineering high-performance in devices, particularly over extended periods of time. Here, we use hybrid functional calculations to explore the role of hydrogen interstitial (H⁺) defects in the electronic properties of a number of attractive solar absorbers within the chalcopyrite and kesterite families to identify how this common impurity may influence device performance. Our results identify that H⁺ can inhibit the highly n-type conditions desirable for several higher-band gap absorbers and that H⁺ incorporation could detrimentally affect the open-circuit voltage \(V_{OC}\) and limit device efficiencies. Additionally, we find that H⁺ can drive the Fermi level away from the valence band edge enough to lead to n-type conductivity in a number of chalcopyrite and kesterite absorbers, particularly those containing Ag rather than Cu. We find that these effects can lead to interfacial Fermi-level pinning that can qualitatively explain the observed performance in high-Ga content CIGS solar cells that exhibit saturation in the \(V_{OC}\) with increasing band gap. Our results suggest that compositional grading rather than bulk alloying, such as by creating In-rich surfaces, may be a better strategy to favorably engineering improved thin-film photovoltaics with larger-band gap absorbers.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and supported by the HydroGEN Advanced Water Splitting Materials Consortium, established as part of the Energy Materials Network under the U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, Fuel Cells Technologies Office.

3:30 PM *ET12.01.05
Defects in Polycrystalline Solar Cell Absorbers—Addressing the Materials Science Paradigm at the Nanoscale Mariana L. Bertoni; School of...
The behavior of solar cells is very often limited by inhomogeneously distributed nanoscale defects. This is the case throughout the entire lifecycle of the solar cell, from the distribution of elements and defects during solar cell growth as well as the charge-collection and recombination during operation, to degradation and failure mechanisms due to impurity diffusion, crack formation, and irradiation- and heat-induced cell damage. This has been known for a while in the field of crystalline silicon, but inhomogeneities are far more abundant in polycrystalline materials, and are the limiting factor in thin-film solar cells where grain sizes are often on the order of the diffusion length.

We will show that the high penetration of hard X-rays combined with the high sensitivity to elemental distribution, structure, and spatial resolution offers a unique avenue for highly correlative studies at the nanoscale. We will present results on CdTe and Cu(In,Ga)Se\(_2\)) where carrier collection is directly correlated to the compositional and structural properties of the material under a large variety of synthesis and operating conditions. The segregation of copper at the grain boundaries of both solar absorbers will be discussed in detail as well as the impact to carrier collection efficiency. Furthermore, the kinetics of copper segregation during growth and processing will be presented.

4:00 PM ET12.01.06
**Probing Defects in Solar Cell Materials Through Microscale-Resolved Tomography**

John M. Howard\(^1,2\), Elizabeth Tennyson\(^3,7\), Bernardo Neves\(^3,7\) and Marina S. Leite\(^1,2\); \(^1\)Department of Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; \(^2\)Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, Maryland, United States; \(^3\)Department of Physics, Federal University of Minas Gerais, Belo Horizonte, Brazil.

Our society’s pressing need for low-cost photovoltaics has triggered an incessant search for materials that can provide high-performance devices, with stable power conversion efficiency. From this class of materials, CIGS is a promising option, with world record efficiency > 22%. Yet, its open-circuit voltage is currently the limiting factor for higher performance. Here, we build a 3D tomography of the voltage response of CIGS solar cells by means of wavelength-dependent photovoltage measurements using confocal optical microscopy. Using only three wavelength-dependent photovoltage scans, we elucidate the spatial variation in the electrical behavior of CIGS devices and assign the voltage response to the top (10 nm thick), the middle (100 nm thick), and the bottom (1000 nm thick) of the thin film. We investigate four devices to compare the influence of their chemical composition and processing method on performance: CIS, Ag-CIS, CIGS with one-step deposition, and CIGS with 3-step deposition processes. We find that, in all cases, the middle section of the tomography map corresponds to the highest yield in voltage (~80% of the overall signal). The Ag-CIS device presents the highest voltage response (192 μV), in agreement with macroscopic measurements. These materials present photovoltage values that negatively contribute to the overall device performance, which is related to the non-radiative recombination centers caused by the boundaries composing the absorbing layers. Our paradigm paves the way for reconstructing the 3D electrical response (voltage and current) of a variety of energy harvesting systems, ranging from photoelectrochemical devices to nanostructured catalysts and perovskite solar cells.

4:15 PM ET12.01.07
**The Role of Hydrogenation on Defect Passivation and Enhanced Performance of GaInNAs Solar Cells**

Anmir Kaphle\(^1\), Gang R. Neupane\(^1\), Vincent R. Whiteside\(^2\), Collin R. Brown\(^2\), Khalid Hassain\(^1\), Mohamed A. Khalifou\(^1\), Mathieu Leroux\(^4\), Ian Sellers\(^2\) and Parameswar Hari\(^7\); \(^1\)Physics and Engineering Physics, Univ of Tulsa, Tulsa, Oklahoma, United States; \(^2\)Homer L. Dodge Department of Physics and Astronomy, The University of Oklahoma, Norman, Oklahoma, United States; \(^3\)Amethyst Research Inc, Ardmore, Oklahoma, United States; \(^4\)CRHEA-CNRS, Valbonne, France.

In this study, we present recent results that show the enhanced performance of GaInNAs solar cells by passivating the defects using a UV-activated hydrogenation process. We have studied four cells, a reference cell with no hydrogenation and three cells with low (0.1×10\(^15\) atoms/cm\(^2\)), medium (0.5×10\(^15\) atoms/cm\(^2\)), and high (1.1×10\(^16\) atoms/cm\(^2\)) level of hydrogen incorporation. Previous work has indicated this process improves the performance of a GaInNAs solar cell by a factor of three through passivation of larger nitrogen-nitrogen related complexes and defects [1]. Here, the capacitance-voltage analysis is used to further understand the nature of this passivation in improving solar cell performance. It will be shown that hydrogenation is very effective in enhancing the depletion width and lowering the background doping concentration via the passivation of non-radiative centers in the absorber region. For the reference cell, a narrow depletion width of 206 nm and background doping concentration of 1.7×10\(^18\) cm\(^{-3}\) was measured. As the hydrogen passivation level is increased to high, the depletion width increased to 768 nm, and this resulted in a decrease in background doping concentration to 2.0×10\(^17\) cm\(^{-3}\). We also analyzed the density of trap states using admittance spectroscopy for different levels of hydrogenation. It was observed that hydrogenation is effective for passivating the trap concentration from 7.4×10\(^17\) cm\(^{-3}\) to 8.7×10\(^16\) cm\(^{-3}\). However, the trap energy is almost constant at 0.30 eV for all the level of hydrogenation. Impedance measurements at different applied biases were also performed. Imp to investigate minority carrier lifetimes. The minority carrier lifetime increased from ~ 2 μs to ~ 6 μs as hydrogen passivation level increased from low to high.

**Ab Initio Defect Characterisation of Candidate Solar Absorber Sb:Se**

Christopher Savory\(^1,4\), Laurie Phillips\(^2\), Jon Major\(^3\) and David O. Scanlon\(^1,3,4\); \(^1\)University College London, London, United Kingdom; \(^2\)University of Liverpool, Liverpool, United Kingdom; \(^3\)Diamond Light Source Ltd., Didcot, United Kingdom; \(^4\)Thomas Young Centre, London, United Kingdom.

As the world’s demand for energy increases, the need for technologies that can efficiently and sustainably generate energy are crucial to our society’s development. Photovoltaics are a rapidly developing renewable market, with capacity growing by a multiple of 57 from 2000 to 2015, to a total of 227GW, a higher rate than the growth in demand for electricity. While the price of silicon, the market leader PV material, has decreased in these recent years, the most cost-effective (S/W) absorber material remains CdTe, which only requires nanometre-thin films to absorb light efficiently. Nevertheless, the toxicity of Cd and low abundance of Te remain potential issues for global deployment of the technology.

In this study, we examine another potential thin-film absorber material, antimony selenide. In our ab initio calculations, we have found that Sb:Se has an ideal pseudodirect 1.3eV band gap and shows a spectroscopically limited maximum efficiency\(^2\) of 28% for a film thickness of 200nm, at which CdTe would have a value of 20% - demonstrating its extremely efficient absorption. Cell efficiencies for Sb:Se have, however, historically been low, at close to 5%. In the past 2 years, however, a number of reports have pushed this efficiency to 7%, and discussed potential resistance to the negative effects of grain boundaries, however measured \(V_{oc}\) are still low in comparison with the band gap of the material.\(^3,5\) Here, together with our experimental collaborators at the University of Liverpool, we attempt to characterise the deep defect levels within Sb:Se that could be limiting its performance. We calculate the transition levels for all intrinsic defect environments in the structure using hybrid Density Functional Theory, and compare them to DLTS measurements performed on a 7.9% efficiency cell to identify detrimental recombination centres. From our results, we can propose a strategy to minimize the impact of these deep defects, and identify potential methods to passivate them and so allow Sb:Se to reach cell efficiencies that could compete with other champion solar absorbers.
We use this new device model to explore the optimization of an intermediate band solar cell, showing how to optimize device performance given fixed material quality, elucidating important figures of merit and design rules. All efficient devices rely on careful design and modeling tools, but there are no existing device modeling tools for IB materials. We present for the first time a coupled Poisson and drift-diffusion device model with ability to simulate both standard semiconductors and IB materials, based on the finite element method (FEM), implemented using the FEniCS platform [5]. The model supports 2D and 3D devices. Semiconductor device models generally face challenges due to the large dynamic range needed to represent carrier concentrations and often need to use extended-precision arithmetic, implemented at the software level, to attain reliable results. We demonstrate high quality, well-converged results using standard 64-bit floating point numbers, allowing high-speed operation and efficient use of memory resources. Performance of the solver is demonstrated for standard semiconductors through comparisons with other simulation tools including TCAD Sentaurus.

characterisation. (We emphasise that special low dose transmission electron microscopy (TEM) methods and dry, ion-free TEM specimen preparation is imperative if an undamaged structure is to be observed [1,2].)

We characterize and compare structure-property relationships in two photovoltaic systems: the mixed organic mixed cation perovskite MAxFAl−xPbI3 (with methylammonium, MA=CH3NH3+ and formamidinium, FA=NH2CH=NH2+) and x=0, 0.15, 0.5, 0.8, 0.9 and 1) [3] and the more structurally stable pure inorganic CsPbI1−xBrx (−x) [4].

We reveal the different crystal structures and defect structures induced by varying composition and identify how these in turn impact upon charge carrier recombination and device performance, providing insights into the structural environments necessary to optimise device performance.

Understanding Perovskite PV Materials from a Defect Perspective Yi-Yang Sun; Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China.

Being a new class of materials achieving commercially competitive efficiency in an amazingly short period, the halide perovskites have set a new horizon for photovoltaic (PV) research. The success has been largely attributed to the unusual defect properties of the halide perovskites. In particular, the materials exhibit surprising defect tolerance even when synthesized by low-cost solution-based methods. The common understanding has been that the halide perovskites are “free” of deep defect levels which usually serve as efficient carrier recombination centers and are detrimental to the solar cell efficiency. While density functional theory calculations using semi-local functionals without including spin-orbit coupling (SOC) support this view, high-level calculations such as those using a hybrid functional including SOC suggest the existence of deep levels. Another puzzle is that the solution-produced halide perovskites exhibit high resistance suggesting an ultralow concentration of the shallow defects, which is at odds with the low formation energy of these defects. In this talk, we attempt to address these puzzles by a systematic comparison of the calculated defect transition levels and formation energies for hybrid halide perovskites, pure inorganic halide perovskites, as well as chalcogenide perovskites using different levels of methods. It is expected that the results will shine a light on the understanding of the role of defects in the perovskite PV materials.

Heterovalent Doping and Defect Formation in Metal Halide Perovskite Material Pabitra Nayak1, Michael Sendner2, Bernard Wenger1, Zhiping Wang1, Kavita Sharma2, Robert Lovricic3, P. K. Madhu1 and Henry Snaith1; University of Oxford, Oxford, United Kingdom; “TIFR Centre for Interdisciplinary Sciences, Hyderabad, India; “InnovationLab, Heidelberg, Germany.

Optoelectronic devices based on intrinsic Pb halide perovskites (HP) based semiconductors have shown wide applications in the recent past. There have been several attempts to introduce heterovalent metal ions (e.g., Li+, Bi3+, Sb5+) in the perovskites in an attempt to induce electronic doping and increase the charge carrier density in the semiconductor. It has been reported that inclusion of heterovalent metal such as Bi3+ decreases the bandgap of the material considerably. However, contrary to the earlier conclusions, despite a definite change in the appearance of the crystal as observed by eye, here we show that bandgap of MAPbBr3 crystals does not change due the presence of Bi3+ them. Formation of optically active defects states in the bad gap region and use of very thick samples for the transmission measurements erroneously give the impression of bandgap shift. Moreover, we find that all the claims regarding the bandgap narrowing in single crystals reported in many reputed journals in the past are also incorrect. Our finding also eliminates the ambiguity regarding the range of bandgap values reported for a single type of perovskite material. We find the bandgap values for the thin film and crystals of a MAPbI3 is same. In the Bi3+ doped crystals, we find that the microstrains and the density of sub-bandgap state (defects) increase due to the inclusion of Bi ions in the crystal. These bandgap states also act as non-radiative recombination centers in the crystals. Our findings give a clear indication of the impact of heterovalent (Bi3+) doping and also highlights the challenges which need to be resolved for this to be of real use. This latter aspect is of critical importance to reach the perovskite research community so that researchers can be mobilized to investigate how to dope HA materials effectively.

9:30 AM ET12.02.05
Passivation and Photo-Brightening in Metal Halide Perovskites Bernard Wenger, Julian Godding and Henry Snaith; University of Oxford, Oxford, United Kingdom.

Lead halide perovskites show impressive optoelectronic properties as demonstrated by their high radiative efficiencies and power conversion efficiencies in photovoltaic devices surpassing 20%. Since this is rather exceptional for materials synthesized directly from precursors in solution with simple coating techniques, the quality of semiconducting lead halide perovskites has sometimes been attributed to their “defect tolerance”. [1] However, substantial improvements of radiative efficiency can be obtained by various post-deposition treatments. The effectiveness of such passivation techniques demonstrates clearly that these materials do suffer from defects and, moreover, that these defects are likely to be localised at the surface of grains in polycrystalline films. In this contribution, we investigate several passivation strategies, compare them and also combine them for the model MAPbI3 perovskite as well as for high performing mixed cation, mixed halide perovskite such as FAxA-Cs1−xPbI3−yBry.

First, we discuss the effect of passivation by the addition of Lewis bases, such as pyridine and related organic molecules. Then, we investigate the effect of several monovalent cations salts (e.g. K+) which have been recently shown to improve massively the photoluminescence efficiency of triple cation (MA/FAS-Cs) perovskites and allowed for the fabrication of highly efficient thin film solar cells [2]. Finally, we compare (and combine) the addition of passivation agents with the photo-brightening effects obtained when exposing the perovskites to light in air in the presence of moisture.

Combining optical, electronic and materials characterisation techniques, we propose a detailed mechanism leading to passivation and demonstrate a new approach to further improve the radiative efficiency by a simple post-deposition treatment.

Defect Photochemistry of Lead-Halide Perovskites

Filippo De Angelis, CNR-ISTM, Perugia, Italy.

An outstanding property of lead-halide perovskites is the incredibly low band-gap to open circuit voltage loss, which in optimized devices is close to the thermodynamic limit (1.6 eV gap; 1.3 V voltage, loss 0.3 V).[1] The high open circuit voltage is extremely attractive for both photovoltaics and water splitting. These observations suggest an apparently low density of carrier traps in MAPbI3, contrary to the expected high defect density of a low-temperature, solution-processed material, suggesting that metal halide perovskites are inherently defect tolerant due to dominant defects introducing only shallow traps in the material band-gap.[2]

We present on overview of first-principles computational analyses devoted to understanding the outstanding optoelectronic properties of lead-halide perovskites. We show that despite the fairly high defect density due to Pb- and MA-related defects, less abundant iodine defects introduce deep electron and hole traps in MAPbI3.[3-5] The peculiar iodine redox chemistry leads, however, to kinetic deactivation of filled electron traps, leaving only short-lived hole traps as potentially harmful defects.[6,7] Hole traps can be eventually converted to electron traps under mild oxidizing conditions, clarifying the surprising material defect tolerance.

Exposing the material to light may initiate light-induced annihilation of iodine defects, that may explain the reversible enhanced PL quantum yield repeatedly observed. Under high irradiation intensity of short wavelength, however, bimolecular photochemical transformations of such iodine defects may start to prevail, leading to PLQ quenching and eventually to material degradation.[8]

Identifying the key factors underlying defect photochemistry in lead-halide perovskites may allow to further improve the material optoelectronic quality and can represent the basis for development of new materials with similar target characteristics, possibly avoiding the environmental risks posed by lead.

Broadband Excitonic and Trap-Assisted Emission in Cs2Bi2I9 Nanocrystals
Giuseppe M. Paterno1, Nimai Misra2, Alex J. Barker2, Zhiya Dang3, Guglielmo Lanzani1, Liberato Manna1, Annamaria Petrozza4 and Daniele Cortecchia1; 1Nanochemistry, Istituto Italiano di Tecnologia, Genova, Italy; 2Center for Nanoscience and Technology, Istituto Italiano di Tecnologia, Milano, Italy.

In the recent past, lead-based perovskite nanocrystals (NCs) have received significant attention for their unique optical and electronic properties.1 This lead-based perovskite nanostructures with chemical formula APbX3 (A: Cs, CH3NH3 (MA), X=Cl, Br, I) have been reported with high PL quantum efficiency (PLQE), tunable quantum confined emission, large absorption cross section, and low-threshold for lasing. However, the toxicity of the lead2 and stability in air limits its practical application.3 Here, we present a study on ligands-capped lead-free Cs2Bi2I9 nanocrystals showing unprecedented structured and broadband (200 nm) emission. We attribute such features to the recombination of self-trapped excitons mediated by ligand vibrations and to the emission from trap-states. Given these interesting features, we envisage application of these materials in solid-state lightning.

Tailoring the Broadband Emission Properties of 2D Perovskites Through Synthetic Design
Daniele Cortecchia1, Tetiana Borzda1, Stefanie Neutzner1, Benny Febriniay2, Jason England1 and Annamaria Petrozza2; 1Centre for Nano Science and Technology, Istituto Italiano di Tecnologia, Milan, Italy; 2Energy Research Institute @ NTU(ERI@N), Nanyang Technological University, Singapore, Singapore; 3Division of Chemistry and Biological Chemistry, School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore, Singapore.

Two-dimensional (2D) perovskites are attracting increasing interest in photonics and light emitting devices. These low dimensional structures are characterized by great synthetic versatility which allows the incorporation of a wide range of organic cations for the fine-tuning of their optoelectronic properties. The excitons confined in these quantum-well-like structures strongly interact with the highly polar perovskite lattice and determine their characteristic optical properties.1 [1] Through careful material’s engineering, it is possible to modulate the emissive properties from narrowband luminescence with high colour purity, to ultrabroad and highly Stokes shifted luminescence. Such broadband emission is generally attributed to trap states with wide energy distribution originating from exciton-self trapping phenomena.2 [2,3] Although recent progresses suggest that broadband emission is favoured in case of strong distortion of the inorganic lattice [2,4], a full understanding of the interplay between the material’s structure and defectivity/luminescence properties is still missing, urging the synthesis and analysis of a broader range of materials. In this work, we report the study of a series of novel 2D perovskites combining temperature dependent and time resolved spectroscopic measurements with structural characterization. We exploit the templating properties of different organic cations to control the structural arrangement of the inorganic motif and show that increased distortion of the octahedral coordination promotes the exciton self-trapping process enhancing the contribution of broadband photoluminescence. On the other hand, we demonstrate that optoelectronically active organic cations (e.g. naphthyl and pyrene based organic molecules) can be used to further tune the luminescence properties of the hybrid perovskite.

Our findings extend the understanding of the processes underpinning broadband luminescence in 2D perovskites and provide fundamental guidelines for the synthetic design of efficient emitters with tunable luminescent properties.
Investigation of Structural and Compositional Defects in Hybrid Organic-Inorganic Triple Cation Perovskite Films and their Effect on Optoelectronic Properties

An issue of critical importance in lead-based halide perovskites, much sought-after class of semiconductors in photovoltaics (PV) research, is defects; “deep” defect levels can prove catastrophic for PV performance by causing non-radiative carrier recombination[1], whereas impurity induced energy levels in the band gap could lead to increased absorption of sub-gap photons which can enhance efficiencies[2]. While experimental detection of defects is non-trivial and identification of the origin of defect states is usually impossible, density functional theory (DFT) calculations have been widely applied to accurately predict defect formation energies and transition levels[3]. In this work, we use DFT to study various intrinsic and extrinsic point defects in mixed bromide/chloride MAPbBr_{3-y}Cl_y perovskites (MA = methylammonium) with varying compositions (y = 0, 0.75, 1.5, 2.25, 3), where the calculated band gap increases from ~ 2 eV for y = 0 to ~ 2.6 eV for y = 3. We simulated all vacancy, self-interstitial and anti-site defects, as well as several transition metal substitution defects at the Pb site and calculated their formation energies in different charged states as a function of the chemical potential of relevant species and the Fermi level in the semiconductor as it moves from the valence band maximum (VBM) to the conduction band minimum (CBM). Our results revealed that in MAPbBr₃, vacancy defects (V₀, V₁, and V₂) are dominant acceptor and donor defects and only create shallow transition levels (i.e., close to the VBM or CBM), while higher energy defects create deeper levels; this is in good agreement with the computational literature[4]. The equilibrium Fermi level changes from inside the VB to the CBM (i.e., the highest level of intrinsic conductivity) on going from Br-rich to Pb-rich chemical potential conditions. Upon adding Cl to the system, it is seen that vacancy defects are again the lowest energy defects and the equilibrium Fermi level follows the same trend as in MAPbBr₃, but halogen vacancies (Vₙ and Vₓ) create deeper levels in the band gap the higher the value of y, indicating that in mixed Br/Cl or pure Cl perovskites, there is a danger of non-radiative recombination of carriers owing to deep defect levels. Further, several extrinsic substitutes like Sc, Y, Zr, Nb and Hf are shown to compensate for the dominant intrinsic defects in MAPbBr₃, MAPbBr₃Cl, and MAPbCl₃ by creating lower formation energy defects and shifting the equilibrium Fermi level towards the CBM, thus making the semiconductor conductivity more n-type. These substituents can not only help overcome the adverse effect of deep intrinsic defects, but their mid-gap states can potentially be exploited for optoelectronic properties of perovskite thin films.

In this talk we will detail a multiscale approach to determine 1) the nature of the defects, 2) their effect on the electronic properties of (MA,FA,Cs)Pb(IₓBr₁₋ₓ)₃ thin films and 3) how a number of the most promising passivation strategies modify defects on the nanoscale and subsequently reduce trap state densities. We spatially correlate high-resolution nano x-ray diffraction and nano x-ray fluorescence maps obtained on the I14 nanoprobe beamline at Diamond Light Source, with scanning electron diffraction, scanning transmission electron microscopy - energy dispersive x-ray, photoluminescence, and photoemission maps to reveal that strain related structural defects have a significant impact on the nanoscale and microscale optoelectronic properties of perovskite thin films. Our work reveals important information on the relevance of defects in the operation of state-of-the-art perovskite optoelectronic devices, which is critical to inform future defect engineering and passivation strategies. We also detail correlated multimodal characterisation techniques with nanoscale spatial resolutions that are applicable to a wide range of inherently beam sensitive materials.

Polarization, Mixed Conductivity and Deep Level Defects in Organometallic Halide Perovskites

Understanding the type, formation energy and capture cross section of defects is one of the challenges in the field of organometallic halide perovskite (OMHP) devices. In more matured semiconductors like Si, the knowledge of defects was one of the major factor in successful technological implementation. This knowledge and its control can make a paradigm in development of OMHP devices. Yet there is limited information on the properties of defects in OMHPs and controversy on the nature and role of these defects. Several studies explained that main intrinsic defects are only shallow level...
defects leading to long carrier diffusion length and carrier life time coupled to efficient OMHP devices suggesting a class of materials with low concentration of defects and/or highly defect tolerance. Recently, it was revealed that the performance of OMHP devices is mainly limited by Shockley-Read-Hall recombination confirming that defects are dynamic elements and have a critical role in development of OMHP devices. Therefore, deep localized defects exist and limit the operation of highly efficient OMHP devices. It is crucial to fundamentally understand how deep levels can explain the long carrier life time and how this characteristic can be used practically in development of OMHP devices. The non-radiative defect assisted carrier recombination is particularly important in operation of solar cells for higher Voc and in detectors for high charge collection efficiency. In this work, we provide a profound insight into crucial electrical and transport properties of OMHPs based on single crystal MAPbBr3 device. The space charge dynamics associated with charged deep level defects was studied by time-of-flight technique (ToF) driven by pulse voltage bias. We have previously shown that current waveform (CWF) used in ToF technique is sensitive to space charge near the contacts, which deforms the electric field inside the device and enables evaluation of the space charge parameters. Such modification of ToF allows us to determine the effect of deep levels on material transport properties such as lifetime, carrier mobility, and electric field profile. Using CWF ToF measurements and polarization theory, we explored polarization dynamic and transport properties of MAPbBr3 single crystals. In order to determine deep level activation energy and capture cross section, for the first time photo-Hall effect spectroscopy (PHES) with enhanced illumination in both steady and dynamic regimes was used. Using these measurements with tunable photon energies, we revealed the inner-bandgap electrical structure of MAPbBr3 single crystals and the activation energy and capture cross section of deep level defects was estimated.

Surface-Terminating Grain Boundaries as Active Sites for Oxygen Electrochemical Reactions Sossina M. Haile1, Ichiro Takeuchi2 and Robert E. Usuki3; 1Northwestern University, Pasadena, California, United States; 2Materials Science and Engineering, University of Maryland, College Park, Maryland, United States; 3Max Planck Institute for Solid State Research, Stuttgart, Germany.

Lanthanum strontium manganite is the canonical cathode for solid oxide fuel cells. It offers a valuable balance between electrochemical activity, chemical stability, and thermomechanical compatibility with the widely used electrolyte, yttria stabilized zirconia (YSZ). Despite its widespread implementation, questions regarding the reaction pathway for oxygen electroreduction on this material remain open. Here, a fundamental study of the reduction mechanism is carried using thin film methods. Libraries of (La0.8Sr0.2)0.98MnO3+δ thin film microelectrodes with systematically varied thickness or growth temperature were prepared by pulsed laser deposition, and a novel robotic instrument was used to characterize these libraries in automated fashion by impedance spectroscopy. All impedance trends are consistent with a reaction pathway involving oxygen reduction over the LSM surface followed by diffusion through the film and into the electrolyte substrate. The surface activity is found to be correlated with the number of exposed grain boundary sites, which decreases with either increasing film thickness (at constant growth temperature) or increasing film growth temperature (at constant thickness). These findings suggest that exposed grain boundaries in LSM films are more active than exposed grains towards the rate-limiting surface process, and that oxygen ion diffusion through polycrystalline LSM films is faster than several prior studies have concluded.

2:00 PM ET12.03.02
Dopant and Vacancy Distribution in Doped Ceria and Its Influence on the Oxide Properties—Theoretical Approach Natalia Skorodumova1, 2; 1Materials Science and Engineering, The Royal Institute of Technology (KTH), Stockholm, Sweden; 2Physics and Astronomy, Uppsala University, Uppsala, Sweden.

Transition metal oxides are often doped in order to tune their performance for particular applications. It is generally known that the properties of doped oxides are sensitive to the details of dopant distribution and its dynamics, however, reports demonstrating exact structure – properties relations are still rare. Here, taking Gd-doped ceria as an example, we show how the ordering of dopants and oxygen vacancies varies with temperature and concentration. The phase diagram for the Gd-doped ceria has been determined by means of a combined Density Functional Theory (DFT), cluster expansion and lattice Monte Carlo approach. In the thermodynamic equilibrium, we observe two transitions: an onset of oxygen-vacancy ordering at ~1300K~3300K for concentrations xGd = 30 – 100% and then, below ~1000 K, a phase separation into CeO2 and C-type Gd2O3 for the whole concentration interval (xGd = 0 – 100%). We also observe that the immobilization of cations below 1500 K does not prevent the oxygen-vacancy C-type order from forming. We demonstrate that this oxygen-vacancy ordering transitions noticeably influences the lattice parameter, bulk modulus and elastic moduli of Gd-doped ceria as well as its oxygen-ion conductivity.

Atomic-Scale Structure and Stability of Dopant-Defect Complexes at Misfit Dislocations in CeO2/MgO Heterointerfaces Pratik P. Dholabhai; School of Physics and Astronomy, Rochester Institute of Technology, Rochester, New York, United States.

Complex oxide heterostructures and thin-films have emerged as promising candidates for diverse applications, wherein interfaces play a critical role in influencing novel properties not present in individual components. In Solid Oxide Fuel Cells (SOFCs), the oxide thin films and heterostructures have found applications as advanced electrolytes. Lattice-mismatched epitaxial-growth of oxide films on substrates above a critical thickness lead to the formation of misfit dislocations, which influence vital material properties. We have employed atomistic simulations to investigate the influence of misfit dislocations on dopant-defect complexes at CeO2/MgO heterointerfaces. In this case, the experimentally observed [110]CeO2||(100)MgO interface orientation relationship has been utilized. For ionic conductivity applications, trivalent dopants are generally added to CeO2 as they have a net effective charge that affects the electrometallity condition, which lead to the formation of oxygen vacancies. In bulk electrolytes, at low temperatures, dopants and oxygen vacancies form complexes that influence ionic conductivity. However, at misfit dislocations, the role of dopant-defect complexes is not well understood. We find that the complexes shaped by trivalent dopants and oxygen vacancies have diverse features at the heterointerfaces. We have considered various scenarios...
Defect Engineering of Bulk Al\textsubscript{2}O\textsubscript{3} and the Al\textsubscript{2}O\textsubscript{3}/Al Interface to Enhance Its Hydrogen Permeation Barrier Properties

Compressive experimental study on how the deposition oxygen pressure and post-annealing control the brownmillerite phase formation and evolution and the formation process for the SFO films grown on LAO substrate, which is in good agreement with our experimental observation. Our results display a single crystalline films on LaAlO\textsubscript{3} (001) substrates by pulsed laser deposition. By tuning the deposition oxygen pressure and post-annealing, the orientation of the perovskite lattice sites. Such vacancies produce both oxygen-ion conduction and electronic conduction, and the former could be exploited in electrolytes in exchange at the surface is typically rate-limiting, tuning of the electrode surface is a key aspect in the development and optimization of materials for energy conversion applications. Sr-doped perovskite materials form passivating Sr-rich layers and particle on the surface due to segregation of the dopant strontium ions. This surface layer inhibits the oxygen exchange at the surface, thus increasing polarization resistance and reducing the energy efficiency of the SOFC.

Although the basic features of the LSM defect chemistry have been well-understood for at least 20 years based on experiments, the more detailed aspects (such as antisite defects and A/B ratio) and their possible implications for Sr segregation are not understood. Due to the large variety of defect species, the surface and bulk defect chemistry of LSM (as well as other perovskites) have not been explored in detail with computational methods in the past. As a consequence, there is little consensus in the literature about the nature and driving force of Sr segregation. We assess the stability of LSM over a wide range of T and p(O\textsubscript{2}) using a combination of DFT calculations on the GGA+U level and DFT-based thermodynamics. We apply these methods to examine the stabilities of the LSM(001) surface and the LSM bulk. We find the clean LSM(001) surface to be unstable and prone to reconstructions and defect segregation. Considering a wide variety of near-surface defects, as well as the growth of SrO as clusters, particles or homoepitaxial layers, we come to the conclusion that Sr segregation should be self-limiting because the surface dipole moment is removed by SrO overlayers that do not cover the entire surface. These surface terminations are stable and not prone to further segregation of Sr.

Experimental studies report the formation of SrO particles on the surfaces of Sr-doped perovskites after annealing, while our findings suggest that these large quantities of Sr cannot come from the surface. We considered the formation of a SrO phase as a new type of defect reaction in a new defect model for LSM that considers all of the defects mentioned above. We find that the equilibrium Sr content in LSM varies considerably within the relevant range of T and p(O\textsubscript{2}), which can effortlessly explain the experimentally observed formation of SrO under SOFC operating conditions, as well as the experimentally observed onset temperature of Sr segregation.

These results allow us to develop a knowledge-based doping strategy that prevents Sr segregation in LSM. Our modeling strategy and principle findings are transferable to other perovskite oxides.

Hydrogen is a promising clean fuel. A key bottleneck to its widespread utilization is the susceptibility of the materials used in hydrogen storage and transport infrastructure (typically steels) to embrittlement and failure. This necessitates the use of permeation barriers to prevent hydrogen ingress into the steel. Al\textsubscript{2}O\textsubscript{3} has been established as a popular hydrogen permeation barrier material, due to its low hydrogen solubility and diffusivity. The goal of this study is to further enhance the permeation resistance of Al\textsubscript{2}O\textsubscript{3} by two means: point-defect engineering of the Al\textsubscript{2}O\textsubscript{3} bulk, and space-charge engineering of the metal-H\textsubscript{2}O interface.
the Al₂O₃/Al interface, to reduce the overall hydrogen solubility and diffusivity of the system. To evaluate the performance of the Al₂O₃ bulk, a combination of first principle calculations and thermodynamic concepts were used to obtain defect concentrations in undoped and doped Al₂O₃. Our findings aid in the identification of suitable dopants that result in superior hydrogen permeation resistance of bulk Al₂O₃. Donor dopants like Ti, Si, Fe or Cr drastically reduce the concentration of free hydrogen interstitials (the primary diffusible defect under room temperature H₂ gas transport conditions) to negligible amounts, with majority of the total hydrogen concentration trapped at aluminum vacancy sites with high binding energy (~3 eV). Hydrogen is thus rendered immobile, with reduced diffusivity in Al₂O₃. In addition, Fe and Cr doping aid in decreasing the overall hydrogen solubility to 1/4 and 1/2 that of the undoped case respectively.

To evaluate the performance of the Al₂O₃/Al interface, first principles methods and continuum modeling were used to establish and tune the nature of the interfacial core and space-charge layer to lower the hydrogen solubility and diffusivity. Accounting for the interfacial band offset and variation in the local environment through defect segregation energies, Poisson’s equation is self-consistently solved to obtain the defect equilibria at the interface. Moreover, dopants have a large tendency to segregate to the Al₂O₃/Al interface, and thus are used to regulate the nature and extent of this space charge. This study thus aids in the atomic-level understanding of the impact of the Al₂O₃/Al interface on overall hydrogen permeability of the coating. This study also helps rationalize experimental findings that multilayer coatings of Al₂O₃/Al have superior permeation resistance than a single layer of Al₂O₃ of the same thickness. It is emphasized that the results of this study can also be extended to other systems where the metal/oxide interface (and interphase formation) affects device efficiency, such as the electrode/electrolyte interface in resistive switching devices and the metal/dielectric interface in MOS devices.

Discovery of Proton- Conducting Ceramic Fuel Cell Materials Using Genetic Algorithm Yeong-Cheol Kim¹, Ki-Yung Kim¹, Yurie Kim², Jason Kim³ and Jun- Yeong Jo¹; ¹School of Energy Materials and Chemical Engineering, KoreaTech, Cheonan, Korea (the Republic of); ²Department of Creative IT Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of).

BaCeO₃ and BaZrO₃ have been the most studied electrolyte materials for proton-conducting ceramic fuel cells for the last four decades. BaCeO₃ shows high conductivity and very sinterability, but poor stability under CO₂ atmosphere. BaZrO₃ shows good stability, but poor sinterability and low conductivity at grain boundaries. Mixing these two materials to take advantage of the merits of both materials have been a trend, and recently BaZr₀.₄Ce₀.₄Y₀.₁Yb₀.₁O₃ (BZCYYb4411) was introduced as a best electrolyte, replacing BZCYYb1711 [1]. Y and Yb are dopants to generate oxygen vacancies in the electrolyte materials. As researchers have increased the number of components to improve the material properties, they had to invest more time and money to investigate the vast materials composition space. We used genetic algorithm to save time and money in searching the vast structure space for better materials. We converted structures into chromosomes and applied crossover, mutation, and compensation to generate next-generation chromosomes. Based on the best chromosomes, we added water molecules to fill the oxygen vacancies. Genetic algorithm was applied again to find optimum configurations of protons in the structure. This technique was also applied to air electrode materials to find optimum solid solution configurations.

Controlled Oxygen-Vacancy Distribution and Intergranular Amorphous Phases to Boost the Ionic Conduction in Perovskite-Oxide Electrolytes Sung-Yoon Chang; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

ABO₃-type perovskites are one of the oxide families where various ionic defects can be created by changing the oxygen partial pressure and adding proper dopants. Among many notable physical properties and transport phenomena observed in perovskites, aspects of high proton conductivity have been intensively investigated in zirconates and cerates over the past three decades in efforts to elucidate the precise conduction mechanisms and further improve the ionic conductivity for real applications as electrolytes in solid-oxide fuel cells operated at intermediate temperature. In the first part of this presentation, we demonstrate that the proton conductivity can be notably enhanced by the association of acceptor dopants and oxygen vacancies in BaZrO₃ and BaCeO₃. The acceptor-vacancy clustering is verified to be remarkably efficient against proton trapping by theoretical DFT calculations and experimental measurements based on impedance spectroscopy along with atomic-scale direct visualization (Angew. Chem. Int. Ed. 55, 13499 (2016)). In addition to the impact of defect association, we clarify that a nanometer-thick amorphous phase at grain boundaries in proton-conducting BaCeO₃ polycrystals is responsible for substantial retardation of proton migration in the second part of the presentation. By a combination of atomic-scale chemical analysis and physical imaging along with consideration of straightforward phase equilibria, it is demonstrated that highly densified BaCeO₃ polycrystals (~98% in relative density) free of a grain-boundary amorphous phase can be easily fabricated by a conventional ceramic process and show sufficiently high proton conductivity (order of 10⁻² S/cm at 600°C) and significantly improved chemical stability (Nano Lett. 18, 1110 (2018)). These findings emphasize the value of direct identification of lattice defects and subsequent manipulation of their distribution in ion-conducting oxide polycrystals.
effects on organic solar cells.

Here, we investigated the characteristics of ZnO layer prepared in different humidity and then explored their effects on the actual devices of organic solar cells. Specifically, the humidity was adjusted from 15% to 80% to coat the ZnO layer. As a result of comparing efficiency of organic solar cell devices using these ZnO layer, it showed the highest efficiency of 8.30% at 25% of humidity. In order to confirm the effect on the efficiency change, the surface characteristics, optical characteristics and defects were analyzed. To investigate the effect of humidity on the thickness and roughness of the ZnO thin film, the Alpha step and AFM were analyzed and the optical characteristics were analyzed by measuring the transmittance. The defects in the organic solar cell were defective through XPS and PL because the charge recombination reduced the efficiency. From the efficiency of organic solar cell device and analysis results, it is thought that ZnO produced at 25% humidity is most suitable as ETL layer of organic solar cell.

ET12.04.02
Hydration of BaCe_{1-x-y}Zr_{y}Y_{y}O_{3-δ} Using Genetic Algorithm Ki-Yung Kim1, Yurie Kim2, Jason Kim2, Young-Bok Kim3, Jun-Yeong Jo1, Dong-Gung Shin1, In-Gyu Cho1 and Yeong-Chool Kim1; School of Energy Materials and Chemical Engineering, KoreaTech, Cheonan, Korea (the Republic of)1; Department of Creative IT Engineering, Pohang University of Science and Technology, Pohang, Korea (the Republic of). Oxygene-coduting solid oxide fuel cells (SOFCs) have been actively studied as an alternative power source because they have high energy conversion efficiency and no use of precious metal catalysts. The high operating temperatures (800-1000°C), however, hinder durability and low fabrication costs of the SOFCs. Proton-conducting FCs is an alternative solution due to their low operating temperatures (400-600°C) [1]. Recently, BaCe_{1-x-y}Zr_{y}Y_{y}O_{3-δ} that can be fabricated by mixing BaCeO_{3} and BaZrO_{3} with Y and Yb as dopants was introduced as an excellent electrolyte material [2]. BaCe_{1-x-y}Zr_{y}Y_{y}O_{3-δ} can take advantage of the strong points of BaCeO_{3} and BaZrO_{3}; BaCeO_{3} shows high conductivity but low stability, while BaZrO_{3} shows good stability but low grain boundary conductivity [3]. The material, however, shows many different configurations of Ce, Zr, Y and Yb atoms in the B site of the ABO_{3} perovskite structure. In this study, we employed genetic algorithm and lattice dynamics to find an energetically favorable BaCe_{1-x-y}Zr_{y}Y_{y}O_{3-δ} solid solution structure. We also investigated the hydration process by adding water molecules to fill the oxygen vacancies that reside in the solid solution structure. The distribution of protons after hydration will be discussed based on the results of genetic algorithm and lattice dynamics.

Equilibrium Space Charges Effect at Halide Perovskite Interactions—The Role of the Ionic Charge Conductions Gee Yeong Kim, Alessandro Spena and Joachim Maier; Max Planck Institute for Solid State Research, Stuttgart, Germany.

Methylammonium lead iodide (MAPI) is the archetype of the halide perovskites that are currently in the focus of photovoltaic research not only because of high conversion efficiencies but also because of intriguing long-time behavior. In this contribution we discuss equilibrium space charge effects at MAPI interfaces and concentrate on the implications for MAPI/TiO_{2} and MAPI/Al_{2}O_{3} contacts. Irrespective of polarization phenomena building up under operation, already the equilibrium situation is dominated by space charge effects. While such space charge effects are only considered as a consequence of electronic charge carrier redistribution, we will apply a generalized picture that discusses both ionic and electronic redistribution. In fact, we will show that the space charges are ionically dominated, in a sense that ions dictated the space charge potential and electrons follow the established field (fellow-traveler effect). Our analysis is based on the measurement of electronic and ionic conductivities in MAPI-TiO_{2} and MAPI-Al_{2}O_{3} composites, a technique that has been successfully applied in solid states Ionics [1-3]. The results are corroborated by Hall effect experiments.

Fano Defect Induced Resonant Thermoelectric Transport in Metallic Nanowires Chumin Wang, Fernando Sanchez and Vicenta Sanchez; Universidad Nacional Autonoma de Mexico, Mexico City, Mexico.

Fano defects consist of atomic chains attached to a low-dimensional system and produce rich wave interferences in its conductivity spectra [1]. Recently, we have analytically proved the existence of a novel ballistic conduction state in two-dimensional belts with a non-periodic arrangement of atoms in both its cross section and along the Fano plane defect [2]. Moreover, enhancements to the ballistic alternating current (AC) conductivity are reported when quasiperiodically placed Fano defects are introduced to a periodic chain or nanowire [3]. On the other hand, the direct conversion between thermal and electrical energies by thermoelectric devices has become an important alternative for the clean energy generation. Low-dimensional materials seem to be promising candidates, whose efficiency is determined by the dimensionless thermoelectric figure-of-merit (ZT) that can be calculated by using the Boltzmann formalism. The inherent correlation between the thermoelectric quantities, such as electrical and thermal conductivities, makes difficult to improve the value of ZT.

In this work, we study the thermoelectric properties of metallic nanowires with periodic and quasiperiodically placed Fano defects by means of a real-space renormalization plus convolution method [4] developed for the Kubo-Greenwood formula, in which tight-binding and Born models are respectively used for the study of electric and lattice thermal conductivities [5]. We analytically demonstrate the existence of a significantly improved ZT due to the Fano defects [6]. In addition, the numerical results suggest that the quasiperiodicity could be another important ZT enhancing factor, since it highly diminishes the thermal conduction of long wavelength acoustic phonons, which are responsible of the phononic conductivity at low temperature and not easy to block their transmission since they do not feel local defects neither impurities [7].

This work has been partially supported by UNAM-DGAPA-IN106317 and CONACyT-252943. Computations were performed at Miztli of DTGC-UNAM.

Effect of Surface and Bulk Defects on Hot Carrier Transport in Ultra-Thin Metallic Films  
Jeremy N. Munday; University of Maryland, College Park, Maryland, United States.

Photon absorption in metal films can result in the excitation of hot carriers, i.e. electrons and holes with kinetic energy in excess of their thermal distribution. For hot carriers generated within a diffusion length of the surface, opportunities arise for extraction of these energetic carriers, which can perform tasks not achievable by thermal electrons including modification of chemical reaction rates, charge injection into nearby semiconductors for current generation, etc. However, one of the key limitations on carrier transport and collection is defects. Both surface and bulk defects can cause carrier relaxation and forfeit their original benefits. Here we will discuss our recent work on excitation and collection of hot electrons and holes in thin metal films and our attempts to mitigate the harmful effects of defects. We will show energy conversion and photodetector devices that can operate over both the visible and near-IR based on injection of hot carriers either into semiconductors or across insulating barriers into an adjacent conductor. We will also discuss future applications of this work for tailoring photon absorption and carrier lifetime.

Precise Design of Photocatalyst Heterostructure with Controllable Photo-Generated Carrier Behaviors for Solar to Fuel Conversion  
Kan Zhang; 1,2, 3Nanjing University of Science and Technology, Nanjing, China; 2Yonsei University, Seoul, Korea (the Republic of).

Solar-driven hydrogen (H2) evolution has been considered as a clean, green and efficient strategy to solve the energy shortage and ameliorate environmental pollution. Heterogeneous photocatalysts comprising an excitable semiconductor and a H2 evolution co-catalyst (HEC) are regarded as a standard configuration to drive efficient photocatalytic H2 reaction. However, photocatalytic H2 generation requires both efficient charge separation and redox steps to occur simultaneously. Loading a HEC on photocatalyst is an efficient means of extracting photogenerated charge carriers, host active sites for catalytic H2 evolution and improve stability by suppressing photo-corrosion. However, H2 generation in photocatalyst remains limited by the electron/hole mutual Coulomb interaction, which seriously inhibits spatial charge separation. When HECs are near the charge generation region of CdS, both electrons and holes can be localized via Coulomb interaction. This localization determines the wavefunction overlap with the HECs and trap states and retards the electron transfer rates. In this sense, generating a long-lived charge-separated state for delocalized electrons is crucial for efficient H2 evolution while accelerating hole consumption by hole scavengers. In this talk, I will discuss how to control photo-induced electrons that successfully deliver to HECs sights towards highly efficient solar hydrogen evolution through structure design of nanomaterials.

8:45 AM ET12.05.03  
Dispelling the Myth of Passivated Codoping in TiO2  
Benjamin A. Willianson1,2, Nicholas P. Chadwick1,3, Sanjayan Sathasivam1, Claire J. Carmalt1, Ivan P. Parkin1 and David O. Scanlon1,2,4; 1Department of Chemistry, University College London, London, United Kingdom; 2Thomas Young Centre, University College London, London, United Kingdom; 3Bio Nano Consulting, London, United Kingdom; 4Diamond Light Source Ltd., Diamond House, Didcot, United Kingdom.

Modification of TiO2 to increase its visible light activity and promote higher performance photocatalytic ability has become a key research goal for materials scientists in the past two decades. One of the most popular approaches to achieve this is “passivated co-doping”, whereby an equal number of donor and acceptor dopants are introduced into the lattice, producing a charge neutral system with a reduced band gap. From the multitude of codoped systems, [Nb+N] and [Ta+N] are widely regarded as the “archetypal” codoping pairs of doped anatase, however the literature results rarely claim 1:1 passivated codoping. Using state-of-the-art hybrid density functional theory, and using the [Nb+N] and [Ta+N] codoped systems as examples, we show that fully passivated TiO2 is unrealisable due to the inherent doping asymmetry of anatase or any other n-type photocatalysts. This research critically discusses the future of passivated codoping as a mode of band gap modulation.

First Principles Modelling of Polaron Formation in TiO2 Polymorphs  
Razak Elmaslmane1, Matthew Watkins2 and Keith McKenna3, 1University of York, York, United Kingdom; 2University of Lincoln, Lincoln, United Kingdom.

We present a computationally efficient and predictive methodology for modelling the formation and properties of electron and hole polarons in solids. Through non-empirical optimization of the fraction of Hartree-Fock exchange (α) in a hybrid functional, we ensure the generalized Koopmans’ condition is satisfied and the self-interaction error is minimized. Our previous work in model systems has shown that accurate densities and energies can be obtained from such an optimization. The approach is applied to model polaron formation in known stable and metastable phases of TiO2 including anatase, rutile, brookite, TiO2(H), TiO2(R) and TiO2(B). Electron polarons are predicted to form in rutile, TiO2(H) and TiO2(R) (with trapping energies ranging from -0.02 eV to -0.35 eV). In rutile the electron localizes largely on a single Ti ion, whereas in TiO2(H) and TiO2(R) the electron is distributed across two neighboring Ti sites. Hole polarons are predicted to form in anatase, brookite, TiO2(H), TiO2(R) and TiO2(B). Electron polarons are predicted to form in rutile, TiO2(H) and TiO2(R) (with trapping energies ranging from -0.02 eV to -0.52 eV). In anatase, brookite and TiO2(B) holes localize on a single O ion, whereas in TiO2(H) and TiO2(R) holes can also be distributed across two O sites. We find that the optimized α has a degree of transferability across the phases, with α=0.115 describing all phases well. We also note the approach yields accurate band gaps, with anatase, rutile and brookite within six percent of experimental values. We conclude our study with a comparison of the alignment of polaron charge transition levels across the different phases. Since the approach we describe is only two to three times more expensive than a standard density functional theory calculation, it is ideally suited to model charge trapping at complex defects (such as surfaces and interfaces) in a range of materials relevant for technological applications, but previously inaccessible to predictive modelling.

9:15 AM ET12.05.05
Anomalous Conductivity Tailored by Domain Boundary Transport in Crystalline Bismuth Vanadate Photoanodes Wenrui Zhang1, Danhua Yan1, Jun Li1, Qiyuan Wu2, Jiajie Cen2, Lihua Zhang1, Alexander Orlov2, Huolin Xin1, Jing Tao1 and Mingzhao Liu1; 1Brookhaven National Laboratory, Upton, New York, United States; 2Stony Brook University, The State University of New York, Stony Brook, New York, United States.

Carrier transport in semiconductor photoelectrodes strongly correlates with intrinsic material characteristics including carrier mobility and diffusion length, and extrinsic structural imperfections including mobile charged defects at domain boundaries, which collectively determines the photoelectrochemistry (PEC) performance. Here we elucidate the interplay between intrinsic carrier transport, domain-boundary-induced conductivity and PEC water oxidation in the model photoanode of bismuth vanadate (BiVO4). In particular, epitaxial single-domain BiVO4 and c-axis oriented multi-domain BiVO4 thin films are fabricated using pulsed laser deposition to decouple the intrinsic and extrinsic carrier transport. In addition to the low intrinsic conductivity that is due to the small polaron transport within BiVO4 domains, we identify anomalously high electrical conductivity arising from vertical domain boundaries for multi-domain BiVO4 films. Local domain boundary conduction compensates the inherently poor electron transport by shortening the transport distance for electrons diffused into the domain boundary region, therefore suppressing the photocurrent difference between front and back illumination. This work provides insights for engineering carrier transport through coordinating structural domain boundaries and intrinsic material features in designing modulated water splitting photoelectrodes.

10:00 AM ET12.05.06
Tuning Catalytic Properties for Water Splitting with Functional Defects Xiaolin Zheng; Stanford University, Stanford, California, United States.

Defects, such as vacancies and dopants, offer rich opportunities to tune the catalytic properties of crystals. In this talk, we will present three examples on using defects to optimize the catalytic activity for water splitting and all examples are supported by density functional theory calculations and experimental results. The first example is related to the well-known hydrogen evolution reaction (HER) catalyst, MoS2. For MoS2, the perfect basal plane is chemically inert, but it can be activated by creating S-vacancies. In addition, the activity of the S-vacancy can be further tuned by either strain or transition metal modification. The second example is also related to another HER catalyst: WS2. I will explain how the basal plane activity of WS2 is activated and optimized by tuning Co doping configurations. The third example is switched to the water oxidation side for water splitting. I will demonstrate how rare earth doping enhances the activity, selectivity and stability of BiVO4 towards H2O2 production.

10:30 AM DISCUSSION TIME

Enhancing Water-Splitting Performance of Hematite Photoanodes via Hydrogenation Induced Defects Hariom Jani1, 2, Mengyuan Zhang3, Lydia H. Wong1, 4 and Thirumalai V. Venkatesan1, 2, 3; 1NanoCore, Singapore, Singapore; 2NUS Graduate School of Integrative Sciences and Engineering, National University of Singapore, Singapore, Singapore; 3ECE, National University of Singapore, Singapore, Singapore; 4Energy Research Institute @ NTU (ERI@N), Nanyang Technological University, Singapore, Singapore; 5School of Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore.

Hematite (α-Fe2O3), is a photoanode material candidate for Oxygen Evolution Reaction in a Photo-Electro-Chemical cell (PEC). It has an optical bandgap (~2.1eV) which straddles the water oxidation and reduction potentials, allowing it to drive water splitting by absorbing solar radiation. Its chemical resistance, non-toxicity and low cost, make it a promising material to manufacture hydrogen in an environmentally friendly way. Unfortunately, its poor electrical conductivity, carrier transport dynamics and absorptivity, yield low solar-to-hydrogen conversion.

In my talk, I will present how we have used a special hydrogen treatment to systematically enhance the bulk electronic transport in Hematite Nanorods. We observe that hydrogen doping increases the electronic conductivity of α-Fe2O3 without changing its optical bandgap or its structural properties. Consequently the PEC performance of treated photoanodes is much higher than their pristine counterparts.

The novel hydrogenated phase of α-Fe2O3 is characterised by X-Ray Diffraction, Raman and UV-Vis Spectroscopy, Electron Microscopy and Impedance Spectroscopy. The physics underlying the electronic changes are elucidated by Ultrafast Optical-Pump Probe techniques, X-Ray Absorption and Ab-Initio calculations. Our work paves way to utilizing novel hydrogen induced defect states to systematically enhance functionality of oxide photoanodes.

11:00 AM ET12.05.09
Minimizing the Grain Boundary Effect by Dopant Segregation on Hematite Photoelectrodes for Solar Water Oxidation Aryane Tofanello1, Andre Luiz M. Freitas2, 3 and Flavio L. De Souza1; 1University Federal-ABC, Santo Andre-SP, Brazil; 2University of California, Santa Cruz, Santa Cruz, California, United States.

This work describes the effect of nitrogen atmosphere and chemical addition of different metal transition elements (M = Sn, Ti or Mn) on the hematite surface electrode and its impact on the photoelectrochemical performance (PEC). For comparison, undoped [Air or N2-Fe2O3] and modified [Air or N2-M-Fe2O3] hematite electrodes were prepared by aqueous solution precursor method under hydrothermal condition at low temperature and at fixed synthesis time (2 hours). The as-prepared materials were subjected to additional thermal treatment at 750 ºC for 30 min in air and nitrogen (N2) atmosphere. The undoped electrodes obtained after 2 hours of synthesis exhibited the columnar morphology with thickness around 300 nm. In case of undoped electrodes, treatment in nitrogen atmosphere (N2-Fe2O3) promoted the oxygen vacancies formation (evidenced by X-ray photoelectron spectroscopy) leading to a better photocurrent response at 1.3 mA.cm-2 at 1.23 VRHE. The chemical addition of metal transition elements (M = Sn, Ti or Mn) followed by the thermal treatment and monitored by top-view scanning electron microscopy (SEM) shows significant changes in the morphology. Additionally, to the morphology changes the “dopant” insertion seems to drastically reduce the grain growth, which increases the number of interfaces and surface area. Although the surface area available for chemical reaction increases with the reduction of grain size, the increased number of interfaces or grain boundaries in hematite normally is a problem to the charge separation by acting as recombination sites. Surprisingly, the chemical addition of Sn and Ti, which was found to be segregated in the hematite grain boundaries, seems to reduce the energy in between grains facilitating the electron transport and enhancing the overall electrode performance. The impedance spectroscopy (Nyquist plot) data revealed that the combination of N2 atmosphere with chemical addition of Sn or Ti significant reduce the electrical resistance increasing the hematite performance for water oxidation assisted by sunlight independent of the final morphology.

as Zintl thermoelectrics (e.g. ZnSb), which are ubiquitously p-type. In this talk, I will present and discuss our recent efforts in modeling point defects in semiconductors, in particular in relation to understanding and predicting their dopability. The focus of the work is on establishing quantitative relationships between the dopability of semiconductors on one side, and their chemical composition and crystal structure on the other, with the main purpose to advance design and discovery of novel optoelectronic and thermoelectric materials. In addition, I will examine more closely our recent prediction of bipolar dopability in the metastable, high-pressure rocksalt phase of ZnO, and discuss significant prospects it implies to overcoming doping asymmetry of semiconductors through polymorphism.

Predictive Design of Defects in Non-Ideal Ternary Nitrides—Off-Stoichiometry, Contamination and Disorder Ji-Sang Park1, Jacob Cordell1, Andriy Zakutayev1, Adele Tamboli1 and Stephan Lany1, National Renewable Energy Laboratory, Golden, Colorado, United States; 2Colorado School of Mines, Golden, Colorado, United States.

II-IV-V2 ternary nitrides offer many advantages in enhancing functionality for optoelectronic applications. For example, ZnSnN2 (ZTN) is a promising absorber material for photovoltaic (PV) applications and ZnGeN2 (ZGN) can be used in light emitting devices. However, the properties of multinary compounds strongly depend on the materials nonidealities, e.g., disorder, stoichiometry, and impurities. For example, in practice, the growth of ZTN thin film incorporates a non-trivial amount of oxygen. The excess amount of oxygen can lead to cation off-stoichiometry, i.e., Zn excess, and disorders in the material. The conventional dilute-defect model does not capture these non-ideal conditions. In this contribution, we present a predictive defect model of these complex ternary nitrides with disorder, off-stoichiometry, and oxygen contamination, e.g., Zn1-xSnxN2-2xO2x, and their effects on materials properties, such as band gap, carrier localization, absorption coefficients, and defect equilibria. The disordered structures were created by Monte Carlo (MC) simulation with simplified Hamiltonians, such as motif-Hamiltonian and cluster expansion. The MC generated structures were then passed on to electronic structure calculations for disordered and off-stoichiometric structures. These calculated changes in the band structure were then fed back to the materials property predictions, such as net doping, defect equilibria.

Effect of Extended Defects on Electrical Properties in Earth Abundant Inorganic Materials Ji-Sang Park1, Sunghyun Kim1, Maria K. Chan2 and Aron Walsh1, Imperial College London, London, United Kingdom; 2Argonne National Laboratory, Lemont, Illinois, United States.

In diamond and zinc-blende structure semiconductors, the stacking sequence can be altered by a missing layer or an additional layer and combinations of them. These extended defects, which is termed as stacking faults, can be regarded as local wurtzite phase in the zinc-blende host, and the material properties are affected accordingly. In a material with at least two types of cation, anti-site domain boundaries, which are periodic arrays of anti-site defects, can be formed as well. We have investigated the extended defects in Cu2ZnSn(S, Se)4 and Si to obtain a general understanding of the defects [1,2]. Cu2ZnSn(S, Se)4 based solar cells have attracted much attention for achieving terawatt scale photovoltaics. While the problem of the open-circuit voltage deficit has not been resolved yet, spatial fluctuations of the band edges by disorder have been regarded as the origin of the deficit. Our hybrid density functional theory calculations indicate that the extended defects also have a role in the lower photovoltaic efficiency [1]. The anti-site domain boundaries, another type of disorder, lower the conduction band. The fact that the anti-site domain boundaries act as electron capture can be understood by the formation of metastable polymorphs or Sn anti-site defects. On the other hand, stacking faults in the material act as electron barriers, while their formation is more likely than the anti-site domain boundaries which formation was experimentally observed. Cation substitutions can promote or suppress the formation of stacking faults.

We also found that the stacking faults affect the stability of point defects. It is known that stacking faults are formed in Si solar cells after the potential induced degradation of shunting type happens. Our calculation shows that the Na interstitials are more stable at the stacking faults where the Na becomes less mobile [2]. Based on the calculation results, we suggest that Na atoms are accumulated at the stacking faults after a long time of operation because of the segregation. Effect of the stacking faults on the device will be discussed.

Oxygen Vacancy in Complex Oxides—The Good, the Bad and the Ugly Ho Nyung Lee; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Functional ionic defects, such as oxygen vacancies, play a central role in the performance of many advanced information and energy materials. While of immediate benefit for low temperature energy production and storage devices and sensors, the ability to artificially control oxygen vacancy content in any environment is also crucial for variety of functional materials, such as high-temperature superconductors, colossal magnetoresistors, memristors, and spintronic devices. On the other hand, for some of functional materials, such as ferroelectrics, the formation of oxygen vacancies is highly detrimental for the performance and endurance of the ferroelectric polarization. However, achieving deliberate control of the oxygen stoichiometry in the oxide thin films has not been much studied, albeit critical for the performance. In this presentation, I will review a synopsis of the major developments and achievements in formation, control, and understanding of oxygen vacancies in correlated oxides. This includes the oxygen sponge SrCoO4 (Jeon et al., Nature Mater. 12, 1057 (2013), Petrie et al., JACS 138, 7252 (2016), Adv. Funct. Mater. 26, 1564 (2016)), oxygen diode formed in LaNiO3 (Guo et al., Adv. Mater. 2018, 1705904), strain control of oxygen kinetics in the Ruddlesden-Popper oxide La6-xSr4-xCuO12-x(Meyer et al., Nature Commun. 9, 98 (2018)), and metal-insulator transition by oxygen stoichiometry control in VO2 (Sharma et al., (unpublished)). Overall, these results summarize the role, importance, and challenge in film growth for the right stoichiometry as well as strain utilization for developing next generation energy and functional materials and devices.

Dramatically Improved UV Photoluminescence from ZnO Nanowires by Selective Introduction of Surface Oxygen Vacancies Danhua Yan1, Wenrui Zhang1, Jiajie Cen2 and Mingzhou Liu1; 1Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 2Department of Materials Science and Chemical Engineering, Stony Brook University, The State University of New York, Stony Brook, New York, United States.

Zinc oxide nanowire arrays (ZnO NWs) have been extensively studied for their versatile applications in optical and optoelectronic devices, such as light-emitting diodes (LEDs), photodetectors, optical modulator waveguides, and photoelectrochemical anodes. Among various techniques that have been used to fabricate ZnO NWs, the wet-chemical approach becomes the most widely adopted method for its simplicity, as well as its capability to synthesize well-oriented single crystalline ZnO NWs. These devices require quality ZnO NW materials grown by the wet-chemical process usually feature a high density of defects, which suppress near band edge emission and contribute to broad defect state emission in the photoluminescence (PL) spectra.

Here, we demonstrate, counter-intuitively, that the near band edge emission may become dominant by selectively introducing surface oxygen defects to ZnO nanowires via surface engineering. Specifically, near band edge emission (NBE) is effectively enhanced after a thermal annealing that removes most bulk defects and a low pressure O2 plasma treatment that spurs off surface oxygen species to produce a reduced and oxygen vacancy-rich surface. Through a combined study by low-energy electron microscopy (LEEM) and ultraviolet photoelectron spectroscopy (UPS), we discover that the effect is attributed to the lowered surface valence band maximum of the reduced ZnO surface that creates an accumulative band bending, which screens the photocarriers at low carrier densities.

Using two Sn-based transparent conductive oxides as model systems, i.e. amorphous zinc tin oxide (a-ZTO) and polycrystalline tin oxide (SnO2), the origin of these subgap defects and routes for their passivation were studied. Previously we have demonstrated that in a-ZTO, the overall optoelectronic properties still provide free electrons maintaining the high conductivity of the film. This simple passivation scheme with SnO2 significantly improves the optical transparency in the visible spectrum range.

Passivating Defects in Sn-Based Oxides—SiO2 Replaces Thermal Treatments Monica Morales-Massie1,2, Esteban Rucavado1, Migle Grauzinyte1, Jose A. Flores-Livas1, Quentin Jeangros2, Federica Landucci2, Stefan Goedecker2, Aicha Hessler-Wyser1 and Christophe Ballif1; 1Ecole Polytechnique Federale de Lausanne, Neuchatel, Switzerland; 2MESA+ Institute of Nanotechnology. University of Twente, Enschede, Netherlands; 3Universitat Basel, Basel, Switzerland.

Tin (Sn)-based metal oxides have been of high technological importance for decades, with applications ranging from photovoltaics, sensors, displays and smart windows. For Sn-based oxides, oxygen deficiencies and undercoordinated Sn atoms result in extended densities of states below the conduction band edge. While shallow states provide free carriers necessary for electrical conductivity, deeper states inside the bandgap create absorption centers affecting the transparency of the films.

Using two Sn-based transparent conductive oxides as model systems, i.e. amorphous zinc tin oxide (a-ZTO) and polycrystalline tin oxide (SnO2) the origin of these subgap defects and routes for their passivation were studied. Previously we have demonstrated that in a-ZTO, the overall optoelectronic properties can be improved by defect passivation via annealing at high temperatures in oxygen-rich environments. Yet, the high thermal budget associated with such treatment is incompatible with many applications such as devices requiring temperature-sensitive materials or fabricated on polymer-based substrates. As an alternative low-temperature passivation route, we propose co-sputtering Sn-based TCOs with silicon dioxide (SiO2). In-depth optoelectronic characterization of the co-sputtered SnO2-SiO2(or a-ZTO-SiO2) films and density functional theory simulations indicate that the SiO2 contribution is twofold. First, oxygen from SiO2 passivates the oxygen deficiencies that form deep defects in SnO2 and a-ZTO. Second, the ionization energy of the remaining deep defect centers is lowered by the presence of silicon atoms. Remarkably, these ionized states do not contribute to subgap absorptance while still providing free electrons maintaining the high conductivity of the film. This simple passivation scheme with SiO2 significantly improves the optical properties without affecting the electrical conductivity, and it is independent of the microstructure of the films, hence overcoming the known transparency conductivity trade-off in Sn-based TCOs.

Probing Defects in Au- and Te-Hyperdoped Si with Deep Level Transient Spectroscopy and Carrier Lifetime Measurements Shao Qi Lim1, Christopher Xiao-Kuan Lew2, Brett Johnson2, Philippe K. Chow1, Senali Dissanyake1, Meng-Ju Sher4, Quentin Hadspeth1, Jeffrey M. Warrender2 and Jim S. Williams1; 1Electronic Materials Engineering, Research School of Physics and Engineering, Australian National University, Canberra, Australian Capital Territory, Australia; 2Centre for Quantum Computing and Communication Technology, School of Physics, University of Melbourne, Melbourne, Victoria, Australia; 3US Army ARDEC - Benet Laboratories, Watervliet, New York, United States; 4Physics Department, Wesleyan University, Middletown, Connecticut, United States.

Developing a technology that can allow Si to efficiently absorb light in the mid infrared region can open-up important applications in fibre-based communications as well as facilitating the fabrication of Si-based infrared (IR) imaging arrays. In this context, recently Mailoa et al. demonstrated that by hyperdoping Si with Au by ion implantation and pulsed-laser melting (PLM), a Si-based photodetector can absorb into the IR up to 2200 nm [1]. The thin Au surface layer (~150 nm) so produced contained up to 1 atomic % Au that was almost all in solid solution at concentrations far exceeding the solid solubility limit for Au in Si. Spectroscopic data suggest that the observed enhanced absorption was associated with the Au deep donor level in the Si bandgap [1].

Enhanced sub-bandgap absorption of Si hyperdoped (HD) with Ti, S, Se and Te [2-4] have also been demonstrated. However, despite considerable literature on the physical, optical and electrical characterization of HD Si, there is a lack of characterization of defect states that lie in the Si bandgap as well as the related carrier lifetime data of such materials. This study aims at using deep level transient spectroscopy (DLTS) and carrier lifetime measurements with THz spectroscopy [5] to investigate the nature of defects present in Au- and Te-HD Si and thus better understand how these defects contribute to the overall photodetector performance.

Several variations of the DLTS method was performed on the Au-HD Si photodiodes from [1], revealing the presence of defects as deep as 1-2 um from the surface, well beyond the HD region. The defect identities currently remain undetermined due convoluted hole and electron trap signals and other experimental complications. However, current efforts have been successful in overcoming such barriers, and concentration depth profiling of individual trap components via small-pulse DLTS will further elucidate the role of each type of defect in the Au-HD diodes. On the other hand, carrier lifetime measurements made on Te-HD Si reveal the presence of both short (picosecond) and long (microsecond) lifetime components. These DLTS and carrier
lifetime results will be discussed in terms of defects emanating from the PLM processing of HD Si, as well as its implications for photodiode properties.

Role of Vacancy-Type Defects in Au-Hyperdoped Si Fabricated by Ion Implantation and Pulsed Laser Melting Wenjie Yang1, Naheed Ferdous2, Philippe K. Chow3, James M. Gaudet4, Peter Simpson5, Austin Akey3, Jeffrey M. Warrender2, Michael J. Aziz6, Elif Ertekin2 and Jim S. Williams1; 1Australian National University, Canberra, Australian Capital Territory, Australia; 2University of Illinois at Urbana-Champaign, Champaign, Illinois, United States; 3U.S. Army ARDEC- Benet Laboratories, Watervliet, New York, United States; 4University of Western Ontario, London, Ontario, Canada; 5Harvard University, Cambridge, Massachusetts, United States.

Ion implantation followed by pulsed laser melting can produce hyperdoped Si with a highly non-equilibrium impurity concentration, giving rise to sub-band gap optical absorption that holds potential in Si-based photovoltaics and infrared light detection. [1, 2] In particular, a Si-based infrared photodetector has been successfully demonstrated on Au-hyperdoped Si, motivating a detailed study on the role of substitutional Au and other related defect complexes that arise from the non-equilibrium hyperdoping process. [3]

In this study, the atomic location of Au in hyperdoped Si is determined using Rutherford backscattering spectrometry combined with ion channelling (RBS/C) and triangulated angular scans. Additionally, the local lattice environment around the Au atoms is examined using a combination of techniques, including high-resolution transmission electron microscopy (HRTEM), high-resolution x-ray diffraction (HRXRD) and positron annihilation spectroscopy (PAS). Surprisingly, the incorporation of large Au atoms into the Si lattice appears to contract rather than expand the lattice. We show that vacancies trapped following pulsed laser melting, and, with the aid of density functional theory (DFT) calculations, propose that the vacancy trapping process is consistent with the local minimisation of lattice strain around the large Au atoms. Finally, we explore the thermal stability and sub-band gap optical activity of these vacancy-type defects. This vacancy trapping process may be global in other laser-melted hyperdoped Si systems with large-size impurities and may affect their efficacy as infrared absorbers.

to increased alkaline layer distance. In this talk, we show the novel interplay between these TM ions and the charged point defects to modulate the electrochemical performance of Na,TM,VO$_2$ through unique ordering and disordering phases. A combined in situ (synchrotron) XRD, atomic resolution (scanning) TEM, neutron diffraction and density functional theory (DFT) simulation techniques are used to understand the coupled sodium, TM charge and magnetic orderings and disorderings. For the Fe containing mixed transition metal system of NaFeTM$_2$O$_2$, a novel disordered phase at high voltage was developed due to the unique electronic property of FeO$_x$ octahedrons, while at low voltage it goes reversibly back to the ordered phase. For NaMnO$_2$ a unique superstructure evolution mechanism related to the Jahn-Teller activity of Mn$^{3+}$ was found to dominate the electrochemical performance through the charged point defects in a special ordering pattern. The underlying connection between the two systems of Na(FeTM)$_2$O$_2$ and NaMnO$_2$ will be discussed to further facilitate the design of new battery cathode materials.

Defect-Enhanced Phase Transition Kinetics in LiFePO$_4$  
Ming Tang, Liang Hong and Kaiqi Yang; Rice University, Houston, Texas, United States.

Lattice defects such as antisite defects are commonly present in battery compounds and traditionally viewed as deleterious features. In this work, however, we use phase-field modeling and theoretical analysis to illuminate a mechanism of antisite defects accelerating phase transition and hence enhancing the rate performance of battery particles for compounds with strong ion diffusion anisotropy. Using LiFePO$_4$ as an example, we show that the inclusion of antisite defects can increase the phase boundary velocity by orders of magnitude in the surface-reaction-limited phase transition regime, which is closely related to the effect of antisite defects on reducing the Li diffusion anisotropy in LiFePO$_4$. As such, defect-rich LiFePO$_4$ particles can be (dis)charged much faster than defect-free particles especially at low overpotentials, where the metastable solid solution does not form. Based on the mechanistic understanding, criteria for optimizing the defect concentration are presented. This finding suggests defect engineering as a fruitful approach to enhance the rate performance of intercalation compounds.

9:30 AM ET12.07.05
Charge Storage and the Critical Role of Defects—Case Study of 2D Layered Delta MnO$_2$ and VO$_2$(B) Nanosheets  
Scott Misiurewicz, Peng Gao, Robert Koch, Madeleine N. Flint and Alec Ladonisi; Alfred University, Alfred, New York, United States.

It has recently become clear that defects may be of great importance in developing new electrochemical energy storage materials. Herein we focus on two model systems, 2-D layered delta MnO$_2$ and 2-D VO$_2$(B) nanosheets, with controlled defect contents, and investigate the atomic-scale mechanisms of charge storage. Using a combined approach of high energy X-ray scattering and X-ray spectroscopy, we find that MnO$_2$ nanosheets possess a peculiar out-of-plane Mn$^{3+}$ defect, forming a “surface Frenkel” defect. In our earlier work, we correlated the concentration of these defects (~20-30%) to the charge storage, where defects increase the overall capacitance from 200 to 300 F/g while decreasing the charge transfer resistance from ~15 to ~3 Ω. In situ XRD and X-ray PDF studies show that in-plane expansion and contraction occurs in the nanosheets upon charge and discharge. In situ XANES reveals a 31% change in the Mn oxidation state in the presence of 30% surface Frenkel defects, promoting ion intercalation and charge transfer. To test the hypothesis of charged defects controlling capacitance, Mm doping into layered VO$_2$(B) nanosheets has also been investigated. Addition of ~9 mol% Mn to the VO$_2$ results in 80% higher capacitance, as well as 2X smaller charge transfer resistance and 2X improvement in cyclability. PDF and X-ray scattering demonstrate distorted local structures with increased cation substitution, which may facilitate Na" intercalation. The formation of more V$^{4+}$ (≈13% higher by XPS) and oxygen vacancies by Mn doping can also help relieve electrochemical strain and increase electrical conductivity. Through these model systems, we provide insight into engineering defects for the next generation of transition metal oxide nanosheet electrochemical supercapacitors.

Guiding Principles for Designing Highly-Efficient Metal-Free Carbon Catalysts  
Li Peng Zhang$^1$ and Zhenhai Xia$^2$; 1 Beijing University of Chemical Technology, Beijing, China; 2 University of North Texas, Denton, Texas, United States.

Carbon nanomaterials are promising as metal-free catalysts for energy conversion and storage. To accelerate the search for the highly-efficient catalysts, it is necessary to establish design principles for the carbon-based catalysts. This review focuses on theoretical analysis and material design of metal-free carbon nanomaterials as efficient photo-/electro-catalysts to facilitate the critical chemical reactions in clean energy technologies, including oxygen reduction reaction (ORR) in fuel cells, oxygen evolution reaction (OER) in metal-air batteries, hydrogen reduction/evolution (HER) in water splitting, iodine reduction (IRR) in dye-sensitized solar cells, and carbon dioxide reduction (CO2RR) in artificial photosynthesis. Intrinsinc descriptors and design principles are analyzed and summarized, and future directions are discussed in development of efficient carbon-based catalysts for clean energy conversion and storage.

The Role of Chemically Pretreated Cationic Species at the Interlayer Region of Layered Oxides in Electrochemical Energy Storage  
Ekaterina Pomerantseva; Drexel University, Philadelphia, Pennsylvania, United States.

Transition metal oxides with layered crystal structures favor reversible intercalation of ions at relatively high potentials and as a result are attractive for cathode application in lithium-ion batteries. However due to the concerns related to the abundance of lithium on Earth and a desire to reduce battery cost, the interest in developing beyond lithium ion energy storage systems fuel discovery of new electrode materials that would be efficient in reactions of intercalation of more abundant and therefore less expensive ions, such as Na$^+$ and K$^+$ ions. The larger size of these ions compared to that of lithium ion dictates the need for expanding the interlayer region of layered oxides to enable facile diffusion of the electrochemically cycled ions. This presentation will focus on new materials synthesis approach, called chemical pre-intercalation, which allows to tune the interlayer spacing of a model bilayered vanadium oxide phase from ~10 to ~30 Å. The effect of introducing inorganic and linear organic ions on charge storage properties in electrochemical systems with different charge-carrying ions will be discussed. Methods to control species in the interlayer region will be highlighted and correlated with functional properties of materials. This talk will also demonstrate that chemical pre-intercalation synthesis approach can be extended to synthesize new layered transition metal oxide phases beyond vanadium oxide. Overall, this presentation will shed some light on ways to chemically control interlayer content in layered oxides to modify their structure and chemical composition with the aim to achieve enhanced electrochemical properties in energy storage applications.

11:00 AM ET12.07.08
Tailoring Mobile Defects for Fast Ionic Conductors  
Yifei Mo; University of Maryland, College Park, College Park, Maryland, United States.

Fast ionic conductor materials are the key component in enabling a variety of electrochemical devices. It is crucial to understand why only a few materials exhibit faster ionic conduction than typical solids and how one can design fast ion conductors following simple principles. We perform ab initio modeling
on a range of novel fast ion conductor materials as model systems. In lithium super-ionics, we show that fast diffusion in super-ionics happens through unique concerted migration mechanism of multiple ions with low energy barrier in contrast to isolated ion hopping in typical solids. We elucidate that low energy barriers of the concerted ion diffusion are a result of unique mobile ion configurations and strong mobile ion interactions in these super-ionics conductor materials. Our theory provides a conceptually simple framework for guiding the design of super-ionics conductor materials.

Using first principles computation, we demonstrate this strategy by designing a number of novel fast ion conducting materials. In addition, our computational studies in other ionics conductors will also be discussed, and newly discovered design strategies will be presented.

11:30 AM ET12.07.09
Tuning Bifunctional Oxygen Electrocatayls and Changing A-Site Rare-Earth Element in Perovskite Nickelates
Le Wang1, 2, Kelsey A. Stoerzinger1, Lei Chang2, Junling Wang3 and Yingge Du4; 1Pacific Northwest National Laboratory, Richland, Washington, United States; 2Nanyang Technological University, Singapore, Singapore;

Perovskite-structured (ABO3) transition metal oxides are promising bifunctional electrocatalysts for efficient oxygen evolution reaction (OER) and oxygen reduction reaction (ORR). In this paper, we investigate a set of epitaxial rare earth nickelates (R(NiO3) thin films with controlled A-site isovalent substitution to correlate their structure and physical properties with ORR/OER activities. The ORR activity is shown to decrease monotonically with decreasing the A-site element ionic radius which lowers the conductivity of the R(NiO3) (R = La, La0.5Nd0.5, La0.2Nd0.8, Nd, Nd0.5Sm0.5, Sm, Gd) films, with LaNiO3 being the most conductive and active. On the other hand, the OER activity initially increases upon substituting La with Nd and is maximal at La0.2Nd0.8NiO3 in which oxygen vacancies (Vo) start to form. Moreover, the OER activity remains comparable within error through Sm-doped NdNiO3. Beyond that, we cannot reliably measure activity due to the potential voltage drop across the film. The improved OER activity is ascribed to the partial reduction of Ni4+ to Ni3+ as a result of Vo, which increases the average occupancy of the eg antibonding orbital to more than one. Our work highlights the importance of tuning A-site elements as an effective strategy for balancing the ORR and OER activities of bifunctional electrocatalysts.

11:45 AM ET12.07.10
Lifting Electrocatayltic Activity in LaNiO3 Perovskite Films with Helium Jonathan Petrie1, Thomas Zac Ward1, Anthony Wong1, John w. Freelander2, Valentino Cooper1 and Ho Nyung Lee1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.

Complex oxides, such as ABO3 perovskites, can catalyze oxygen reduction and evolution reactions essential for fuel cells, metal-air batteries, and other energy-related devices. Similar to noble metal films such as Pt, in-plane compressive strain was recently reported to generate significant enhancements in the electrocatalytic activity of LaNiO3 (LNO) perovskite films epitaxially grown on different substrates. Greater amounts of in-plane compression induced by the substrate increases the out-of-plane (c) lattice parameter via the oxide’s Poisson relationship. The increased tetragonality in turn improves the catalytic activity due to strain-induced splitting of the eg orbitals in the film’s NiO6 octahedral units. However, this sole reliance on in-plane epitaxial strain to facilitate uniaxial changes in the c-parameter limits our ability to optimize the activity.

Recently, low energy helium (He) ion implantation was demonstrated as a means to directly control uniaxial c-axis lattice expansion in epitaxial perovskite oxides. Here, we show that this “strain doping” process presents an additional avenue towards manipulating catalytic activity in LNO films coherently grown on STO substrates. Through the introduction of controlled amounts of interstitial He atoms into the film, we can continuously adjust the c-axis lattice expansion that drives changes in the eg orbital asymmetry essential for greater catalytic activity. Consequently, we can use these He point defects to raise the activity of LNO films by over an order of magnitude. Furthermore, the LNO activities seen surpass any yet found through straightforward substrate-induced epitaxial strain. The considerable enhancement in oxygen activity through the tailored incorporation of He into LNO demonstrates the emerging power of this ‘defective’ dial to enhance oxide functionality.

Designing Dopants for Higher Performance TCOs
David O. Scanlon; University College London, London, United Kingdom.

The combination of electrical conductivity and optical transparency in a single material gives transparent conducting oxides (TCOs) an important role in modern optoelectronic applications such as in solar cells, flat panel displays, and smart coatings. The most commercially successful TCO so far is tin doped indium oxide (Indium Tin Oxide – ITO), which has become the industrial standard TCO for many optoelectronics applications; the ITO market share was 93% in 2013. Its widespread use stems from the fact that lower resistivities have been achieved in ITO than in any other TCO; resistivities in ITO have followed by in situ atomically resolved imaging with scanning tunneling microscopy (STM) and subsequently with ex situ x-ray diffraction (XRD).

2:00 PM ET12.08.02
Controlling Surface Mobility and Step Barrier Heights in Oxide Film Growth
Arthur P. Baddorf1, Alexander Tselev1, Rama K. Vasudevan1, Anthony Gianfrancesco1, 2, Liang Qiao1, Tricia Meyer1, Ho Nyung Lee1, Michael Bielajewski1 and Sergey V. Kalinin1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Control of defects during nonequilibrium growth requires an understanding of surface mobilities and diffusion barriers, such as step barrier heights. We have explored these parameters and their influence on structure in epitaxial La0.5Ca0.5MnO3 thin films grown with pulsed laser deposition by varying laser fluence, oxygen pressure, and substrate-induced strain. Films were examined in operando using reflective high-energy electron diffraction (RHEED) followed by in situ atomically resolved imaging with scanning tunneling microscopy (STM) and subsequently with ex situ x-ray diffraction (XRD).
Regardless of the laser fluence, RHEED intensity oscillations were observed, characteristic of layer-by-layer growth. For SrTiO$_3$ substrates (and not the better lattice matched NdGaO$_3$) the envelope of the oscillations first drops with film thickness, then increases. Such RHEED behavior can be interpreted as first roughening of the film surface, then a decrease of the roughness and eventual conversion to a stable layer-by-layer growth. STM images confirm this interpretation. Remarkably, this indicates that the suboptimal layer-by-layer growth involving multiple exposed layers evolves into a nearly ideal layer-by-layer growth with the prototypical three exposed layers. At intermediate film thicknesses, atomically resolved images show that the surface consists of both A$\chi$- MnO$_3$ and B-site, (La, Ca, O)$_3$ terminations with (12$\times$2$\times$8$\times$2) reconstructed surfaces. The A-site termination is clearly more highly ordered. As the film thickness increases, the less ordered B-site domain dominates and by 250 layers is the sole termination. This surface morphology is largely independent of the laser fluence, but layer-by-layer growth could be delayed by reducing the growth pressure. Rough growth is frequently associated with an Erlich−Schwoebel barrier for adatoms to descend steps resulting in a reduction of the downhill flux. This interpretation is confirmed by atomically resolved images with a high concentration of adatoms along the terrace edges. Image analysis and Monte Carlo simulations estimate the height of the Erlich−Schwoebel barrier to be 0.18 ± 0.04 eV for deposition at 750 °C. Similarly, the evolution of adatom mobility can be inferred from STM images based on adatom island sizes and spacing. In the layer-by-layer regime, an increase in the adatom mobility with increasing thickness is accompanied by an increase in the out-of-plane lattice parameter. STM images reveal a pattern of extended stoichiometric surfaces, which can be ascribed to subsurface defects created during growth.

2:15 PM ET12.08.03 Non-Stoichiometry-Induced Metal-to-Insulator Transition in Nickelate Thin Films Grown by Pulsed Laser Deposition Jongmin Lee$^1$, Kyoung Soon Choi$^2$, Tae Kwon Lee$^3$, Il-Seok Jeong$^4$, Sangmin Kim$^5$, Jaesun Song$^6$, Chung Wung Bark$^7$, Joo-Hyoung Lee$^8$, Jong Hoon Jung$^9$, Jouhahn Lee$^{10}$, Tae Hoon Kim$^{11}$ and Sanghun Lee$^{12}$.

The chemical stoichiometry in transition-metal oxides influences their physical properties due to the multi-valent nature of the transition-metal element. In perovskite rare-earth nickelates (RNiO$_3$, except for $R$ = La), which undergo metal-to-insulator phase transitions (MITs) with the decreasing temperature, the oxidation state of the transition-metal Ni$^{3+}$ ion is very sensitive to the stoichiometry and the transport property becomes different relying on the Ni valence state. Thus, it has been extensively studied how off-stoichiometry in either bulk or thin-film RNiO$_3$ modifies the Ni oxidation state and then, affects the MITs eventually. However, the detailed study of the non-stoichiometry effect has been rare due to a difficulty in the systematic control of cation and oxygen contents. Herein, we manipulate the cation stoichiometry in RNiO$_3$ bilayer films (NdNiO$_3$/LaNiO$_3$ on SrTiO$_3$ (001)) epitaxially grown by a pulsed laser deposition technique. Through a training process by laser irradiation, we can systematically control the RNi compositional ratio in RNiO$_3$ target. Interestingly, a Ni-excess RNiO$_3$ bilayer film shows MITs at around ~ 50 K. In contrast, a stoichiometric RNiO$_3$ bilayer film is metallic at all temperatures. Based on the first-principle calculations results, the possible origin of the non-stoichiometry-dependent transport behaviors will be discussed in conjunction with x-ray reflection (XRR) and x-ray photoemission spectroscopy (XPS) analyses.

2:30 PM ET12.08.04 Machine Learning Guided Design of Functional Materials with Targeted Properties Prasanna V. Balachandran, Department of Materials Science and Engineering & Department of Mechanical and Aerospace Engineering, University of Virginia, Charlottesville, Virginia, United States.

Computational strategies that enable identification of predictive design rules have the potential to rationally design materials for targeted applications. In this talk, I will discuss some of our recent works that have rationally guided experiments and computational codes (eg., density functional theory) towards promising regions in the vast design space of functional materials. The uniqueness of our approach lies in the integration of machine learning methods with experimental design in an adaptive feedback loop. The role of machine learning is two-fold: (i) to establish a relationship between the features and property of interest and (ii) to quantify uncertainties. Experimental design, on the other hand, uses the machine learning outcome to recommend the next experiment or simulation. I will demonstrate examples showing the efficacy of these approaches to design novel complex oxides and alloys with improved properties.

3:30 PM ET12.08.05 Neuromorphic Computing Based on Dynamic Control of Dopants in Organic and Inorganic Materials A. A. Talin; Sandia National Laboratories, Livermore, California, United States.

Inspired by the efficiency of the brain, CMOS-based neural architectures and memristors are being developed for pattern recognition and machine learning. However, the volatility, design complexity and high supply voltages for CMOS architectures, and the stochastic and energy-costly switching of memristors complicate the path to achieve the interconnectivity, information density, and energy efficiency of the brain using either approach. In my talk I will describe a non-volatile redox memory (NVRM): a device with a resistance switching mechanism fundamentally different from existing memristors, based on the concept of reversible, electrochemical reduction/oxidation of a material to tune its electronic conductivity. The first type of NVRM that I will describe is based upon the control of Li vacancy concentration in Li$_2$CoO$_2$ through reversible Li-ion intercalation. Li vacancies act as positive dopants, resulting in linear, highly symmetric, and low voltage switching between hundreds of analog conductance states and achieving high classification accuracy when implemented in neural network simulations. The second type of NVRM I will describe operates on a similar principle but is based on the polymer system PEDOT:PSS, and utilizes the proton as the mobile ion to control the polaron carrier density in the channel. Plastic NVRMs are fabricated on flexible substrates enabling the integration of neuromorphic functionality in stretchable electronic systems. (1) Fuller, E. J.; El Gabaly, F.; Leonard, F.; Agarwal, S.; Plimpton, S. J.; Jacobs-Gedrim, R. B.; James, C. D.; Marinella, M. J.; Talin, A. A. Li-Ion Synaptic Transistor for Low Power Analog Computing. A non-volatile organic electrochemical device as a low-voltage artificial synapse for neuromorphic computing. Nature Materials 2017, 16, 414.
which are responsible for the plasmonic response. However, electronic state modification can be further amplified via strain engineering which is limited to film/substrate lattice mismatch and deposition pressure. An alternative approach to induce strain within these systems is through size confinement and morphology control. This work focuses on utilizing wet-chemical processes to control defects (oxygen vacancies and dopant) to tune the optical response of a host nanocrystal (SrTiO3, STO) doped with Nb ions, Sr1-xTixNb1-yO3+δ (STNO).

STNO nanoparticles were synthesized via a two-step co-precipitation/pressure-controlled molten salt technique. This low-pressure synthetic route limits available oxygen during the crystallization process allowing for systematic control of oxygen vacancies and dopant incorporation. The resultant particles have been identified as highly doped, cubic STNO nanostructures via TEM, EDX, and XRD. The average strain on the host matrix due to different dopant concentrations and oxygen pressures was calculated to be ~1%. Additionally, it is possible to induce the expected optical response by controlling the oxygen partial pressure and subsequent annealing processes. This optical response was confirmed to be due to the formation of Nb5+, as opposed to the more stable Nb3+ state, in the STO lattice using X-ray photoelectron and X-ray absorption spectroscopy. These results on low dimensional Nb-doped SrTiO3 nanoparticles demonstrate a capacity for infrared light harvesting which has the potential for applications in optical communication, remote sensing, spectroscopy, and thermal imaging.

4:15 PM ET12.08.07
Exploring Defect-Coupled Polarization Dynamics in Ferroelectrics via Multimodal X-Ray Imaging Qian Li1, Ben Xu2, Bo Wang3, Joshua Agar4, Hua Zhou1, Nouamane Laanait1, Lane W. Martin1, Long-Qing Chen1, Sergei V. Kalinin2 and Haidan Wen1; 1Advanced Photon Sources, Argonne National Laboratory, Lemont, Illinois, United States; 2School of Materials Science and Engineering, Tsinghua University, Beijing, China; 3Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; 4Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 5Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

It is broadly acknowledged that oxide ferroelectric materials inherently contain significant amounts of defects, such as oxygen vacancies, that form during fabrication due to thermodynamic defect equilibria. These defects are also known to interact with ferroelectric polarization, though in many cases leading to adverse effects such as polarization fatigue. It is thus crucial to understand the configuration and dynamical behavior of defects in order to enhance the functional properties of ferroelectric materials. Diffuse scattering is one of a few widely applicable methods that gives microscopic insights about defects, with its quantitativeness, nondestructiveness and high sensitivity. Here at the Advanced Photon Source, we have developed a new materials characterization instrument which combines scanning probe microscopy (SPM) in-situ with nano-focused X-ray diffraction imaging (XDM). We have devoted the initial application of this development to an examination of the defect-coupled polarization dynamics in Pb(Zr,Ti)O3 ferroelectric epitaxial thin films. This model system has been found to show mechanical switching behavior, that is, the polarization can be switched under mechanical pressure exerted by an SPM tip. We have performed XDM around such mechanically written regions and observed remarkably enhanced diffuse scattering in these regions, which nonetheless preserve the pristine average structure. Defect scattering modeling based on the classical Huang theory and phase-field modeling based on the Landau-Ginzburg theory, both informed by atomistic simulations of the defect (oxygen vacancy) configuration, have been performed to obtain a deep understanding of the pertinent dynamic processes. Altogether, they lead to a coherent picture that the tip pressure drives a redistribution of ionized oxygen vacancies in the films due to the Vegard strain coupling; slave to this process, the polarization switching occurs due to the electrostatic coupling. While our discovery substantially challenges the prevailing belief that flexoelectricity drives the mechanical switching, it points to a fundamentally different route to manipulate ferroelectric polarization at the nanoscale and prompts a rethinking of the functional roles of oxygen vacancies. Beyond ferroelectrics, this methodology may well be applied to a wide range of condensed matter systems where oxygen vacancies and the-like ionic defects modulate electronic transport, magnetism and other physical properties.

This work is supported by U.S. Department of Energy (DOE), Office of Science, Basic Energy Sciences (BES), Materials Sciences and Engineering Division. This research used resources of the Advanced Photon Source, a U.S. DOE Office of Science User Facility operated for the DOE Office of Science by Argonne National Laboratory under Contract No. DE-AC02-06CH11357.

4:30 PM ET12.08.08
Mapping Potential Energy Landscapes via Electron Beam Induced Atomic Impurity Dynamics Maxim Ziatdinov1, Ondrej Dyck1, Feng Bao2, Ali Yousefzadi Nobakht3, Rick Archibald1, Kody Law4, Stephen Jesse1 and Sergei V. Kalinin1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Department of Mathematics, The University of Tennessee at Chattanooga, Chattanooga, Tennessee, United States; 3The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 4The University of Manchester, Manchester, United Kingdom.

Atomic fabrication of materials remains the ultimate goal of nanotechnology. The modern-day scanning transmission electron microscope allows to simultaneously image and manipulate matter at the atomic scale and is therefore considered one of the most promising tool for building new forms of matter from the atom up. Accomplishing this goal requires detailed understanding of the mechanisms of beam-induced transformations. Here we show that moving atomic impurity under beam excitation can be used to map atomic scale potentials in solids and determine beam-induced effects on chemically-relevant time scale. We first used stochastic reconstruction of molecular dynamic simulations to extract information on the random force exerted by the beam on Si dopant in graphene (arxiv:1804.03729). We then extended our approach to recover the potential along step edge of graphene nanohole with multiple impurities and to study cooperative effect between substrate reconstruction and 1D crystallization-like behavior under electron beam irradiation. Our study paves the way towards controllable electron beam induced transformations of matter.

SYMPOSIUM ET13
Materials for Multifunctional Windows
November 26 - November 28, 2018

Symposium Organizers
Arun Gupta, University of Alabama
Paul O'Brien, University of Manchester
Luminescent solar concentrators (LSCs) are envisioned to reduce the cost of solar electricity by decreasing the usage of more expensive photovoltaic (PV) materials and diminishing the complexity of multi-cell PV modules. The LSC concept can also enable unconventional solar-energy conversion devices such as PV or “solar” windows that can be especially useful in highly populated urban areas. Due to their high emission efficiencies and readily tunable emission and absorption spectra, colloidal quantum dots (QDs) have emerged as promising LSC fluorophores. The focus of this presentation is on both fundamental studies of luminescent concentration exploiting nearly ideal LSC characteristics of engineered QDs [1, 2] as well as practical, high-performance devices demonstrating commercial viability of a QD-LSC approach [3]. Specific topics of discussion will include practical concentration limits tested using nearly perfect QD emitters with >95% quantum efficiencies [1], various approaches to Stokes-shift engineering [4, 5], single- and double-layer LSC architectures, as well as cost/efficiency considerations for QD-LSCs [3, 6]. The overall conclusion of the reviewed studies is that engineered QDs represent a promising materials platform for realizing inexpensive, high-efficiency sunlight collectors applicable as both semi-transparent building-integrated solar windows and stand-alone, large-area LSC-PV modules.

regarding the use of near infra-red lead sulphide (PbS) quantum dots (QDs) as in planar LSCs. The results of this study indicated that PbS LSCs generate nearly twice the photocurrent in silicon cells compared to a traditional dye and cadmium selenide QDs, achieving an integrated optical efficiency $\eta_{opt}$ of 12.6%. This was primarily due to the broadband absorption of PbS, and a smaller overlap between the absorption and emission spectra, which reduces SA. However, despite the superior performance, PbS also exhibits a gradual and permanent photo-oxidation, which decreases the photocurrent at the rate of 0.1% per minute. Tuning the device architecture led to some improvements in PbS-based LSCs, as we demonstrated next, fabricating solid and hollow cylinders from a composite of QDs in polydimethylmethacrylate. The experimental results were in good agreement with theoretical calculations, with hollow LSCs having a higher absorption of incident radiation and lower SA compared to solid cylindrical and planar geometries with similar geometric factors. In addition to optical efficiency almost thrice that of planar LSCs, these also exhibited improved photo-stability under both laboratory and ambient conditions. Most recently, we have begun exploring the suitability of organic–inorganic hybrid perovskite (PVSK) thin films as the active medium in planar LSCs. PVSK compounds are at the forefront of photovoltaic research, and their high refractive index, broad absorption spectrum, and superior QY make them theoretically ideal candidates for LSCs. In practice, however, the possibility of high self-absorption in a continuous film, coupled with the inherent instability of PVSK materials, have hindered their use. Our results display an impressive $\eta_{opt}$ in the range 15%–29% despite high SA losses, and the devices remain operational for up to seven weeks in ambient conditions. We attribute this to the high QY and refractive pushed the efficiency to 34.7%. Further, using 3D Monte Carlo simulations that incorporate our experimental results, we have demonstrated the possibility of scaling these LSCs up to almost 100 cm, thereby providing a route toward optimizing thin film PVSK materials for these and other optoelectronic and photovoltaic applications. This work was supported by funds from the National Aeronautics and Space Administration grant no. NNX15AQ01A.

Light Scattering in Poly(methyl methacrylate) Doped with Functionalized Si Quantum Dots Samantha Hill1; Ryan Connell2; Vivian Ferry3 and Uwe R. Kortshagen1; 1Mechanical Engineering, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States; 2Chemical Engineering & Materials Science, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

The near-infrared emission and large effective Stokes’ shift of Si quantum dots (Si QDs) are attractive properties for light-management technologies like downshifting layers on photovoltaics or luminescent solar concentrating windows. In the case of the latter, the Si QDs must be finely dispersed in a transparent matrix, like a polymer, in order to achieve high light concentration factors. Our Monte Carlo models show that increasing the average light scattering length from 1 mm to 1 m in a 1 m2 device would provide a 4-fold increase in collected light for devices using Si QDs with a quantum yield of 50%. This gain only increases in the case of more efficient Si QDs. However, obtaining low-scattering dispersions of Si QDs in relevant, cost-effective polymers remains a challenge, and few reports of Si QD/polymer composites exist. Here, we studied the effect of surface ligand choice on the light scattering properties of Si QDs incorporated within mass polymerized poly(methyl methacrylate). Nanocomposites were made using Si QDs capped with a typical, nonpolar ligand or an ester-ended analog. We find the two surface treatments lead to significantly different dispersion characteristics in methyl methacrylate: either a primarily singly dispersed mixture is achieved, or agglomeration produces strongly scattering Si QD clusters at least 10 times larger than a single QD diameter. Fully polymerized nanocomposites exhibit increased light scattering corresponding to the agglomeration state in the monomer, especially at higher QD loading fractions. UV-Vis measurements of these composites indicate that choosing ligands similar in structure to the composite monomer can help reduce scattering losses within the nanocomposites. These results offer a strategy to improve Si QD luminous solar concentrator performances in a low-cost, structural polymer suitable for window applications.

10:45 AM ET13.01.05
Flexible Bragg Reflectors for Efficient Deformable Luminescent Solar Concentrators Mark Portnoi1; Christian Sol, Tom S. Robbins, Johannes Schlaefer, Clemens Tummler and Ioannis Papakonstantinou2; Electronic and Electrical Engineering, University College London, London, United Kingdom.

Structural flexibility of photovoltaic devices can lead to an expanse of applications such as wearable technologies, flexible electronics, self-powered sensors and roll-to-roll manufactured smart facades. Luminous solar concentrators (LSCs) composed of flexible host matrices such as polydimethylsiloxane (PDMS) have been proposed as a means of providing this flexibility. The elastomer sheets doped with luminophores can be fabricated in a range of sizes, transparencies, colours and rigidities to the designer’s needs.

This additional functionality can come at a cost to efficiency. Curvature results in increases in both reabsorption and escape cone losses. In this work we explore how curvature affects these losses and propose a solution for their mitigation. We investigate the effect of curvature on LSC efficiency by means of an experimentally verified Monte-Carlo model (MCM) for curved LSCs. We show that for large scale devices, the optimal concentrations of fluorophore concentrations at fixed thicknesses required to achieve the highest external optical efficiency differ for curved and flat LSCs.

To mitigate escape cone losses, we propose flexible distributed Bragg reflectors (DBRs) consisting of alternating PDMS and PDMS-titanium composite thin films with a refractive index contrast of ~0.3. These DBRs are designed to have omnidirectional reflectivity in the spectral region of the emission of the luminophores but high transmission in the absorption region. We fabricate prototype DBRs and compare reflectance to transfer matrix model (TMM) calculations. Combining our MCM and TMM into a hybrid package we optimise the application of such DBRs to Lumogen Red 305 doped flexible LSCs and demonstrate the DBR effect on their efficiency. We then use the model to predict the full potential of this pairing.

This work will pave the way for efficient and deformable LSCs. We plan to incorporate these into devices for use in everyday life.

11:00 AM ET13.01.06
Powering Future Cities with Quantum Dot-Tinted Glass Luminescent Solar Concentrator Windows Hunter McDaniel; Matt Bergren, Karthik Ramasamy, Aaron Jackson, Nikolay Makarov, Andres R. Velarde and Nicolai C. Archuleta; UbiQD, Inc., Los Alamos, New Mexico, United States.

In urban settings where demand (and price) for electricity is high, the space available for solar modules is minimal. Tall buildings utilize vast amounts of electricity that is transmitted from remote power stations on lossy transmission lines. Emerging competing sunlight-harvesting window solutions are expensive and have poor aesthetics. Competing quantum dot (QD) technologies are costly, toxic, and/or unstable. UbiQD invokes proprietary methods for low-cost manufacturing of stable, high performance, non-hazardous QD composites that are utilized in luminous solar concentrators (LSCs). Partially transparent LSCs provide a simple method of harvesting sunlight wherein absorbed light is effectively redirected to small solar cells hidden in the frame of a window. The company has achieved a certified record performance for solar windows, and is close to its target of 50 W/m2 of power output at 50% visible light transmittance, enough to turn an 80-story skyscraper into a >1GWh/yr urban power station. In this talk I will provide an overview to the market opportunity for solar windows, competitive landscape, and how our QD LSC technology compares. I will also provide a status update on UbiQD's best performing prototypes to date, and other recent milestones at the company.
Single junction photovoltaic devices exhibit a bottleneck in their efficiency due to incomplete or inefficient harvesting of photons in the low- or high-energy regions of the solar spectrum. This can be overcome through the retrofitting of a spectral converter to the device, which is used to convert solar photons into energies that are more effectively captured by the solar cell through a photoluminescence process. However, while a lumophore may show seemingly ideal optical characteristics for spectral conversion in an ideal solution (high emission quantum yield, strong absorption), disappointment frequently awaits its translation to the solid-state, where aggregation and quenching effects lead to significantly reduced photoluminescence yields.

In an effort to overcome this limitation, our research focuses on the bottom-up design of integrated lumophore-host materials for solar spectral converters, in which materials chemistry design strategies are used to control the packing, orientation and placement of p-conjugated lumophores in solid-state host materials. Since the electronic properties depend explicitly on the arrangement and packing of the p-conjugated species, this approach provides a means of modulating the optical properties. In this talk, we will report our recent results on the design of II-conjugated composite materials that utilise a family of organic-inorganic hybrid polymers known as the ureasils as the host. Ureasils are comprised of a siliceous skeleton that is chemically-grafted to poly(ethylene oxide) (PEO)/poly(propylene oxide) (PPO) chains through urea cross-linkages, the number of which depends on the degree of branching in the organic polymer precursor. Ureasils are intrinsically photoluminescent, exhibit high refractive indices and function as optical waveguides. Through judicious selection of the degree of branching and length of the organic backbone and the incorporation method (grafting vs immobilization vs permeation), we can control the packing, orientation and placement of the II-conjugated species in the ureasil host. This in turn provides a means of modulating the optical properties. For example, a dramatic enhancement in the emission quantum yield to >60% is observed due to exciton localization at isolated nanodomains of a conjugated polyelectrolyte entrapped within the ureasil host. Similarly, Förster resonance energy transfer from the ureasil to embedded or grafted conjugated lumophores can be exploited to tune the emission color and even obtain white-light emission. These characteristics can be exploited to improve light-harvesting and trapping within the integrated material, which can be used to develop highly efficient LSC’s to enhance the performance of silicon solar cells.

High performance QDs, dispersing agents, and controlled resin curing are all important for manufacturing successful LSC materials and solar windows. Our CIS QDs have high QY and are stable in air at high temperatures. This allows formulation and curing of QD resins in air with minimum QY reduction. The high temperature stability also opens future opportunities for extrusion processes. In fact, we demonstrate that our CIS QDs can withstand 190°C for more than 10 minutes with minimal QY reduction. We incorporate QDs into windows as part of an interlayer in a glass laminate configuration where the laminate is made by a casting manufacturing technique. The glass has minimal surface defects which allows highly efficient TIR. Typically, the hydrophobicity of the QDs limits QD resin formulations to low viscosity, low adhesion, and low concentration formulations. However, by using dispersing agents and controlled curing techniques, we are able to formulate our resins with functionality similar to commercial polymers. For example, our resins use a variety of viscosity modifiers, plasticizers and adhesion promoters that allow scalable manufacture such as roll-to-roll coating and polymer casting. With these complex formulas, our QD LSCs with a VLT of 50% allow solar windows to be made with 29W/m² as certified with testing at NREL.
Luminescent solar concentrators (LSCs) appear as an intriguing way to cope with the mismatch between the photovoltaic (PV) cells absorption and the solar spectra, with the additional advantage of urban integration of photovoltaics [1,2]. We present LSCs based on bundles of triangular hollow-core plastic optical fibers (POFs) filled with amine-functionalized organic-inorganic hybrids (di- and tri-ureasils) doped with Rhodamine 6G, Rhodamine 800 or an Europium b-diketonate complex with visible-to-NIR tunable emission. The LSCs are characterized by optical conversion efficiency values up to $h_{opt}=5.3\%$ and when coupled to commercial Si PV cells yield maximum power conversion efficiency values of PCE=0.74% [3].

Aiming at following a sustainable route for the designing novel LSCs, photosynthesis was an inspiring natural mechanism and chlorophyll-based LSCs were processed and optically characterized. The chlorophyll molecules were extracted from Spirulina maxima which is an abundant cyanobacteria and an attractive natural source. To enable the easy and controlled processing of planar LSCs, the chlorophyll molecules were incorporated into di- and tri-ureasils with the added advantages of avoiding the formation of non-luminescent dye-aggregates, enhancing quantum yield and photostability. The chlorophyll-based LSCs were coupled to a Si-based PV device, revealing $h_{opt}$ and PCE values $~3.70\%$ and $~0.10\%$, respectively, demonstrating the huge potential of nature-inspired LSCs for sustainable PV energy conversion [4].

**3:45 PM ET13.02.06**
Advances and Challenges in Luminescent Solar Concentration for Building Integrated Photovoltaics Francesco Meinardi; Department of Materials Science, University of Milano-Bicocca, Bicocca, Italy.

Luminescent solar concentrators (LSCs) could facilitate the green architecture revolution by enabling the realization of semi-transparent photovoltaic (PV) systems, which could potentially convert the façades of urban buildings into distributed electrical power generators. LSCs were first proposed in 1976 as cost-effective alternatives to silicon solar cells. However, only after the recent breakthroughs in the realization of new classes of colloidal semiconductor nanocrystals, which combine suppressed reabsorption with broadband spectral coverage, the performances of the LSCs have been boosted to such a degree that they become the most promising technology for the next generation of PV glazing units. The LSC technology is now set on a clear path to become a PV technology that can be “irresistibly” integrated into the built environment without detrimental effects to the aesthetics of the building or the quality of life of the inhabitants in the form of colorless and electrodeless solar windows or as other semi-transparent architectural elements. Nevertheless, this final integration step, and in particular the optimization of the power efficiency for devices on the meter scale, will require scientists and engineers to face new emerging challenges.

This talk will review the successful strategies that have allowed this historical change of pace, examining and comparing the different types of developed nanomaterials, and discuss the issues that remain to be investigated for further progress. On the materials side, the realization of high-quality optical waveguides will be the most demanding task. It will require a perfect pattern of the nanocrystals inside the waveguide matrix to avoid detrimental light-scattering losses and, probably, also the adaptation to LSCs of highly transparent polymers or glass variants currently used in photonics and telecommunications will be necessary to produce very large LSCs. Finally, the optical-to-electrical conversion by the PV cells at the LSC edges will have to be suitably designed and optimized. This last step in the luminescent solar concentration process has not yet been fully investigated because of the challenges in the realization of highly performing optical waveguides. Together with the role of the waveguide absorption, this will soon be at the forefront of research into LSCs for real-world applications.
Encouraged by the commercial utility of organic molecular electrochromes in electrochromic windows and mirrors, we are developing scalable and solution processable conjugated electrochromic polymers (ECPs), which provide a unique encompassing set of structurally tunable colorimetric and redox properties, stable over thousands and tens of thousands of redox switches. Processing of these materials is carried out using a variety of solution methods including spin-coating, spray-coating, blade-coating, slot die coating, and ink jet printing. In this lecture, we demonstrate how the optical absorbance spectra of ECPs can be tuned to yield materials of all colors that can be switched to highly translucent forms as desired for absorptive/reflective (display type) and absorbive/transmissive (window type) devices. We will show how random copolymerization has been used to broaden spectral absorption yielding a family of black-to-transmissive ECPs. We have also developed a set of fast switching, high contrast, black and brown ECP blends, where the precise hues are readily tunable. We use these brown blends to showcase a practical application of ECPs in color changing eyewear. In addition to their yielding a family of black-to-transmissive ECPs. We have also developed a set of fast switching, high contrast, black and brown ECP blends, where the aesthetic qualities, their optical memory in both the colored and colorless states allow these devices to be run at low power. Photo-oxidative stability will be addressed using encapsulated films and ECDs. Finally, we combine our ECP and OPV technologies into possibilities for solar powered electrochromic windows.

9:00 AM ET13.03.02
Digitally Inkjet Printed Electrochromic and Electrofluorochromic Polymer for Dual-Mode Display Applications
Manuel Pietzsch1, 2, Johannes Zimmermann1, 2, Tobias Rödlmeier1, 2, Stefan Schlüske1, 2, Carlos Romero-Nieto3 and Gerardo Hernandez-Sosa1, 2, 1LTI, Karlsruher Institute of Technology, Karlsruhe, Germany; 2KIT, InnovationLab GmbH, Heidelberg, Germany; 3OCI, Ruprecht-Karls-University Heidelberg, Heidelberg, Germany.

Electrofluorochromic devices (EFCD) receive increasing attention in investigation in the past years, because they offer the possibilities for dual-mode display devices, which combine the advantages of reflective and emissive displays. Besides that, the low power consumption, the low voltage requirement and simple device architecture (i.e. electrochemical cell) provide the opportunity for low-cost display devices. To provide a cost-effective method with the freedom of design necessary for smart windows and display applications, inkjet printing can be used as a suitable method with high throughput, low material waste and upscaling capabilities to industrial fabrication. Here, we report the synchronous electrochromic and electrofluorochromic switching of polyindenofluorene-8-tryarylamine (PIF8-TAA). The investigated devices consisted of a layer of PIF8-TAA and a polymer electrolyte gel (PEG), using poly(methyl methacrylate) (PMMA), tetrabutylammonium hexafluorophosphate (TBA PF6) and propylene carbonate (PC), sandwiched between two indium tin oxide (ITO) electrodes. In its neutral state the polymer is transparent in the visible range and changes its color to deep red upon oxidation. Simultaneously, the blue colored fluorescence intensity is quenched. Besides its high stability in ambient conditions, the devices showed switching times of <2s, a coloration efficiency of 542±10 cm2/C at 395 nm, a fluorescence contrast ratio of 4,1±0,3 and an electrochromic contrast of 50±4% in the visible spectrum. These figures of merit ranking in the upper range of literature values make it a promising material for dual-mode display applications. Furthermore, by changing the working electrode to inkjet printed poly(3,4-ethylenedioxythiophene) (PEDOT) we demonstrate the fabrication of an electrofluorochromic device with independently addressable pixels to demonstrate the functionality of inkjet printed, structured EFCDs. Thus demonstrating the potential of these devices in display and smart window applications.

9:15 AM ET13.03.03
Polymer Dispersed Liquid Crystal Optimization for Low Power DC Field Application
Caitlyn Cook, Elaine Lee, Brian Giera, Herbert Wakefield, Andrew Pascall, Marcus A. Worsley and Joshua Kuntz; Lawrence Livermore National Laboratory, Livermore, California, United States.

Polymer dispersed liquid crystals (PDLC) have been heavily researched for applications such as smart windows in buildings, displays, and automobiles. A large focus on improving smart window production is in the reduction of production cost and required power. Here, the developed PDLC provides transmittance contrast ratios up to 30, with required power on the order of micro-Watts. Our smart PDLC windows can maintain a steady state of high transparency in DC field application and does not require high power (milliWatt), high frequency AC fields like conventional PDLCs with similar contrast ratios. When using commercially available pre-polymer, significant relaxation of the transparent state back to a translucent or opaque state occurs when holding a voltage at a steady state for a few seconds. This phenomenon occurs increasingly so at lower voltages (10V), as determined via UV-VIS (transmission) and custom color difference quotient (reflection) characterization techniques. To further understand and improve relaxation with DC voltage application, a series of photosensitive acrylate-based pre-polymer chemistries similar to PN393 were formulated and tested. Each formulation component has been systematically modified and characterized via the aforementioned characterization techniques in conjunction with scanning electron microscopy and UV-Rheology in a trend towards decreasing the power requirements and reducing electro-optical relaxation with DC field application. With polymerization induced phase separation speeds completing within two seconds in response to 365 nm light, such a formulation can be incorporated into a roll-to-roll production method and thus can be utilized for flexible electronics. Prepared by LLNL under Contract DE-AC52-07NA27344.

Transparent Intelligence—Progress in Chromogenic Materials and Devices for Glazing
Claes-Goran Granqvist; The Ångström Laboratory, Uppsala University, Uppsala, Sweden.

This paper outlines the essential properties of the radiation around us, and uses this information to specify a number of requirements for energy efficient glazing. Spectral selectivity, angular dependence, and time variability stand out as important concepts. Focus is then put on novel results for thermochromic and electrochromic materials and devices. In particular, I present a number of strategies for boosting the cycling stability of electrochromic thin films of tungsten oxide and nickel oxide by electrochemical pretreatment or post treatment in lithium-ion-conducting electrolytes, or by intermixing of several
oxides.

Stretchable Array of Active-Matrix Based Poly-(3-methylthiophene)/Prussian Blue Electrochromic Devices with Low Power Consumption

Dong Sik Kim, Heun Park and Jeong Sook Ha; Korea University, Seoul, Korea (the Republic of)

We report on the fabrication of low power operated, stretchable array of active-matrix based electrochromic devices (ECDs). ECD consists of poly(3-methylthiophene) and prussian blue grown on indium tin oxide coated polyethylene terephthalate film, and mixed gel electrolyte of acetonitrile, poly(methyl methacrylate), propylene carbonate, and LiClO4. Upon application of a bias voltage at -1, 0, and 1 V, the ECD displays red, green, and blue colors, respectively. For the operation of the ECD, low powers of 373 μW/cm² at -1.0 V and 378 μW/cm² at 1.0 V are consumed but with a high coloration efficiency of 201.6 cm²/C at 1.0 V.

On a stretchable Ecoflex substrate, 4x4 array of ECDs with corresponding 4X4 n-type FETs as active-matrix elements for preventing the cross-talk, are integrated using patterned liquid metal, GanSn interconnections. Such fabricated ECD array exhibits a mechanical stability by biaxial stretching by 30% and bending deformation. Finite element method analysis of the strain distribution also confirms that the strain is only concentrated onto the Ecoflex area between the active devices of ECD and FETs. This work demonstrates the high potential of our fabricated stretchable ECD array in the application to full-color display associated with stretchable electronics, wearable devices, and electronic skin.

Hybrid Organic-Inorganic Materials for Multifunctional Window Application

Elsa John and Aswani Yella; Indian Institute of Technology-Bombay, Mumbai, India.

Hybrid lead halide based perovskites have gained much interest as an absorber material in solar cells owing to its low cost, easy processing method and suitable optoelectronic properties like broad absorption, small exciton binding energy, long lived photogenerated carriers and ambipolar charge transport. The wide variety of the organic and inorganic moiety that can be incorporated into these perovskites not only make the structure very flexible but also enable fine tuning of the material specific to the application. Within a few years of its inception in the solar cells, the certified power conversion efficiency of these perovskite solar cells have increased from 3.8% to 22.1%, making it one of the most explored material in the field of photovoltaics. The most common general formula for these halide perovskites is ABX₃, where A is a large monovalent cation (methylammonium CH₃NH₃⁺, formamidinium CH(NH₂)₂⁺), B is usually Pb²⁺ and X is a halide ion. Three dimensional corner-sharing PbX₆ octahedra with the central site occupied by organic cations form the structure of these perovskites. Although these materials have most extensively been used in the solar cells, they have also garnered significant interest in other fields such as field effect transistors (FET), light emitting diodes (LED), laser diodes and photodetectors. Changes in the structure of these hybrid materials induced by electrochemical changes bring about a change in the optical property making it a suitable material for multifunctional windows. This work highlights the structural changes in the material brought out by electrochemistry and the underlying phenomenon. The change in optical property is studied to optimize the device performance for window application, making it an environmentally sustainable material.

11:00 AM ET13.03.07
Designing Tunable On/Off Electrochromic Bragg Stacks

Sungyeon Heo, Ankit Agrawal and Delia Milliron; Chemical Engineering, The University of Texas at Austin, Austin, Texas, United States.

Dynamic tuning of Bragg stacks with wide spectral range and reflection is desired for efficient energy-saving windows, camouflage platforms, and military purposes. Especially for window applications, color neutrality and efficient heat blocking can be achieved via visible or near-infrared reflection compared to dominant approach that utilizes light absorption. Previous approaches of designing dynamic electrochromic Bragg stacks used optical constants of thin films from ex-situ ellipsometry measurement. However this ex-situ method doesn’t reflect dynamic reflection measurement condition and predicted reflection with simulation was missing. Moreover significant reflection at both charged and discharged states compromises its window applications, which is generally expected to show transparency in the discharged state. Here, we designed nanocrystals (NCS)-based Bragg stack films consisting of WO₃ and ITO NCs, and demonstrated their on/off reflection tuning over visible and near-infrared ranges. We provide a complete analysis with a combined approach of in-situ ellipsometry and transfer matrix simulation to rationalize and predict the optical behavior of the Bragg stacks. Combining our novel processing approach with judicious material design, we show how an optimized 1-D Bragg stack can be implemented for electrochromic applications. First, Bragg stacks on the ITO-PET flexible substrates without any annealing process were demonstrated with the advantage of ligand stripped NCs. The Bragg stacks with annealing process gave more enhanced reflectance, predicted by the in-situ ellipsometry analysis. By adjusting the ITO film thickness, the reflectance was changed from visible to near-infrared range, and the each film’s reflectance and peak position were tuned by changing the potential, matched with simulation. We expect this approach with simulation will guide us to rationally design the more enhanced NCs-based Bragg stack for efficient energy-savings in windows.

Smart Materials Based on Multifunctional AIEgens

Benzhong Tang; The Hong Kong University of Science and Technology, Hong Kong, China.

Chemists are always seeking new methods to obtain artificial smart materials with multiple on-demand functionalities. Although the responsive process of these smart materials can be monitored by various methods, such as NMR, IR, MS and electron microscopy, etc., a problem associated with these methods is that they are all invisible to our naked eye. Fluorescence shows rich advantages such as superior sensitivity, high selectivity, fast response, and simplicity. More importantly, it can provide high spatiotemporal resolution for precise visualization into complicated processes in a noninvasive way. Another thing that need to be considered is that most of the smart materials function in the condensed phase which show notoriously ACQ effect to result in compromised sensitivity. Diametrically opposed to conventional luminophores, AIEgens are nearly non-luminescent in the isolated state but luminesce...
strongly in the aggregate/clustered state. Based on different AIEgens, we have fabricated various intelligent materials which can respond to different stimuli, such as force, temperature, moisture, pH, electric, and light. These smart materials show fascinating applications in sensors, actuators, and biological processes.

Phase Transformation and Photophysical Properties of Silver Doped Copper Indium Sulphide Colloidal Quantum Dots for Solar Cell Applications Shanna-Kay Spencer1, Richard A. Taylor1, Paul Menautarg2 and Paul O'Brien2; 1Chemistry, University of the West Indies, St. Augustine, Trinidad and Tobago; 2Chemistry and Materials, University of Manchester, Manchester, United Kingdom.

Ternary chalcopyride silver doped copper indium sulphide (Ag-CIS) quantum dots are currently being explored as promising materials for photovoltaic applications. Quantum dots <10 nm have been synthesized via a hot injection colloidal method using a unique combination of precursors and capping agents over a range of temperatures. Those synthesized at 140, 180 and 210 °C show quasi-spherical morphology with fairly narrow size distribution (5.6 ± 1 nm) exhibiting predominantly chalcopyrite structure. However, nanoparticles synthesized for 10 minutes at 180 °C have the narrowest size distribution with a wurzite structure instead of chalcopyrite. Furthermore, structural data confirm a change from wurzite to chalcopyrite structure as the annealing temperature increases up to 200 °C. The Ag concentration in CIS nanoparticles increases with temperature and with an increase in Ag concentration the Ag ions substitute Cu sites in the CIS lattice. The photoluminescence (PL) peak peak of as-synthesized Ag-CIS quantum dots is at 660 nm. The PL peak redshifts significantly as the temperature of annealing increases from 180 °C to 210 °C. The Ag-CIS nanoparticles over a range of temperatures up to 600 °C but there are no reports to the best of our knowledge which employs the use of dopants or show an influence of synthesis duration on phase transformation.

These findings suggest an attractive route to tune structure and optical properties and an effective means for possibly enhancing photovoltaic performance. To this end, we will be focused on making a plausible and crucial connection between the effect of synthesis duration and dopant content on phase transformation in colloidal Ag-CIS nanoparticles. Further we will discuss the effect of dopant concentration on the photo-physical properties including time-dependent luminescence and the role of the dopant Ag ion in these CIS quantum dots for tunable photovoltaic effects.

Chemical Solution Deposition Process of Advanced Multifunctional Transparent Thin Films—Inorganic Octahedral Metal Cluster and Electrophoretic Deposition Process Fabien Grasset1, 2, Ngan T. Nguyen2, 1, Adele Renaud3, Maxence Wilmet4, 1, 5, Marion Dubernet3, 1, Noee Dumait3, Yann Moillard3, Marian Amelia-Cortes4, Stephane Cordier4, Naoki Ohashi2, 1 and Tetsuo Uchikoshi2, 1; 1UMI 3629 LINN, National Institute for Materials Science, Tsukuba, Japan; 2RCFM, National Institute for Materials Science, Tsukuba, Japan; 3UMR 6226 ISCR, Université de Rennes 1, Rennes, France; 4Saint-Gobain Recherche, Aubervilliers, France.

Transparent thin films or coatings, with thickness ranging from nanometers to few tens micrometers are playing a very important and indispensable role in daily life [1]. Recently, the demand of new robust, low cost and friendly-environmental functional hybrids thin films with high transparency for optical applications is increasingly growing. The main targeted applications are lightening and color design [2], self-cleaning [3], photovoltaic luminescent solar concentrators [4-6] or window solar control [7-9]. Moreover, the use of solution processes are highly desirable in order to reduce the cost and waste and that can enable fabrication method for large area and even flexible devices.

This presentation will summarize our very recent works on the synthesis of multifunctional nanocomposites thin films or coatings on glass by chemical solution deposition processes (CSD) [10-18]. CSD processing of inorganic nanocolloidal solutions is generally acknowledged to be highly flexible in terms of precursor composition, targeted substrate and processing procedures (dip-spin coating, electrophoretic deposition process (EPD)...) in ambient pressures, and thus can be faster and less expensive than vapor based deposition routes while providing materials with matching or even superior properties. In this study, the EPD appears as an efficient process to fabricate highly transparent and functional nanocomposite thin films on glass for optical and energy applications. Several octahedral atom clusters were used to prepare thin films with high transparency in the visible. Several octahedral atom clusters were used to prepare thin films with high transparency in the visible. Each octahedral atom cluster were used to prepare thin films with high transparency in the visible. Each octahedral atom cluster was used to prepare thin films with high transparency in the visible. Each octahedral atom cluster was used to prepare thin films with high transparency in the visible. Each octahedral atom cluster was used to prepare thin films with high transparency in the visible. Each octahedral atom cluster was used in the aggregate/clustered state. Based on different AIEgens, we have fabricated various intelligent materials which can respond to different stimuli, such as force, temperature, moisture, pH, electric, and light. These smart materials show fascinating applications in sensors, actuators, and biological processes.

Transparent Electrodes for Multifunctional Windows—A Brief Overview Daniel Bellet; LMGP, Grenoble Institute of Technology, Grenoble, France.

Both energy and material consumption of buildings are and will remain a major concern for the next decades. In every buildings, either residential or
commercial, the overall energy use can significantly be lowered through optimization of heat accumulation and heat loss of façades and windows. This leads to research devoted to novel materials for smart windows which can be conceived as affordable multifunctional systems that offer enhanced energy control. Therefore development of materials for multifunctional windows is of huge importance. For instance electronically switchable windows, called as well smart windows, enable the alteration of their optical transparency thanks to an applied electric field. Generally speaking the topics of multifunctional windows concerns materials which can be photochromic, electrochromic, piezoelectric, transparent/semi-transparent etc. Very often these technologies required two parallel and opposite transparent electrodes: this is for example the case for creating an electric field to actuate an electrochromic material as well as for transparent/semitransparent photovoltaics to collect the photo-generated carriers. Therefore transparent electrodes should as well be thoroughly understood and optimized for an efficient integration into multifunctional windows.

The present contribution focuses on the different technologies associated to transparent electrodes. The various studied materials are for instance the classical transparent conductive oxides (TCO) and more recently metallic nanowire networks. We will describe and compare the main structural, optical and electrical properties of the different materials developed for transparent electrodes in multifunctional windows. The main scientific challenges associated with transparent electrodes for improving performance of multifunctional windows, as well as their stability, will be discussed. Stability can indeed be a crucial issue, involving optical and thermal aspects, ageing and chemical degradation.

Thermal Insulation via the Photothermal Effect of Chlorophyll Thin-Film Coating—An Energy Efficient “Green Window” Yuan Zhao and Donglu Shi; Dept of Mechanical and Materials Engineering, University of Cincinnati, Cincinnati, Ohio, United States.

One of the critical components in energy saving is thermal insulation, especially for large-area high-rise public building windows in cold climates. The conventional approach mainly relies on optimization of the thermal insulators and window designs (double-pane). It has remained a great challenge, however, to implement single-panes due to conflicting intrinsic materials properties (i.e. thermal insulation vs. transparency). In this study a new concept is developed to prevent heat loss without any insulating medium such as gases within double-panes and low-e coatings. A “Green Window” has been designed for single-pane applications that meet the U-factor specifications of Department of Energy for colder regions of the United States. The “Green Window” is structurally composed of a thin film window coating of naturally occurring chlorophyll that exhibits pronounced photothermal effect, while remaining highly transparent. Upon collecting solar light, considerable heat is created, effectively raising the window surface temperature, leading to a reduced U-factor less than 1.7 W m-2 K-1, even below the values of double-panes. As such we demonstrate of new concept in “thermal insulation” via optical means instead of sole dependence on thermal insulators. This concept lifts the dependence on insulating materials making single-pane window highly plausible.

ET13.05.02
Joule-Heating-Induced Infrared Switching in Flexible VO2 Nanoparticles Film Nan Shen and Chun Cheng; Southern University of Science and Technology of China, Shenzhen, China.

As a typical metal-insulator transition (MIT) material, vanadium dioxide has attracted much attention due to its distinct infrared and resistive switching characteristics. However, the relatively high phase transition temperature and uncontrollable thermally driven phase transition of VO2 inhibited its practical applications. In our work, we fabricated flexible VO2 nanoparticles films using a scalable printing method and investigated joule-heating-triggered infrared switching of VO2 films by applying voltages. Well-matched luminous transmittance (Tlum=57.3%) and solar energy modulation ability (∆Tsol=13.8%) of VO2 films can be achieved at 2.0 wt.% solid content. The infrared switching of VO2 nanoparticles films is well controlled by input voltages and exhibits high stability. A quite small increase (6.8%) after 10000 bending cycles is observed for normalized Tlum and ∆Tsol of VO2 samples, reflecting excellent flexibility. Our results provide an alternative strategy to regulate the infrared switching performance of flexible VO2 films, which would significantly promote the development of thermal-sensitive VO2 devices.

ET13.05.03
Ladder-Structured Polysilsesquioxane/Al2O3 Nanocomposites for Transparent Wear-Resistant Windows Min Seon Kim1, Yejin Ahn1, Sunyoo Kim2, Ji Ho Youk2 and Bong-Gi Kim1; 1Department of Organic and Nano System Engineering, Konkuk University, Seoul, Korea (the Republic of); 2Department of Chemical Engineering, Inha University, Seoul, Korea (the Republic of).

As a protective layer for deformable displays, we synthesized ladder-type polysilsesquioxanes (LPSQs) containing cyclic epoxy as a curable unit. The mechanical properties after photo- and thermal-curing of LPSQs with a small amount of added Al2O3 nanoparticles were compared with those of the pure LPSQs. The prepared LPSQ-Al2O3 nanocomposites and the pure LPSQs exhibited comparable optical transparencies and thermal stabilities. In addition, the degree of conversion of the applied epoxy units in LPSQs and the resulting mechanical properties, as monitored by Fourier transform infrared spectroscopy and nanoindentation tests, indicated that the addition of nanoparticles to LPSQs moderately enhanced the epoxy conversion rate and remarkably improved the wear resistance, including hardness, after photo-thermal-curing processes. The LPSQ-Al2O3 nanocomposites achieved higher wear resistance than epoxy-silica nanocomposites containing similar curable functional groups and reinforcing fillers (silica). The excellent mechanical properties of the LPSQ-Al2O3 nanocomposites could be attributed to three-dimensionally interconnected networks of organic-inorganic hybrid-type chemical structures in the LPSQ as well as additional reinforcement from amine-functionalized Al2O3 nanoparticles covalently interconnected with the LPSQ. We believe that the devised LPSQ-Al2O3 nanocomposites could serve effectively as a wear-resistant platform for deformable display windows.

ET13.05.04
Low Temperature Growth of Conductive SrVo3 Thin Films on Various Substrates by RF Sputtering Deposition Daeho Jung, Hosun Lee, Hyeon Seob So and Sangbin Hwang; Kyunghee Univ, Yongin-si, Korea (the Republic of).

It is very important to improve the performance of transparent conducting oxide (TCO) for display applications. Recent studies have suggested a novel method of making transparent conductors. Perovskite metal oxides have correlated electrons, and become transparent in the visible spectral range due to the carrier mass renormalization. The effective mass becomes heavier, by the interaction between the electrons. To have high electrical conductivity and to be transparent in the visible light region, absorption and reflection of light must be minimized in the visible region, and high carrier concentration and small carrier scattering are required. Particularly, strontium vanadates (SrVO3) have been intensively studied due to high electrical conductivity as well as high optical transparency in the visible range.

SrVO3 thin films were grown on various substrates using RF magnetron sputtering deposition with a commercial SrVO3 target as low as at 400°C with a mixed gas of H2 and Ar. Film thicknesses varied between 40 and 90 nm. We used (LaAlO3)0.5( Sr2AlTaO6)0.5 (LSAT), LaAlO3, SiO2/Si, a-c-m- and r-plane sapphires as substrates. The structural and morphological properties of SrVO3 films were studied using grazing-incidence-angle X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), and X-ray photoemission spectroscopy (XPS). The electrical properties of all samples were measured using Keithley 4200.

SrVO3 films grown on LSAT substrates showed crystalline peaks of cubic phase SrVO3 films at 53.3° (210) using GIXRD. SrVO3 films grown on SiO2/Si showed crystalline peaks of cubic and orthorhombic phases as well as Sr3V2O7 phase. SrVO3 films showed grain boundaries with the average grain size between 100 nm and 150 nm according to SEM. High-resolution TEM images of SrVO3 thin films grown on LSAT showed high crystallinity and a well-ordered cubic phase.
We found the binding energy for multivalence state of \(V_{2p}\) from \(V^{4+}\) (516.8 eV) to \(V^{5+}\) (516.3 eV) for SrVO\(_3\) thin films on LSAT with increasing film thickness. We note that the insulating phase of SrV\(_2\)O\(_3\) (in \(V^{5+}\) state) films can be changed to SrVO\(_3\) (in \(V^{4+}\) state) films as the growth times increased due to \(H_2\) gas-induced reduction phenomenon. The resistivity of the SrVO\(_3\) films on LSAT was lower than other substrates because SrVO\(_3\) films were nearly latticed-matched to LSAT substrates. XRD, TEM, and XPS depth profiles showed a good crystallinity of SrVO\(_3\) thin films grown on LSAT substrates. The transmission spectrum of SrVO\(_3\) films with various film thicknesses grown on LSAT substrate were measured between 300 nm and 1000 nm of photon wavelength. The transmission was measured to be about 60% and 97% for film thickness of 40 nm and 70 nm, respectively, in the visible range. This work demonstrates that high-quality cubic phase of SrVO\(_3\) films can be grown using RF magnetron sputtering deposition with growth temperature as low as 400°C.

**Electrochromic Perovskite Nickelate Windows**

Yifei Sun\(^1\), Zhaoyi Li\(^2\), Nanfang Yu\(^2\) and Shiriram Ramanathan\(^1\); \(^1\)Purdue University, West Lafayette, Indiana, United States; \(^2\)Columbia University, New York, New York, United States.

Electrochromic windows are of interest in energy efficient adaptive architectures as well as various tunable optical devices. In this work, we present a class of correlated perovskite nickelate thin films (such as SmNiO\(_3\) (SNO) and NdNiO\(_3\) (NNO)) as promising next generation electrochromic materials. We will discuss results from electrochromic devices comprising indium doped tin oxide (ITO) coated glass as transparent electronic conductors, NNO thin film as electrochromic layer and salt solution as liquid ionic conductor exhibiting quick response and excellent stability upon coloring and bleaching cycles. The mechanism of color change in perovskite nickelates is distinct from conventional electrochromic materials which are based on redox reactions and become more conductive upon electron doping. During ion intercalation, a colossal phase transition in nickelate occurs that is an effect of strong electron-electron correlation, which makes them highly insulating and transparent due to charge carrier localization. We further show that the nickelate films allow for continuous and large tuning of optical transmissivity across the entire visible, near-infrared and mid-infrared spectra, which is of interest for control of sunlight transmission and variable emissive coatings.

**High Transparency and Self-Healing Liquid-Infused Surfaces for Optical Devices**

Meiling Zhang\(^1\), Qi Liu\(^1\), Jun Wang\(^1, 2\) and Rongrong Chen\(^3\); \(^1\)Key Laboratory of Superlight Material and Surface Technology, Ministry of Education, Harbin Engineering University, Harbin, China; \(^2\)Institute of Advanced Marine Materials, Harbin Engineering University, Harbin, China.

High transparency is one of the basic requirements for optical devices, such as smart windows, solar cell panels and optoelectronic devices, to function well. However, frequent exposure of these devices to different outdoor environments, inevitably stains their outermost surfaces, which might diminish their performance. Superhydrophobic surfaces have anti-adhesion properties with water contact angle greater than 150° and slide angle below 5°. However, during the process of droplet condensation on a rough surface, the droplets on the surface can transform from the Wenzel-Cassie state to the Wenzel state, leading to the failure of superhydrophobic effect. Aizenberg et al. [1] first proposed the concept of a slippery liquid-infused porous surface (SLIPS). They poured lubricating oil into the porous surface for the preparation of super-slippery surfaces, along with the formation of a dynamic oil film, solving the problem of super-hydrophobic failure efficiently. Silica is often chosen as the alternate material because of its low refractive index and low absorbance of visible light. Herein, we propose to use tube-like SiO\(_2\) textures for trapping a lubricant liquid inside, and choose this liquid for allowing a drop of another liquid to float on this mixed substrate. A micro-mesoporous hollow tubular material with a wall thickness of about 100 nm and an inner diameter of about 1 \(\mu\)m was prepared successfully. Inspired by Yao Lu et al. [2], they use glue to make the coating robust on the surface, in this paper, glutaraldehyde was chosen as an adhesive to adhere the porous hollow tube-like SiO\(_2\) on the glass substrate and then a lubricant oil is poured into the surfaces after modification with FAS. As a consequence, these surfaces have remarkable slip properties: drops hardly pin on them, which makes them roll off readily and continuously retract as evaporating, contrasting dramatically with usual solids. It should be a promising candidate for long-term transparent optical devices.

**Composition and Structural Characterization of Photochromic Gd-Based Oxy-Hydrides Thin Films**

Giorgio Colombi\(^2\), Steffen Cornelius\(^2\), Alessandro Longo\(^1\), Herman Schreuders\(^2\), Fahimeh Nafizarefi\(^2\) and Bernard Dam\(^1\); \(^1\)Institution Netherlands Organization for Scientific Research (NWO), The European Synchrotron, Grenoble, France; \(^2\)Chemical Engineering, Delft University of Technology, Delft, Netherlands.

On average 30-40% of the energy consumption in the developed world is in the building sector. In this context, smart energy saving windows are envisaged to play an important role in bringing this number down and help with the urban air-pollution that is typical of the warm season. The recently discovered Rare Earth-based metal oxy-hydrides (MH\(_x\)O\(_y\)) are a particularly promising class of inorganic materials which show photochromic properties under ambient condition. The optical transmittance in these materials can be decreased reversibly by exposure to sunlight. The largest contrast change is observed between 400 and 1000 nm, however, the photochromic contrast extends up to the MID-IR region. Therefore these materials are not only suitable for the light-modulation in the visible range (where the darkening is colour-neutral) but they also act as a barrier to the heat irradiated by the sun at longer wavelengths. Despite the efforts of the last years, the darkening and bleaching mechanism is still under debate and it remains unclear which parameters affect its amplitude, speed and persistence upon several illumination cycles. In the interest of this open question, this work attempts to tackle the somehow elusive chemical nature of this materials.

The focus is given to Gd-based oxy-hydrides, a case-study chosen for its high optical contrast and for its sensitivity to several scattering techniques. Phase purity, Gd lattice and long-range order are probed by XRD, while XAS gives information on the local coordination of the Rare Earth and on the position of the lighter atoms within the lattice. The hydrogen to oxygen ratio and the exact composition are measured by RBS and ESR. These compositional and structural information can serve in future computational works to depict the band structure of the material: a first step to shed

```
light on the chemical interplay of oxygen and hydrogen and on their effect on the electronic structure of the Gd oxy-hydrides.

**Reversible Responsive Multifunctional Porous Particle by Chemical Vapor Deposition**

Wenny Wenny and Hsien-Yeh Chen; Chemical Engineering, National Taiwan University, Taipei, Taiwan.

A challenging fabrication of porous particle with reversible responsive functions is being approached by chemical vapor deposition (CVD). The compatible poly-para-xylylenes are utilized to cloak chemicals without changing their characteristics. Solidified droplets of solution is carried out to undergo the process of sublimation and used for the vapor deposition. The sublimation process also allows the polymer to go through vapor deposition. Remarkably, it is able to imitate the shape of the droplets and maintaining their specialties such as reversible magnetic, temperature responses, etc. This study is demonstrated by ferroferric oxide (Fe3O4), which is well known for its magnetic response and poly(N-isopropylacrylamide) (PNIPAM), that is renowned for its temperature response. It is capable to be applied in biomedical materials to support chemicals with specific roles and expectantly may lead to an excellent drug carrier with detection, targeting and delivering abilities.

**ET13.05.09**

**Field Effect Smart-Glass for Near Infrared Reflection and Transmission**

Mark C. Altweege, Iulian Gherasoiu and Harry Efistathiadis; SUNY Polytechnic Institute, Albany, New York, United States.

We report the development of a versatile and robust, metamaterial that can reflect near infrared heat radiation (NIR) in the range 0.7-2.5 μm while transmitting more than 90% of the visible light intensity. Metal oxides can be used to manage the light reflectance over the long wavelength range. However, to obtain high reflectivity starting at shorter wavelengths, the doping concentration of the metal oxide must be increased above the level of 1x10^{21}/cm^3. At these concentrations the dopant incorporates not only substitutionally, but large amounts will also be found interstitially. Interstitial dopants have been shown to produce carriers with heavier effective mass, decreased mobility, and deeper donor states that significantly decrease the transmittance. Ultimately substitutional dopants degrade the crystallinity of the host material, generating compensating defects that limit the achievable carrier density. To circumvent the need for excessive dopant incorporation we deposited a multilayer structure that alternates insulating and conducting layers of silicon dioxide (SiO2) and silicon doped zinc oxide film (ZnO:Si). This structure is deposited by RF magnetron sputtering from Si and ZnO targets at low temperature. The structure uses the electric-field enhancement of carrier density to regulate the bandwidth of the NIR and in turn the amount of heat reflected. This is achieved through the formation of a quasi 2-dimensional electron gas in a thin layer at the dielectric/ZnO:Si interface. In this paper, the synthesis conditions as well as the results of the electro-optical and structural characterization of the device, through Hall effect measurements, x-ray diffraction (XRD), scanning and transmission electron microscopy (SEM, TEM), atomic and conducting force microscopy (AFM/CAFM), Rutherford Back Scattering (RBS), as well as transmittance measurements in the range from 0.3μm to 1.3 μm are presented. The fabrication challenges are discussed and a path for improving the performance of the device is outlined.

**Hydrothermal Synthesis and Characterization of Mn-Doped VO2 Nanowires**

Gen Long, Mostafa Sadoqi, Asher Suissa and David Matatov; Saint John's University, Jamaica, New York, United States.

Monoclinic VO2 is a known polymorph of vanadium dioxide that has received much attention due to its layered structure, high energy storage capacity, moderate work potential and promising applications in functional windows. VO2 can usually be obtained through a hydrothermal method under high pressure. In this work we report a study of synthesis and characterization of VO2 doped with Manganese using a rapid single-step hydrothermal process with V2O5, Mn- Acetate and citric acid as precursors. Different syntheses were carried out in which the concentration of V2O5 and citric acid remained constant whereas the concentration of Manganese (II) Acetate was varied. The reactants underwent a stirring phase for 30 minutes before being loaded into a hydrothermal reactor for 2.5 hours at 200°C. The resultant was washed three times to remove the residual precursors. Imaging and spectroscopy characterizations such as TEM, SEM, XRD, EDS and UV-VIS-NIR have been performed on different doping concentration and the results display a dependence on doping concentrations. The successful doping of Mn in VO2 provides another possible approach of tuning (through magnetic field) in the relevant applications.

**A Novel Viologen-Based Electrochromic Device Containing All-in-One Self-Healing Polymer Electrolyte**

Yi Wang, Rongzong Zheng and Chunyang Jia; School of Electronic Science and Engineering, University of Electronic Science and Technology of China, Chengdu, China.

Electrochromism refers to a phenomenon where materials undergo electrochemical reactions accompanied by the change of their optical characteristics from a bleaching to a coloration state through the manipulation of potential biases. This technology enables several useful applications, including smart windows, antiglare rear view mirrors and electrochromic (EC) displays. The efforts in recent years were mainly focused on development of various EC materials, while less attention has been paid to the problems arises in practical application of these ECDs. These devices not only require excellent EC performance, but also reliability and resistivity against various external forces (such as repeated bending) and irreversible physical damages unavoidable during practical applications. Hence, excellent self-healability and renewability are important for the development of ECDs aiming for extending lifetime and lower cost of materials and devices. Here, a novel viologen derivative has been synthesized to perform as chromophores and dissolved in the self-healing polymeric electrolyte for the fabrication of ECDs. The self-healing polymer electrolyte has been synthesized containing acrylic acid, 1-vinylimidazole and vinyl hybrid silicone nanoparticles copolymerizing. A type of hybrid ECDs was fabricated containing the self-healing electrolyte with viologen EC materials and polyaniline film counter electrode. The devices shown higher optical contrast (over 45%), fast switching time (2.0 s for coloring and 1.8 s for bleaching), coloration efficiency (406.96 cm2/C) and cycling stability (~5000 cycles). The self-healing polymer electrolyte shows excellent mechanical properties (tensile strength 11 kPa, elongation at break 210%), and noticeable self-healing performance with healing efficiency of 90.5% within 20 min. This work highlights the important of self-healing property for the ECDs and opens up a new strategy for manufacturing ECDs to further development of the devices for advanced smart windows.

**Microcapsule Display Based on Polyurethane Acrylates**

Jihong Bae, Kyung Seok Kang, Chanhyuk Jee, Hyo Jin Jung, WonBin Lim, Byeongjoo Kim and PilHo Huh; Pusan National University, Busan, Korea (the Republic of).

The different molecular weight of polyurethane (PU) prepolymer were successfully prepared using polycaprolactone diol (PCL) and Isophorone diisocyanate (IPDI) as soft segment of prepolymer, dimethylolbutanoic acid (DMBA) as emulsifier, and trimethylamine (TEA) as neutralizer. Synthesized prepolymer and liquid crystals (LC) were stirred at the constant rate. And de-ionized water (DI) containing bishexamethylenetriamine (BHMT) was added
in the reaction mixture for the polyurea reaction. LC contains photo-curable acrylate, which allows to have a certain oriented direction in the micro droplet by UV irradiation. Generally, the study of polymer isolated liquid crystal (PILC) are founded on the combination of UV epoxy and liquid crystal or the mechanical dispersion using membrane filters. The most problem of these studies is the lack of capsule size control and the aggregation of polymer. In this study to control the microcapsule size by the molecular weight of the prepolymer in the waterborne polyurethane form. We measured the molecular weight and the peak of the functional group of the polyurethane through the GPC and FT-IR. Various properties to apply as opto-electronic device were also evaluated the response time, contrast ratio and voltage-transmittance curves. These microcapsule LC research using polymer matrix is being applied to the variety fields of next-generation display such as 3D printer material, smart window and flexible display.

Recently, colorful and semitransparent organic photovoltaic (OPVs) are growing due to their demand in aesthetically power generating windows. Traditionally, different colors in OPVs has been fabricated by employing different active layer materials exhibiting distinct absorption spectra, while semitransparent OPV mainly focus from less opaque top electrodes. Thus, this will complicate the process of fabrication and cause deviations in device performance among differently colored OPVs. Herein, colorful semitransparent OPVs with a single active layer material are demonstrated using Ag–TiO2–Ag Fabry-Perot resonant cavity color filters (CFs) electrodes. Thermal evaporation of Ag layer and spin coating technique of solution process TiO2 layer will help to restore the active layer material from damage. The CF enables the OPV to transmit spectrally pure colors with peak transmission efficiencies surpassing 25% average transmission for window application, and allows the colors to be freely tuned by changing the thickness of TiO2 layer. Besides being effective color electrode, this CF works as a mirror to reflect the absorption light thus enhance the short-circuit current. It is shown that when compared to a transparent OPV consisting of the same active layer material and thickness, CF-integrated OPVs generate more short circuit current. With this current result, simple and convenient fabrication technique is needed to achieve pure color, high transmission and higher efficiency compare to only semitransparent OPVs.

ET13.05.15 Phonon and Magnetoelastic Coupling in Multiferroic A\textsubscript{6}Ga\textsubscript{5}FeO\textsubscript{3} Karuna K. Mishra, Alvaro Instan, Mohan K. Bhattacharai, Sita Dugu and Ram Katyar; University of Puerto Rico, San Juan, Puerto Rico, United States.

Multiferroic materials that exhibit coexistence of both magnetic and ferroelectric order parameters are of research interest because of the intriguing coupling phenomena among spin, phonon, and charge degree of freedoms. A\textsubscript{6}Ga\textsubscript{5}FeO\textsubscript{3} (ALF) is a lead-free multiferroic exhibits ferrimagnetism near room temperature. We report phonons and magnetic ordering in ALF using our experimental findings involving temperature dependent Raman scattering and magnetization measurements. A single phase polycrystalline sample was prepared by solid-state reaction method and its phase purity was confirmed from the XRD analysis. Energy dispersive X-rays analysis and X-ray photoelectron spectroscopic results indicate nearly stoichiometry of the elemental compositions. Temperature dependent magnetization studies in both field-cooled and zero-field-cooled conditions identify the Neel’s temperature T\textsubscript{N} around ~220 K. ALF stabilizes in orthorhombic (Pna2\textsubscript{1}) phase with eight formula units which translate into a total of 117 Raman active optical phonons. However 30 modes are experimentally observed in our measured Raman spectra. The temperature dependence of phonon frequencies are analyzed based on the standard anharmonicity model in the paramagnetic phase. In the low temperature ferromagnetic phase, a large departure of phonon frequencies from the extrapolated theoretical curve which essentially represents the normal phonon behaviors, suggests the existence of spin-phonon coupling in this system. In addition to lattice modes, several bending modes of octahedral are found to be strongly affected by the magnetic ordering. Further studies on ALF thin films are in progress. The detail experimental results will be presented in the meeting.

SESSION ET13.06: Dye and Perovskite Solar Cells
Session Chair: Richard Lunt
Wednesday Morning, November 28, 2018
Hynes, Level 3, Room 303

8:30 AM *ET13.06.01 Electrical Control of Photoluminescence in Hybrid Perovskite Films Juan Bisquert; University of Jaume I, Castello, Spain.

The development of organic-inorganic lead halide perovskites with very high efficiency requires us to understand the operation of the solar cell. These materials have excellent semiconductor and optoelectronic properties, but they are ionic as well as electronic conductors. The motion of ionic defects can regulate the number of nonradiative recombination centers, hence electrical control of planar devices with lateral contacts can give a switch of PL. This property may be exploited to extract information on transport and recombination and for the realization of new of new applications. Finally we adress new methods of characterization of the optical by means of light modulated spectroscopy.

9:00 AM ET13.06.02 Hybrid Nanowires and 3D Nanoflowers on a Large Scale for Dye-Sensitized and Perovskite Solar Cells Jose Rajan\textsuperscript{1}, Zinab Bakr\textsuperscript{1}, Bhupender Pal\textsuperscript{1}, Naveen Kumar Elumalai\textsuperscript{2} and Mashtiah Mohd Yusoff\textsuperscript{2}; 1Faculty of Industrial Sciences & Technology, University of Malaysia Pahang, Kuantan, Malaysia; 2School of Photovoltaic and Renewable Energy Engineering, University of New South Wales, Sydney, New South Wales, Australia.

Optical transparency and workability at low light conditions enable the dye-sensitized solar cells (DSSCs) and the perovskite solar cells (PSCs) as desirable choice as smart windows in modern buildings for adding aesthetics with diverse choice of colours while producing clean electricity so as to realize zero-energy buildings. In both of these solar cells, the photoactive material is chemically developed from solutions on a wide bandgap material, known as photoelectrode. The photodetector influence the performance of the solar cells in many ways as they are either the charge separation medium or the charge transport medium or both. Commercially available mesoporous TiO2 has been a widely investigated material, but its sluggish charge kinetics due to the surface states and intrinsic poor electrical conductivity triggered an intensive search on new materials worldwide. As a result many materials and materials architectures are developed with superior properties than the commercial choice; however, most of new materials are hardly scalable to the industrial levels. Among them, nanowires and 3D nanostructures such as flowers offer many advantages such as anisotropic charge dynamics, large surface area, and high crystallinity. Again, most of the materials synthesized thereby are through hardly scalable chemical processes. We have now developed nanowires and 3D nanoflowers as a composite of two binary wide bandgap metal oxide semiconductors (SnO\textsubscript{2}–TiO\textsubscript{2}) in large quantities (100 g scale) using multineedle electrospinning technique by controlling the nucleation and growth of inorganic species in a polymeric nanofibrous growth vessel. In the conventional
electrospinning to synthesize inorganic nanowires, the metal precursor dispersed in the polymeric fiber is allowed to nucleate and grow at appropriate
conditions—which took place at equilibrium conditions, i.e., the growth vessel (the polymeric fiber) is large enough to accommodate all the nuclei. On the
other hand, to synthesize composite nanofilaments a non-equilibrium situation is produced such that the nuclei developed could not be located within
the growth vessel such that growth requires an expansion of space. The electron microscopic investigations show that this strategy is successful and the large
scale electrospinning could be applied to produce the two type of materials architectures. The composite formation, surface properties, and electrochemical
properties of the composite materials are systematically investigated and compared with their single component counterparts. Finally, DSSCs and PSCs
were fabricated using the composite nanowires and 3D nanoflowers. The devices fabricated using the 3D nanoflowers showed superior photovoltaic
properties than those of the nanowires; the best performing device in this study is a perovskite solar cell with a photo conversion efficiency of 17.25%.
open circuit voltage of ~1 V, short circuit current density of ~23.73 mA/cm² and fill factor 73.07%.

9:30 AM BREAK

SESSION ET13.07: Other Windows
Session Chair: Richard Taylor
Wednesday Morning, November 28, 2018
Hynes, Level 3, Room 303

10:00 AM **ET13.07.01
Highly Transparent Solar Cells for Distributed Applications Richard R. Lunt; Michigan State University, East Lansing, Michigan, United States.

Solar energy offers a viable solution to our growing energy demand, but adoption has been hindered by cost, aesthetics, and difficulties with integration.
Excitonic materials offer new opportunities for unique solar harvesting science and applications that can help accelerate solar deployment in new areas
previously inaccessible. In the first part of this talk I will introduce our work on developing highly transparent photovoltaics (TPVs) that can maximize the
product of the transparency and efficiency for seamless solar harvesting around buildings, automobiles, mobile electronics, and greenhouses. These devices
are enabled by the manipulation of excitonic semiconductor materials with selective harvesting in the invisible components of the solar spectrum. I will
describe key photophysical properties, outline the thermodynamic and practical limits for a range of TPVs, and discuss their commercial impact for a
variety of applications. I will also discuss new figures of merit necessary to characterize and test TPVs. In the second part, I will describe the development
of several new classes of materials for TPV integration including: 1) organic salts that allow selective photosresponse beyond 1600nm; 2) luminescent
nanoclusters with massive downconversion; and 3) halide perovskites with ideally tuned bandgaps and transparencies above 70%. TPVs ultimately represent
a new paradigm for solar energy harvesting that could generate nearly half of the US electricity demand when deployed at full-scale, while also creating
additional functionality in managing solar heat.

10:30 AM ET13.07.02
100 cm² Dynamic Windows Based on Reversible Metal Electrodeposition with Sub-Minute Switching Speeds Michael Strand1, Tyler S. Hernandez1,
Christopher Barile2 and Michael D. McGehee1, 3, 4; 1Stanford University, Stanford, California, United States; 2University of Nevada, Reno, Reno, Nevada,
United States; 3University of Colorado Boulder, Boulder, Colorado, United States; 4National Renewable Energy Laboratory, Golden, Colorado, United
States.

While the demand for optically tunable windows is paramount in today’s residential and industrial communities, traditional electrochromic windows have
not yet been commercialized on a large scale. Dynamic windows based on reversible metal electrodeposition (RME) have emerged as an exciting,
developed class of electrochromic devices poised to overcome the challenges inherent to conventional technologies. Metals are ideal light-modulators for
dynamic windows because they can be color-neutral, inert, IR-reflective, and opaque at 20-50 nanometer thicknesses. Our team has demonstrated metal-
based dynamic windows that boast cheap processing, fast switching, and stable performance over thousands of cycles on the 25 cm² scale.

Several technical challenges hinder further scalability of the technology. Common transparent electrode materials like indium tin oxide (ITO) have
relatively high sheet resistance. By Ohm’s Law, maintaining a uniform current density through resistive electrodes necessitates a voltage drop proportional
to the electrode area. Large-scale dynamic windows must be engineered with a tolerance to the non-uniform potential distribution across the electrode
surface in order to maintain optical uniformity during switching. Additionally, undesired side reactions like the hydrogen evolution reaction (HER) set
strict limits on the potentials that may be applied in aqueous electrolytes. The ideal system will enable uniform nucleation and growth of metal films over
the potential range set by side reactions inherent to aqueous electrolytes, and the voltage drop inherent to transparent conductors. Prudent design of electrode structure enables uniform and reversible electrodeposition over large areas. Using a scalable process, we fabricate transparent
electrodes coated with Pt nanoparticles for dynamic windows. The Pt nanoparticles serve as preferred nucleation sites for the electrodeposition reactions.
By controlling the nanoparticle surface density, we have direct control over the active site density for nucleation, and thus the subsequent growth of the
metallic film. This nucleation control enables transparent electrodes that exhibit uniform transmission versus time relationships over a large range of
applied potentials.

Finally, we demonstrate 100 cm² dynamic windows based on reversible metal electrodeposition that switch uniformly despite the voltage drop across the
working electrode. The devices switch reversibly from a clear state (60% transmission) to a color-neutral, opaque state (~5% transmission) in less than one
minute.

10:45 AM ET13.07.03
Dynamic Windows with High Contrast, Neutral Color and Excellent Durability Using Metal Electrodeposition and Dissolution Christopher Barile1,
Michael McGehee2, Shakirul Islam3, Tyler S. Hernandez1, Michael Strand1, 2 and Daniel Slotcavage1; 1University of Nevada, Reno, Reno, Nevada,
United States; 2University of Colorado Boulder, Boulder, Colorado, United States; 3University of Colorado Boulder, Boulder, Colorado, United States.

Optoelectronically tunable windows have applications in buildings, automobiles, and switchable sunglasses. By controlling solar lighting and heating,
dynamic windows significantly improve the energy efficiency, comfort, and aesthetics of spaces as compared to traditional window technologies. The
majority of research on switchable windows over the last several decades has focused on transition metal oxides and polymers as the optically-active
materials. In contrast, we are developing dynamic windows based on the reversible electrodeposition and dissolution of metals. These windows display
clear-to-black transitions with ~80% optical contrast in 1 minute. 25 cm² device prototypes cycle thousands of times without significant deterioration.
Applications

11:00 AM

Electrolyte and Electrode Engineering for Dynamic Windows Based on Reversible Metal Electrodeposition

Tyler S. Hernandez, Michael Strand, Christopher Barile, Dan Slotcavage, and Michael D. McGehee;
Stanford University, Menlo Park, California, United States; University College London, London, United Kingdom.

In recent years vanadium dioxide (VO$_2$) has generated a broad range of interest due to its heat-mediated structural phase transition from a semiconductor to a metallic state at living temperatures. In many parts of the world, this entails the use of both heating and cooling during daylight hours depending on ambient temperatures. Optically tunable dynamic windows demonstrate many advantages over static lighting controls, such as blinds and shades. This technology allows users to control both heat and light flow into and out of buildings, without sacrificing their comfort or view. Despite both the aesthetic and energetic appeals of these reversibly tinting windows, existing electrochromic technologies have yet to perform ideally. Dynamic windows based on reversible metal electrodeposition (RME) offer an exciting alternative to traditional electrochromic technologies. The use of metals is an attractive option for electrochromic applications due to their high optical extinction coefficients, color neutral metallic state, chemical inertness, and high solubility in aqueous electrolytes. Our group has recently designed 25 cm$^2$ RME dynamic windows that demonstrate color-neutral, fast switching speeds over thousands of cycles with minimal degradation.

These windows operate by the reversible, electrochemical movement of metallic ions from a transparent conducting electrode to a metal counter electrode frame through an aqueous electrolytic medium, usually consisting of Bi$^{3+}$ and Cu$^{2+}$ ions. Despite a promising initial design, indium tin oxide (ITO) working electrodes degrade under the acidic environments necessary for aqueous Bi-Cu halide electrolytes. Furthermore, the counter electrode frame design will be problematic at a larger scale due to the voltage drop associated with increasing ionic diffusion lengths. We address both the durability and scalability issues associated with these initial devices by designing RME dynamic windows with an acid stable working electrode, a halide-free Bi-Cu electrolyte, and a plane-parallel counter electrode.

11:15 AM ET13.07.05

Color Degradation of Organic Semiconductors in Power Generating Windows

Bharati Neelamraju, Michael Anderson and Erin L. Ratcliff;
The University of Arizona, Tucson, Arizona, United States.

Organic Photovoltaics (OPVs) have incredible prospects for next-generation, flexible opto-electronic energy harvesting and storage devices. Their unique properties of being semi-transparent, flexible, light-weight, low cost and scalable with customizable color perception makes them an ideal candidate for energy generating windows technology for buildings and green houses. Their tunable transparency and color selectivity gives them an aesthetic edge over conventional technology while maintaining the power conversion efficiencies. In green houses, this tunable wavelength approach of OPVs allows maximum usage of the photosynthetically relevant light to reach the plants, while using the unused wavelengths for generating electricity. Yet challenges still exist in terms of degradation of organic semiconductors in these devices which could affect both the efficiency and the color of the OPVs in the long run for use in power generating windows. This effort considers the following “How does degradation of organic semiconductors effect the color and power conversion efficiency (PCE) of the OPV devices in a given architecture”. Electronic properties and color measurements in CIE coordinates are analysed using spectroscopy and correlated with density of states. Transport properties are analyzed using mobility, conductivity and PCE measurements. Collectively, these measurements allow us to design organic semiconductor systems with controllable behaviors for next-generation of organic photovoltaic technologies.

SESSION ET13.08: Thermochromic and Photochromic Windows

Wednesday Afternoon, November 28, 2018

Hynes, Level 3, Room 303

Fabrication and Spectral Properties of Textured Phase Change VO2 Nanostructures Obtained via Oxidation of Thermally Evaporated Metallic Vanadium Films

We demonstrate the growth of highly textured VO2 nanocrystals via annealing of amorphous e-beam deposited metallic V. Temperature dependent ellipsometry results reveal the pronounced reflection near the IR spectrum above the transition and an almost temperature independent weak reflection in the visible spectrum. The infrared reflection displays a strong hysteresis during heating and cooling near the transition temperature at 68°C, indicating a first order transition and a strain-free structure. Our work demonstrates the feasibility to obtain high quality phase change nanostructures that transmit the visible spectrum but reflect infrared and is suitable for large scale fabrication.

2:00 PM ET13.08.03
Interdependence of Molecular Precursors, Morphology and Phase Transitions in Thermochromic VO2 Nanostructured Thin Films

In recent years, monoclinic/rutile vanadium dioxide VO2 (M1/R) has attracted attention as a promising candidate for energy saving window applications due to its unique thermochromic reversible metal-insulator transition (MST) at 68°C. Phase selective chemical vapor deposition of nanostructured vanadium dioxide (VO2) on a glass substrate and use the simulations to guide the fabrication process. The design makes use of coherent interference within the multi-layered structure to suppress reflection of visible light and improve the reflective component of solar modulation. In doing so, we are able simultaneously improve the visible transmission and solar modulation of the film above what would be possible with a single layer film. Additionally, the use of thin film VO2 also acts to reduce the detrimental transition hysteresis typically seen in small domain sized nanoparticulate VO2 films. The multilayer structure is fabricated via spin coating of sol-gel based precursors and subsequent annealing. After which the structure is optically characterised and results are compared with simulation along with standard single layer VO2 films and other nanoparticulate based VO2 films.

2:15 PM ET13.08.04

SYMPOSIUM ET14/BI01/NM04
TUTORIAL: Life Cycle Analysis from an Industrial Perspective
November 25 - November 25, 2018

* Invited Paper

TUTORIAL Life Cycle Analysis from an Industrial Perspective
Sunday Afternoon, November 25, 2018
Hynes, Level 2, Room 200

Environmental issues keep steadily increasing, thus there is a strong urge to discuss how materials scientists could more rapidly respond to the worldwide concerns. This joint tutorial effort would be organized by the three symposia together. To ensure the success of such synergistic efforts it is also urged a close dialogue with society so to establish guidelines for policymakers, thus this tutorial will incorporate both the societal and the engineering aspects of life cycle analysis (LCA) would be covered. The main objective of this tutorial is to explore communications pathways between companies and materials researchers that further elevate the profile and challenges of sustainability that represents a societal necessity and a viable and critical topic for research.
Materials are not simply the product of an engineering discipline, Materials Science, but also "social constructs" that have entertained a close relationship with society all through the historical timeline and remain a core element of our modern world, what is called a Key Enabling Technology. How this can be analyzed by parallel approaches of hard and soft sciences will be explained in the class as well as the tryptic of economic, environmental and social values of materials. Examples reported in the 13 past SAM conferences will be used as examples.

The instructor will provide an overview on all the aspects considered in a life cycle analysis aimed to the engineering design of an industrial process. A part of the tutorial will involve the interaction with the audience in order to apply some of the concepts described in the first part of the tutorials to common objects.

The symposia organizers will divide the participants into groups and a sustainability challenge will integrate the concepts presented by the instructors so to review and facilitate networking among participants and instructors.

A large class of strong-base anionic exchange resins with quaternary ammonium ions as the fixed cationic charge and carbonate, bicarbonate or hydroxide for mobile anions exhibit equilibria with gaseous CO2 that are strongly affected by the presence of water. At room temperature, changing the relative humidity of air over the resin from 20% to 100% changes the equilibrium pressure of CO2 in the gas phase for a fixed dissolved inorganic carbon loading of the resin five hundredfold. This novel phenomenon is of interest for capture of CO2 from ambient air as it can support novel sorption/desorption cycles driven by moisture rather than temperature or pressure changes. It can support novel membranes where a concentration gradient in moisture can pump CO2 against a chemical potential across the membrane. The impact of water on CO2 sorption is so large that it cannot be explained through simple competition for sorption sites. Instead, theoretical analysis suggest that the effect is mediated through changes in the hydration states of the ions present in the resin. The emergence of superacids in nano-droplets as was described by Colussi and his group provides an analogy. The analysis suggests that the process is...
complicated and goes to the heart of the nature of water and its behavior in confined spaces and its interactions with ions. A better understanding and more detailed experimental analysis would be extremely valuable. There are a number of unanswered questions a more detailed research program would need to answer: how does the interaction of water with ions affect the ionic equilibrium; how does the nature of the polymer structure of the resin impacts this behavior, in terms of equilibrium conditions, but also transport conditions. The nature of the cation is also of great interest. If indeed the simple models which suggest that the nature of the cation and the polymer structure are of secondary concern proves correct under experimental scrutiny, then one can focus on cost, and long-term stability in choosing among different polymer structures and cations. Answers to these questions would open a new field of sorbent technologies that could have impact well beyond the immediate application in direct air capture.

9:00 AM ET14.01.02
Nano Porous Polymeric Composite Membranes—Excellent Carbon Dioxide Separation Performance and with Processible Membrane Properties
Ali Sekyzkardes1,2, Saurendra Venna1,2, Victor Kusama1,2 and David Hopkinson1; 1National Energy and Technology Laboratory (NETL), U.S. Department of Energy, Pittsburgh, Pennsylvania, United States; 2AECON Pittsburgh, Pittsburgh, Pennsylvania, United States.

Nano porous polymers such as polymers with intrinsic microporosity (PIMs) have attracted great interest in Materials Science to applied as gas separation membranes. PIMs are constructed by contorted monomer backbones and given its inefficient polymer chain packing, PIM-1 possesses an intrinsic micro porosity with an unprecedented amount of free volume for a polymeric membrane. The unique polymer structure of PIM-1, however, constirates two major drawbacks: Average pore size of PIM-1 (~1nm) is too large, hence permeate most of small gas molecules such as H2, N2, CO2, CH4 and consequently PIMs show lower gas selectivity properties compared to other polymeric membranes. The second drawback is weak mechanical properties for PIM due to the lack of sufficient hydrogen bond capability between polymer chains, affording brittle film formation. Here we study novel composite membrane fabrication and characterization by incorporation of flexible in house synthesized polymer (NETL-PE) and porous organic fillers in PIMs. PIM/NETL-PE membranes show distinct improvement in brittle film properties of PIM-1 by greatly improving low strain to failure (~ 1%) of PIM-1 to as high as 10.5%, which is indicative of a very flexible and durable film formation. The resultant membranes showed an excellent CO2/N2 selectivity of 40 while maintain high CO2 permeability of up to 2500 barrer. Comparing these membranes with reported polymeric membranes above the 2008 Robeson upper bound shows that these membranes are one of best materials for CO2/N2 separation applications while having good mechanical properties. Fabrication and characterization of the membranes with pure and mixed gas permeation tests will be presented.

9:15 AM ET14.01.03
Quaternary-Ammonium Grafted Macroporous Resin for Direct Air Capture of CO2
Yusong Wu, Chenglong Hou, Xinru Wang, Tao Wang and Mengxiang Fang; Zhejiang University, Hangzhou, China.

Global warming, believed to be triggered by the emission of CO2, has become the focus of the sustainable development of human society nowadays. It is imperative and urgent to take some effective actions to reduce the global CO2 emission. Considered to be one of the key technologies to achieve the negative CO2 emissions, Direct Air Capture (DAC) has attracted worldwide attention since 2000. After decades of fundamental research on DAC sorbents, the low sorption kinetics, higher energy consumption for regeneration, and the insufficient stability become the major obstacles for DAC application in practical processes. Aiming to solve the problem above, this paper proposed a novel resin sorbent synthesized by chemical grafting the quaternary ammonium groups onto the nonpolar macroporous resins. Three different support materials (XAD-4, XAD-16, D101) with preferred porosity were selected as supports and the CO2 adsorption performance were demonstrated with isothermal experiments. The structure-activity relationship of the sorbent were further revealed with multiple characterization methods including FESEM, FTIR, MIP and elemental analysis. Results indicated that the CO2 adsorption isotherms of quaternary- ammonium grafted resins were in line with the classic Langmuir model. Quaternized XAD-16 sample, with a moderate pore size, had the highest CO2 adsorption capacity of 0.42 mmol/g, and the quaternized XAD-4 and D101 samples were only 0.28 mmol/g and 0.21 mmol/g, respectively. Combined with the results of elemental analysis and pore analysis, it was inferred that the macropores in the resin are conducive to the grafting density of quaternary ammonium groups, while the quaternary ammonium groups confined in the micropores could reach a higher CO2 adsorption efficiency. The adsorption kinetics of the optimized adsorbents could be one magnitude higher than commercial resin at 400 ppm CO2. The stability of the adsorbents were verified with a cyclic adsorption-desorption test based on moisture swing technique, showing no evident decline in working capacity in 10 cycles under 25 C. Owing to higher kinetics and the energy-efficient moisture swing process, it can be suggested that the quaternary-ammonium grafted macroporous resin could be a promising and cheap material for direct air capture.

9:30 AM DISCUSSION TIME

9:45 AM BREAK

10:15 AM ET14.01.04
Carbon Dioxide Capture in Diamine-Appended Metal-Organic Frameworks
Rebecca Siegelman1,2, Phillip Milner1,2, Jeffrey Martell1, Alex Forse1,2, Miguel Gonzalez1, Eugene Kim1, Tomce Runceski1, Jarad Mason1,2, Thomas McDonald1,2,3, Jeffrey Reimer1,2 and Jeffrey R. Long1,2; 1University of California, Berkeley, Berkeley, California, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3Mosaic Materials, Inc., Berkeley, California, United States.

Owing to their high surface areas, tunable pore dimensions, and adjustable surface functionality, metal-organic frameworks (MOFs) can offer advantages for a variety of gas storage and gas separation applications. In an effort to help curb greenhouse gas emissions from power plants, we are developing new MOFs for potential use as solid adsorbents in post- and pre-combustion CO2 capture, and for the separation of O2 from air, as required for oxy-fuel combustion. In particular, MOFs with diamine-functionalized surfaces have been demonstrated to provide high selectivities and capacities for the adsorption of CO2 over N2 under dry flue gas conditions. Thermogravimetric cycling and multicomponent adsorption measurements now further show that compounds of this type remain highly effective in the presence of water, while calorimetry data reveal a low regeneration energy compared to aqueous amine solutions. Most significantly, as determined by in situ nuclear magnetic resonance, infrared, x-ray absorption spectroscopy experiments, crystal structure determinations, and computational simulations, the unusual stepped CO2 adsorption isotherms exhibited by these materials arise from a unique cooperative insertion mechanism to form one-dimensional chains of metal-bound ammonium carbamates. A detailed understanding of this mechanism now enables us to design new materials for the low-energy separation of CO2 from a wide variety of key gas mixtures, including flue gases, air, biogas, and natural gas deposits.

10:45 AM ET14.01.05
Nano Fabricated Polybenzimidazoles with Chemically Robust Membrane
Jung Ji Hye, Moon Ki Jeong and Sang Yong Nam; Gyeongsang National University, Jinju, Korea (the Republic of).

Polybenzimidazole is well known for its superior heat resistance and good mechanical properties. Due to an excellent various property, PBI has been used
in a lot of fields such as gas separation, OSN and secondary battery membrane. This work is focused on fabrication of meta-Polybenzimidazole(m-PBI) and control of morphology according to concentrations or manufacturing conditions. The membranes were prepared via the phase inversion method from casting solutions with predetermined amounts PBI, dimethylacetamide (DMAc) and tetrahydrofuran (THF). The polymer solutions were cast on a clean glass plate by using casting knife. The membrane was immersed in IPA to remove the residual solvent and dried in vacuum oven for 24 h. The membrane was crosslinked by α, α’-Dibromo-p-xylene. Also, this membrane can be prepared by electro-spinning. Electro-spinning can make highly porous non-woven fabrics consisted of nanofibers with the small diameters and overall porous structure. Also, electrospun fabrics have high specific surface area. To observe morphology, Scanning electron microscope (SEM) was used. In case of gas transport properties, H2, CO2 Permeability and selectivity of this membrane was measured via pure gas.

Ultra-selective Defect-Free Interfacially Polymerized Molecular Sieve Thin-Film Composite Membranes for H2 Purification and Carbon Capture Zain Ali, Federico Pacheco, Ingo Pinnau and Yingge Wang; King Abdullah University of Science and Technology, Thuwal, Saudi Arabia.

Ultra-selective defect-free interfacially polymerized molecular sieve thin-film composite membranes for H2 purification and carbon capture Purification is a major bottleneck towards generating low-cost commercial hydrogen from syngas mixtures. According to reports published by United States Department of Energy (USDOE), reduction is hydrogen purification costs can immediately increase the hydrogen market by 10-fold promoting its use in desulfurization, hydrotreating, chemical manufacture, power generation and use as a potential energy carrier. In this work, inexpensive high-performance H2 separating membranes were fabricated by modifying the commercially successful reverse osmosis membrane production method. Defect-free thin-film composite membranes were formed that demonstrate unprecedented mixed-gas H2/CO2 selectivity of ≈ 50 at 140 °C with H2 permeance of 350 GPU, surpassing the permeance/selectivity upper bound of all known polymer membranes by a wide margin. Coupled with excellent H2/CH4 separation properties, given the targets specified by the USDOE, the membranes are excellent candidates for pilot-scale testing aimed at hydrogen purification from syngas while simultaneously promoting capture of accompanying CO2. Fortunately, these ultra-high-performance membranes can be produced by making only small changes to existing commercial membrane manufacturing processes. Therefore, their fabrication cost should be similar to standard RO membranes – only ≈ 1 – 2 $/ft², which would lower the membrane cost by 50-100-fold based on the USDOE target value of 100 $/ft². This study demonstrated that varying fabrication parameters can tune permselectivity to meet the needs of specific processes. A few simple modifications to a time-tested commercial membrane production process can produce membranes that meet a key industrial need. These membranes also demonstrated remarkable selectivity for O2/N2, CO2/CH4, H2/N2 and CO2/N2 separations. With rapidly developing economic and environmental pressures to increase efficiencies for separation processes, such highly-selective, low-cost, commercial barrier materials fabricated as ultra-thin films show potential for a paradigm shift to streamline industrial use of membranes for a large number of gas separation applications, including but not limited to hydrogen separations, air separations as well as a number of liquid-bases separations. The combination of exceptional separation performance and low manufacturing cost makes interfacially polymerized thin-film composite molecular sieves excellent candidates for cost-effective hydrogen purification from steam cracking and similar processes.

11:30 AM ET14.01.07
Tailoring Molecular Architecture of Graphene Oxide for CO2-Selective Membrane Jae Eun Shin, Jun Kyu Jang, Inho Park and Ho Bum Park; Hanyang University, Seoul, Korea (the Republic of).

Graphene Oxide (GO) has been extensively investigated as a membrane material for CO2 separation due to their high CO2 sorption properties and 2-dimensional nanosheets structure for membrane formation. Although GO membrane is considered as one of promising membrane, it has a limitation to apply for practical application because of low gas permeability. In general, gas molecules are passed along the layered structure, which lead to increase of diffusional pathway and resistance to oxygen functional groups on the basal plane of GO. As such, in this study, we prepared modified GOs to reducing the diffusional pathway and increasing structural stability by adjusting the architecture of GO using the following methods; (1) surface porosity and interlayer distance control by sol-gel reaction, (2) tailoring sp2-graphitic and sp3–oxidized regions with mild hydrothermal treatment, (3) creating and decorating pores on the basal plane of GO nanosheets without thermal reduction. Finally, we fabricated membranes to confirm gas transport behaviors. From these results, the CO2 permeability was significantly increased up to 30 times compared to the pristine GO membrane and CO2/N2 selectivity was increased up to as high as 30. These results have the potential to open up new approaches for an improvement in the transport properties of two-dimensional membrane materials for use in next-generation membrane for CO2 separation.

Design of CO2-Sorbing Materials and Their Compatibility with Practical, Scalable Direct Air Capture Processes Christopher W. Jones; Georgia Institute of Technology, Atlanta, Georgia, United States.

A variety of classes of materials have been established for CO2 adsorption from gaseous mixtures. One particular challenge that has emerged in recent years is the design of materials that bind CO2 suitably strongly and selectively that they can efficiently extract CO2 from ultra-dilute mixtures, such as ambient air (400 ppm). Such materials and processes will play an important role in future climate mitigation strategies if society chooses to try and limit global climate change, being one of the only highly scalable approaches to achieve negative CO2 emissions. In this contribution, I will discuss various classes of materials that have been proposed for use in such “direct air capture” technologies, highlighting strengths and weaknesses of assorted compositions in these applications, as well as critical research challenges that the field should address.

2:00 PM ET14.02.02
Fabrication of Large and Free-Standing Nanomembranes Preferential CO2 Separation Under Atmospheric Pressure Shigenori Fujikawa, Toyoki Kunitake and Roman Selyanchyn; WPI-ICNER, Kyushu University, Fukuoka, Japan.

Biological lipid bilayer membrane is an ideal example for precise and efficient molecular separation. One of its characteristics is a free-standing property
with molecular thickness, and molecular scale phenomena become dominant in the direction of the membrane thickness. Thus, artificial membrane with a free-standing properties and nanometer thickness would be a unique property different from conventional thicker membrane. Especially in membrane separation, the thickness plays an important role for the efficient separation. Based on this idea, we have developed free-standing nanomembranes (thickness: 100 nm or less) with preferential CO₂ permeation ability even under low partial pressure difference of CO₂ across a membrane. Our developed nanomembranes showed very high CO₂ flux (about ~10,000 GPU, 1GPU ≈ 7.5 × 10⁻¹² m²/ Pa), without losing CO₂ selectivity which is identical to that of thicker membranes. This unique feature of free-standing nanomembranes, high CO₂ flux with preferential CO₂ separation, would be beneficial to capture CO₂ from the air, so-called "direct air capture". Indeed, our free-standing nanomembrane showed preferential CO₂ separation even under very small pressure difference.

2:15 PM ET14.02.03
Techno-Economic Analysis of Membrane-Supported \( H_2O \) Splitting with CO₂ capture Xiao-Yu Wu, Yu-Dong Chen and Ahmed F. Ghoniem; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

In this presentation, we show the techno-economic analysis of an advanced hydrogen production technology: membrane supported water splitting with CO₂ capture. Oxygen permeable membranes such as \( La_0.9Ca_{0.1}FeO_3_\delta \) (LCF) [1,2] and \( BaCo_xFe_yZr_zO_3_\delta \) (BCFZ) [3, 4] are used to in \( \textit{ situ} \) separate the water splitting products. On the feed side of the membrane, \( H_2O \) splitting occurs and high purity hydrogen is produced. On the sweep side, methane oxidation takes place to consume the permeated oxygen and to maintain the oxygen potential gradient across the membrane. CO₂ produced from methane oxidation is ready to be captured at high pressure.

First, we built a thermodynamic model to compare the membrane reactor with the conventional methane reforming for high purity hydrogen production. Results show that membrane reactors have higher efficiency (as high as 8 percent points), especially when renewable heat source, e.g., solar and geothermal energy is incorporated into the system. The energy cost of hydrogen production with CO₂ capture is lower for the membrane reactors.

Secondly, a high-fidelity reactor model is built to simulate a monolith membrane reactor with 100 kmol/h \( H_2 \) production rate. The dimensions and operating conditions are similar to the solid oxide fuel cell stacks, and 90% methane conversion is achieved. Two well-studied perovskite membrane materials, i.e., LCF and BCFZ are compared. Results show that BCFZ membrane can produce more hydrogen per unit surface area, so the required LCF membrane surface area is 5.3 times larger than the BCFZ membrane area.

As the BCFZ membrane contain critical minerals, e.g., cobalt and zirconium, the membrane reactor cost can be impacted by the fluctuating mineral prices. Based on the quoted prices from Alibaba website on April 2018, the raw materials to produce the BCFZ membrane is 2.3 times more expensive than those for the LCF membrane. However, as the required LCF membrane surface area is larger, the cost for the LCF membrane reactor is 2.4 times more expensive than that for the BCFZ reactor. Sensitivity analysis shows that if cobalt price increases by 2.82 times, the cost for the BCFZ reactor can be more expensive.

Furthermore, it has been showed that BCFZ membrane is susceptible to performance instability due to the cobalt segregation [5], while LCF membrane can perform stably under both oxidizing and reducing environments [1]. Life-cycle analysis will be carried out to compare the costs of these two membrane reactors for a hydrogen plant designed with 20-year operating life.

Nano-/Microscopic Design for the Hybrid Biological | Inorganic System of Electricity-Driven CO₂ Reduction Chong Liu; University of California, Los Angeles, Los Angeles, California, United States.

A hybrid biological | inorganic (HBI) system combines the benefits of both inorganic and biological catalysts and leads to high energy efficiency of electricity-driven CO₂ reduction to commodity chemicals. However, the reactor throughput and the versatility of chemical feedstock may not be optimal yet, as biocatalysts can be kinetically slow and have stringent requirements of substrates and liquid environment. In this talk, we will discuss some design strategies at micro-/nanoscopic scale to address these questions.

3:45 PM ET14.03.02
Photocatalyst-Biocatalyst Integrated Artificial Photosynthesis System for Highly Selective Solar Fuel Production from CO₂ Jin-ook Baeg; KRICT, Daejeon, Korea (the Republic of).

The natural photosynthetic process has fascinated chemists for long due to its high specificity in solar energy conversion to sugar. However, given the structural and functional complexity, it is a challenge to mimic this natural process. In recent years, these efforts have intensified due to increasing emphasis on the development of emission-zero systems/technologies for production of solar fuel/chemicals. Utilizing the natural photosynthesis as blueprint, a number of covalent, and non-covalent donor-acceptor conjugate dyes have been studied as systems for CO₂ fixation. Although capable of efficient photoinduced intra- and intermolecular electron transfer(ET), they suffer from low conversion efficiency, poor product selectivity and lack of
Rising atmospheric carbon dioxide levels make CO₂ an abundant source of carbon for synthesis of commodity chemicals. One of the most promising methods of CO₂ reduction developed in recent years is the use of a hybrid biological inorganic system that couples an electrochemical cell and CO₂ reducing microbes to simultaneously split water and fix carbon dioxide. While this system is highly energy efficient, the low solubility of the redox carrier, H₂ gas, in aqueous environments is hindering the scale-up of the hybrid biological inorganic system. We propose that bio-compatible perfluorocarbon nanoemulsions can serve to increase the H₂ gas solubility to overcome this kinetic limitation. We discovered that perfluorocarbon nanoemulsions not only increase the average concentration of H₂ generated from electrochemical water splitting, but also accelerated the local H₂ transfer rate in proximity to the microbes. Both factors contributed to an average 20% (n ≥ 3) enhancement in overall device efficiency with high device throughput. We believe that our improved hybrid system could be used at point sources of CO₂ emissions to generate important chemical building blocks while reducing atmospheric CO₂.

**4:15 PM *ET14.03.04**
**Carbon Negative Production of Living Biofertilizers** Daniel G. G. Nocera and Daniel Loh; Harvard University, Cambridge, Massachusetts, United States.

Global soils store 2-3 times more carbon than the atmosphere, acting as a massive reservoir for carbon sequestration. Increasing soil carbon reservoirs by 0.4% per year would completely halt the increase of atmospheric CO₂ levels from human activity. These efforts to sequester carbon simultaneously enrich agricultural soils, supporting soil biology and reducing the need for synthetic fertilizers, a production system responsible for >245 million tons CO₂/year. To both sequester atmospheric CO₂ and replace synthetic fertilizer production, we have developed a living, CO₂-negative biofertilizer. This work adapts the rate in proximity to the microbes. Both factors contributed to an average 20% (n ≥ 3) enhancement in overall device efficiency with high device throughput. We believe that our improved hybrid system could be used at point sources of CO₂ emissions to generate important chemical building blocks while reducing atmospheric CO₂.

**4:45 PM ET14.03.05**
**Photosynthesis-Mimicking Cell with 15.6% Solar-to-CO Efficiency** Junlang Liu, Yuhang Wang and Gengfeng Zheng; Fudan University, Shanghai, China.

The vigorous growth of atmospheric CO₂ level has posed a threat on sustainable development of our blue planet. The solar-energy-driven electrochemical CO₂ conversion into various value-added chemicals (namely artificial photosynthesis) is regarded as one of the most promising solutions to alleviate this urgent environment pressure and energy crisis. Compared to the other configurations of artificial photosynthesis systems such as photocatalysis and photoelectrochemical conversion, electrocatalysis powered by photovoltaics has shown the highest solar-to-fuel efficiency to date, which has achieved over 10-fold enhancement compared to natural photosynthesis. Nonetheless, the operation of all artificial photosynthesis systems still strongly relies on sunlight illuminations, which are altered significantly over time of a day, weathers and regions. Thus, designing artificial photosynthesis devices capable of CO₂ reduction reaction (CO₂RR) under different sunlight conditions is of crucial significance.

Delighted by the temporary energy storage function of ATP and NADPH in green plants, we propose that a redox medium can be introduced between oxygen evolution reaction (OER) and CO₂RR. The redox medium forms a loop with OER electrode to store the photogenerated electrons in the step of light reaction, as the charging of battery. These photogenerated electrons can be released spontaneously to reduce CO₂ in the following artificial carbon fixation step, as the battery discharge.

Therefore, we develop a green-plant-mimicking artificial photosynthesis-battery system, by introducing Zn/Zn(OH)₂⁺ redox pair as the energy transfer medium between artificial light reaction and carbon fixation to simulate ATP/ADP: Nano-Au and NiFe hydroxides were employed as electrocatalysts for CO₂RR and OER, respectively. A GaAs solar cell was utilized to drive oxygen evolution reaction and store electrons in Zn/Zn(OH)₂⁺. The further release of electrons proceeded without light and led to an unassisted CO₂ electroreduction. The solar conversion efficiency of artificial light reaction is 28.7%. During carbon fixation, the unassisted electrochemical CO₂ reduction achieved a record-high solar-to-CO efficiency peaking at 15.6% under 1-sun intensity at the current density of 10 mA/cm². By tuning CO₂ electroreduction current density in the range of 2 to 10 mA/cm², a tunable and light-independent selectivity of CO₂ production was realized.

Our two-step, artificial photosynthesis-battery design possesses high efficiency, tunable selectivity, excellent stability and flexibility to various sunlight conditions even in the dark, owing to the mutual independence of light reaction and carbon fixation. Combining with further robust electrocatalysts as well as new redox media able to provide higher potential difference for carbon fixation, our design actually suggests new opportunities in anthropogenic manufacture of fossil fuels from CO₂ and sunlight with such a green-plant-mimicking approach.
Increasing atmospheric carbon dioxide and sulfur dioxide emissions from combustion of fossil fuels, such as coal and oil, are considered as a globally alarming environmental issue. Hence, the quest for an immediate solution for sequestration and storage of carbon dioxide and sulfur dioxide is warranted. Recently, amine and ionic liquid based absorption process have attracted widespread attention to capture these gases but this process passes several disadvantages such as severe corrosion, highly energy intensive, and low contact area. One viable alternative is adsorption technology, which is recognized to be attractive to replace current absorption technology. Therefore, development of novel porous carbon based materials has become one of the hot areas due to their extensive applications in gas storage and separation. In this regard, first we have modeled an experimentally observed 3-D porous structure of graphene sponge (GS) using molecular dynamics simulations (MD). The initial structure is composed of randomly distributed graphene flakes and inclusion particles of variable dimensions following the lognormal distribution. [1] MD simulations are performed using Adaptive Intermolecular Reactive Empirical Bond Order (AIREBO) potential to mimic the synthesis of 3-D graphene sponge. Further, we have used this graphene sponge as an adsorbent to capture CO2/SO2. We have performed Grand Canonical Monte Carlo (GCMC) simulation to get adsorption isotherm and to examine selectivity for CO2 and SO2 in graphene sponge. Our simulation results show that graphene sponge obtained using smaller size inclusion particles have large uptake capacity at post combustion conditions. We first tested pure component flue gas adsorption capacity in graphene sponge then we moved on for more realistic ternary mixture (CO2/SO2/N2) of flue gas adsorption. Pure component adsorption results show that SO2 adsorbs preferably over CO2 and N2. At 1 bar, extent of excess adsorption of SO2 and CO2 in GS of 10 Å pore size are found to be 13 mmol/g and 2.6 mmol/g, respectively. Upon increasing pore size to 20 Å excess amount decreases by 56 % and 38 % for SO2 and CO2 respectively. In case of ternary mixture, we have found that adsorption follow the same order as in the pure component flue gas adsorption but adsorption amount decreases significantly. Selectivity analysis of adsorption show that adsorption selectivity of SO2 over N2 is highest followed by selectivity of CO2 over N2 and SO2 over CO2. Thus, our results indicate that graphene sponge obtained using smaller size inclusion particles is a promising material for treatment of flue gas at post combustion conditions.

Determining the Role of the Ionic Radii of Interlayer Cations for CO2 Capture in Synthetic Smectite Clay Kristoffer W. Humble1, Leide Cavalcanti2, Matthias Daub3, Barbara Pacakova4, Paolo H. Brito5, Kenneth Knudsen6, Josef Breu7 and Jon O. Fossom11; 1Department of Physics, Norwegian University of Science and Technology, Trondheim, Norway; 2Institute for Energy Technology, Kjeller, Norway; 3Lehrstuhl für Anorganische Chemie, University of Bayreuth, Bayreuth, Germany.

Large amounts of clays are found in cap-rock formations and act as pressure barriers in storage sites for anthropogenic CO2 [1,2]. Clays are also relevant as capture/recovery elements for combustion gases, such as methane or CO2. Recent experiments and simulations have shown that CO2 (like H2O) can intercalate in smectite clays, both in the supercritical (scCO2)[3], and in the gaseous/liquid phase[4]. Understanding how clay swells and adsorbs CO2 interacts with clay capture elements for combustion gases, such as methane or CO2. Recent experiments and simulations have shown that CO2 (like H2O) can intercalate in smectite clays, both in the supercritical (scCO2)[3], and in the gaseous/liquid phase[4]. Understanding how clay swells and adsorbs CO2 interacts with clay is vital for CCS and capturing applications. The group has previously demonstrated that CO2 intercalates into dry synthetic (Na, Ni and Li)-Fluorohectorite (Fh), with Li-Fh clay being able to retain CO2 (0.23 ton of CO2/m3 captured) up to a temperature of 35°C, at ambient pressure, and that the captured CO2 can be released by heating above this temperature. Na+ showed much slower intercalation dynamics than the Ni2+ and Li+, which might relate to its larger ionic radii, and thus a lower ability polarize CO2:[5]

We have studied (Li, Ca, Ba, Ni)-fluorohectorite [6] with a capillary based high-pressure cell with synchrotron X-ray powder diffraction. Here we show that dehydrated Ni-Fh is able to adsorb CO2 at higher temperatures range than Li-Fh, and that dehydrated Ca-Fh and Ba-Fh is not able to adsorb CO2:

Efficient CO2 Conversion to CO Catalyzed by Metal Nanoclusters Hong Seong, Yongjin Lee and Dongil Lee; Department of Chemistry, Yonsei University, Seoul, Korea (the Republic of).

Significant progress has been made recently in the electrochemical CO2 conversion to value-added products. Various polycrystalline metal electrodes have been investigated as electrocatalysts for electrochemical CO2 conversion, but they typically require high overpotentials and show relatively low catalytic activities. In this paper, we present that atomically precise metal nanoclusters, such as Au132(SR)130, where SR is thiolate ligand, can efficiently catalyze the CO2 conversion to CO with high selectivity. The electrochemical CO2 reduction was studied with Au132 nanoclusters immobilized on gas diffusion electrode in CO2-saturated aqueous solution containing KHCO3 and KCl. We found that Au132 nanoclusters can catalyze the CO2 conversion to CO with high selectivity (>90%) at high current density of nearly 100mA cm-2. Additional studies on the effects of compositions and pH of the media on the electrocatalytic activities reveal the key factors controlling the catalytic activities of the nanoclusters. To further circumvent CO2 mass transport limitations in aqueous solutions, we explored the possibility of using flow electrolyzer that supplies continuous CO2 stream at the electrode-electrolyte interface. The electrocatalytic activity of the Au132 nanoclusters was found to be drastically enhanced with high CO selectivity when the electrocatalysis was conducted with the flow electrolyzer.

Electrochemical CO2 Reduction Catalyzed by Atomically Precise Copper-Hydride Nanoclusters Yongjin Lee1, Woogjun Choi1, Dongil Lee1, Qing Tang2, De-En Jiang3, Dai-Ying Li1 and Chen-Wei Liu1; 1Department of Chemistry, Yonsei University, Seoul, Korea (the Republic of); 2Department of...
Electrochemical CO₂ conversion into valuable fuels and feedstocks has been the focus of recent research in electrocatalysis. In particular, copper-based electrocatalysts have received much attention because they can catalyze the formation of significant amounts of hydrocarbons at high reaction rates. However, the mechanistic understanding of CO₂ reduction on nanostructured Cu catalysts has been lacking. In this poster, we show that the atomically precise Cu-hydride nanoclusters, such as Cu₃H₂₆L₁₂, where L is di(thiophosphate) ligand, offer unique selectivity for electrocatalytic CO₂ reduction at low overpotentials. Density functional theory (DFT) calculations have predicted that the presence of the negatively charged hydrides in the copper cluster plays a critical role in determining the selectivity of the reduction product, producing HCOOH over CO at lower overpotential. To confirm the DFT prediction, Electrochemical CO₂ reduction was performed on the Cu₃H₂₆L₁₂ loaded electrode in aqueous media. Analysis of the reaction products demonstrated that HCOOH was indeed produced with 89% selectivity at low overpotential, while H₂ production occurred at higher overpotential. The unique selectivity observed in this system can be understood by the lattice-hydride mechanism offered by the unique Cu-hydride nanocluster.

ET14.04.05
Gas Separation Membrane of poly(ethylene glycol)-polyimide Copolymer for Separating Carbon Dioxide Sang Yong Nam, Jin Woo Jo and Ji Hyun Kim; Gyeongsang National University, Jinju, Korea (the Republic of).

The study of polymer separation membrane for carbon dioxide separation for global warming is drawing attention. Among various polymer membranes materials, Polyimide (PI) has excellent thermal and mechanical properties, good chemical stability and high gas transport property. Many researchers have studied gas transport property of polyimide membrane for gas separation. However, polymer membrane still have low performance compared with ceramic membrane and absorption process. Many researchers have been studied to complement this weak point, and can improved permeability of membranes by controlling diffusivity and solubility. Poly(ethylene glycol)(PEG), rubbery polymer, can improve solubility. The moieties with high fractional free volume (FFV) such as cardo fluorene and durene group can improve diffusivity. In this work, Diamines containing cardo fluorene and durene group were used to obtain polyimide having the high FFV. we synthesized PI-PEG copolymer to improve solubility. Finally, chemical structure, thermal property (thermal degradation and glass transition temperature) were investigated and PI-PEG copolymer membrane formed via immersion precipitation process and then membrane morphology was observed and gas transport property of PI-PEG membrane was investigated.

ET14.04.06
Hydrogen Production by Methane Decomposition Over Carbon Catalysts with Different Structures Dai Miyamoto1, Haruki Nishii2, Yoshito Umeda3, Hiroaki Hamaguchi1, Masashi Suzuki1, Toru Hariga1, Tsuyoshi Tanimoto1, Hirofumi Takikawa1 and Sada Yoshiyuki1; 1Electrical and Electronic Information Engineering, Toyohashi University of Technology, Toyohashi, Japan; 2Toho Cryogenics Co., Ltd, Nagoya, Japan; 3Aichi Center for Industry and Science Technology, Toyota, Japan.

Thermo-catalytic decomposition (TCD) of methane is an attractive hydrogen production process to mitigate CO₂ emissions commonly associated with the conventional processes (such as steam methane reforming). However, the problem of the process is catalyst deactivation by carbon deposition [1]. The purpose of this study is to investigate the relationship between the catalysts structure and the catalytic activity of produced carbon during TCD of methane by using four types of carbon catalysts with different structures.

Four types of carbon catalysts were tested in the TCD of methane: activated carbon (AC), mesoporous carbon (MC), carbon black (CB), and carbon nanofiber (CNF). Experiments were carried out in a fixed-bed reactor using 1.7 g of the catalysts with space velocity of 360 h⁻¹, at a reaction temperature of 1173 K. The produced gas was analyzed by a hydrogen detector and gas chromatography. Carbon catalysts before and after the experiments were analyzed by Raman spectroscopic analysis. The methane conversion ratio was derived from the hydrogen concentration obtained by gas analysis. Temporal change of methane conversion ratio of each catalyst is evaluated by the concentration ratio of produced hydrogen and methane. Methane conversion ratios of all the tested catalysts eventually reached about 25%. We also investigated the temporal change of the intensity ratio of the G band and the D band in Raman spectrum (I_D/I_G) of the produced carbon. I_D/I_G is used to evaluate the degree of graphitization of carbonaceous materials [2]. After 600 min elapsed, I_D/I_G of the produced carbons of all the tested catalysts was about 1.5. Therefore, we found that the produced carbon shows the same activity and degree of graphitization regardless of the structure of catalysts. We also found that Raman spectroscopy is an effective method for evaluating initial catalytic activity for methane decomposition.

References
process is not currently competitive (economically) with fuels refined from fossil hydrocarbon sources. The capex of required supply chains is too high and CO2 emission penalties are not effective. The optimal geographic location for sufficient levels of low-cost solar electricity generation may not coincide with the location of sufficient point sources of carbon emissions required by a commercial scale solar fuels production facility. The viability of solar fuels depends on a continual decline in the cost of renewable power and on realizing disruptive performance improvements in direct air CO2 capture and conversion technologies.

Electrochemical routes, such as Co-electrolysis of H2O and CO2 to CO, may offer a competitive alternative for CO2 conversion compared to "standard" catalytic technologies, both in terms ofCAPEX and OPEX. An overview of Shell’s current co-electrolysis program will be presented along with an industrial view of what targets needs to be improved to make the “solar e-refinery” concept a success. Some examples of current projects designed to achieve these targets will be presented.

E-Refinery—Towards the Sustainable Electro-Refining of Chemicals and Fuels from Renewable Resources

Wilson Smith; Delft University of Technology, Delft, Netherlands.

Electrification is a key enabler towards reducing CO2 emission. The availability of renewable electrical energy does however not remove the demand for fuels, chemicals and other materials. In addition, the variability of nature calls for electricity storage to safeguard continuous electricity supply. Electrosynthesis is a promising approach to electrify the manufacturing of fuels, chemicals and materials and to contribute to energy storage. Given the Dutch strategic position in the international chemical, renewable energy and transport sectors, TU Delft sees exciting opportunities to establish a national consortium taking the first steps towards industrialscale ‘e-refinery’ systems to convert electricity into molecular bonds. Flexible energy storage in the form of chemicals produced by using electrical energy offers prospects for the energy sector to deal with the growing challenge of demand versus supply mismatch. The large-scale production of synthetic fuels, for example for heavy long-distance transport and aviation, platform chemicals and other materials using electrical energy from renewable sources addresses sustainability demands and is a decisive step towards creating a circular economy. In this presentation, we explore the challenges that lie ahead, dividing them according to the three scales involved: the micro scale (Materials, Catalysts, Electrochemistry), the meso scale (Transport phenomena, Reactor Engineering & Process Intensification, Energy Technology & System Engineering) and the macro scale (Process and System Integration, Societal Embedding). We envision a national consortium and a long-term (10+ years) research and development programme to tackle these challenges, in line with the recent advice by the Electrochemical Conversion and Materials (ECCM) committee to the Dutch Top Sectors HTSM, Energy and Chemistry. TU Delft started the e-refinery initiative and is motivated to play a key role in such a national activity. Across all the disciplines involved, from fundamental research to societal implementation, TU Delft has the expertise to pioneer the topic of large scale electrosynthesis of chemicals and fuels from renewable feedstock. A systems integrated approach to CO2 electroreduction will be given as an example of how process integration and intensification can provide relevant reaction conditions at the micro and nanoscale that differ significantly from current areas of academic research. Therefore, materials science and chemistry research can benefit from understanding the 'big picture', and lead to more rapid technological development.

Fe-Doped Carbon Spheres Architecture as a Catalyst for CO/CO2 Methanation

Arturo Reza Ugalde, Hani E. Naguib, Pin Tsung Liao and Olivia Kesler; University of Toronto, Toronto, Ontario, Canada.

The CO2 is one of the greenhouse gases with higher impact in the global warming. Although a natural cycle regulates the CO2 concentration by the photosynthetic organism, the large-scale burning of fossil fuels has increased considerably the concentration in the atmosphere producing an unbalanced carbon cycle. Nowadays, the only solution available is the underground storage of the CO2, however, this method is extremely expensive and require continuous monitoring. An alternative solution is the sequestration and utilization of the CO2, where the greenhouse gas is captured and reduced into different products (mainly hydrocarbons), which then can be used to produce energy. With this system, the cycle of CO2 can be completed reducing the environmental impact. Among the post-capture treatments of CO2, the catalytic hydrogenation into methane is one of the most studied routes, nevertheless, the lack of a durable and cost-efficient catalyst is still a problem. This work presents the fabrication process (through nitration and impregnation) of a Fe-doped carbon spheres architecture as the electrocatalyst for CO2/CO methanation via hydrogenation. Through a thermodynamic analysis, we studied the degradation of carbon during the methanation process to ensure the longevity and stability of the carbon spheres. Furthermore, the selectivity and activation of the Fe and its transition into Fe2+ and Fe3+ were considered to guarantee the catalyst efficiency.

C2CNT—The Inexpensive, Efficient Direct Transformation of Atmospheric or Emitted CO2 to Valuable Carbon Nanotubes by Molten Electrolysis

Stuart Licht; George Washington University, Washington, District of Columbia, United States.

”C2CNT” (CO2 to carbon nanotube) is a Carbon XPRIZE technology for transforming CO2 to the most valuable product. An incentive to remove CO2 is provided by a low energy, low cost, high yield conversion to valuable products such as carbon nanotubes. Displaying superior strength, conductivity, flexibility and durability, carbon nanotube (CNT) applications had been limited due to their cost intensive their synthesis. An inexpensive source of CNTs made from CO2 will facilitate its adoption as an important societal resource for building, transportation, renewable energy, sporting and consumer electronics, while concurrently consuming CO2. We present an inexpensive, high-yield and scale-able synthesis of CNTs. A new chemistry for the effective capture of CO2 and its high yield, low energy transformation is via dissolution in a molten carbonate electrolyte and electrolytic splitting to CNTs and O2.\textsuperscript{1-10} The CO2 reactant is directly absorbed from air (without the need for pre-concentration), or can be used and removed from industrial emissions. CNTs are a compact, stable storage for the removal of anthropogenic CO2. We show that common metals act as CNT nucleation sites in molten media to efficiently drive high yield electrolytic conversion of CO2 dissolved in molten carbonates to CNTs. The CNT structure is tuned by controlling the electrolysis conditions, such as nucleation sites, composition of the electrolyte, and the control of temperature and current density. Upward scalability of the process is demonstrated over several orders of magnitude. Our goal is to transform CO2 from a pollutant to a desired resource. Molten carbonate electrolysis production is significantly less expensive than contemporary CVD to produce CNTs, and uses CO2 as the reactant. An inexpensive source of CNTs has demand as a preferred, lighter weight, stronger replacements to metals and plastics, which can provide a large market to mitigate anthropogenic CO2.

Selective Electrochemical CO₂ Reduction to CO on Ultrathin MXene Nanosheets

Data on … CNTs made directly from CO₂ by molten electrolysis, Data in Brief, 14, 593 (2017).
Transformation of the greenhouse gas CO₂ by molten electrolysis into a wide controlled selection CNTs, J. CO₂ Utilization, 18, 335 (2017).

Anthropogenic release of CO₂ is believed to be a leading cause of global climate change. An attractive proposed strategy to limit this change is to capture CO₂ after production and if possible to electrochemically convert it into value added chemicals using renewable energy. Research is presented that investigates the catalytic activity of Mo₆C and Ti₂C MXenes towards the electrochemical CO₂ reduction reaction (CO₂RR) as a cheaper alternative to precious metals that are known to catalyze this reaction. The metallic nature, large surface area of the 2D nanosheets and the ability of these MXenes to spontaneously bind CO₂ are key factors that make them attractive materials for the CO₂RR. We report very high faradaic efficiencies, ~90% for the reduction of CO₂ to CO at low overpotentials, ~300 mV, in acetonitrile/ionic liquid electrolytes on Mo₆C MXene. Ti₂C MXene shows ~65% FE at an overpotential of ~600 mV for the cathodic half reaction. The use of ionic liquid 1-ethyl-2-methylimidazolium tetrafluoroborate suppresses the competing H₂ evolution reaction and also acts as the electrolyte. High selectivity and high FE of CO₂ reduction to CO makes these MXenes, which are composed of earth abundant elements, an attractive non-precious metal electrocatalyst for the CO₂RR.

Indirect Ocean Capture of Atmospheric Carbon Dioxide

Negative emissions technologies (NETs) are needed to limit the increase in average global temperature to less than 1.5 °C. In this talk, I will present the design, prototype performance characterization, and techno-economic analysis for a new negative emissions technology (NET) termed indirect ocean capture (IOC). IOC removes carbon dioxide gas from the atmosphere by leveraging both air-ocean gas exchange and the pH sensitivity of the ocean’s carbonate buffer system. I will present the predicted net cost per ton of removed carbon dioxide for multiple scenarios, including co-location with desalination plants, and discuss the tradeoff between minimizing cost and maximizing impact. Finally, I will explain the results of a techno-economic sensitivity analysis to highlight the research and development areas that hold the most promise for future cost reduction.

CarbFix – Reducing Emissions by Rapidly Petrifying CO₂ in the Subsurface with Added Economic, Social and Economic Value

Global emissions must be put on a permanent downward trend by 2020 if severe consequences of global warming are to be prevented. CarbFix involves capturing otherwise emitted CO₂, dissolving it in water and injecting it into basaltic geological formations. There, the CO₂ is turned into rock in less than two years and is thereby permanently removed from the atmosphere. The CarbFix team has developed the method from scratch over the past twelve years; moving from laboratory-scale and numerical simulations, through pilot-scale field injections, to stage-wise build-up of industrial-scale capture and injection. Innovative equipment and methods for capturing, injecting, and monitoring have been designed and built. The annual CO₂ emissions of Hellisheidi geothermal power plant, the home of CarbFix, were reduced by 34% since industrial scale CCS operations began in 2014 until 2017. The CarbFix team, in collaboration with the Swiss company Climesworks, is currently running a pilot demonstration of a conjugated direct air capture and subsurface CO₂ mineral storage through support of the EU’s H2020 framework program. Large worldwide potential lies in joint application of direct capture of CO₂ from ambient air and CCS technologies in favorable rock formations, as this allows for rapid, permanent removal of CO₂ from the atmosphere.

The CarbFix method provides a safe and efficient alternative to conventional CCS methods in which CO₂ is stored in less reactive rock formations as a supercritical phase. It only takes two years to petrify the injected CO₂ in CarbFix, whereas mineralization happens on the scale of hundreds to thousands of years in conventional CCS. Risks of leaks are also eradicated in CarbFix as the injected phase is denser than the surrounding groundwater and therefore...
CarbFix checks all three pillars for sustainability, providing added environmental, social and economic value. The method imitates and accelerates processes already happening in nature and is, as such, environmentally benign. Added social value from CarbFix e.g. involves dissemination of knowledge, training of next generation students, on-site access to facilities, and raised awareness of available climate solutions in mass media. Added economic value can be achieved by using the method to co-capture and mineralize other environmentally important gases. At Hellisheiði power plant, the method was used for co-capturing CO₂ and H₂S. Significant savings on both capital and operational expenses were achieved compared to conventional gas removal methods. The value of those savings is over US $100 million for this single power plant.

2:00 PM ET14.06.02
Controlled Synthesis of MgO with Diverse Basic Sites and Its CO₂ Capture Mechanism Under Different Adsorption Conditions Wanlin Gao and Qiang Wang; College of Environmental Science and Engineering, Beijing Forestry University, Beijing, China.

Mesoporous MgO adsorbents with diverse basic sites were prepared via a urea hydrolysis synthesis method for CO₂ capture. With elevated hydrolysis temperatures, the phase transition process made great contributions to the morphological changes of the precursor architectures. In situ DRIFTS analysis demonstrated that various carbonate surface species including bicarbonate, bidentate, and unidentate carbonates were formed on the obtained MgO during interaction with CO₂. Furthermore, the main component of adsorbed CO₂ surface species swings from bicarbonate to bidentate and unidentate carbonates with increase of adsorption temperature. The highest CO₂ uptake of 1.22–1.99 mmol g⁻¹ was attained for MgO sample at the lowest calcination temperature in a wide temperature range of 60–300 °C. High specific surface area (372.0 m² g⁻¹), large pore volume (0.38 cm³ g⁻¹) as well as diverse basic sites of the synthesized MgO make it an eligible candidate for CO₂ capture, with a nearly 20-fold enhancement of the commercialized light MgO. Additionally, the results of CO₂ uptake studied under diluted and wet (H₂O containing) CO₂ conditions for the as-prepared MgO adsorbent also suggested good prospect in practical applications.

Technoeconomics of Electrochemical Carbon Dioxide Conversion on the 100-kW Scale Stafford W. Sheehan; Catalytic Innovations, Adamsville, Rhode Island, United States.

Key discoveries in the last century have demonstrated the breadth of products that could be made electrochemically from carbon dioxide, including carbon monoxide, formic acid, methanol, ethylene, and others. We conducted an economic assessment of both beachhead market opportunities and bulk commodity chemicals that use each of these compounds as feedstock material, with a focus on value propositions unique to products made from carbon dioxide (on-site production, cost tied to electricity prices, and use of renewable feedstock). Our findings identify pathways to implementation of electrochemical carbon dioxide conversion technologies across diverse industries that have been under-explored until now, and we identify technological roadblocks that remain for economically viable implementation.

3:15 PM ET14.07.01
Materials Science Facing Global Warming—So What? Jenny G. Vitillo; University of Minnesota, Minneapolis, Minnesota, United States.

More than the cost. Carbon capture, as any technology, is not free of costs, as evaluated in different ways: money, energy and carbon dioxide production itself. Unlike others, it is a technology that does not have a one-to-one correspondence with the person or the group paying for it, being the benefits of its application spread on a global scale. This is a problem because it makes less appealing to invest in it, unless driven by humanitarian or environmental interests. Nevertheless, it is clear from purely economical projections that investing in technologies aimed to the mitigation of the global temperature rise to 1.5 °C will allow significantly saving with respect to the cost to pay for the impact of climate change in terms of money.¹ And if extreme weather events are considered the cost to be paid will be not be restricted only to that.² Several studies will be presented during the symposium giving different perspectives on the solutions envisaged for the reduction of the CO₂ concentration in the atmosphere and its possible use.

This presentation will summarize and compare the results presented along the symposium, trying to give a more general background to the conclusions made. A discussion involving the speakers, the organisers and the audience will be stimulated trying to understand which among the different technologies are the most mature working tools to face the global warming. The possibility to size down a direct air capture technology and the benefits/drawbacks of this will be envisaged, in order to evaluate if the large sensitization of the general public on this theme can be exploited through its direct involvement (person-sized DAC devices) or indirect involvement (carbon tax or carbon credits) and then centralized carbon capture centers are more viable solutions.

4:00 PM CLOSING REMARKS
An Integrated Strategy for Defense Waste Immobilization

Kevin Fox; Savannah River Nat Lab, Aiken, South Carolina, United States.

The US Department of Energy is actively retrieving, treating, and immobilizing defense nuclear wastes at multiple sites. The Savannah River Site employs borosilicate glass and saltstone to immobilize high-level and low-activity wastes, respectively. The Hanford Site will use borosilicate glass for both of these waste streams. An integrated strategy is needed to guide the multiple unit operations necessary for the success of these operations. This strategy must bring together aspects of the feed streams, requirements of the final product, and manufacturing technologies in a manner that maximizes both waste throughput and operational flexibility. DOE’s waste immobilization efforts will take decades to complete; therefore, advances in technology are needed to reduce mission schedule and cost. Recent advances include improved property/composition predictive models for glass waste forms, higher waste loading concentrations in cementitious waste forms, accelerated salt waste decontamination, reduced need for feed pretreatment, facility lifetime extension, and more economical disposal systems. Each of these advancements must consider impacts to the overall flow sheet, both up- and down-stream, to maintain an integrated processing strategy.

What Has Been the Evolution and Structure of the Scientific Basis for Nuclear Waste Management?

Francois Diaz-Maurin1, 2, Hilary C. Sun3 and Rodney C. Ewing1, 4; 1Center for International Security and Cooperation (CISAC), Stanford University, Stanford, California, United States; 2Amphos 21 Consulting S.L., Barcelona, Spain; 3Computer Science Department, Stanford University, Stanford, California, United States; 4Department of Geological Sciences, Stanford University, Stanford, California, United States.

Nuclear waste management is at the interface between the technologies of the nuclear fuel cycle and the natural hydrologic and geochemical cycles of geologic repositories. Yet, despite its clear interdisciplinary scope, nuclear waste management, as practiced, is not a unified scientific field. Subdisciplines continue to work in relative isolation from one another: materials science dealing with the immobilization of nuclear waste; engineering science dealing with the design of the waste package and engineered barriers; geoscience dealing with the long-term behavior of host rocks and the hydrology; health science dealing with the effects of radiation; social sciences dealing with the issues of trust, risk and ethics. Each one of these fields is just one way of looking at the same issues. Defining a unified scientific basis of nuclear waste management requires working at the interfaces of these subdisciplines. Based on a comprehensive review and analysis of the scholarly and scientific literature, we discuss the evolution and structure of research in nuclear waste management between 1940 and 2017. We performed a corpus analysis and a citation network analysis based on the Elsevier B.V.’s Scopus® database aiming to identify the main themes, methods and authors for each one of the relevant disciplines dealing with nuclear waste management issues. We also analyzed the level of interdisciplinarity for each of the subdisciplines by exploring their citation patterns and impact on the other subdisciplines. Using the proceedings published on the MRS Online Proceedings Library Archive, we also analyzed papers in the MRS symposia “Scientific Basis for Nuclear Waste Management” held since 1978 as a reference case and compare its structure and evolution with those of the main academic corpus. Based on this study, we suggest the framework of the scientific basis for nuclear waste management as a unified discipline.

Uncertainty in Safety Assessments of Geological Repositories—Quantitative Performance Assessment vs the Safety Case Approach

Francois Diaz-Maurin1, 2 and Rodney C. Ewing1, 4; 1Center for International Security and Cooperation (CISAC), Stanford University, Stanford, California, United States; 2Amphos 21 Consulting S.L., Barcelona, Spain; 4Department of Geological Sciences, Stanford University, Stanford, California, United States.

Quantification of uncertainty is one of the key issues in analyzing the safety of geological repositories for the disposal of radioactive waste. In the U.S., quantitative performance assessments have been adopted as the standard method used in repository licensing. Quantitative performance assessment relies on the quantification of both stochastic (i.e., aleatory) and subjective (i.e., epistemic) uncertainties on parameters and models used as inputs to the models for the total system performance analysis. In this approach, both the random variations of aleatory uncertainties and the subjective variations of epistemic uncertainties are treated with the same mathematical methodology. Yet, although these “treatments” can be mathematically computed, the value of
quantitative performance assessments has been challenged. In repository design, epistemic uncertainties arise when projecting coupled geophysical and geochemical processes involved over large scales. These uncertainties can be qualitatively characterized by expert judgment, but they limit the ability of the analysts to predict—the long-term behavior of the repository because of the unavoidable lack of knowledge about future geological conditions. Because of the large uncertainties in such assessments, one has to expect public skepticism of statements that a repository is “safe enough.”

The “safety case” concept has been proposed as an appropriate method for analyzing the safety of a geologic repository. The safety case approach relies on the quantification of parameter variations and on scenarios that capture uncertainties in conceptual models and changing boundary conditions. Similar uncertainty quantification is still performed for stochastic parameter variations and uncertainties in projection models. But, the quantification of epistemic uncertainties will only be performed for guiding a qualitative argument (i.e., a “safety case”) about the possible long-term behavior of the repository. This hybrid approach to the safety analysis of geologic repositories thus seeks to address uncertainties for which the quantification poses epistemological constraints on the safety analysis of geologic repositories.

We discuss the use of uncertainty quantification in the safety case approach. Based on the methods of value of information and sensitivity auditing, we show simple examples of how to incorporate both quantitative and qualitative judgements in a performance assessment. In doing so, we seek to develop an analytical framework that better acknowledges the existence of unavoidable uncertainties in the assessment of the long-term performance of geologic repositories and better defines the safety case concept for its introduction in the US repository development program.

Reducing Risk and Uncertainty Associated with Nuclear Waste Processing and Disposal—A Hanford Tank Waste Case Study

Carolyn J. Pearce1, David K. Peeler2, Rolf Sjöblom2, Mark B. Triplet1, Kirk J. Cantrell1, Robert C. Moore1, Michael J. Schweiger1, Vicky L. Freedman1, Matthew S. Fountain1, Sue B. Clark1 and Albert Kruger1;

1Pacific Northwest National Laboratory, Richland, Washington, United States; 2The University of Sheffield, Sheffield, United Kingdom.

The Department of Energy’s Environmental Management cleanup effort is focused on developing and implementing innovative and high impact technologies and solutions that positively impact the overall mission lifecycle by: (1) reducing lifecycle costs; (2) accelerating lifecycle schedules; (3) mitigating mission uncertainties, vulnerabilities, and risks; and (4) minimizing the mortgage associated with long-term, post-closure and post-completion stewardship. Pacific Northwest National Laboratory and its partnering institutions, are focused on reducing risk and uncertainty across the integrated flowsheet which includes safe waste storage, retrieval, pretreatment, immobilization, disposal, and tank closure. In this presentation, an overview of the major Hanford flowsheet unit operations will be provided and examples of specific projects focused on reducing risks and uncertainties will be explored. For example, a key issue of Hanford tank waste processing and disposal is that, although radionuclides (e.g., technetium) drive the disposal risk for the low-activity flowsheet, the presence of ‘benign’ elements (e.g., aluminum) dictate processing limits or rates in both retrieval and pretreatment unit operations and have other potential downstream negative impacts. Thus, safe, cost-effective, and efficient waste processing depends on a fundamental understanding of aluminum chemistry in high strength, highly alkaline solutions where water activity is low. Once the waste has been retrieved, processed, and immobilized, controlling the behavior of risk driving elements (e.g., Tc and/or I for low-activity waste) in the waste form and the environment becomes essential for waste form disposal or tank closure. With respect to low-activity waste form disposal, material solutions must demonstrate that the risk driving radioactive elements can be contained in a manner wholly consistent with statutory requirements. Modelling future performance remains a challenge for performance assessment (PA) formalism. An appealing option is to perform an inverse PA (IPA) and look far into the past. Archeological artifacts, analogous to wasteform materials (i.e. glass and concrete) that have been left by our ancestors and exposed to the environment for thousands of years can be used to check for comprehensiveness as well as to validate and refine predicted wasteform durability. An IPA describes the features, events and processes that have influenced the corrosion of a material over time and can help establish the most likely scenarios that should be included in PA for the future. An IPA for ancient glass from a hillfort at Broborg, Sweden (ca. 400-575 AD), used to fortify the fort walls will also be one of the key focal points of this presentation.

Ceerrium Substitution in Zirconolite Ceramic Waste Form

S. K. Sundaram and Braeden M. Clark; Alfred University, Alfred, New York, United States.

Compounds with the formulae Ca2(1-x)Ce(x)Ti2O7 with x = 0.1-0.5 were synthesized by solid state reaction. Cerium was used as a surrogate for actinide elements. Sintering was carried out via spark plasma sintering (SPS), during which the perovskite phase (Ca0.6Ce0.4TiO3) was stabilized due to the reducing conditions of this technique. A transition from the 2M polymorph to the 4M polymorph (expanded unit cell due to cation ordering) in zirconolite was observed with increasing cerium content. In 2M-zirconolite, trivalent Ce co-substituted on both the Ca and Zr sites, while both trivalent (Ca and Zr sites) and tetravalent (Zr sites) Ce substituted into 4M-zirconolite. Conversion of 4M-zirconolite to perovskite and 2M-zirconolite occurred during the SPS process due to the reducing environment. This was due to the reduction of Ce4+ into Ce3+, where the 2M-zirconolite was charge balanced by co-substitution of Ce0+ on the Ca and Zr sites and the perovskite formed due to the partial reduction of Ti4+ to Ti3+ leaving excess Ca and Ti to react with the trivalent Ce to form perovskite. The presence of both trivalent Ce, contrary to formulation, was confirmed using X-ray absorption near edge spectroscopy (XANES), suggesting substitution on both Ca and Zr sites. Scanning electron microscopy (SEM) and energy dispersive spectrometry (EDS) revealed that the 2M polymorph was dilute in Ce content in comparison to the 4M-zirconolite. High temperature X-ray diffraction (HTXRD) was used to detail the kinetics of perovskite to zirconolite transition. It was found that CaCeTi2O7 (cubic pyrochlore) forms as an intermediate phase during the transformation. CaCeTi2O7 formed as an intermediate phase up until 1300°C, and 4M-zirconolite began at 1350°C. The re-oxidation of Ce3+ and Ti3+ to their tetravalent states allowed the original phase assemblage to be attained. The transformation to 4M-zirconolite was slow, but complete conversion to the original phase assemblage was achieved with a 24h heat treatment in air. Our results showed that a transition from 2M- to 4M-zirconolite occurred with increasing Ce content and the transition could be controlled by adjusting the P02 and the heat treatment temperature.

10:00 AM BREAK
The immobilisation and disposal of fissile materials from civil and defence nuclear programmes requires compatible, passively safe and proliferation resistant wasteforms. In this study, we demonstrate the application of an albitic glass – zirconomelite ceramic material for immobilisation of chloride contaminated plutonium oxide residues in the United Kingdom. The chlorine solubility limit in the albitic glass phase was determined to be 1.0 ± 0.1 wt. %, above the maximum envisaged chlorine inventory of 0.7 wt. %. Cl K-edge of X-ray absorption Near Edge Spectroscopy (XANES) was exploited to confirm partitioning of Cl to the glass phase, speculated as the chloride anion, with exsolution of crystalline NaCl above the chlorine solubility limit. Combinatorial fitting of Cl XANES data, utilising a library of chemically plausible reference spectra, demonstrated the association of Cl with Na and Ca modifier cations, with environments characteristic of the aluminosilicate chloride minerals. The partitioning of Cs, as a Pu analogue, within the glass-ceramic was not adversely impacted by incorporation of Cl. The significance of this research is in demonstrating the compatibility of the glass-ceramic wasteform toward Cl solubility at the expected incorporation rate, below the determined solubility limit.

11:00 AM ET15.02.03
Synthesis and Sintering of Th-Based Cheralites from Rhabdophane-Type Precursors
Danwen Qin, Adel Mesbah, Stéphanie Szenknect, Nicolas Ducheux and Nicolas Clavier; ICSR, CEA, CNRS, ENSCM, Univ Montpellier, Bagnols/Cèze, France.

Monazite-type ceramic wasteforms have been investigated for long for the specific conditioning of actinides. Indeed, they are known to provide high weight loadings in actinides, good sintering capability and strong resistance to aqueous corrosion and radiation damages. The incorporation of tetravalent actinides generally processes through coupled substitutions, leading to monazite-cheralite solid solutions with the general formula MIIxAnIVxLn1-2xPO4. Nevertheless, the preparation of such samples was mainly achieved using dry chemistry methods, which can lead to heterogeneities in the solid and to the degradation of the properties of interest.

The incorporation of thorium in CaxThxNd1-2xPO4 solid solutions (0 ≤ x ≤ 0.15) was then investigated through wet chemistry processes based on the initial precipitation of rhabdophane-type precursors. A multiparametric study was undertaken to specify the operating conditions (starting stoichiometry, temperature, heating time) leading to single-phase CaxThxLn1-2xPO4.nH2O powdered samples. Particularly, the excess of calcium appeared to be a prevailing factor, with a suggested initial Ca:Th ratio of 10:1. Similarly, the recommended heating time should exceed 4 days while the optimal temperature of synthesis lies around 110 °C.

The transformation of rhabdophane-type precursors into highly durable CaxThxLn1-2xPO4 cheralites was further studied. TG analyses showed that the conversion first proceeded with a dehydration step occurring around 210-220°C, this temperature increasing linearly with the thorium content in the sample. Additionally, the phase transition between anhydrous rhabdophane and cheralite was determined by dilatometric measurements and varied from 700°C to about 820°C depending on the chemical composition considered. After heating at high temperature (i.e. typically at 1100°C), XRD analysis revealed the formation of single phase cheralite-monazite solid solutions without any trace of side products such as α-ThP2O7 or Th4(PO4)4P2O7.

Finally, first insights concerning the sintering of CaxThxLn1-2xPO4 wasteforms directly from the shaping and heating of low-temperature precursors were obtained. Full densification (i.e. > 95%TD) was achieved after 4 hours of heating at 1400°C for all the samples investigated. Nevertheless, the chemical composition was found to strongly influence the sintering process and the final microstructure. Indeed, thorium incorporation was found to slightly enhance the densification temperature determined by dilatometry, while the presence of small amounts of calcium in excess can drastically increase the final grain size.

11:15 AM ET15.02.04
Microstructure Control of Gd:TiO2 Pyrochlore by Spark Plasma Sintering and Its Dissolution Behavior
Yachun Wang and Jie Lian; Rensselaer Polytechnic Institute, Troy, New York, United States.

Pyrochlore, with a chemical composition of A2B2O7 (A and B are metals), shows great potentials as advanced waste forms for effective nuclear waste immobilization due to its capability to incorporate wide range of radionuclides, exceptional radiation tolerance, and desirable chemical stability. Those properties can be profoundly affected by microstructure features. However, the effect of grain size, particularly of nanometer length scale, on the dissolution behavior of pyrochlore has not been studied yet. This study explored the connection between grain size of Gd2Ti2O7, a type of Pyrochlore, and its chemical durability in acidic condition. Specifically, bulk Gd2Ti2O7 pellets with different grain sizes were fabricated by spark plasma sintering (SPS) and post sintering annealing. Subsequently, we focused on the dissolution behavior of different grain sized Gd2Ti2O7 pellet under aqueous condition (with isotope tracer 18O, at high temperature (90 °C) and acidic conditions (pH=1 and 2)). Dissolution rate of Gd and Ti were analyzed by inductively coupled plasma mass spectrometry (ICP-MS). Elements depth profile in dissolution alternated layer probed by secondary ion mass spectrometry (SIMS) showed the formation of a surface passivation layer enriched by O18, providing new insights into the dissolution mechanism of Gd2Ti2O7. The results highlighted the great potential for nano grain sized Gd2Ti2O7 with enhanced dissolution resistance for nuclear waste immobilizations.

New Engineered Forms of Zeolites for the Selective Removal of Cs and Sr from Effluent
Joe Hriljac, Ryan George, Mohamed Karmaoui and Tzu Yu Chen; University of Birmingham, Birmingham, United Kingdom.

Aluminosilicate zeolites, such as clinoptilolite and chabazite, are the traditional inorganic materials for removal of water-soluble radioactive cations such as 137Cs+ and 90Sr2+. In addition to the need for excellent selective ion exchange properties, the materials need to be available in a physical form that is suitable for use in a gravity flow column. Use of very fine-grained powders will often cause problems due to a slow liquid flow causing blockage. Synthetic zeolites and other ion exchangers such as the titanosilicate CST used in IONSIV crystallise as submicron to a few micron sized powders. Therefore they are unsuitable for column use unless produced in an engineered form such as IONSIV R9120-B where the CST is blended with an inert binder material into a pellet form. We are investigating alternative means of producing new forms of ion exchange materials and in this talk I will discuss two of those. The first is the production of zeolite monoliths via 3D printing methods for use in traditional gravity flow columns. The second is producing magnetized systems which can be separated from effluent via magnetic trapping after use.

2:00 PM ET15.03.02
Sequestration of Radionuclides in Metal-Organic Frameworks from First Principles Calculations
Shubham Pandey, Zhilin Jiu, Brian Demaske, Ekaterina Dolgopolova, Natalia Shustova, Wahyu Setyawan, Chuck J. Henager and Simon R. Phillpot; Department of Materials Science and
Metal-organic frameworks (MOFs) could lead to development of novel class of hybrid materials emerging as potential wasteforms to sequester nuclear waste. Density Functional Theory (DFT) calculations were used to determine the favorability of substitution of relevant radionuclides in various parent MOF clusters. The radionuclides of interest are U, Th, Am, Cm and Tc. Results from various levels of treatment of the exchange-correlation functional are compared to establish the robustness of the results. We find that Tc incorporation is energetically well-favored in all of the MOFs considered. The electronic structures of both the actinide-based MOFs and radionuclide substituted MOFs are analyzed and correlated with experimental data. We also study the effect of the electronic properties tunability as a function of transition metal incorporation.

This work was supported by the Center for Hierarchical Waste Form Materials (CHWM), an Energy Frontier Research Center (EFRC) funded by the United States Department of Energy Office of Basic Energy Sciences through Award DESC0016574.

2:15 PM ET15.03.03

Synthesis and Ion Exchange Properties of Zirconogermanates Ryan George and Joe Hriljac; School of Chemistry, University of Birmingham, Birmingham, United Kingdom.

The synthesis of novel ion exchange materials for uses in nuclear waste management and environmental remediation is a key area of research. The established methodology for the removal of caesium and strontium from effluent in the UK involves the use of a natural zeolite material clinoptilolite1, but future waste streams and POCO activities may be better tackled with other systems. Much effort is being placed in designing materials with better selectivity and ion exchange capacity than clinoptilolite.

One family of materials which have been widely investigated are mixed octahedral and tetrahedral framework metal silicates due to potentially interesting ion exchange properties as well as better chemical and radiation stability than aluminosilicate zeolites. One of these types of materials, a natural zirconosilicate mineral umbite (K$_2$ZrSi$_3$O$_9$.H$_2$O), has been synthesised as have related materials with both Sn and Ti as the octahedral component replacing some or all of the Zr, for which the ion exchange properties have been explored in the literature2. The variation of the tetrahedral (Si) component has been explored in this work with the successful synthesis of a germanium derivative of the mineral umbite (K$_2$ZrGe$_3$O$_9$.H$_2$O).

Subsequent ion exchange results show both caesium and strontium uptake by Ge-Zr-umbite (K$_2$ZrGe$_3$O$_9$.H$_2$O) but at low levels. This is substantially improved by chemical modification of the umbite structure with the incorporation of up to 25% Nb/Sb for Zr at the octahedral site. High resolution synchrotron X-ray powder diffraction data shows complex structural behaviour of these doped materials when they undergo caesium exchange. Further attempts at doping higher levels for Zr results in mixed phases with the formation of pharmacosiderite phases (HK3Ge$_7$O$_{16}$.4H$_2$O and HK$_3$Ti$_4$Ge$_3$O$_{16}$.4H$_2$O), with these also showing interesting ion exchange properties. The thermal decomposition products of the pharmacosiderite phases have all been analysed for potential wasteform candidates.

Nuclear Waste Form Corrosion Gerald S. Frankel*, John Vienna†, Jie Lian‡, John R. Scully§, Seong Ho Kim∥, James Saal¶, Joseph Ryan∥, Stephane Gin∥, Wolfgang Windl*, Jincheng Du†, Jianwei Wang‡, Christopher Taylor§, Jenifer Locke∥ and Daniel Perea¶; 1The Ohio State University, Columbus, Ohio, United States; 2Pacific Northwest National Laboratory, Richland, Washington, United States; 3Rensselaer Polytechnic Institute, Troy, New York, United States; 4University of Virginia, Charlottesville, Virginia, United States; 5The Pennsylvania State University, State College, Pennsylvania, United States; 6QuesTek Innovations, Evanston, Illinois, United States; 7French Alternative Energies and Atomic Energy Commission, Marcoule, France; 8University of North Texas, Denton, Texas, United States; 9Louisiana State University, Baton Rouge, Louisiana, United States.

This talk will summarize the activities of WastePD, an Energy Frontier Research Center focused on the performance and design of nuclear waste forms. The Center has 13 PIs from 9 institutions and comprises three thrusts based on materials classes: waste glass, crystalline ceramics, and metals. Commonalities in the degradation of these materials and synergies between the thrusts have led to new understanding of the environmental degradation processes. A framework for the design of materials with improved corrosion resistance was developed, called Science of Environmental Degradation of Materials, SEDMat. Existing approaches for design for corrosion resistance are largely empirical and based on qualitative models and experimental data. The ultimate goal is to develop a fully descriptive synthesis of detailed models of all of the elementary processes. While working toward that goal, calculable parameters are being combined to generate expressions with predictive capabilities. Examples of the scientific findings of each of the materials thrusts will be presented including state of the art characterization of the gel alteration layer on waste glass using flash freezing, cryo-processing of samples, and cryo atom probe tomography. New corrosion-resistant high entropy metallic alloys will be described, as well as studies of ceramic degradation in aqueous environments.

3:30 PM ET15.04.02

Lead/Lead-Based Alloy Canister for High Level Nuclear Waste and Used Nuclear Fuel Revisited—Insight from Advances in Lead Solution Chemistry Yongliang Xiong*, Yifeng Wang**, Sungtae Kim*** and Greg Roselle†; 1Sandia National Laboratories, Carlsbad, New Mexico, United States; 2Brigham Young University-Idaho, Rexburg, Idaho, United States.
The canister for high level nuclear waste (HLW) and used nuclear fuel (UNF) is important for the safe disposal of such wastages, as a canister serves as the first line of defense in the multiple engineered barrier systems. The lead and lead-based alloy canisters were proposed in several countries’ repository designs. For instance, in the Argentine repository design, the containers for reprocessed and vitrified wastes have a thick intermediate layer made of lead with a 10 cm width, owing to its excellent radiological protection and corrosion resistance. In Russia, lead and lead-based alloys are also considered as prospective matrices for containers for used nuclear fuel, and are being used for conditioning spent sealed radioactive sources at radioactive waste disposal facilities. Lead containers are also used in the Brazil repository design.

In this presentation, we revisit the lead and lead-based alloy canister for HLW and UNF, based on the insights from the recent advances in lead solution chemistry including lead corrosion experiments in corrosive, high ionic strength solutions, and recent archaeological studies on ancient lead artificial products.

In environments where dissolved sulfide and oxygen are absent or poor, the corrosion products of lead are likely to be lead oxide (litharge, PbO) or lead carbonate (cerussite, PbCO₃). Archaeological studies have indicated that litharge was formed when lead was corroded under anoxic conditions. In our corrosion experiments with lead in high ionic strength solutions at P_{CO2} > 10^{-12} atm, we observed cerussite and tamowskitize [[(Cu, Pb)CO₃] as corrosion products.

The solubility of lead corrosion products is a key to the performance of a lead container, as the corrosion products usually behave as a protection layer. We have developed the thermodynamic model for lead solution chemistry valid to high ionic strengths, which can accurately describe solubilities of various lead solid species under various conditions. In this presentation, we evaluate lead solubilities in various repository designs by applying our thermodynamic model. The repository designs include those in granites, shales, crystalline rocks, salt formations, and sedimentary basins.

3:45 PM ET15.04.03 The Corrosion of Copper Nuclear Waste Containers in Sulphide-Containing Groundwaters David Shoesmith, Jian Chen, Taylor Martino, Mengnan Guo and James Noel; University of Western Ontario, London, Ontario, Canada.

The Canadian/Scandinavian concept for the permanent disposal of high level nuclear waste is to seal it in a container with an outer copper coating/shell and bury it in a deep geologic repository. While the container could experience a number of corrosion processes, the most likely long term corrosion process will be the reaction of Cu with sulphide present in the groundwater. The nature of this corrosion process and the morphology of damage distribution will eventually determine the time to failure of the copper coating/shell.

We have been studying these processes using electrochemical, corrosion science and surface analytical techniques. With a particular emphasis on the nature of the corrosion product deposits (copper sulphides) and the morphology of the corroding copper/deposit interface. This latter feature will determine the local loss of wall thickness required to define the required copper coating/shell corrosion allowance.

Using electrochemical impedance spectroscopy (EIS), we have shown the corrosion product deposit to be porous at the low sulphide concentrations anticipated in a repository, and to vary in morphology depending on the sulphide concentration, groundwater ionic type and concentration (in particular chloride), and the transport conditions prevailing at the copper surface. Using EIS and voltammetry techniques we have demonstrated that passivation of the copper surface, which could potentially lead to pitting, will not occur. Based on SEM images recorded on focussed ion beam cut cross sections, some localization of corrosion can be observed due to micro galvanic coupling of the copper substrate to the electrically conducting chalcocite (Cu₇S₈) deposit. This localization is facilitated by the transport of copper, as either soluble complexes or neutral clusters (Cu₅S₄) from the corroding anodic locations to the cathodic locations were copper sulphide deposit occurs.

The presence of H₂S in underground water is a factor that has to be considered in the safety assessments of deep geological repositories (DGR) for spent nuclear fuel because H₂S drives the corrosion of many metal. The canister material that is planned to be used in the Swedish DGR, copper, is no exception to this and the formation of copper sulfide films has been observed in experiments where the metal was exposed to H₂S(aq). In order to understand the phenomenon at the atomic-scale, we performed density functional theory (DFT) investigations of the molecular and dissociative adsorption of H₂S and of its dissociation products, HS and S₂, at perfect and defective Cu(110) surfaces described using large supercells with c(6x6) periodicity. For single and pairs of adsorbates, we investigated the adsorption at a diversity of sites such as pits, terraces and holes. For the perfect surfaces we scanned through all possible binding sites for the adsorbates, studied the interactions between adsorbates as a function of their distance, and investigated electronic structure effects such as the formation of surface dipoles in order to develop a rationale for the construction of models for the growth of thick layers of surface products.

We found that the adsorption modes and energies of the products of dissociation of H₂S are largely dependent on the presence of defects and that for high coverages, H₂S forms stacked half-monolayers that interact with each other via a complex hydrogen bond network. The surface perturbation induced by S₂ can be explained by the charge transfer model, H₂S leads to a perturbation that arises mostly from Pauli exclusion effects, while HS shows mixed: charge transfer-Pauli exclusion effects. These effects have a large contribution to the long range adsorbate-adsorbate interactions observed. We considered then two models for the growth of a layer of S-atoms at the surface: the formation of islands vs the formation of more homogeneous surface distributions of S-atoms. For coverages lower than 0.5 ML, S-atoms cluster as islands that evolve to stripes with increasing coverage. At 0.5 ML a homogeneous distribution of S-atoms becomes more stable than the formation of stripes. For the coverage equivalent to 1 ML, the formation of two half-monolayers of S-atoms that disrupt the Cu-Cu bonds between the first and second layers is more favorable than the formation of 1 ML homogeneous coverage of S-atoms. Here the S-Cu bond distances and geometries are reminiscent of pyrite, covellite and to some extent chalcocite. The small energy difference of ≈0.1 eV that exists between this structure and the formation of 1 ML suggests that in a real system at finite temperature both structures may coexist leading to a structure with even lower symmetry.

4:30 PM ET15.04.05 Anoxic Corrosion of Low-Carbon Steel at Elevated Temperatures—Effects of Chloride and Sulfide Charlotte Sisk Scott; Jonathan Icenhower, Chase Kicker, Cassie Mars, Leslie Kirkes and Praveen Sirirama; 1 Repository Performance, Sandia National Laboratories, Carlsbad, New Mexico; 2 Sandia National Laboratories, Albuquerque, New Mexico; 3 Sandia National Laboratories, Livermore, California.
Anoxic experiments were carried out on low-C steel coupons in dilute solutions and simulated brines with and without sulfide to determine gas generation rates, iron-release rates, and secondary corrosion phases. Corrosion rates were determined in a flow-through system (90°C) and a static apparatus (70°C) at pH (25°C) = 9. The experiments comprised of two sets of solutions, consisting of either Simplified Generic Weep Brine or deionized water. Each of the sets had substrates containing sulfide in the form of NaHS. Polished coupons of steel were reacted in the flow-through experiments whereas unpolished cylinders were reacted in the static experiments. Dissolution rates were quantified by analysis of Fe released to solution (Fe^{2+} and total Fe) and by liberation of H_{2}. In the case of the flow-through experiments, H_{2} was collected in-stream and analyzed by GC-TCD. In the static experiments, the increase of pressure was monitored and H_{2} was collected and analyzed by GC-TCD at experiment termination. Steel coupons and cylinders, and the secondary corrosion products, were analyzed post-test and ex-situ by Raman, SEM and XRD. In sulfide-free SGWB at 90 °C the calculated surface retreat rate based on the Fe-release rate, measured in the flow-through system, was ~3.1±1 μm/yr. In contrast, the retreat in sulfide-bearing SGWB was measured to be 0.02 μm/yr, a factor of ~160 slower. In deionized water, the average surface retreat rate was measured to be 0.08 mm/yr. In the static experiments, the highest gas generation rate based on H_{2}(g) production was 0.4 mol/m^{2}·yr. Examination of the secondary phases by Raman spectroscopy indicated the presence of Fe(OH)_{2} and magnetite in sulfide-free SGWB and DIW and mackinawite and pyrrhotite as reaction products in sulfide-bearing solutions. Green rust was also identified as a reaction product in sulfide-free SGWB experiments.

as they form complex eutectic mixtures during early stage melting. In LAW melting, this alkali salt phase can preferentially incorporate radioactive Cs, halides, and peroxoanions. During melting of the feed, some oxoanions sequentially break down during melting, such as some carbonates, sulfates, and other inorganic acids. Alkali-salt phases can form gases, or partially volatilize, such as some halides. Sulfates, however, tend not to volatilize but have limited solubility in the final borosilicate glass waste form. Excess salts, usually related to high concentrations of sulfate, form a water soluble salt phase on the cooled glass surface compromising the waste form long-term chemical durability. To better understand these low temperature processes, a scoping study was undertaken to synthesize melts of equimolar ratios of K₂SO₄-ZnSO₄ (a known glass-forming system) with added nitrates, halides, carbonates, or various halides. Some of the materials formed single phase glasses and some underwent more or less crystallization upon quenching. Characterization of these quenched materials, including thermal analysis, vibrational spectroscopy, and diffraction, will be discussed.

ET15.05.04 Effect of TiO₂ Doping on Crystallization of Alkali and Alkaline-Earth Molybdate Phases in an Improved High Level Waste Glass-Ceramic Prashant Rajbhandari1, Kristian Barnsley1, John Hanna1, John S. McCloy2, Russell Hand3 and Neil Hyatt1; 1University of Sheffield, Sheffield, United Kingdom; 2Washington State University, Pullman, Washington, United States; 3University of Warwick, Coventry, United Kingdom.

The incorporation of high molybdenum and rare earth elements in the conventional borosilicate glass can induce liquid-liquid phase separation and that is followed by crystallization of alkaline-earth molybdates CaMoO₄ (water-durable) and alkali molybdates Na₂MoO₄ (water-soluble). The resistance against water attack can be significantly reduced due to the formation of water-soluble crystalline phase (Na₂MoO₄) during the melt cooling. In this work, the impact of small amount of TiO₂ (1-4 mol%) on the crystallization of Molybdate phases on simplified Mo-containing borosilicate glass is investigated. The differential thermal and XRD analysis were implemented to study the thermal behavior of the compositions and nature of the crystalline phases. The results indicated that the addition of TiO₂ significantly reduced the formation of water-soluble Na₂MoO₄ phases. The morphology and structural modification of the material were investigated by implementing SEM and solid state NMR analyses respectively.

ET15.05.05 Multinuclear NMR Methods for Characterising Precipitates During Simplified MW25 Glass Dissolution Rui Guo and Ian Farman; Univ of Cambridge, Cambridge, United Kingdom.

The presence of Mg in the UK high-level waste glass MW25 has shown to increase the aqueous reactivity when compared with Mg-free glasses like SON68 (the inactive analogue of French R77 high-level waste glass)[ii]. The exact mechanism by which Mg reduces the aqueous durability of glasses is not clear, but it has been concluded that the effect is not a primary one in which changes induced in the glass structure (and composition) by the addition of Mg alter the initial dissolution rate[iii].

The accepted mechanism of passivation in glass dissolution is that an altered layer forms on the surface of the underlying glass by in-situ mechanisms of hydrolysis and re-condensation of the glass network. This retards further dissolution by acting as a diffusion barrier or molecular sieve[iv]. A significant degree of re-incorporation of Mg, Al, Si had been observed during Mg-containing glasses dissolution in our experiments. Thus, it was proposed that the “passivating” altered layer formed on Mg-containing glasses have an inferior retarding efficacy because of the secondary co-precipitations that might alter the “conventional” passivating mechanisms.

Multinuclear (²⁵Mg, ¹⁷O, ²⁷Al, ¹H) NMR methods have been exploited to determine the atomic speciation of the precipitates (and altered layer) in question. In addition, first-principle electronic structure calculations combined with GIPAW to calculate NMR parameters on several Mg-silicate/silicate structures have been conducted to constrain the type of local atomic environments in support of interpreting experimental results.

and-ilw-glasses-the-effect-of-magnesium;
The accident at the Fukushima Daiichi Nuclear Power Plant (1F-NPP) occurred following the Great East Japan Earthquake on 11 March 2011, and led to the release of volatile radionuclides, which were deposited on the environment in the Fukushima prefecture and the surrounding areas. After the short-lived I-131, radiocaesium such as Cs-134 and Cs-137 have controlled radiation dose rate. The authors derived the apparent diffusion coefficients ($D_a$) of some radionuclides such as Cs-134 and Cs-137 based on time variation of the depth profiles of respective radionuclides in soil obtained in field investigations in earlier studies. Almost all $D_a$-values were of order 10^{-14} (m^2/s) and well consistent with distribution coefficients ($K_d$) obtained from batch experiments. Whilst, field investigations for the relaxation mass depths of Cs-137 in soil by a scraper plate method were conducted at totally 85 locations over a period of nearly 6 years in Fukushima Prefecture, south part of Miyagi Prefecture and north part of Ibaraki Prefecture from December 2011 to October 2016, and time variation of the relaxation mass depths was recently reported. Consequently, the relaxation mass depths of Cs-137 showed a tendency to linearly increase with an increase of elapsed time. This indicates that radiocaesium gradually moves to the deeper part of soil with time. In this study, $D_a$ based on Fick’s diffusion equation was derived based on time variation of the relaxation mass depths of Cs-137 in soil. In order to calculate $D_a$ based on Fick’s law, correlation between relaxation depth and square root of elapsed time was derived from the correlation between relaxation mass depth and elapsed time (where, relaxation depth is defined as the depth of 1/e of radioactivity concentration at the ground surface and can calculate by relaxation mass depth/soil density). The calculated $D_a$ of Cs-137 was of order 10^{-12} (m^2/s), which was about 2 orders of magnitude higher than $D_a$-values that we previously reported as described above. Considering that almost all relaxation depths of Cs-137 were shallow within 2cm in depth from the ground surface and near the surface layer of soil is unsaturated, it is considered that $D_a$ derived in this analysis includes the effect of dispersion by advection (by flow in the vertical direction of rainwater).

8:30 AM *ET15.06.01
Hot Isostatic Pressing of Advanced Nuclear Waste Forms Daniel Gregg, Eric Vance, Rohan Holmes and Gerry Triani; Australian Nuclear S&T Org, Sydney, New South Wales, Australia.

ANSTO Synroc Technologies has a significant focus on the use of hot isostatic pressing (HIPing) technology to fabricate tailored candidate glass–ceramic and ceramic waste forms for different types of actinide, high- and intermediate level wastes. Such advanced waste forms can offer performance and economic benefits for the immobilisation of different types of waste which are problematic for glass matrices or existing vitrification process technologies. The HIP technology itself offers several advantages such as increased density, minimum grain size and removes the need for costly and bulky off-gas systems. In addition, it has been demonstrated that glass, glass-ceramic, ceramic and metal encapsulated waste forms can all be produced using this one flexible process technology.

The industrial demonstration of Synroc technology will be achieved at ANSTO with the first of a kind Synroc Waste treatment Facility (SyMo) to treat waste arising from molybdenum-99 production. Construction of this facility commenced in 2018. Hot isostatic pressing is a key process for this facility, with significant technical challenges being addressed for industrial implementation. ANSTO Synroc’s approach has been to employ a multidisciplinary team which uses systems integration and risk mitigation to nuclearize waste treatment processes. The plant delivery model has been to develop the process chemistry and the process engineering including mock up and full scale demonstration to mitigate integration risks. This paper will discuss the engineering principles behind the development of the SyMo facility for the treatment of Mo-99 wastes as well as the application of ANSTO Synroc Technology as an advanced waste form and technology platform for many other intractable nuclear wastes.

9:00 AM ET15.06.02
Vanadinite Ceramic Waste Forms by High Energy Ball Milling and Spark Plasma Sintering for Chlorine Confinement Penghui Lei1,2, Tiankai Yao1, Guang Ran2 and Jie Lian1; 1Department of Mechanical, Aerospace, and Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States; 2College of Energy, Xiamen University, Xiamen, China.

Apatite structure type, with a typical chemical composition of A$_2$(BO$_4$)$_6$C$_2$ (e.g., A=Ca, Na, Pb, rare earth, fission product, actinides; B=P or V; C=F, Cl, I) shows tremendous potentials as advanced waste forms for effective nuclear waste management. A wide range of radionuclides can be incorporated into its crystal structure by coupled substitutions at both cation and anion sublattices. Pb$_3$(VO$_4$)$_2$Cl$_3$, a potential waste form for long-lived CI-36 immobilization, is used to confine highly volatile chlorine. In this work, Pb$_5$(VO$_4$)$_3$Cl powder samples are synthesized by solid state reaction at room temperature by using High energy ball milling (HEBM). Low-temperature consolidation of dense vanadinite pellets by spark plasma sintering(SPS) at various temperature (753K, 783K, 793K, 823K, 843K, 873K) were performed. Microstructure analysis indicates a nanocrystalline ceramic with an average grain size less than 200nm at 723K. No significant chlorine loss was identified by HEBM and during densification SPS process. The effects of sintering on microstructure, density, thermal stability and mechanical properties were investigated. These results highlight the immense potential of SPS combining with HEBM as an advanced materials fabrication technology for immobilization of volatile radionuclides including radioactive chlorine.

9:15 AM ET15.06.03

High level waste (HLW) waste form containers shall take no aqueous durability credit when considering non-spent fuel HLW. Yet immobilisation of spent power plant fuel currently will rely strongly on metal encapsulation, particularly for the highly soluble fission products that do not inhabit UO$_2$. This is probably due to the absence of widely accepted waste form candidate phases other than a very low waste loaded glass at the time relevant research on spent fuel immobilisation began. More recent work however, has demonstrated relevant tailored waste form options with acceptable waste loadings. Here we propose a pyrochlore glass-ceramic made by hot isostatic pressing at ~1250°C/100MPa as a strong candidate wasteform for spent fuel. It is also as an ILW waste form for 99Mo production waste produced from irradiation of UO$_2$ targets. The U oxide and rare earth fission products would be incorporated in the pyrochlore and the fission products in the glass. We have put forward the pyrochlore mineral phase before for the ILW but have more recently favoured a glass-ceramic containing around 50-80 wt% pyrochlore plus 20-30 wt% borosilicate glass. Depending on the redox conditions in calcination and the addition of Ti metal to the canister for HIP, the pyrochlore phase is sensitive to redox conditions with slightly oxidising conditions favouring brannerite as...
an extra ceramic phase and perovskite and UO₂ as extra phases being favoured by highly reducing conditions. Optimisation of the phase assemblage is discussed.

10:00 AM *ET15.07.01
Dissolution of Uranium Dioxide and Associated Solid Solutions in Nitric Acid—Impact of Fission Products and Microstructure Nicolas Dauchoux, Theo Cordara, Thomas Dalger, Florent Tocino, Laurent Claparede, Stéphane Szenknect, Nicolas Clavier, Adel Mesbah and Renaud Podor; IC3M, CNRS, CEA, ENSCM, Univ Montpellier, Bagnoles sur Ceze, France.

The dissolution or leaching of the spent nuclear fuels (SNF) is a key step either in the field of their reprocessing or their long-term storage in underground repository. Their structure and microstructure become very complex due to the formation of actinides and Fission Products (FP). In order to discriminate the role of several parameters on the chemical durability, a large variety of sintered materials were prepared from hydroxide or oxalate precursors then submitted to multiparametric dissolution tests.

The impact of actinides incorporation was examined through the study of U₁₋₅,Th₂O₃ solid solutions dissolution in nitric acid. Uranium mole loading clearly impacted the chemical durability. Indeed, for the lower uranium incorporation rates (x₅<0.5), the dissolution was mainly controlled by surface-controlling reactions at the solid/solution interface involving the adsorption of protons on reactive sites. On the contrary, for uranium enriched materials (x₅>0.5), oxidation of uranium (IV) into uranyl at the solid/solution interface became clearly preponderant (leading to the decrease of the chemical durability, as shown for pure UO₂). Partial order related to the proton concentration as well as apparent activation energy associated to the reaction of dissolution were affected by this change. The role of nitric acid on the normalized dissolution rate of U₁₋₅,Th₂O₃ was particularly examined.

The impact on the chemical durability of several FP (lanthanides or PGM’s) within the structure of UO₂ was also studied. Thus, several samples incorporating 1 to 20 mol.% of a mixture of lanthanide elements (13% La; 7.4% Y; 25.6% Ce; 12% Pr; 42% Nd) or 0.6 to 3 mol.% of PGM’s (55% Ru; 9.6% Rh; 35.4% Pd) were prepared through oxalate or hydroxide precipitation, respectively, then sintered.

The presence of lanthanide elements in UO₂ did not affect significantly the normalized dissolution rates in concentrated nitric acid solutions (C > 1M). On the contrary, the effect was more important in less concentrated solutions (e.g. a factor of 100 compared to pure UO₂ observed in 0.5M HNO₃) when the role of surface-controlling reactions on the overall dissolution became predominant. Moreover, the chemical durability of UO₂ samples doped with PGM’s was significantly lowered compared to pure UO₂. This effect was strengthened in less acid media; a factor of 4500 being observed after 175 days of leaching in 0.1M HNO₃.

Such a macroscopic description of the ceramics dissolution was connected to operando monitoring of the evolving solid/solution interface (including reactive surface area, composition) during dissolution tests. Preferential dissolution was observed within Ln-enriched UO₂ grain boundaries or near the UO₂/PGM’s interface, indicating different progresses of the dissolution at the solid/solution interface. Moreover, variations in the distribution of cations also affected the chemical durability of heterogeneous U₁₋₅,Th₂O₃ pellets through a clear incongruent dissolution.

10:30 AM ET15.07.02
Effect of Nuclear Fuel Additives on the Spent Nuclear Fuel Reprocessing Dissolution Step Theo Cordara, Hannah Smith, Claire L. Corkhill, Martin Stennett and Neil Hyatt; Department of Materials Science and Engineering, University of Sheffield, Sheffield, United Kingdom.

Nuclear power producers are seeking to lower the cost of generating electricity through the development and application of new fuels that are capable for being “burnt” for longer within the reactor. One of the main limitations for how long fuel can remain in the reactor is the ability of the fuel to accommodate fission products, especially fission gases like Kr, Xe, He, etc. The build-up of these gases can lead to a swelling of the fuel and to cladding failure, resulting in downtime of the reactor. The solution to this issue is to improve the UO₂ fuel by promoting the growth of larger grains and increasing the rate of diffusion of fission products to the grain boundaries during fission. This is achieved by doping UO₂ with additives; the most extensively applied are Cr₂O₃, Al₂O₃ and a mixture of Cr₂O₃-Al₂O₃.

In this presentation, we describe the synthesis and characterisation of Cr, Al and Cr+Al-doped-UO₂ materials, containing between 100 and 1,500 ppm of dopants. Samples were prepared by dry (oxides mixing) and wet (oxalic or nitrate precipitation) synthesis routes. Oxide powders thus obtained were pelletized and sintered at 1,700°C during 8h under a reducing atmosphere. SEM images and pycnometer measurements have respectively highlighted an increase of the grain size and of the densification rates in presence of additives. XRD patterns confirmed that the fluorite structure (space group Fm3m), the characteristic crystalline structure of UO₂, was retained when the samples were doped. Further characterisations (e.g. HR-XRD and EXAFS) were performed to further determine the solubility limit of Cr and Al within the UO₂ lattice, the lattice parameter and the Cr-coordination in these materials. Finally, pellets produced through the above methods were compared to those obtained using hot-isostatic pressing (HIP), which is a sintering method where the pellet is heated at the same time as the application of gas pressure.

10:45 AM ET15.07.03
Long Term Structural Stability During Storage of Self-Damaged Nuclear Spent Fuel Simulant Oliver Dietze, Thierry Wiss, Emanuele de Bona, Jean-Yves Colle, Ondrej Benes, Dragos Staica and Rudolph J. Konings; JRC, Karlsruhe, Germany.

The plutonium together with the minor actinides will be responsible for the long term radiotoxicity of spent nuclear fuel, and for the medium term heat loading of the fuel in open nuclear fuel cycles. As these transuranic elements present on the nuclear waste are mainly alpha-emitters, increasing amounts of alpha-damage and helium during spent fuel storage and in the repository will be generated. Most of the defects produced by alpha-decays are generated through elastic energy losses from the recoil of daughter nuclei. In addition, when the alpha-particle comes to rest it becomes a helium atom that can alter the microstructure of the material, e.g. by forming microscopic bubbles. The fluorite structure, shared by all actinide dioxide, is known as being a radiation damage resistant crystal configuration. However, high alpha-dose can have detrimental effects on the long term stability of materials envisaged as fuels. To be able to predict the behavior of the spent fuel on the very long term storage, surrogates are being used to simulate the high alpha damage that will be accumulated on the waste after millennials of storage and beyond.

In the present work we report on experimental observations of alpha-damage effects on samples with high content of ²³⁹Pu that serve as surrogates for very
old spent fuel by transmission electron microscopy (TEM), energy loss electron spectroscopy (EELS), x-ray diffraction (XRD) and thermal diffusivity, among others.

11:00 AM ET15.07.04
Dissolution of Uranium Thorium Mixed Oxides—The Role of Nitrous Acid

Laurent Claparede1, Thomas Dalger2, Stéphanie Szenknect3, Philippe Moisy3 and Nicolas Dacheux1; 1ICSM, University of Montpellier, Bagnols sur Cèze, France; 2ICSM, Commissariat à l’énergie atomique et aux énergies alternatives, Bagnols sur Cèze, France; 3DMRC, Commissariat à l’énergie atomique et aux énergies alternatives, Bagnols sur Cèze, France.

Mixed actinide dioxides (MOX) are currently used as fuels in Gen III reactors. MOX-fuels with higher plutonium loading stand as potential candidates for several concepts of Gen IV fast reactors. In this field, the reprocessing of actinides coming from spent nuclear fuel is considered, but the hydrometallurgical processes need to be optimized. In particular, the dissolution step appears to be one of the main issues concerning the recycling of Gen IV MOX fuels. Although dissolution of MOX fuel in nitric acid is already used in industrial processes, the role of several nitrogen based species such as NO3− and HNO2 in the oxidative mechanism of uranium-based mixed oxides remains unclear.

In this study, dissolution tests were performed on sintered pellets of U0.75Th0.25O2 in various acid solutions (from 10−3 M to 4 M) under dynamic conditions. Therefore, a multiparametric study of the kinetics of dissolution was achieved in order to quantify the influence of several species of interest. In aerated hydrochloric acid solutions, the kinetics of the overall dissolution reaction appeared to be controlled by adsorption and desorption of protons at activated surface sites. The dissolution rate determined in aerated sulfuric acid solution was enhanced compared to hydrochloric acid solution of the same acidity. This result was interpreted in terms of formation of sulfate ions surface complexes that favor the detachment of the actinides from the mixed oxide solid solution. In nitric acid solutions, the dissolution of the ThO2.5U0.5O2 pellets followed several successive steps. During this first steady state period, the kinetics of the overall dissolution reaction appeared to be controlled by the oxidation of U(VI) by HNO3 at the solid/solution interface. A rate law was established by adding a redox contribution to the proton-promoted surface contribution defined for aerated hydrochloric acid solutions. Then, an increase of the normalized dissolution rate was observed, which was attributed to the simultaneous increase of the specific surface area of the pellet and of the HNO3 concentration in solution. Therefore, the monitoring of the solid/liquid interface by ESEM during dissolution allowed to discriminate the impact of these phenomena on the normalized dissolution rate.

11:15 AM ET15.07.05

Dirk Boubach, Felix Brandt, Martina Klinkenberg, Victor Vinograd, Juliane Weber and Guido Deissmann; IEE-6, Forschungszentrum Jülich, Juelich, Germany.

The waste containers emplaced in geological disposal facilities for nuclear wastes built in crystalline rocks or clay formations will inevitably come into contact with ground water post-closure, after re-saturation of the repository. Even in repositories in salt rocks, the presence of water cannot be completely ruled out for less probable scenarios, for example, an early failure of shaft seals and plugs. As a consequence, after container failure due to aqueous corrosion, radionuclides can be released from the degrading waste forms into the near-field water and subsequently migrate into the geo-/biosphere via the water pathway. The mobility of radionuclides released from the wastes into the repository near- and far-field is controlled by various processes such as sorption onto minerals and colloids (e.g. by surface complexation or ion exchange), precipitation/dissolution of solid phases, as well as entrapment in, or solid solution formation with other minerals. However, the aspect of solid-solution thermodynamics and the effects of solid-solution formation on radionuclide solubility and mobility are considered only rarely in specific cases in long term safety assessments for nuclear waste repository systems at present.

Here, we present and discuss the development and application of thermodynamic models for solid solution – aqueous solution systems and their relevance to nuclear waste management and safety assessments for deep geological repositories, emphasizing the significance of complementary experimental and state of the art computational approaches (e.g. atomistic modelling). Using the uptake of radium by barite (BaSO4) as an example, it is demonstrated that an improved mechanistic understanding of solid solution thermodynamics and its consideration in performance assessments leads to a more realistic and scientifically corroborated picture on release, solubility, and subsequent migration of safety relevant radionuclides in the repository near- and far-field.

Thermodynamics of mixing for the binary (Ba,Ra)SO4 and ternary (Ba, Sr, Ra)SO4 solid solution system were determined on the basis of first principles calculations and experimentally validated by batch type Ra uptake experiments. The Ra uptake experiments yield homogeneous solid solutions via dissolution and re-precipitation within 1000 days at room temperature and also at elevated temperature up to 90 °C. These thermodynamic data allow for a full quantitative description of solid solution – aqueous solution equilibria. Application of state-of-the-art micro- and nano-analytical methods (FIB, TEM, APT) provided a mechanistic understanding of the relatively fast Ra uptake and the fact that a homogeneous solid solution forms. This Ra uptake was established via internal micro- and nano-porosity opening the possibility to form a chemically homogeneous mixed phase at room temperature via dissolution and re-precipitation (excluding solid state diffusion).
scales that are not accessible to experimentation. After describing the basic principles that have guided how these reactive transport models are constructed, their usefulness will be exemplified on the modelling of clay-concrete interaction. The modelling of a ten years in-situ experiment will illustrate the complexity of the multiphase and temporal-scale issues that must be taken into account.

Thermal and Thermophysical Behavior of Bentonite Investigated by Means of Thermal Analysis Techniques
Ekkehard Post, NETZSCH Geraetebau GmbH, Burlington, Massachusetts, United States.

Bentonite clay was investigated with regard to its potential application as a sealing material for nuclear material storage. Bentonite is a clay with high swelling ability under humid conditions. Due to this behavior and its chemical and physical properties, bentonite is widely used, e.g., in the oil drilling industry for sealing the bore hole. In nuclear waste management, in some countries it is considered or even used as a sealing material in repositories or waste containers. Depending on the water content, the volume and density of bentonite (consisting mainly of montmorillonite) can vary considerably. Below a certain temperature, water loss and uptake are reversible, this means this material contracts during water loss, but also expands again in a humid atmosphere. In this contribution, bentonite clay was investigated by means of TGA-DSC, dilatometry/TMA, LFA and evolved gas analysis. The results for the thermal stability and thermal expansion in dry and under wet conditions and the thermal diffusivity will be discussed.

Raman and X-Ray Absorption Spectroscopic Studies of Hydrothermally Altered Borosilicate Nuclear Waste Glasses
David A. McKeeown, Isabelle Muller, Andrew Buechele and Ian L. Pegg, Catholic Univ of America, Washington, District of Columbia, United States.

Raman spectroscopy and X-ray absorption spectroscopy (XAS) are used to characterize structural changes that take place in a variety of hydrothermally altered borosilicate glasses used in durability studies of these materials for nuclear waste storage. The glasses investigated range from simplified five component (Na,K)-alumino-borosilicates to complex composition borosilicates that include more than 20 components to more closely model actual nuclear waste glasses. The hydrothermal experiments, or vapor hydration tests (VHT), were performed on glass wafers up to 30 days from 200 to 238°C to simulate and accelerate long-term alteration processes that may occur in a nuclear waste repository. Raman spectra indicate two major glass structure changes that take place during alteration: one, partial depolymerization of the alumino-borosilicate network, and two, introduction of water or OH in the altered layers that can approach 10 wt.%. Raman, as well as supporting X-ray diffraction and scanning electron microscopy (SEM) evidence indicate analcime and other tectosilicate crystals at or near the altered sample surface with some altered layers containing intergrowths of amorphous silicate gels with zeolites and fine-grained clays. More localized information from XAS show expanded Na environments in the VHT samples with longer Na-O distances and more nearest-neighbor oxygen atoms, compared with the original glasses, which may be due to hydrous species introduced into the Na-sites. Changes in Si K-edge also show some depolymerization of the network in the VHT altered samples, consistent with the Raman trends. SEM profiles indicate diffusion of many elements across the alteration layers, where one example, Tc, is enriched toward the altered sample surface. XAS measurements of the same samples show that much of the original oxidized Tc(VI) pertechnetate in the glass reduces to Tc(IV) species in six-fold coordination in the VHT altered sample. Latest Raman profiles and map images of VHT altered sample cross-sections will be presented to illustrate distributions of the different crystalline and amorphous phases within the altered layers, as well as how water is incorporated into the glass at different stages of the alteration process.

3:30 PM ET15.09.02
On Alteration Rate Renewal Stage of Nuclear Waste Glass Corrosion
Michael I. Ojovan, IAEA, Vienna, Austria.

The four generically-accepted stages of glass corrosion are reviewed with focus on fourth stage termed alteration rate renewal (or resumption) stage when the glass may start corroding with the rate similar to that at the initial stage. It is emphasised that physical state and physical changes that occur in the near-surface layers can readily lead to effective increases of leaching rate similar to alteration rate renewals. Corrosion of glass in a geological repository is typically considered to occur into four stages [1, 2]: Stage I: Upon initial contact by water alkali cations are extracted by interdiffusion. The process of interdiffusion is followed by two simultaneous reactions: hydration and dissolution of the glass network. Stage II is when glass corrosion rate becomes dependent on the solution saturation state. Unlike the rate of ion exchange, the dissolution rate of the glass network decreases. Stage III: The solution becomes saturated and secondary minerals begin to form; the alteration phase is often a simple clay mineral, such as a smectite or chlorite. Stage IV: Alteration rate renewal may occur depending on the type of alteration phase formed. Experimental data on long-term (during few decades) corrosion of radioactive borosilicate glass K26 designed to immobilise NPP radioactive waste evidence on resumptions of radionuclides (129I,131Cs) leaching [3]. The cause of that was however related not to chemical changes in the leaching environment but rather to physical state of glass surface. Formation of small cracks on the surface results in new fresh-glass areas in contact with water. Both experimental and molecular dynamic simulations prove that the freshly formed glass surfaces are enriched in alkali elements including 137,134Cs [3,4]. Because of that the leaching of radionuclides is not monotonic and has distinct step-like additives at the times of cracks formation which resembles resumption of initial stages of glass leaching. This paper emphasises that not only alteration phase formed can lead to an increased rate of corrosion and return to the forward rate, and that physical state and physical changes that occur in the near-surface layers can readily lead to an effective alteration rate renewal. Nuclear waste glass corrosion in the disposal environment is of primary importance for ensuring safety of nuclear waste disposal therefore the research programmes focused on long-term behaviour of glasses [5, 6] should account for both chemical and physical effects.

3:45 PM ET15.09.03
A glass-ceramic waste form is being considered for immobilization of waste streams of alkali (A), alkaline-earth (AE), lanthanide (Ln), and transition metals generated by transuranic extraction for reprocessing used nuclear fuel. Benefits over an alkali borosilicate waste form are realized by the partitioning of the glass-insoluble fission product fraction into a suite of ceramic phases through controlled crystallization, including AEMO$_3$ (powellite) and (Ln,AAE)$_2$Si$_6$O$_{26}$ (oxyapatite). In this study, a simplified 8-oxide system was used, 33.5 SiO$_2$ - 21.9 Nd$_2$O$_3$ - 9.6 CaO - 8.9 Na$_2$O - 8.2 B$_2$O$_3$ - 6.6 Al$_2$O$_3$ - 6.4 MoO$_3$ - 4.9 ZrO$_2$ (in mol%).

In-situ neutron diffraction experiments were attempted to capture crystallization upon cooling from 1300°C. The combination of high temperatures and reactivity of borosilicate glass with typical containers such as vanadium and niobium prevented their use, so methods using sealed thick-walled silica ampoules were developed. Unexpectedly, high neutron absorption (despite isotope substitution with B-11), low crystal fraction, and high silica container background made quantification difficult for high temperature measurements. Proof of concept measurements were then performed on different potential high-temperature container materials, emphasizing crystalline materials so that residual glass in the sample could be more easily analyzed. Room temperature measurements were conducted with a crystallized sample in ‘ideal’ containers stable at low temperatures (vanadium and thin-wall silica capillaries) and compared to the same in containers stable at high temperatures (platinum, single crystal sapphire, and thick-walled silica ampoules).

Results suggested that sapphire is probably the best choice if suitably sealed to prevent contamination from the sample after neutron activation. Companion experiments are suggested for high-temperature in-situ x-ray diffraction measurements. With high energy x-rays, levitation experiments might be possible despite sample volatility, since collection times are much shorter at synchrotrons than those required for neutron experiments. Additionally, wire heater methods using a very small amount of sample are also possible with x-ray interrogation. Other possibilities for obtaining in-situ crystallization data upon cooling from molten glass are suggested.

The UK is currently in the process of adopting a modified seven-oxide base glass (ZnCa MW), containing ZnO and CaO for the vitrification of high level waste at a molar ratio of ZnO/CaO 40:60 in the nominal Mixed Windscale (MW) formulation. Previous studies have given an insight to how Zn and Ca may influence glass dissolution, however the dual role of Zn and Ca remains poorly constrained.

This investigation studied a series of six ZnCa MW compositions with different ZnO/CaO ratios, with the aim of understanding how the varying ratios influence the structure of the glass and how this relates to the aqueous durability in all stages of glass corrosion. Structural analysis using 26Si and 11B NMR has been utilised to determine the relative influence of Zn and Ca on the borosilicate glass network and on the altered glass post-dissolution. Dynamic flow-through (SPFT) and static (MCC-1 and PCT-B) batch dissolution experiments give insight to the behaviour of the various ZnO/CaO ratios, whereby dissolution rates and formed altered layers were sensitive to small compositional changes.

Waste-loaded ZnCa MW formulations with varying ZnO/CaO ratios and varying waste loads (20, 28 and 35 wt.%) were developed and subjected to static dissolution (MCC-1 and PCT-B) in clay, granite and saline groundwaters under conditions relevant to geological disposal. From these studies, optimised glass formulations have been suggested in terms of their long-term aqueous durability.

4:15 PM ET15.09.05 Probing the Temperature Dependence of Aqueous Glass Dissolution Mechanisms Thomas J. Gould1, Edward Tipper1, Sambuddha Misra1, Madeleine Bohlin1, Rui Guo1, Aleksy Sadekov2,3 and Ian Farrat1; 1University of Cambridge, Cambridge, United Kingdom; 2Centre for Earth Sciences, Indian Institute of Science, Bengaluru, India; 3School of Earth Sciences, The University of Western Australia, Crawley, Western Australia, Australia.

Countless simulants nuclear waste glass dissolution experiments have taken place at 90 °C to accelerate glass alteration. It is implicitly assumed that the dissolution mechanisms occurring at 90 °C would be the same as those in a deep geological disposal facility post-thermal pulse, which would be at around 40 °C. Accurately predicting vitrified package lifespans within a repository therefore requires a comprehensive understanding of the dissolution mechanisms occurring at both temperatures; by extension an assessment of whether dissolution rates measured at 90 °C can be applied to repository conditions. Elemental releases and images of surface alteration alone from variable temperature experiments provide limited insight into the underlying dissolution mechanisms at each temperature, simply investigating whether glass dissolution rates follow an Arrhenius-type temperature dependence.

Static batch experiments conducted on a simultaneous UK Magnox waste glass at temperatures of 40 °C, 60 °C, 70 °C, 80 °C and 90 °C investigated the temperature dependence of the concentrations leached into solution and the kinetics of alteration product formation, but could not discern the dominant dissolution mechanism at each stage of dissolution. Consequently, more evidence was required to provide a complete picture of glass alteration and complement the concentration and surface alteration results. Based on the significant differences in the morphology of the altered glass as predicted by conflicting models of glass alteration, it was expected that different magnitudes of isotopic fractionation for mobile glass species leached into solution would be observed depending upon the extent and structure of the altered layer and the dominant dissolution mechanism. Through preliminary proof of concept experiments on a simplified simulant Magnox waste glass analogue leached at 90 °C and a simulant Magnox waste glass leached at 40 °C and 90 °C, we observed systematic temperature-dependent isotopic fractionation which was consistent with the mechanisms and altered layer morphologies described in interdiffusion models of glass dissolution which arise from a highly passivating altered layer structure.
Self-radiation damage from the decay of radionuclides can affect microstructural evolution, phase stability, and thermodynamic properties in ceramic nuclear waste forms. The principal sources of radiation are beta-decay of the fission products and alpha-decay of the actinide elements. In general, beta-decay of the short-lived fission products is the primary source of radiation and heat generation in high-level waste forms during the first 600 years of storage; however, there is no evidence of significant long-term effects of fission product decay on the physical properties of nuclear waste forms. Because of the long half-lives of the actinides and their daughter products, alpha-decay is dominant over very long timescales. Alpha decay produces energetic alpha particles (4.5 to 5.5 MeV) and recoil nuclei (70 to 100 keV), which result in both radiation damage and the accumulation of helium. The evolution of radiation damage due to alpha-decay has been studied using short-lived actinides, such as $^{238}$Pu and $^{244}$Cm, in several candidate ceramics for the immobilization of actinides. Ion beam irradiations of candidate ceramics are more frequently employed due to decreased costs, shorter irradiation timescales and the non-radioactive nature of the irradiated materials. Ion irradiations are performed over a wider range of irradiation conditions to implant helium, study radiation damage kinetics, understand the separate and combined effects of alpha particles and alpha recoils, and benchmark against alpha-decay damage due to short-lived actinides. At ion energies typically used to study alpha-decay damage in nuclear waste ceramics, the electronic and nuclear energy losses are both important, and local ionization along the ion path can affect damage production and evolution. For heavy ions used to mimic radiation damage from alpha recoil nuclei, the spatial coupling of electronic and nuclear energy loss can lead to reduced or enhanced damage production along the ion trajectory. The athermal annealing induced by electronic energy loss of heavy ions can significantly impact the evolution kinetics of radiation damage. While alpha particles are much less damaging than alpha recoils, the electronic energy loss from the alpha particles can also cause athermal annealing of heavy ion damage (i.e., alpha-recoil damage) that can impact the evolution of radiation damage. Helium implantation studies have shown that the accumulation of helium and heavy ion damage leads to the formation of helium bubbles above a threshold helium concentrations. These results have significant implications for interpreting and modeling the radiation response of nuclear waste ceramics in accelerated testing using MeV ion irradiation.

This work was supported by the U.S. DOE, BES, MSED.

9:00 AM ET15.10.02 Molecular Dynamics Simulation of Ballistic Effects in Simplified Nuclear Waste Glasses Anręen Iau1, 2; Jean-Marc Delaye1; Sebastien Kerisit3 and Stephane Gin4; 1CEA Marcoule, Bagnols-sur-ceze, France; 2Geochemistry, Pacific Northwest National Laboratory, Richland, Washington, United States.

Immobilization of High Level Waste (HLW) in borosilicate matrix and further disposal into geological repository has been regarded as one of the best way for long term isolation of HLW from biosphere. Radionucleides are expected to stay confined until glass matrix has been breached by water and it begins to alter. Recently, an increase in glass alteration rate was observed in irradiated samples (with dominant ballistic dose) as compared to non-irradiated samples. Other studies using doped glasses, external irradiation techniques and molecular dynamics have now confirmed that ballistic effects caused by recoil nuclei, on alpha decay, will be the dominant source of irradiation damage on the long term. Ballistic effects have been observed to induce macroscopic and microscopic structural changes e.g. swelling, decrease in hardness, increase in fracture toughness and structural disorder and depolymerisation in the glasses. Thus, it becomes necessary to study such changes and their impact on the physical and chemical durability of this glass. In the current study, molecular dynamics simulation of ballistic effects have been investigated in simple sodium borosilicate [$Na_2O:SiO_2-B_2O_3=1$] and sodium alumino-borosilicate [$Na_2O:Al_2O_3-SiO_2-B_2O_3=1$]glass compositions, by exposing such glasses to series of displacement cascades, wherein heavy projectiles cause atomic displacements by elastic collisions and progressively damage the bulk glass. The accumulated pressure or stored energy inside the glass was found to saturate with deposited energy. Furthermore, structural analysis of the irradiated glasses revealed a decrease in density, depolymerisation, increase in intermediate, short range disorder and randomness. The magnitude of damage was found to depend on the glass composition and, in general, alumino-silicate glasses were found to be slightly less damaged, after irradiation, as compared to borosilicate glasses. An ongoing study on, impact of such structural evolutions under irradiation, on alteration of glass will also be discussed.

9:15 AM ET15.10.03 Investigation of the Structural Behavior of YSZ Under Ion Impact—Effect of Grain Size, Temperature and Specific Energy Loss Parswajit Kalita1, Santanu Ghosh1 and Divesh K. Avasthi2; 1Indian Institute of Technology Delhi, New Delhi, India; 2Amity University, Noida, India.

A crucial issue regarding the use of nuclear energy is the safe management of radioactive plutonium and minor actinides since they are unavoidable byproducts of nuclear energy generation using the conventional uranium fuel technology. A possible solution to this problem might be the ‘inert matrix fuel’ (IMF) concept, which is based on ‘uranium free’ plutonium or minor actinide compounds embedded in an inert material matrix. Since these fuels are being contemplated to burn plutonium or minor actinides instead of uranium, they have the dual advantage that they do not breed plutonium or higher actinides during burn-up and that the existing stockpiles of plutonium and minor actinides can also be reduced. Amongst many different potential materials, the oxide ceramic yttria stabilized zirconia (YSZ) is considered to be very promising for application as the inert matrix material.

Now, the materials employed in nuclear reactors are prone to un-desirable damages (amorphization, point defect clustering, volume swelling, etc.) since they are subjected to an extremely harsh environment consisting of extensive radiation (fission fragments that create damage via electronic energy loss, alpha recoil particles that create damage via nuclear energy loss, neutrons etc.) and high temperatures (~ 1000 K). Accumulation of such radiation damage over a period of time may lead to material failure ultimately resulting in catastrophic nuclear accidents. It is therefore vital to understand the behavior of YSZ under such extreme conditions, before using it as the inert material matrix in IMFs, for the design of safe, durable and efficient nuclear energy systems.

A number of factors, such as: (i) Specific energy loss (electronic energy loss ($S_e$) & nuclear energy loss ($S_N$)) of the energetic particles (ii) Grain size of the material (iii) Temperature of the environment (irradiation temperature) etc., needs to be taken into consideration for an in-depth understanding of the radiation induced damage.

Motivated by this, YSZ pellets having different grain sizes (ranging from tens of nano-meters to few microns) were irradiated with different ions (single beam irradiation with low energy ions or single beam irradiation with high energy ions or simultaneous dual beam irradiation with low and high energy ions) at different temperatures (room temperature and 1000 K) in an attempt to understand the dependence of radiation damage on the above mentioned factors. The low energy and high energy ions were chosen so as to simulate the damage produced by alpha recoil particles and fission fragments respectively, while the irradiations at 1000 K helped to better simulate a typical nuclear reactor environment. We will show that the irradiation damage depends critically, and in a complex manner, on the crucial interplay between the specific energy loss/type of irradiation (single beam or simultaneous dual beam), grain size (grain boundaries) and environmental temperature.

9:30 AM BREAK
Role of Volatiles Elements, Halogen and Noble Gases in Glass and Melt

Volatiles elements in glass and melt can induce very strong changes both in properties and structure. They can play a fundamental role during glass making, glass processes, and also in Earth Sciences since they can change drastically the dynamism of some eruptions, in particular during degasifying processes. In detail, volatile elements, such as chlorine and fluorine, have a significant role in the generation, dynamics, and evolution of magmas as they influence the solubility of minerals as well as the melts viscosity and thermodynamic properties. This results, for example, in a strong control of the main volatile element that is water on the extraction rate of magmas from the upper mantle and crust. At surface, the amount of water and CO2 dissolved in magmas influence the dynamics of volcanic eruptions. Furthermore, other elements such as SO2 and iodine also affect the melt properties as well as on their geochemical signature. Fluorine and chlorine can also produce very big disasters especially during andesitic volcanic eruptions.

Therefore, volatile elements influence in various ways the geologic dynamic of the Earth and play important role in materials science. Therefore, we need to quantify the proportion and understand the speciation of dissolved volatiles in silicate melts. In order to tackle such challenging subject, we propose to investigate glasses, including natural magmatic compositions and industrial glasses, which contain dissolved CO2, H2O, SO2, I2, F, and Cl by using Raman spectroscopy, a powerful and non-destructive technique.

Glass Structure and Crystallization in Boro-Alumino-Silicate Glasses Containing Rare Earths and Transition Metals

Nuclear wastes generated from reprocessing of used nuclear fuel tend to contain a large fraction of rare earth metals (RE e.g., Nd), transition metals (TM e.g., Mo, Zr), alkali metals (A e.g., Cs), and alkaline earth metals (AE e.g., Ba, Sr). Various strategies have been considered for immobilizing such waste streams, varying from nominally crystal-free glass to glass-ceramic to multi-phase ceramic waste forms. For glass and glass-ceramic waste forms, the added glass-forming system is generally alkali-alumino-earth-alumino-boro-silicate (i.e., Na-Ca-Al-B-Si oxide).

In this US-UK collaborative project, we investigate the glass structure and crystallization dependence on compositional changes in simulated nuclear waste glasses and glass-ceramics. Compositions ranged in complexity from 5 oxides to 8 oxides. Specifically, the roles of Mo and lanthanides are investigated, since a proposed glass-ceramic waste form contains crystalline phases such as powellite [(AE,A,RE)MnO4] and oxyzapatite [(RE,AE,Al)2SiO5], and the precipitation of molybdenum phases is known to be affected by rare earth concentration in the glass. Additionally, the effects of other chemical additions have been systematically investigated, including Zr, Ru, P, and Ti. A series of studies was also undertaken to ascertain the effect of the RE size on glass structure and on partitioning to crystal phases, investigating similarities and differences in glasses containing single RE oxides of Sc, Y, La, Ce, Nd, Sm, Er, Yb, or Lu. Finally, the effect of charge compensation was investigated by considering not only the commonly assessed peralkaline glass, but also metaluminous and peraluminous compositions.

Glass structure and crystallization studies were conducted by spectroscopic methods (Raman, x-ray absorption, nuclear magnetic resonance, optical absorption, x-ray photoelectron spectroscopy), microscopy (scanning electron microscopy, transmission electron microscopy, electron probe microanalysis), x-ray and neutron diffraction, small angle measurements, and physical characterization (scanning calorimetry, viscosity, density). This talk will give an overview of the research program and some characteristic results.

Alkali-Silica Gel Reaction in Glasses Dissolved at High pH—Implications for Co-Disposal of Vitrified and Cementitious Nuclear Wastes

International consensus is that vitrified nuclear waste should be disposed of underground where it can safely undergo radioactive decay, isolated from the environment and future populations. Cement will be ubiquitous in all disposal facility concepts. For example, cement will be used to line vaults, in seals and plugs, as buffer material and in general construction. It is expected to play a key role in the Belgian and UK deep geological disposal concepts for high- and intermediate-level vitrified waste, respectively, and possibly also for the shallow disposal facility at Hanford site in the USA. The interaction of cement with vitrified waste is a key issue, since the generation of a hyperalkaline plume could accelerate glass dissolution mechanisms, thereby enhancing radionuclide release from the vitrified waste.

Here, we discuss the results of investigations developed to elucidate the mechanisms and kinetics of sodium aluminoborosilicate glass dissolution in the presence of simplified, buffered high-pH alkali solutions (K2SiO3, Na2SiO3, CaSiO3, MgSO4, and H2SiO4), synthetic cement leachates, including a young cement water (K, Na-rich; pH 13.7), an evolved cement water (Ca, Na-rich; pH 12.5) and an old cement water (Ca, Na-rich, pH 11.8), and also real cement leachates (containing mixed alkalis; pH ~13). The surfaces of glass powders and monoliths were characterised using SEM, TEM, EDX, XRD and NMR. The rate of degradation of the glass in these solutions was found to be the result of two key mechanisms: i) the formation of a porous alkali- or alkaline-earth silica gel, where mean pore diameter was governed by pH, and the type of alkali or alkaline-earth element retained depended on the relative abundance of K, Na, Ca or Mg, the hydrated ionic radius and the ΔG of hydration of the alkali or alkaline-earth species; and ii) the precipitation of crystalline phases—including zeolite (e.g. phillipsite-K), phyllosilicate (e.g. rhodesite) and clay (e.g. smectite)—that, depending on the combination of glass composition, solution chemistry and the phase, either formed a dense layer, impervious to solution species, that protected the surface from further dissolution or, conversely, promoted the ongoing dissolution of the glass through continual consumption of dissolved silica and re-precipitation of Si-bearing phases. These results highlight the complex, but significant effects of high pH, cementitious solutions on the dissolution of nuclear waste glasses, which should be included in future models of vitrified waste disposal in a cement-containing geological disposal facility.
Researchers in many fields are interested in the understanding of iodine behavior in solid and molten materials, however, only a few data on iodine solubility and speciation are available in the literature. Iodine is the heaviest stable halogen element, and in spite of its low natural abundance, it is interesting in Geosciences, mainly because of its link to xenon since most of the iodine isotopes become xenon isotopes by β radioactive decay. In the framework of the Comprehensive Nuclear-Test-Ban Treaty, the atmospheric radioxenon analyses provide the only distinctive signature of a nuclear explosion. \[1\] It is of particular concern because it will be a major contributor to the radioactivity released by a geological repository site for nuclear wastes, but previous studies show that iodine mobility is strongly dependent on the redox.

For all these reasons, it is important to understand the mechanisms related to the solubility of iodine depending on the composition of the glass and to analyze its solubility, redox state, and distribution in a glass network.

We investigated the iodine solubility, speciation, and the influence on properties and glass structure, depending on bulk chemistry, temperature and pressure. Iodine redox state studies were carried out both by Raman and X-ray Absorption Spectroscopy. Our studies on silicate glasses show that iodine could be stabilized with different valences (as $I^-$, $I_3^-$ and $I_5^-$) and with concentrations up to 3.3 wt.\% when B is introduced.

SESSION ET15.12: Managing Corium and Degraded Nuclear Fuels from Severe Accidents

Session Chairs: Nicolas Clavier and Claire Corkhill

Wednesday Afternoon, November 28, 2018

Hynes, Level 3, Room 308

2:00 PM ET15.12.01

Synthesis, Characterisation and Preliminary Corrosion Behaviour Assessment of Simulant Fukushima Nuclear Accident Fuel Debris Clémence Gausse1, Martin Stennett1, Neil Hyatt1, Charilaos Paraskevoulakos1, Mahmoud Mostafavi1, Tomooki Shiba1 and Claire Corkhill1; 1University of Sheffield, Sheffield, United Kingdom; 2Japan Atomic Energy Agency, Tokai-mura, Japan; 3University of Bristol, Bristol, United Kingdom.

The earthquake and the tsunami that occurred on the 11th March 2011 at the Fukushima Daiichi Nuclear Power Plant (NPP) induced a loss of coolant accident and the partial meltdown of boiling water reactor Units 1 to 3. The temperature within the reactor rose in excess of 2000°C causing melting and reaction of UO2 pellets with the steam-oxidised zircaloy fuel cladding, forming nuclear accident fuel debris (NFD) and, where melting of other reactor components occurred (e.g. concrete, steel from the pressure vessel), corium. We present results of an investigation aimed at simulating NFD and corium, including an assessment, by μ-focus XAS methods, of the distribution of simulant fission products (Ce as a surrogate for Pu and Nd to represent trivalent rare earth fission products), which is an important prerequisite to fuel debris retrieval from the Fukushima reactors, due to commence in 2021. Synthesis of materials in the $U_xZrO_2$ solid solution was performed by wet and dry chemistry routes, and materials in the $U_xLn_2O_3$ ($Ln = Ce$ and/or $Nd$) solid solutions were mixed with $Zr$ metal and heated >2000°C by oxyfuel processing. Selected phases were further melted with concrete and steel to synthesise simulant corium materials. Analysis of each phase was performed by techniques including XRD, SEM/EDX, XPS and Raman spectroscopy.

After the accident, continuous filtered water injection (firstly seawater, followed by Fukushima NPP ground water and filtered water) has been used to cool the NFD and corium, and reduced the temperature below 100°C. \[1\] In this so-called stable cold shutdown situation, analysis of coolant water effluent evidenced the presence of Pu, indicating the fuel debris is dissolving. Since the aqueous alteration of fuel debris is expected to alter its chemical and mechanical properties, and may also result in the formation of secondary alteration products, we here present preliminary results of leaching experiments of the above materials in relevant solution compositions.

\[1\] Technical Strategic Plan 2016, 2016, Nuclear Damage Compensation and Decommissioning Facilitation

2:15 PM ET15.12.02

During the tsunami-caused 2011 meltdown at Fukushima Daiichi nuclear power plant, melted nuclear fuel (corium) was exposed to emergency cooling aqueous media, especially borated and sea water, which may have an effect on the stability of the fuel. The corium consists of solidified melt of nuclear fuel, fission products, cladding, control rods and other structural materials. Up to 600 tons of corium debris lies in Fukushima damaged units. It is important to provide data on stability of corium in these aqueous media in order to provide indications about potential radionuclide release mechanisms and their environmental impact and science-based advice for the decommissioning and remediation of the damaged sites.

In order to assess the stability of corium in aqueous cooling media used in Fukushima, experiments were carried out at JRC-Karlsruhe in collaboration with CRIEPI (Japan) using genuine irradiated corium samples taken from the TMI-2 accident.

Static leaching experiments were performed in air and at hot-cell temperature in deionized water and in water containing 2g/L of boric acid. In all cases the solution was continuously stirred and renewed several times during the experiments. The results are compared with similar experiments carried out on LWR spent nuclear fuels (with average burnups of 54 and 60 GWd/tHM), carried out in deionized water and boric acid water, but also in sea water and simplified groundwater (1 mM NaHCO3 and 19 mM NaCl).

After approximately one year of experimental campaign, the releases of matrix elements such as uranium, neptunium, cerium, the instant release fraction of elements like caesium as well as the release of less soluble elements like zirconium in water containing boric acid do not differ significantly from the releases observed in deionized water. The results reveal no significant effect due to the origin of the sample, core or crust, and to the presence of boric acid on the mobility of the radionuclides in the studied samples. As partial exception, the amount of silver found in solution was higher in experiments carried out with core samples. The presence of heterogeneously distributed silver metallic spheres in TMI-2 corium samples (originating from control rod material) has been previously reported and is most probably responsible for this specific effect. Chemical analysis to determine the inventory of the samples will be used for normalisation and comparison.

A detailed comparison between corium samples and undamaged irradiated fuel samples is complicated because of the different morphology of the fragments. The results of surface area determination by SEM image analysis will be reported.

The present experimental results are part of a programme dedicated to the analysis and the management of LWR after severe accidents. In particular, they will be useful in support to defining the decommissioning and remediation strategies of the Fukushima Daiichi nuclear power plant.

Tc-99 and I-129 Immobilization by Ettringite Formation in Cementitious Waste Forms Sarah Saslow1, Sebastien Kerisit1, Tannas Varga2, Matthew Asmussen1, Wooyong Um1, Gary L. Smith1 and Reid Peterson1; 1Pacific Northwest National Laboratory, Richland, Washington, United States; 2Pohang University of Science and Technology, Pohang, Korea (the Republic of)

Immobilization of technetium-99 (Tc) and iodine-129 (I) at the Hanford site in Washington State, USA, is a persistent challenge that can be assisted by using cementitious waste form (CWF) technologies. In response to the dynamic compositional range of Tc- and I-containing low activity waste (LAW) and secondary waste streams generated by LAW vitrification, the development of alternative CWF formulations is required to address composition-specific challenges related to contaminant immobilization. For example, sulfatic acid neutralization of highly alkaline waste streams generates a high-sulfate liquid waste that cannot be immobilized by the baseline Cast Stone CWF formulation (8% ordinary portland cement (OPC)/47% blast furnace slag (BFS)/45% fly ash (FA)). At the anticipated sulfate concentrations in these waste streams the Cast Stone CWFs are less likely to cure and prolonged formation of ettringite [Ca6Al2(SO4)3(OH)12●26(H2O)] will lead to expansion and subsequent cracking that increase risk of contaminant release.1-2 Recently, some of these challenges were overcome by increasing the calcium content in the waste form through substitution of hydrated lime (HL, Ca(OH)2) for FA, providing a sink for excess sulfate during the early curing period.2 However, the most striking observation came from contaminant leach tests, where Tc effective diffusivity decreased by two orders of magnitude as ettringite-growth continued relative to previous testing campaigns.3 This suggests that ettringite may aid contaminant retention throughout the CWF life cycle. Here, the mechanism for Tc and I incorporation into ettringite is explored using X-ray diffraction and X-ray absorption spectroscopy techniques combined with ab initio molecular dynamics simulations. Evidence for TcO4- and IO3- substitution for Cl- and SO4- is observed. Molecular dynamics simulations provide insights into the radiation and chemical effects of Tc and I incorporation into ettringite, which can be used to predict the performance of CWFs in field conditions.

4:00 PM ET15.13.02
Establishing Radiation Effects in Silica Based Waste Forms Laura Levy, Aaron Daubney and Alex J. Potts; University of Manchester, Moor Row, United Kingdom.

In order to fully understand the performance of a nuclear waste form, the effects of radiation must be understood. Silica based materials can be used to treat waste; glass is the material of choice for HLW immobilisation and geopolymers are now being considered as an alternative to cementitious grouts for ILW. These materials are both comprised of an amorphous network of silica modified by elements such as Al or B as well as cationic species such as Na or K. This represents a complex system where the effects of network reorganisation and ion migration must be understood. In addition, mechanisms of energy transfer to an aqueous phase in contact with this material, and the radiolysis effects, must also be considered. Ongoing experimental studies into radiation effects using external radiation sources such as gamma and heavy ion acceleration are underway. Here we present some preliminary finding and invite further discussion into irradiation effects in amorphous silica based waste forms.

4:15 PM ET15.13.03
Solidification of HyBRID Waste Using Metakaolin Based Geopolymer Waste Form Jinmo Ahn1, Seongye Kwon1, Won-Seok Kim1, Seonbyeong
The hydrazine based reductive metal ion decontamination (HyBRID) process is recently developed for decontamination of primary coolant system of nuclear power plant and considered as an attractive process because of no organic chelates used. The HyBRID sludge waste is the final product of HyBRID process formed through BaSO₄ precipitation, containing high content of sulfate. The presence of sulfate in HyBRID sludge waste may cause defective cement waste forms due to the potential formation of sulfate bearing mineral such as ettringite \([\text{Ca}_6\text{Al}_2(\text{SO}_4)_2(\text{OH})_12\cdot 26\text{H}_2\text{O})]\). Therefore, instead of cement waste form, geopolymer waste form was developed in this study for solidification of HyBRID sludge waste. Metakaolin was used as geopolymer precursor and the two types of alkaline activators were prepared to test: sodium hydroxide solution with fumed silica and potassium hydroxide solution with fumed silica. Geopolymer waste forms were formulated with desired molar ratio of Si/Al (1.6-2), (Na⁺ or K⁺)/Al (0.8-1), and H₂O/Al (5-7.8). All geopolymer pastes were poured into cylindrical mold (23 mm in diameter x 46 mm in height) and cured for 7 days at room temperature. Geopolymer waste forms with waste loading (>30%) were successfully synthesized to meet the acceptance criteria (>3.45 MPa). Potassium-based geopolymer has better waste loading than sodium-based geopolymer. Moreover, geopolymer waste forms with 1 (Na⁺ or K⁺)/Al molar ratio showed higher compressive strength than geopolymers formed with 0.8 (Na⁺ or K⁺)/Al molar ratio, where the absorbance band of amorphous silica was detected. This suggests that amorphous silica was not fully dissolved when geopolymers were formed with 0.8 (Na⁺ or K⁺)/Al ratio. Besides, the result of FT-IR spectra showed that the absorbance band at 964-976 cm⁻¹ indicated the vibrations of Si-O-Si and Si-O-Al groups of the geopolymer gel network. The each geopolymer waste forms were characterized by X-Ray diffraction (XRD) and scanning electron microscopy with X-ray energy dispersive spectrometry (SEM-EDS): (1) XRD results revealed that there was no change in the crystalline structure of HyBRID sludge after geopolymerization process. (2) Elemental mapping results indicated that there was no change in the crystalline structure of HyBRID sludge after geopolymerization process.

Cementitious materials are widely applied in nuclear waste management in particular due to their capability for radionuclide retention and immobilization. However, the mechanisms governing the immobilization of various safety relevant radionuclides in these materials on the molecular scale are still not completely understood. Here we present experimental and computational studies to enhance the mechanistic understanding of radionuclide uptake and retention in cementitious materials. To obtain a more detailed understanding of the radionuclide uptake by the different constituents of hardened cement pastes and concretes, a bottom-up approach is applied by investigating radionuclide interactions with various synthesized cement model phases like calcium silicate hydrates (C-S-H), monosulfate (AFm) and ettringite (AIF₆) phases, as well as hardened cement pastes made from ordinary Portland and low pH cement. Batch-type sorption experiments under anoxic conditions were performed to analyze the sorption kinetics and the effects of solution composition and solid to liquid ratio on radionuclide uptake. We observed a strong retention of Ra by C-S-H phases with a distinct dependency of the distribution coefficients on the Ca/Si ratio of the C-S-H and the alkali content in solution. TRLFS studies on the uptake of Eu by C-S-H phases indicated two different Eu(III) species in the C-S-H structure, in addition to the formation of a surface precipitate (probably Eu(III)-hydroxide). In order to interpret the experimental data and to obtain closer insights into the incorporation mechanisms, we constructed a set of structural models for the Ra and Eu uptake in C-S-H phases with different Ca/Si ratios based on modified tobermorite structures suitable for ab initio calculations. Using density functional theory (DFT) simulations we computed the energetics of the uptake of Ra and Eu species into the C-S-H phases, comparing in particular the incorporation of the Ra and Eu cations on different crystallographic sites. We found that, in addition to Ra sorption on surface sites, Ra can be exchanged also for Ca in the C-S-H interlayer, in particular at low Ca/Si-ratios, which is in line with the experimental findings on Ra uptake. The calculations of Eu uptake give a slightly different picture, confirming the possible Eu uptake on both interlayer and Ca intralayer positions, consistent with the experimental observations. We will discuss the importance of atomistic modeling studies for the interpretation of radionuclide uptake mechanisms and further possible developments for such joint experimental and computational studies on cementitious materials.

Influence of Mineral Salts Solubility on Bituminized Wastes Products Leaching Behavior in Free Swelling Conditions Jean-Baptiste Championniet, Rémi Blinder3, Arnaud Leclerc4, Armel Guillermo5, Michel Bardet6 and Arnaud Poulesquen7; 1CEA Marcoule, Bagnols-sur-Cèze, France; 2Univ. Grenoble Alpes, CEA, INAC; 3Grenoble, France; 4Univ. Grenoble Alpes, CEA, CNRS, INAC; 5SYMMES-UMR 5819, Grenoble, France.

During the last decades, some nuclear wastes of low/intermediate activity level were incorporated into a bituminous matrix. The behavior under water-induced leaching of the resulting bituminous waste products, which were elaborated by extrusion process and composed of approximately 60 wt % of bitumen and 40 wt % of various salts, has to be evaluated in the prospect of their acceptability into a deep geological disposal. This work aims at assessing the influence of the solubility of the incorporated salts on the water uptake, by studying the leaching behavior of simplified bituminized waste products (containing only one type of salt).

In order to model bituminized waste products, a series of simplified bituminized waste products was elaborated by incorporating 40 wt % of mineral salts of increasing solubility ranging from 2.5 10⁻³ to 912 g / L, by using barium, strontium, calcium, magnesium, sodium sulfates and sodium nitrate. The amount of water uptake was monitored for each sample as a function of time by using gravimetric measurements. In addition, the ingress of water was simultaneously monitored by using ³H-nuclear magnetic resonance and the corresponding samples morphology was evaluated with environmental scanning electron microscopy. Gravimetric measurements show that the higher the solubility of the incorporated salt, the higher the amount of uptake water. Simultaneously, it was observed that the lower the solubility, the lower the mean diameter of pores, and the deeper the water ingress. These results were of particular interest to discuss the leaching behavior of industrial bituminized waste products that incorporated many salts with a similarly wide range of solubilities.
Technetium is a high yield fission product with 22 isotopes all of which are radioactive. Due to its long half-life ($t_{1/2}=211,000$ years), Tc-99 requires immobilisation in a suitably robust host matrix prior to final disposal in a GDF. Iron phosphate glasses are an attractive solution as they can accept a wide range of ions in the glass network and have sufficient aqueous durability. The inherent difficulty of working with technetium and its compounds necessitates prior investigation using analogues before beginning investigations proper. A series of 40:60 iron phosphate glasses doped with rhenium were produced and characterised by Raman spectroscopy, powder X-ray diffraction, scanning electron microscopy and Mössbauer spectroscopy to determine the effect of rhenium addition on the glass network and iron redox. The results of this investigation provide useful insight as to the possible influence of technetium on iron phosphate glasses.

Strategies for the Capture and Immobilization of Radioiodine Josef Matyas; Pacific Northwest National Laboratory, Richland, Washington, United States,

To support the revival of nuclear energy, advanced materials and processes are needed to capture and safely store radioiodine released during reprocessing of spent nuclear fuel. During this process, about 94-99% of the total iodine is volatilized to the dissolver off-gas, with the rest partitioned among off-gas streams from the vessel ventilation, cell, and melter. The iodine is primarily present in the form of $I_2(g)$ with small concentrations of organic iodides (e.g., $(Na,Li,Ca)_{0.5}(Al,Fe,B,P)SiO_4$, we sought to study the effects of substitution in the nepheline based glasses on the resulting crystallization. We summarize

9:15 AM ET15.14.03
Durability Testing of Iodine Waste Forms Matthew Asmussen, Joseph Ryan, Jarrod Crum and Nancy Avalos; Pacific Northwest National Laboratory, Richland, Washington, United States.

The release of radioiodine would need to be controlled in the off-gas management system during the dissolution of used nuclear fuel. Several material classes have been investigated for the capture of radioiodine including solid sorbents. Two examples are silver mordenite (AgZ), which is considered the benchmark material and silver functionalized aerogels (SFA), which have higher iodine capacity than AgZ. Both materials capture iodine through the formation of silver iodide (AgI). Due to the long half-life of I-129 (15.7 million years), this captured inventory of iodine must be safely managed for disposal in a repository. While AgI has low water solubility ($K_{sp} = 8 \times 10^{-17}$) it can have deleterious interactions with the environment; examples being pH changes in the near field, redox processes that destabilize the AgI, and interference from species such as sulfide. Thus, a durable waste form will be required to ensure containment of the radioiodine upon the disposal of these AgI-laden materials. However, limited work to date has been performed to assess the durability of iodine waste forms. This presentation will provide an overview of recent corrosion testing efforts carried out on iodine waste form materials. Two samples systems were investigated: iodine-loaded AgZ material processed with hot isostatic pressing (HIP) and iodine-loaded SFA material with spark plasma sintering. These materials were assessed using aqueous corrosion methods including single-pass flow-through testing (SPFT), the product consistency test (PCT), dilute reactor analysis (DRCA), and electrochemical analyses. The results from these tests were supplemented with characterization of the microstructure to track the progression of corrosion on the surface using scanning electron microscopy with energy dispersive X-ray spectroscopy, X-ray diffraction, and optical profilometry. It was generally observed that corrosion attack was most prominent in areas of low Si for SFA and at low Si and Al for the AgZ samples. As well the boundaries between Si- and Al-rich particles in the remaining matrix experienced general inward attack.

9:30 AM *ET15.14.04
Compositional Dependence of Nepheline Crystallization in High Level Waste Glasses Ashutosh Goel1, Ambar Deshkar1, Ping Lu1, Yaqoot Shaharyar1, José Marcial2, Mostafa Ahmadzadeh3, Paul Bingham3 and John S. McClay2; 1Department of Materials Science and Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Washington State University, Pullman, Washington, United States; 3Sheffield Hallam University, Sheffield, United Kingdom.

Owing to high concentrations of Al$_2$O$_3$ from dissolved fuel cladding and Na$_2$O from basification of the waste, about half of the high-level waste by volume at Hanford, Washington, USA is rich in both Na and Al. Formulations of high waste-loading glasses result in lower amounts of SiO$_2$, which often leads to undesirable precipitation of nepheline (NaAlSiO$_4$). Nepheline crystallization can be affected by both framework and non-framework cations which are present in the glass network. At Hanford, Washington USA, nepheline has been identified in the near field, redox processes that destabilize the AgI, and interference from species such as sulfide. Therefore, a durable waste form will be required to contain the radioiodine upon the disposal of these AgI-laden materials. However, limited work to date has been performed to assess the durability of iodine waste forms. This presentation will provide an overview of recent corrosion testing efforts carried out on iodine waste form materials. Two examples systems were investigated: iodine-loaded AgZ material processed with hot isostatic pressing (HIP) and iodine-loaded SFA material with spark plasma sintering. These materials were assessed using aqueous corrosion methods including single-pass flow-through testing (SPFT), the product consistency test (PCT), dilute reactor analysis (DRCA), and electrochemical analyses. The results from these tests were supplemented with characterization of the microstructure to track the progression of corrosion on the surface using scanning electron microscopy with energy dispersive X-ray spectroscopy, X-ray diffraction, and optical profilometry. It was generally observed that corrosion attack was most prominent in areas of low Si for SFA and at low Si and Al for the AgZ samples. As well the boundaries between Si- and Al-rich particles and the remaining matrix experienced general inward attack.

10:30 AM *ET15.15.01
Microparticle Production as Reference Materials for Particle Analysis Methods in Safeguards Stefan Neumeier, Philip Kegler, Martina Klinkenberg, Irmgard Niemeyer and Dirk Bosphach; Forschungszentrum Juelich GmbH, Juelich, Germany.

The International Atomic Energy Agency (IAEA) implements technical measures, or safeguards, in order to verify the compliance of member states their international legal obligations to use nuclear material and technology only for peaceful purposes. Predisposal and geological disposal of high-level radioactive waste and spent nuclear fuel, if declared as waste, is also subject to safeguards. One of the technical measures used are analytical measurements...
of samples taken during inspections of nuclear facilities. The application of this measure goes hand in hand with the development and advancement of analytical measurements and of reference materials for quality control purposes.

To this end, a two-step process has been developed and established at Forschungszentrum Juelich which is capable to produce microparticles intended as source material for certified reference materials for particle analysis methods applied in safeguards. The first step is an aerosol-based particle production process. A monodisperse particle size distribution as well as the single phase UO2 structure was confirmed by SEM, mass spectrometry and μ-X-ray methods. Mass spectrometry analysis performed on single uranium microparticles confirmed consistency of the uranium isotopic ratios in comparison to the initial precursor solutions. In the second step the particles are transferred into suspensions for which the stability of the particles in suspension was investigated with respect to dissolution. It turns out that ethanol is a suitable medium for the storage of particles over a period of several months. Our results from systematic particle analyses by SEM/EDX demonstrate that the two-step process developed at Forschungszentrum Juelich enables the reproducible production and homogeneous distribution of monodisperse microparticles and particle mixtures on several types of substrates, such as quartz discs and cotton swipes. Hence, it allows for a very flexible and time-saving preparation of various types of test samples suitable as reference materials for particle analysis methods applied in safeguards.

11:00 AM ET15.15.02
Wet Chemistry Route to Uranium Oxide Micropheres as Reference Materials for Nuclear Safeguards Nicolas Clavier1, Jerome Maynadie1, Victor Trillaud1, Jerome Manaud1, Laure Sangely1, Thippatai Tranpaphan1 and Nicolas Dachere1; 1ICSM, Bagnols, France; TAE, Vienna, Austria.

The preparation of morphology-controlled uranium oxide particles is currently attracting a growing interest, notably due to its importance in the field of nuclear safeguards. Particularly, provided certain homogeneity and stability requirements, such particles could act as reference materials for microanalytical methods. In this framework, several protocols have been already tested, but frequently required specific equipment and cannot be easily implemented in standard chemistry labs. On this basis, we developed from several years original wet chemistry routes aiming to precipitate directly morphology-controlled actinide oxides from mixtures of solutions. Such methods are mostly based on the hydrolysis of tetravalent actinides which leads to the formation of amorphous An(OH)3 samples, finally aging to AnO2.nH2O.

In this aim, hydrochloric solution containing tetravalent uranium (natural isotopic composition) was first mixed with aspartic acid, used both as complexing and shaping agent, to yield an amorphous uranium(IV) aspartate precipitate. Solid phase and supernatant were then transferred in a Teflon-lined autoclave and placed under mild hydrothermal conditions (T = 160°C). A multiparametric study was then undertaken, in order to evidence the impact of pH, aspartic acid concentration, or mechanical stirring. On the one hand, acid concentration was found to be the most critical parameter, as microspheres were only obtained for pH values close to 2. On the other hand, the size dispersion of the particles produced could be improved by using a large excess of aspartic acid during the initial precipitation step. Finally, the addition of a mechanical stirring during the hydrothermal treatment step allowed us to control more accurately the size of the particles produced in the range 100 nm – 1 µm. For all the compounds prepared, further XRD analysis attested the formation of UO2.nH2O samples, while TG experiments revealed the presence of residual organics. Nevertheless, additional heating treatments performed up to 600°C led to produce anhydrous and carbon-free dense particles without altering their initial morphology.

Finally, preliminary tests of these samples as reference materials for nuclear safeguards were performed. In this aim, UO2 microspheres were first deposited on carbon planchets after dispersion and dilution with ethanol. The number of particles deposited, the spacing between them, the cleanliness of the areas not intended for particle deposition and the absence of uranium background between the particles was found to be satisfying. Also, first LG-SIMS experiments aiming to determine the isotope composition of uranium led to very good results, the behaviour of the particles under the IMS beam being comparable to typical field sample particles.

SESSION ET15.16: Management and Long Term Behavior of Spent Nuclear Fuel II
Session Chairs: Dirk Bosbach and Laurent Claparede
Thursday Afternoon, November 29, 2018
Hynes, Level 3, Room 308

1:30 PM ET15.16.01
Leaching of Spent Nuclear Fuels—Influences of Sample Preparation and Matrix Composition on Radionuclide Release Patterns Olivia Roth1, Anders Paranen1, Daqing Cui1, Alexandre Barreiro Fidalgo1, Lena Evins2 and Kasriost Spahiu2; 1Studsvik Nuclear AB, Nyköping, Sweden; 2SKB, Stockholm, Sweden.

The rate of release of the radionuclide content from spent nuclear fuel during water contact is a central issue to the safety assessment of spent nuclear fuel repositories. Although the area has been subject to studies for several decades there are still issues to be resolved. The general trend among reactor operators is to increase the burn-up of the fuel. There are also new fuel types on the market where additive or dopants have been added to the fuel matrix in order to enhance the in-reactor fuel performance. Both these factors alter the spent fuel matrix and can be expected to influence the leaching behavior. Many spent nuclear fuel deep repository designs involve large amounts of iron in the disposal canister and canister cladding gap, the samples have been prepared in different manners. Furthermore, the effect of fuel matrix dopants on the hydrogen effect has been studied by performing leaching of Al/Cr doped fuel both in aerated conditions and under hydrogen atmosphere and comparing the results with results from leaching of standard UO2 fuel.

2:00 PM ET15.16.02
Electrochemical Simulation of the Influence of Radiolytically-Produced Hydrogen on the Corrosion of Uranium Dioxide Nazhen Liu1, Fraser King2, David Shoesmith1 and James Noel1; 1University of Western Ontario, London, Ontario, Canada; 2Integrity Corrosion Consulting Ltd, Nanaimo, British Columbia, Canada.

The ability of hydrogen to inhibit the corrosion of uranium dioxide has received considerable attention since this process has the potential to suppress radionuclide release from spent fuel exposed to groundwater inside a failed nuclear waste container emplaced in a deep geologic repository. A number of mechanisms have been proposed to explain this inhibition. Hydrogen oxidation on the noble metal particles present in spent fuel leading to
the prevention of oxidation of the galvanically-coupled uranium dioxide matrix has been clearly demonstrated. However, the direct reaction of hydrogen on the uranium dioxide surface also appears capable of preventing fuel corrosion and radionuclide release by consuming the OH radicals produced by hydrogen peroxide dissociation on the oxide surface. In addition, the combination of radiation (gamma) and hydrogen can be shown to suppress the corrosion potential of uranium dioxide to values below which the oxide should be thermodynamically immune to oxidation. This suppression appears to be partially irreversible suggesting a chemical reduction of the oxide matrix by H radicals. In this study, we have attempted to simulate this influence of radiation by generating H atoms via water/proton reduction on the oxide surface. A similar suppression of the corrosion potential is achieved and, on removing the radiation field, only a partial recovery of the corrosion potential, towards the value which prevailed before irradiation, is observed. By conducting a series of electrochemical experiments on oxides with various degrees of non-stoichiometry, it is shown that the oxide matrix is reduced with the extent of reduction depending on the degree of non-stoichiometry of the oxide. Also, by performing similar experiments in solutions with a range of pH values, it was shown that the extent of oxide reduction increases at low pH when the generation rate of H atoms is increased.

These studies indicate that a combination of radiation and hydrogen can lead to the direct reduction of the oxide matrix via a reaction with absorbed H atoms.

2:15 PM ET15.16.03
Powder Leaching Study for Grain Boundary Inventory of Two High Burnup Fuels Alexandre Barreiro Fidalgo1, Olivia Roth1, Anders Puranen1, Lena Evins2 and Kastriot Spahiu2; 1Studsvik Nuclear AB, Nyköping, Sweden; 2SKB, Stockholm, Sweden.

In the context of a deep geological repository safety assessment, the Instant Release Fraction (IRF) is defined as the fraction of radionuclides in spent fuel which rapidly dissolves in contact with water. The IRF is sourced both from the pellet-cladding gap and the grain boundary. It is however uncertain how much the grain boundary inventory contributes to the IRF. Commonly, the IRF is determined by using short-term dissolution experiments, which does not distinguish between these two fractions. However, a few experiments have been performed to specifically investigate the grain boundary fraction through simultaneous grinding and leaching experiments [1-2].

For this study, the main goal is to establish the closed grain boundary inventories of two Swedish fuels with high burnup (local burnup 58 and 65 MWd/kg). In addition, the results will be compared to those already obtained for another high burnup fuel (local burnup 75 MWd/kg) [3].

The experiments are performed on fuel fragments without cladding. The selected fragments are samples that have already been leached in previous campaigns and therefore the IRF of exposed grains and matrix dissolution behavior under aerated conditions have already been established [4-5].

The fuel fragments were exposed to an initial leaching period under aerated conditions in 10:10 mM NaCl:NaHCO3 solutions for 3 months. The main objective of this initial step is to wash away any pre-oxidized phases formed during humid-air storage in cell.

After the washing step, the fuel fragments are placed in a mill together with simplified groundwater (10:2 mM NaCl:NaHCO3 solution) under oxidizing conditions (air) at room temperature. The grinding and simultaneous leaching is performed in similar conditions as tested in a previous campaign [3]. The solutions are analyzed with Inductively Coupled Plasma Mass Spectroscopy (ICP-MS) and gamma spectroscopy. Additionally, the grinded fuel is taken for Scanning Electron Microscope (SEM) analysis.

The preparations, experimental setup as well as the experimental results will be presented and discussed in the conference presentation.

Radionuclides Present at Inner Cladding Surfaces of Irradiated PWR Fuel Rod Segments in the Context of Safety of Extended Dry Storage of Spent Nuclear Fuel Michel Herrn, Ernesto González-Robles, Nikolaus Müller, Tobias König, Kathy Dardemne, Jörg Rothe, Dieter Schild, Ron Dagan and Volker Metz; Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen, Germany.

In the German waste management concept, spent nuclear fuel (SNF) is designated for direct disposal in a deep geological repository available by 2050 at the best. However, considering the delay in the site selection process so far as well as the time needed for exploration, construction, and commissioning of a repository for high-level waste, start of waste emplacement is expected by the end of this century. Thus, a prolonged dry interim storage of SNF assemblies is inevitable.

Integrity of the irradiated Zircaloy cladding after 50 to 100 years of dry interim storage is of importance e.g. to ensure a safe reloading of fuel assemblies from storage casks to final disposal casks. However, cladding integrity is affected by various processes during reactor operation and beyond, e.g. fuel cladding chemical interactions. Moreover, inner cladding surfaces exposed to precipitates of fission/activation products released from fuel pellets are possibly prone to corrosion processes. In particular, the presence of cesium, iodine, tellurium, and chloride at the fuel-cladding interface and their impact on the integrity of the cladding are analyzed.

Irradiated Zircaloys-4 specimens, currently under investigation, are sampled from the plenum section as well as cladding tube in contact with SNF of an UO2 fuel rod segment (50.4 GWd/kg). Experiments with irradiated cladding in contact with MOX fuel (38.0 GWd/kg) have been started recently.

Composition of agglomerates found on the inner surface of the plenum cladding and fuel-cladding interaction layers were analyzed by means of SEM-
The microstructure, in particular grain size, grain orientation and dopant distribution (i.e. either in solid solution within the UO₂ matrix or segregated on dissolution behaviour e.g. regarding the larger grain size in doped fuels and contributions of grain boundaries, the model material pellets were synthesized free of any grinding steps to be applicable in a dedicated glove box line. Process optimization was achieved by a systematic investigation of various process to mimic fuel ages between 1,000 and 10,000 years, later in DISCO. Syntheses were performed by co-precipitation and wet-coating methods and had to be pellets, Cr-doped UO₂ as well as Cr- and alpha doped (238Pu) pellets. A wet chemical route was favored due to the very low doping levels of 238Pu required reactor (LWR) fuels such as Cr-, Al-, and Si-doped UO₂ fuels. For these modern types of LWR fuel it is still not known, whether their performance in a deep geological waste repository will be similar to conventional spent LWR-fuels. Corrosion experiments with spent nuclear fuel (SNF) cannot unravel all alteration model will be presented.

In a deep geological repository, the fate of spent UO₂ fuel and the associated release of radionuclides depend on UO₂(s) corrosion kinetics, precipitation kinetics of secondary phases as well as on thermodynamic constraints. These processes are influenced by a variety of factors such as the radiation field, the resulting dose rate, the availability of oxidizing radiolytic products, the groundwater composition and the redox potential. As a result of numerous studies it turns out that corrosion of spent UO₂ fuel is strongly inhibited under hydrogen overpressure. In contrast to earlier results, radiolysis driven fuel corrosion appears to be less relevant for most repository concepts. Even though the protective hydrogen effect on corrosion of spent UO₂ fuel has been evidenced in many experiments open questions remain related to the exact mechanism.

Using batch-type corrosion experiments with depleted UO₂(s) under gamma-irradiation, we studied alteration of the UO₂(s) surface under H₂ overpressure. Prior to the corrosion experiments, a series of UO₂(s) samples were annealed at 1150°C in Ar/H₂ gas stream. Immediately after cooling of the samples to ambient temperature, surfaces of one sample were characterized by XPS. The other UO₂(s) samples, annealed in the same batch, were placed in autoclaves with aqueous near neutral pH solution. The autoclave experiments were irradiated for several months in the GB77 Co-60 source at Institut für Oberflächenmodifizierung, Leipzig. The mean gamma-dose rate at the position of the autoclaves were measured with a Fricke dosimeter and was below 600 Gy/h. Surfaces of UO₂(s) samples recovered from the autoclave experiments were analyzed by means of SEM-EDS, Raman spectroscopy, and XPS techniques. A UO₂(s) reference sample (CBNM#106, EC Reference Material no. 106) was fractured in ultra high vacuum of our XPS device, to provide baseline measurements for uranium oxidation states. Solely 4f elemental lines and respective satellite signals were detected in the reference sample with a UO₂.0 stoichiometry. Similarly, the depleted UO₂(s) sample measured immediately after annealing in Ar/H₂ gas stream contained solely U(IV). After storing the annealed UO₂(s) under dry conditions in a glovebox with Ar atmosphere (containing < 1 ppm O₂) for one year, both U(IV) and U(V) were detected on the sample surface. We detected metaschoepite and Na-diuranate type precipitates on the UO₂(s) samples recovered from the gamma-radiolysis experiments. Besides layers of U(VI) secondary phases, U(IV) was detected at these samples when precipitates were removed. Experimental results and conclusions with respect to the spent UO₂(s) matrix alteration model will be presented.

The current efforts to improve fuel performance in nuclear power generation resulted in an increased utilization of a variety of new types of light-water reactor (LWR) fuels such as Cr-, Al-, and Si-doped UO₂ fuels. For these modern types of LWR fuel it is still not known, whether their performance in a deep geological waste repository will be similar to conventional spent LWR-fuels. Corrosion experiments with spent nuclear fuel (SNF) cannot unravel all of the various concurring dissolution mechanisms entirely due to the chemical and structural complexity of SNF and its high beta- and gamma radiation field. Technical restrictions allow only for a very limited number of experiments. Therefore, within the EU-DISCO project (www.disco-h2020.eu) experiments on irradiated modern fuels are complemented with systematic dissolution studies carried out with synthesized and well characterized, simplified UO₂-based model materials. A bottom up approach is followed to understand how the addition of Cr-oxide into the fuel matrix affects SNF dissolution behavior under repository relevant conditions.

Here, we show recent results on the development and optimization of the process steps for a wet-chemical route to produce nominally pure UO₂ reference pellets, Cr-doped UO₂ as well as Cr- and alpha doped (238Pu) pellets. A wet chemical route was favored due to the very low doping levels of 238Pu required to mimic fuel ages between 1,000 and 10,000 years, later in DISCO. Syntheses were performed by co-precipitation and wet-coating methods and had to be free of any grinding steps to be applicable in a dedicated glove box line. Process optimization was achieved by a systematic investigation of various process parameters such as calcination temperature and pressing forces. In order to provide insights into the effects of the material's micro structure on the dissolution behaviour e.g. regarding the larger grain size in doped fuels and contributions of grain boundaries, the model material pellets were synthesized. The microstructure, in particular grain size, grain orientation and dopant distribution (i.e. either in solid solution within the UO₂ matrix or segregated on grain boundaries) in the model materials were characterized using various complementary methods e.g. SEM, EBSD, and XRD. First results of accelerated dissolution studies with UO₂-based Cr-containing model systems were performed using H₂O₂ to mimic the oxidative radiolysis species to study the effect of micro structure and Cr-doping upon the dissolution rate.

How the Microstructure of the Alumina Layer Can Lead to Full Growth Reproducibility of Millimeter-Tall Forests of Carbon Nanotubes

Gilbert D. Nessim and Eti Teblum; Bar Ilan University, Ramat Gan, Israel.

The chemical vapor deposition (CVD) synthesis of millimeter-tall carbon nanotube (CNT) forests using iron catalyst on alumina underlayer has now become established. Many studies have elucidated the role of precursor gases and water vapor, catalyst coarsening, and possible models for growth termination. However, it is well-known to the practitioners that the synthesis is not always fully reproducible and can be affected by tiny amounts of carbon or water vapor present in the reactor, by laboratory temperature or humidity, etc. To solve this problem, we assumed that the key issue is the interface between the catalyst and the alumina underlayer and the subsurface diffusion of iron (catalyst) into alumina (underlayer). We focused on tuning the microstructure of the alumina underlayer and studied how different microstructures would affect CNT growth, keeping all the other process and material parameters constant. We postulated that the issue was the grain size of the underlayer and thus the amount of grain boundaries. Since the iron catalyst subsurface diffusion into the alumina underlayer will strongly be affected by the amount of grain boundaries, with grain boundary diffusion being much faster compared to lattice diffusion, we decided to control the grain size of the alumina. Using electron-beam evaporation, we prepared samples where we heated the substrate at 350 °C during deposition and slowly evaporated the alumina with the goal to obtain large grains in order to minimize the amount of grain boundaries. We also prepared samples where we evaporated the alumina at a fast rate to obtain small grains and to maximize the amount of grain boundaries.

Carbon nanotubes (CNT) had received broad attention in the past decades due to its dramatic physical and chemical performance of individual tubes and became a powerful candidate of future star materials. As synthesis determined the future, in this talk, I will focus on the controlled growth of SWNT arrays with ultra-high density, high ratio semiconducting properties and special chiral angles. For the SWNTs arrays with ultra-high density, Trojan catalysts (released from substrate) was developed and the density can be as high as 150 tubes/µm. For the SWNTs arrays with semiconducting properties, oxides catalysts with oxygen vacancy, bimetal catalysts and uniform Mo$_2$C catalyst were used to grow semiconducting SWNTs arrays and ratio of semiconducting tubes can be higher than 95%. For the SWNTs arrays with special chiral angles, it is based on a consideration of nanotube/catalyst interfacial thermodynamics determined by symmetry, and the kinetic growth rates set by the number of kinks. Using these strategies, horizontally aligned metallic ((12, 6), abundance >90%) and semiconducting ((8, 4), abundance >80%) SWNT arrays with an average density higher than 20 tubes/µm and 10 tubes/µm, respectively, were successfully obtained on uniform solid catalysts.

Locally Controlled Growth of Single Lambda-Shape Carbon Nanofibers

Christian Lutz, Tobias Loritz, Julia Syurik, Sharali Malik, C.N. Shyam Kumar, Christian Kübel, Michael Bruns, Christian Greiner, Michael Hirtz and Hendrik Hoelscher, Karlsruhe Institute of Technology, Karlsruhe, Germany.

Since first studies of branched carbon nanotubes (CNTs) with L-, Y- and T-shapes were published in the mid of the 1990 various approaches were presented to grow such structures. Branched carbon nanotubes are of high interest due to their unique electrical properties making them a promising material for advanced nano-electrical devices. However, SWCNTs are not easy to grow in a defined way. Therefore, Y-shaped MCNTs or CNTs are also of interest as a material mimicking hierarchical nanostructures found in nature.

In general, the growth of branched or non-branched CNFs or CNTs is conducted with an elaborate infrastructure relying on a certain amount of process gases and considerable energy input. We present an approach to grow inverted V-shaped or Y-shaped CNFs in an open ethanol flame. Due to their resemblance to the Greek letter lambda we named them Λ- or λ-shaped CNFs depending on their actuals shape. Λ-shaped CNFs consist of two CNFs attached to the substrate with one end and connected to each other with the other end resulting in a free standing lambda-shape. An additional CNF can be grown from the connecting point of the first two CNFs with increasing growth time resulting in λ-shaped CNFs. Our experiments suggest that the connecting point of the lambda-CNFs is the nickel catalyst and that the third CNF growth from that center. The exact growth position of the overall structure on the substrate can be determined through microchannel cantilever spotting (µCSP) or dip-pen nanolithography (DPN) via the locally controlled deposition of nickel catalyts. Down-scaling to a spot size that results solely in one single lambda-shaped CNF is demonstrated.
Single-walled carbon nanotubes (SWCNTs) are one-dimensional materials exhibiting unique properties, so they have been anticipated for various electronic devices in future. Presently, catalyst-assisted chemical vapor deposition (CVD) are widely used to obtain high-yield SWCNTs, where alumina buffer layers are used to enhance the catalyst activity. However, the enhancement mechanism of catalyst activity by the alumina buffer layers remains poorly understood. In this study, we performed SWCNT growth at 600°C by alcohol catalytic CVD using Rh catalysts on different types of alumina buffer layers prepared using different processes, and the effects of oxidation and crystallinity of alumina buffer layers on catalysts activity were investigated. Five kinds of alumina buffer layers were used to support Rh catalysts; native oxidation of Al layer deposited by electron beam (EB); thermal oxidation of Al layer deposited by EB; EB deposition of Al2O3 powder; native oxidation of Al layer deposited by rf-sputtering; thermal oxidation of Al layer deposited by rf-sputtering. After deposition of Rh catalysts (nominal thickness ~ 0.2 nm) on them, we carried out SWCNT growth by alcohol catalytic CVD [1]. The grown SWCNTs were characterized by Raman measurements, FESEM and TEM. The alumina support layers were analyzed by XPS, XANES, AFM, TEM and ellipsometry. Rh particle sizes and subsurface diffusion were characterized by TEM and depth profile using XPS.

Although Rh nanoparticles were formed on all alumina layers, SWCNTs were not grown on the alumina buffer layer in which metallic Al was contained. Deposition profile showed that the large inward diffusion of Rh catalysts occurred on the "metallic" alumina buffer layer, resulting in the reduction of SWCNT yield. For the alumina buffer layers prepared by thermal oxidation, disordered-type alumina polycrystals were formed and that Ostwald ripening of Rh catalysts was enhanced on them, leading to small SWCNT yields. Conversely, on the amorphous alumina layers, Ostwald ripening was suppressed and Rh particles suitable for SWCNT growth were formed. Additionally, the inward diffusion of Rh catalysts was suppressed on the diaspore-type amorphous layers with higher densities. Our results demonstrated that amorphous alumina support layers with high densities are suitable for suppressing both Ostwald ripening and inward diffusion of catalysts, making them favorable for high-density SWCNT growth.

Hyperspectral Raman Spectroscopy—A Powerful Method to Investigate Plasma Treatments of Graphene Films
Pierre Vincion1, Germain Robert Bigras1, Xavier Glad1, Charlotte Allard2, Richard Martel2 and Luc Stafford1; 1Physique, Université de Montréal, Montréal, Québec, Canada; 2Chimie, Université de Montréal, Montréal, Québec, Canada.

Raman spectroscopy is an efficient tool giving distinctive features for pristine, damaged and even doped graphene. Typical Raman methods are however limited by their intrinsic microscopic nature, only allowing to probe the area exposed to the laser beam (~1 μm). Hence, Raman mapping is often used to assess a broader region of graphene samples. Nonetheless, especially when graphene is grown on a polycrystalline substrate, strong discrepancies may appear on a scale larger than the available mapping area (~ tens or hundreds of μm). Moreover, in the case of plasma irradiation of graphene, it is essential to understand the impact of the small heterogeneities in pristine graphene (local defects, grain boundaries, etc.) on the resulting graphene structure after treatment. In this context, recent advances in laser technology combined with increased efficiencies of Charged-Coupled Devices (CCD) and the development of efficient Bragg filters opened the road to new Raman imaging methods with reasonable integration time. In particular, hyperspectral Raman Spectroscopy or RIMA (Raman Imaging) is a very powerful method to obtain qualitative as well as quantitative Raman data on a macroscopic scale [1]. In this work, RIMA was used to examine plasma-induced modification of CVD-grown graphene films. Experiments were realized in a low-pressure inductively-coupled plasma. This method is a commonly used post-processing technique to alter materials properties and thus, is a good candidate to tune graphene films. It is however difficult to decouple doping and damage mechanisms. In damage studies of graphene, ions beams are operated at energy above a few tens of eV [2] while ions energy in our plasma conditions is below the energy threshold for atom displacement (T.dis = 15-20 eV) [2]. Yet, defects generation by such plasmas are reported in few studies [3] but are not clearly understood.

Graphene films were exposed to an argon plasma and RIMA measurements were performed on different areas to study the sample homogeneity. These results reveal how the initial state of graphene films is a key factor to understand plasma irradiation effects. In addition, the very large number of Raman data (>10^6) was used to establish links between doping, strain and damage types in both as-grown and plasma-processed graphene films. To further understand plasma-graphene interactions, plasmas conditions were adjusted as to vary ion energy and fluence of plasma-generated species.

Chirality Distributions of SWNTs—Experimental Evaluation versus Thermodynamic Modeling
Annick Loiselle1, Frédéric Fossard1, Yann Magnin1,2, Hakim Amani1, François Ducastelle1, Esko Kauppinen1,2,3,4 and Christophe Bichara1; 1LEM, CNRS-ONERA, Chatillon, France; 2MultiScale Material Science for Energy and Environment, Massachusetts Institute of Technology, Boston, Massachusetts, United States; 3CNRS-Université Aix Marseille, CINAM, Marseille, France; 4Department of Applied Physics, Aalto University School of Science, Aalto, Finland.

Although significant progress has been made since 25 years, one major obstacle to realization of Single-walled carbon nanotubes (SWNTs)-based nanotechnology has been the lack of control for designing selective synthesis conditions. This is partly due to the incomplete understanding of the physical and chemical effects driving the kind of tubes able to nucleate and grow under given experimental conditions [1].

A way to address this basic question is to consider SWNT growth from a thermodynamic point of view. To that aim, we have developed a statistical thermodynamics model, valid in the case of a perpendicular growth [2], which has been experimentally proven to yield a near-armchair selectivity [3]. This model relates the stable (n,m) tube structures to the tube/catalyst interfacial energies for zigzag and armchair edges and the temperature [4]. Taking the configurational entropy of the tube edge into account is a central point that explains how chiral tubes become stable at finite temperature, while ground state structures are either zig-zag or armchair. Exploring the parameter set enables one to display temperature dependent chirality maps, locating the most stable tube structure. More precisely, for each set of interfacial energies and temperature, this model yields a probability distribution of (n,m) SWNTs.

With this model in hand and thanks to a scrupulous analysis of our previous results and data of the literature, we will compare in this talk experimental measured and model chirality distributions facing two difficulties. A first notorious difficulty is the experimental evaluation of the chiral distribution of tubes produced in a CVD process, as most of characterization techniques might fail either in the identification of the different kinds of tubes present in a sample or in determining their relative fractions. On the other hand, the model, being purely thermodynamic, does not take into account kinetics and experimental conditions which may impact the tube selectivity such as a possible preferential etching of metallic tubes.

These limits given, we will show the efficiency of the model in understanding the origin of the frequently reported near-armchair selectivity and for
accounting for chirality distributions observed under given synthesis conditions. Finally we shall evaluate the potential of the model for providing guidelines for catalyst design and growth condition optimization.

Large-Scale Dynamic Energy Driven Assembly of Two-Dimensional Layered Materials on Polymer Substrate
Dong Zhou and Bo Li; Villanova University, Villanova, Pennsylvania, United States.

Two dimensional layered materials (2DLMs) are important candidates of flexible electronics applications, used for health monitors, displays, batteries, and sensors. Despite the significant progress being made in synthesis technologies and in the prototyping of 2DLM flexible electronics, the work in the scalable integration of 2DLMs with flexible polymer substrates has proven, thus far, to be minimal and limited to several specific 2DLMs and polymer substrates. In this work, we demonstrated directly assemble wafer-scale 2DLM film on a polymer substrate through a dynamic energy driven assembly (DEDA) method seamlessly integrating a liquid exfoliation and a new assembly strategy. The DEDA method includes three steps: exfoliation of 2DLM in a designated solvent using sonication, and submerge polymer substrate to process the assembly, and take out the assembled substrate to dry. The principal innovation of DEDA is to control the relative interfacial energy among solvent, 2DLM and polymer substrate such that a relative low-energy 2DLM-polymer interface and a relative high-energy solvent-polymer interface will enable effective assembly of 2DLM on the polymer. Unlike the traditional assembly strategies, which start with a stabilized solution and emphasize good wetting among all components, DEDA theory suggests poor-wetting solvent is the key that determines the assembly quality. As a proof-of-concept, we have successfully used DI water, a non-toxic but poor wetting solvent for PDMS, to exfoliate and then assemble different 2DLMs (graphene, h-BN, and MoS2) on a PDMS substrate. A uniform film can be formed as short as 10 seconds after immersing PDMS substrate in the solution and by adjusting the solution concentration and assembly time, the thickness of the assembled film can be easily tuned from several nanometers to hundreds of micrometers. It is also interesting to notes, adding 2-propanol into water decreases the assembly efficiency dramatically. This results matching the prediction from DEDA theory where improved wetting between the solution and PDMS diminish the driving force of assembly. In summary, the unique features of this DEDA method are (1) a new interfacial energy driven assembly strategy that has the potential to be generalized broadly to arbitrary 2DLMs and polymers, (2) the usage of the non-equilibrium 2DLMs solution for rapid assembly, and (3) high controllability of the assembly through simple concentration and assembly time controls. This study not only creates a new assembly method for the scalable and hierarchical fabrication of 2DLM flexible electronics but also advances knowledge in nanomaterials assembly and will promote the field of nanomanufacturing.

SESSION NM01.02: Synthesis and Characterization II

Evaluation Methods for Quality Control of Carbon Nanotubes and Graphene Toshiya Okazaki; AIST, Ibaraki, Japan.

Due to their extraordinary electrical and mechanical properties, carbon nanotubes (CNTs) and graphene are widely regarded as very attractive nanomaterials. For example, CNT production capacity has rapidly increased worldwide. For commercialization of CNT and graphene-based products, the qualities of CNTs and graphene must be controlled. In this talk, we will show effective methods for quality evaluation of CNTs and graphene.

First, the lengths of CNT are estimated by far-infrared (FIR) spectroscopy. Based on the plasmon resonance model, the length of the clean channel qualities of CNTs and graphene must be controlled. In this talk, we will show effective methods for quality evaluation of CNTs and graphene.

Efficient CVD Growth of Single-Wall Carbon Nanotube Carpets Using Industrial Gaseous Waste as a Feedstock
Haider Almkhelfe1, Xu Li1, Rahul Rao2, and Placidus B. Arnma1; 1Tim Taylor Department of Chemical Engineering, Kansas State University, Manhattan, Kansas, United States; 2Materials & Manufacturing Directorate, Air Force Research Laboratory, WPAFB, Ohio, United States; 3UES, Inc., Dayton, Ohio, United States.

A gaseous product mixture from Fischer-Tropsch synthesis (FTS-GP) has been utilized as an efficient feedstock for growth of high-quality, well-aligned, single-wall carbon nanotube (SWCNT) carpets of millimeter-scale heights on Fe and (sub) millimeter-scale heights on Co catalysts via chemical vapor deposition (CVD). Growth conducted at optimal temperatures for Co and Fe catalysts yielded predominantly SWCNTs that are largely free of carbon impurities. Growth on Fe is characterized by a growth rate of ~50 μm/min and catalyst lifetime that is longer than 90 min, with the catalyst showing no decay of activity. In contrast, growth on a Co catalyst shows a lifetime of ~60 min, with a slower growth rate of ~7μm/min. Resulting area densities of SWCNT carpets grown on Fe and Co catalysts, determined by the weight-gain method, were 1.0 × 1012 and 6.0 × 1012 cm2, respectively. The catalyst
lifetime and area densities of SWCNTs are among the highest achieved on standard catalysts. Unlike SWCNT carpet growth involving conventional feedstocks (such as $\text{C}_2\text{H}_2$, $\text{C}_2\text{H}_4$, and CO), growth rate and density of SWCNTs on Fe are less sensitive to the FTS-GP fraction and thus allow for relatively easy optimization and scale-up.

2:15 PM NM01.02.03  
**Defect-Free Graphene Growth at Low Temperatures via Plasma Enhanced Chemical Vapor Deposition**  
Bilge Bekdüz, Yannick Beckmann, Jan Mischke, Jonas Twellmann, Wolfgang Mertin and Gerd Bacher; University of Duisburg-Essen and CENIDE, Duisburg, Germany.

Plasma enhanced chemical vapor deposition (PE-CVD) is the method of choice to fabricate graphene films at temperatures well below 1000°C. Low growth temperatures are of interest e.g., to decrease the production cost, to make the process suitable for roll-to-roll implementation or to facilitate the growth of graphene on other non-catalytically substrates. Although few groups showed nearly defect-free PE-CVD grown graphene at low temperatures, a detailed understanding of the growth mechanism is still missing [1].

In order to study the growth mechanism in PE-CVD we used a commercially available 4" cold wall reactor to fabricate graphene on electrochemically polished high-quality copper foils [2]. A cost-effective DC plasma is applied to dissociate the precursor methane. To suppress unintended vertical graphene growth and ion acceleration to the substrate we introduced a sacrificial Cu foil into the growth chamber. The growth temperature was systematically varied from 1020°C down to 600°C. By varying the growth time at different temperatures two types of samples were prepared: graphene flakes and graphene films. By analyzing the flake areas the growth rate could be determined in dependence of growth time and growth temperature.

Almost defect-free graphene with negligible ($\mu_{\text{eff}} < 0.1$) contributions of the D peak in Raman spectroscopy could be prepared even at 600°C. Compared to thermal CVD we found that the activation energy for the growth rate decreases from 4 eV down to 1.8 eV in PE-CVD, indicating efficient precursor dissociation in the plasma. From our studies we conclude that the carbon attachment step is the limiting factor for the PE-CVD growth. During the early stage of growth, we observed crystalline graphene grains surrounded by amorphous carbon in Raman spectroscopy. With increasing growth time graphene flakes grow at the expense of amorphous carbon and eventually merge into an almost defect-free graphene film with a sheet resistance down to 470 $\Omega$/sq.

**Layer Number Determination of Graphene on Nickel Substrate Using EELS Spectra with Scanning Auger Electron Spectroscopy**  
Masahide Shimizu1, Hiroki Kato1, Kota Shihomatsu2 and Yoshikazu Homma2; 1JEOL Ltd., Tokyo, Japan; 2Tokyo University of Science, Tokyo, Japan.

Graphene is one of the atomic layered materials which has interesting physical properties such as mechanical strength, optical transparency, electron and thermal conductivity. The identification of a layer number is necessary for graphene based technology, because these properties strongly depend on a number of layers. Optical microscopy, Raman spectroscopy, scanning electron microscopy and other microscopic techniques are used to image a map of graphene layer. SEM has superior character among these various techniques for its high spatial resolution and large field of view. In order to observe graphene using scanning electron microscopy, it is necessary to detect electrons emitted by the interaction between electron beam, graphene and substrate. When the graphene on substrate are observed with SEM using secondary electrons emitted from not only graphene but also the substrate. In the present study, the effect of graphene layers on the secondary electrons including elastic and energy loss peaks were investigated using Auger electron microscopy. A carbon-doped poly crystalline nickel foil was heated (up to 900 degree or more) by electrical current supply and cooled rapidly. Through the thermal process, graphene having different number of layers was precipitated on the nickel surface by segregation. SEM observation and reflection electron energy loss spectroscopy (REELS) measurement was performed using a scanning Auger electron microscope (JAMP-9510F, JEOL Ltd.). The accelerating voltage was 1.5 kV. The full width at half maximum of the back scattered electron peak was about 0.9 eV. The angle between the SEM column and electron analyzer was 60 degree. The sample tilting axis of the sample stage was perpendicular to the plane made by SEM beam axis and analyzer collection direction, so called sagittal plane. Therefore, the sample could be set in specular geometry such as the incident and outgoing angle of electrons were the same, by tilting 30 degree. All experiments in this report were performed in the specular condition to get highest intensity for zero-loss and energy loss spectra. At the first, the sample was observed with SEM using out-lens secondary electron detector. The SEM image shows that various layer graphene segregated from the nickel foil. There was the same foil region near at the center of the foil ribbon because the center was highly heated by the DC current feed through. The SEM image shows that the layer number of graphene increased along the ribbon.

The result of REELS measurement is that the intensity of zero-loss peak monotonically decreased depending on the layer number of graphene and the shape of energy loss spectra has specific feature of each layer number of graphene on any kinds of substrate can be determined by using the elastic peak and energy loss spectra.

2:45 PM NM01.02.05  
**Scalable CVD Manufacture and Heterostructure Integration of Graphene and h-BN with Domains Size, Alignment and Layer Control**  
Ruizhi Wang1, Robert Weatherup1,2, Stephan Hofmann1 and Oliver Burton1; 1University of Cambridge, Cambridge, United Kingdom; 2University of Manchester, Manchester, United Kingdom.

Chemical vapor deposition (CVD) has emerged as the most promising method for scalable growth of two-dimensional materials (2DM), such as graphene and hexagonal boron nitride (h-BN). To improve growth, the focus has mainly been on fine-tuning the deposition process using a copper (Cu) catalyst. Notable progress has been made in understanding the nature of the as-grown 2DM. However, the high vapour pressure of Cu is a source of reactor contamination and its low melting point sets a challenging limit for any process optimization. Furthermore, 2DM are prone to contamination by trace Cu, which is a constraint for CMOS integration.[1] Here we present a holistic approach for CVD of 2DM starting with the choice of the catalyst. Based on considerations including accessible CVD parameter space, ease of CMOS integration, feasibility of growth and strategies for transfer, we have determined platinum (Pt) as the optimal catalyst for growth of graphene and h-BN.

The growth of graphene on Pt is critically dependent on the supply and removal of carbon from the catalyst surface by bulk diffusion. By tuning this kinetic process, it is possible to grow graphene isothermally, by precipitation or through both mechanisms. By careful tuning of the growth conditions, we can achieve continuous single-layer graphene with large domains (>0.1 mm), isolated bi-layer graphene domains (>0.05 mm) and continuous bilayer graphene.

Layer Number Determination of Graphene on Nickel Substrate Using EELS Spectra with Scanning Auger Electron Spectroscopy  
Masahide Shimizu1, Hiroki Kato1, Kota Shihomatsu2 and Yoshikazu Homma2; 1JEOL Ltd., Tokyo, Japan; 2Tokyo University of Science, Tokyo, Japan.

Graphene is one of the atomic layered materials which has interesting physical properties such as mechanical strength, optical transparency, electron and thermal conductivity. The identification of a layer number is necessary for graphene based technology, because these properties strongly depend on a number of layers. Optical microscopy, Raman spectroscopy, scanning electron microscopy and other microscopic techniques are used to image a map of graphene layer. SEM has superior character among these various techniques for its high spatial resolution and large field of view. **Scalable CVD Manufacture and Heterostructure Integration of Graphene and h-BN with Domains Size, Alignment and Layer Control**  
Ruizhi Wang1, Robert Weatherup1,2, Stephan Hofmann1 and Oliver Burton1; 1University of Cambridge, Cambridge, United Kingdom; 2University of Manchester, Manchester, United Kingdom.

Chemical vapor deposition (CVD) has emerged as the most promising method for scalable growth of two-dimensional materials (2DM), such as graphene and hexagonal boron nitride (h-BN). To improve growth, the focus has mainly been on fine-tuning the deposition process using a copper (Cu) catalyst. Notable progress has been made regarding the quality of the as-grown 2DM. However, the high vapour pressure of Cu is a source of reactor contamination and its low melting point sets a challenging limit for any process optimization. Furthermore, 2DM are prone to contamination by trace Cu, which is a constraint for CMOS integration.[1] Here we present a holistic approach for CVD of 2DM starting with the choice of the catalyst. Based on considerations including accessible CVD parameter space, ease of CMOS integration, feasibility of growth and strategies for transfer, we have determined platinum (Pt) as the optimal catalyst for growth of graphene and h-BN.

The growth of graphene on Pt is critically dependent on the supply and removal of carbon from the catalyst surface by bulk diffusion. By tuning this kinetic process, it is possible to grow graphene isothermally, by precipitation or through both mechanisms. By careful tuning of the growth conditions, we can achieve continuous single-layer graphene with large domains (>0.1 mm), isolated bi-layer graphene domains (>0.05 mm) and continuous bilayer graphene.[2] While high-quality graphene alone is sufficient for certain applications, most require a van der Waals (vdW) heterostructure, where graphene is embedded within layers of h-BN. Currently, h-BN is mainly obtained through exfoliation of bulk crystals due to lack of clean methods of transferring CVD grown h-BN. Here, we present an approach to grow high quality h-BN on Pt, with domain sizes exceeding 0.5 mm, and to transfer these layers using a delamination-based process, which avoids the contamination associated with traditional transfer methods. These layers can then be used to sequentially pick up additional layers of h-BN or graphene for scalable fabrication of vdW heterostructures. To demonstrate the feasibility of our approach, we have fabricated devices that outperform existing devices relying on CVD 2DMs.[3]

Based on the in-depth understanding of the CVD growth mechanism and the subsequent integration pathway, we present a new approach to scalable
fabrication of 2DM. Instead of additional process optimization, we show how by choosing the optimal catalyst, it is possible to offer solutions to some of the pressing challenges for the scalable manufacture of 2DM. We demonstrate the growth of both graphene and h-BN, with control over layer number, domain size and alignment, and show how these layers can then be cleanly assembled to form vdW heterostructures.

process through molecular dynamics simulations. The combined approach of in situ experimental work and theoretical studies paves the way to design suggested which of the generated species are stable at synthesis conditions, showed the geometrical structure they form, and followed the nucleation species, and (c) the catalyst. Different morphologies were obtained by controlling the dimension of the catalyst particles. Our theoretical calculations led us to design an experimental set-up that allows the control of three important factors for the formation control; namely (a) B species, (b) N structured of the BNNTs that formed later. Magnesium, a component of the precursor, was found to play a vital role that served to generate the formation. At the early stages of production large amounts of nanospheres were formed possessing tail-like structures and these were found to be the seed BNNTs in large quantities, the fundamental science particularly the nucleation and growth of BNNTs must be first understood.

Herein, we report

In Situ Experimental and Theoretical Studies of the Nucleation and Growth Towards Controlling the Morphology of Boron Nitride Nanotubes Using Chemical Vapour Deposition Techniques Jesus A. Acapulco1, Seyyed Shayan Meysami1, Vitaliy Babenko1, Koen Evers1, Ruth S. Jones1, Marcel Swart1 and Nicole Grobert1; 1Department of Materials, University of Oxford, Oxford, United Kingdom; 2ICREA and IQCC, Universitat de Girona, Girona, Spain.

Structurally analogous to carbon nanotubes (CNTs), boron nitride nanotubes (BNNTs) exhibit similar mechanical and thermal properties. However, BNNTs offer additional features such as greater thermal and chemical properties, electrical resistance, and they absorb radiation. Because of these properties BNNTs have attracted much interest due to the wide range of potential applications in which they could enhance, for instance, fuel efficiency particularly in space applications, thermal management for batteries and devices1, as tissue engineering scaffolds in biomedical applications, and in applications where strong, lightweight and thermally conductive but electrically insulating materials are required. To date, the exploitation of BNNTs in applications has been hampered by their limited availability. Although few teams were able to reach yields of up to ca. 20g, the final morphology of the up-scaled BNNT suffers from massive entanglement turning the BNNTs into a felt-like material. Only a very limited number of reports investigating the actual formation of BNNTs are available. In order to produce BNNTs in large quantities, the fundamental science particularly the nucleation and growth of BNNTs must be first understood.

Herein, we report in situ short time reaction studies revealing the formation mechanism of BNNTs and show the nucleation and embryonic stage of BNNTs formation. At the early stages of production large amounts of nanospheres were formed possessing tail-like structures and these were found to be the seed structured of the BNNTs that formed later. Magnesium, a component of the precursor, was found to play a vital role that served to generate the intermediate species and medium for the diffusion of BN species essential for the formation of BNNTs. Our findings led us to design an experimental set-up that allows the control of three important factors for the formation control; namely (a) B species, (b) N species, and (c) the catalyst. Different morphologies were obtained by controlling the dimension of the catalyst particles. Our theoretical calculations suggested which of the generated species are stable at synthesis conditions, showed the geometrical structure they form, and followed the nucleation process through molecular dynamics simulations. The combined approach of in situ experimental work and theoretical studies paves the way to design
efficient production lines for the up-scaling of BNNTs and therefore provides a practical route to the efficient exploitation of BNNTs.

Use of Refractory-Metal Diffusion Inhibitors to Slow Ostwald Ripening of Catalytic Metal Particles—A Route to Ultra-Long Carbon Nanotubes (CNTs) Michael J. Bronikowski and Melissa J. King; University of Tampa, Tampa, Florida, United States.

Growth of Carbon Nanotubes (CNTs) to lengths useful in many materials applications is currently limited by a number of factors, the most important of these being Ostwald ripening and subsequent deactivation of the metal catalyst particles from which the CNTs nucleate and grow. Here is proposed and demonstrated a novel method for overcoming this limitation. It is shown that inclusion of refractory, high-melting-point metals in the metallic catalyst used for CNT growth can substantially enhance the lifetimes of the particles of catalytic metals, enabling growth of CNTs to much greater lengths than possible using the pure catalytic metals. This lifetime enhancement occurs because the refractory metal inhibits the surface diffusion of the catalyst metals, slowing the Ostwald ripening of the catalytic particles and allowing them to grow CNTs for greater times, resulting in longer CNTs. This effect has been demonstrated for several catalyst/diffusion-inhibitor systems, and results are presented and discussed here.

NM01.04.04
Computational Study on Optimization of Sheet Conductance of Carbon Nanotube Transparent Films Masaki Tsukuda and Takahiro Yamamoto; Department of Electrical Engineering, Tokyo University of Science, Katsushika, Japan.

Although Carbon nanotube (CNT) thin films are expected as flexible transparent conductive films, the physical origin of their high electric performance remains to be clarified yet due to complexity of nanotube network. This is because that individual variations in nanotube length and chirality are involved in nanotube network and its electrical conductivity also depends on geometrical network structure such as nanotube density and alignment. Therefore, understanding various properties of CNT thin film has been the subject of controversy over the last few years.

In order to understand various properties of CNT thin film, it is essential to understand relation between the network structure with the nanotube densities, alignment, length and diameter, and their electrical transport property. We thus theoretically explored how nanotube alignment affects electrical transport properties of CNT thin films, using a numerical stick-percolation-based model. In the present study, we investigate electric properties of a CNT films consisted of metallic CNTs. First, we generated two-dimensional random networks in a film. Nanotubes are distributed in a film with the fixed values of the film length of L=5 μm, the film width W=5 μm, nanotube length l_{CNT}=0.5 μm and the chirality of a nanotube as (10,10) and the angle between the axis of nanotube and x-axis as Θ. The value of Θ takes a uniformly random value in the range Θ_{max} < Θ < Θ_{min}, where Θ_{min} < Θ < 90° (we define Θ_{max} as nanotube alignment). CNT network is transformed into effective resistor network composed of the resistance R_{CNT} along an individual CNT and the junction resistance R_{j} between CNT pairs, using ref [1]-[2]. Then, we apply a nodal analysis method to calculate a current value flowing in a film and calculate the sheet conductance in the film by changing the value of angle alignment Θ_{max} for several different nanotube area densities σ.

Our simulation reveals two characteristic of CNT thin films. First, when exceeds the percolation threshold, the sheet conductance increases, depending on the increase of when Θ_{max}=90°. Sheet conductance at σ=200 tubes/μm² is 37.6 kΩ/sq, which is in good agreement with the previous experimental work (40.0 kΩ/sq)[3]. Second, when, the sheet conductance exhibits a maximum at a certain nanotube alignment angle while there is a drop of the sheet conductance caused by the function of junction resistance of the (10,10) - (10,10) CNT. This is because of the competition between the decrease in the number of junctions and lengths of the electrical conducting paths. These results would be helpful for understanding electric transport properties of complicated nanotube network structure.

NM01.04.05
Behavior of Graphite and Graphene Under Mechanochemical Activation with Hematite and Magnetite Nanoparticles Monica Soreesco and Mark Allwes; Duquesne University, Pittsburgh, Pennsylvania, United States.

Graphite-doped hematite and magnetite nanoparticles systems (~50 nm) were prepared by mechanochemical activation for milling times ranging from 2 to 12 hours. Their structural and magnetic properties were analyzed by 57Fe Mossbauer spectroscopy. The spectra corresponding to hematite milled samples were analyzed by considering two sextets, corresponding to the incorporation of the carbon atoms into the iron oxide structure. For ball milling time of 12 hours a quadrupole split doublet has been added, representing the contribution of ultrafine particles. The Mossbauer spectra of graphite-doped magnetite were resolved considering a sextet and a magnetic hyperfine field distribution, corresponding to the tetrahedral and octahedral sublattices of magnetite, respectively. A quadrupole split doublet was incorporated in the fitting of the 12-hour milled sample. The recoilless fraction of all samples was determined using our previously developed dual absorber method. It was found that the recoilless fraction of graphite-doped hematite nanoparticles decreases as function of ball milling time. The f factor of graphite-containing magnetic nanoparticles for the tetrahedral sites stays constant, while that of the octahedral sublattice decreases as function of ball milling time. These findings reinforce the idea that carbon atoms exhibit preference for the octahedral sites of magnetite.

Graphene-hematite and graphene magnetite nanoparticles systems were synthetized using mechanochemical activation for time intervals of 2-12 hours. Their structural and magnetic properties were analyzed by Mossbauer spectroscopy. For ball milling times of 2-12 hours, the least-squares fitting revealed the presence of a sextet for hematite (50.84 T), a sextet for carbon-substituted hematite (46.57 T), a broad sextet for iron carbides (29.34 T) and a quadrupole split doublet for iron-containing carbon nanoclusters (0.73 mm/s). Similarly, the Mossbauer spectra of ball-milled graphene and magnetite were consistent with the occurrence of two sextets for the tetrahedral and octahedral positions of magnetite (49.26 and 46.12 T) and the formation of iron carbides (29.5 T) at long milling times (8 and 12 hou ). Also, the appearance of the doublet representing the iron-containing carbon nanoclusters (0.73 mm/s) was manifest at the longest milling times employed. The recoilless fraction was determined from the Mossbauer spectra using our dual absorber method and it could be evidenced that the recoilless fraction exhibits maxima for the occurrence of additional phases at long milling times. If we relate the present results with the previous ones regarding milling graphite and iron oxide nanoparticles, we should note the additional appearance of the iron carbide phases and the occurrence of carbon nanoclusters. This means that graphite is not merely a source of carbon, but exhibits its own reactive properties during mechanochemical activation.

NM01.04.06
Laser Scribed Graphene Carbon “Grass” Establishing a Highly Selective, Sensitive and Low Detection-Limit, Point-of-Care Dopamine
A range of novel carbon nanomaterials, including 0D fullerene, 1D carbon nanotubes, 1D carbon nanofibers, 2D graphene and graphene oxide, and 3D carbon aerogels, has attracted considerable interest and investments from across the scientific society. Due to their excellent performance, the carbon nanomaterials have contributed significantly towards the development of miniaturized integrated point-of-care biological and chemical sensors. Graphene, as a sensing and signal transducing material is well established, and the recently developed method of “laser scabbing” has already been demonstrated as a facile approach for manufacturing graphene electronics for highly selective, sensitive biological sensing devices [1, 2]. Inspired by the different morphologies and derivatives of the carbon nanomaterials that have been fabricated, including carbon nanowalls, graphene nanoribbons, vertically aligned CNTs and laser induced graphene fibers, we first fabricated laser scribed graphene (LSG carbon grass) with a novel 3D vertical aligned tree-like morphology. We have then used the LSG carbon grass in the application of dopamine detection by means of cyclic voltammetry (CV) and differential pulse voltammetry (DPV). The electrochemical anodic peaks of dopamine (DA), ascorbic acid (AA) and uric acid (UA) using LSG carbon grass electrode were well resolved, where UA and AA were considered as interference. The sensitivity of LSG carbon grass for DA sensing was highly improved compared to normal LSG. The fabricated LSG carbon grass sensor exhibits a sensitivity of 0.299 μA/μM and detection limit of 1 μM. The outstanding performance for dopamine detection using LSG carbon grass is a reflection of the promising future of carbon nanomaterials with interesting high surface area morphologies.

NM01.04.07 Electrochemical Tunneling through Atomically-Flat Hexagonal Boron Nitride Matej Velicky1, 2, 3, Sheng Hu4, Andre K. Geim2 and Robert A. Dryfe1; 1Chemistry and Chemical Biology, Cornell University, Ithaca, New York, United States; 2School of Physics and Astronomy, University of Manchester, Manchester, United Kingdom; 3School of Chemistry, University of Manchester, Manchester, United Kingdom.

Two-dimensional (2D) materials hold promise for a range of electrochemistry-related applications, including energy storage/conversion and sensing. The tunability of the electronic structure of these materials by their thickness or external stimuli such as electric field or strain suggests a range of opportunities in optoelectronics, electrochemical switching, and photocatalysis [1]. Here, we demonstrate electrochemical tunneling across monolayer and few-layer hexagonal boron nitride (hBN), a wide-gap insulator that has gained interest in device encapsulation and solid-state tunnel field-effect transistors [2]. The electrochemical behavior of tunneling devices based on ~5 μm diameter ultramicroelectrodes is studied using reversible redox mediator systems. Optical microscopy, Raman spectroscopy, and atomic force microscopy, are used to characterize the devices. We show that the tunneling current, electron transfer kinetics, and the breakdown voltage depend on the number of hBN layers between monolayer and bulk. We compare our results to other well-studied tunneling systems, such as alkylthiol chain monolayer or thin-layers of solid-state dielectrics.

Our findings show that varying the thickness of the hBN yields a tunable electrochemical response, which provides fundamental insight into the electrochemical tunneling behavior across atomically-flat insulating materials and could be exploited in applications such as electrochemical switching or surface passivation.

NM01.04.08 Electrochemical Supercapacitors from Hybrid Porous Graphene-Based 3D Structures Decorated Carbon Nanotubes-Nanoparticles Neftali L. Carreno, Jose H. Alano, Bruno Noremberg, Ricardo Marques Silva, Guilherme Maron and Lucas Rodrigues, University Federal-Pelotas, Pelotas - RS, Brazil.

The search for new supercapacitors materials is extreme importance for the development of the future of the energy sector. This is due to the fact that the technology evolution, which demands increasingly alternative devices, fast load, high power and great storage. Thus energy storage devices are currently the focus of several studies, both in the academic and industrial sector, the energy sector depends strongly on the development of the new materials. At the forefront of the materials used for electronic devices, the carbon-based materials such as graphene hybrid system with oxide (GO), carbon nanotubes (CNT) could be significant modified by chemical methods and morphology. These materials are widely used due to low density, high surface area and high hold capacity. Thus, the objective of this work is to obtain a composite on porous graphene-based 3D structures (like sponge) decorated with nanoparticles like chalcogenides (ZnS, MoS2), transition metal (Ag, Fe, Ni), nickel cobaltite (NiCo2O4), metal oxides (In2O3, SnO2, ZnO), each nanoparticles system were previously grew homogeneously and well dispersed on the multiwalled carbon nanotubes (MWNTs), under microwave-assisted hydrothermal synthesis (MHS). These hybrid composite display interesting morphology and appropriate electrochemical properties to be applied as electrodes for supercapacitors.

NM01.04.09 Temperature Dependence of Photoluminescence Spectra from a Suspended Single-Walled Carbon Nanotube with Water Ad sorption Layer Yuichiro Tamaka1, Yuta Saito1, Kazuki Yoshino1, Akiko Ora1, Shohei Chiashi1 and Yoshikazu Honma2; 1Tokyo University of Science, Shinjuku, Japan; 2The University of Tokyo, Bunkyo, Japan.

Thermal property of the single-walled carbon nanotube (SWCNT) has been intensively studied because the SWCNT is expected to be an excellent heat transport material. Many measurement methods of thermal conductivity of SWCNTs have been proposed and photoluminescence imaging spectroscopy is one of the powerful methods [1]. In this method, a suspended SWCNT is irradiated by laser, and the spatial distribution of the PL emission energy (E11) along the SWCNT axis is measured by a near-IR 2D camera, which is converted to the temperature distribution. The thermal conductivity is obtained from the temperature distribution. Thus, the accurate conversion of E11 emission energy to temperature is crucial in this method. The temperature dependence of E11 is simply expressed by Varshni’s equation independent of SWCNT chirality (n,m) when SWCNTs are in vacuum. On the other hand, when SWCNTs are located in the ambient air, water molecules adsorb on the outer surface of SWCNTs and they affect the energy of E11 [2]. Elucidation of the temperature dependence of E11 of SWCNTs with water adsorption layer is necessary to measure the thermal conductivity of SWCNTs in the ambient air. In this study, we measured the temperature dependence of the E11 in suspended SWCNTs with water adsorption. Suspended SWCNT was synthesized by
chemical vapor deposition method on a quartz pattern substrate. PL spectra were measured from suspended SWCNTs with different chirality under controlling temperatures (220 to 300 K). SWCNTs were exposed to water vapor at 300 K and the water adsorption layer was formed. It was found that the energy shifts of E11 exhibited a complicated temperature dependence depending on chirality in the case of SWCNTs with the adsorption layer. The energy shift was understood as the summation of intrinsic temperature dependence of the band-gap, the strain effect and the change of the dielectric constant of the adsorption layer. When the temperature decreased, axial strain due to the adsorption layer occurred in SWCNT. The strain changed E11 and the change clearly exhibited type-dependence [3]. The dielectric constant of the adsorption layer simply increased with decreasing temperature. Although the interaction between SWCNT and the water adsorption layer is weak, the adsorption layer drastically affected the optical properties of SWCNTs. By taking those effects into account, we could accurately determine the temperature along the tube axis.

Multifunctional Graphene Nanocomposites for 3D Printing Applications
Maria Soria Sanchez and Gerard Tobias Rossell; Solid State Chemistry, Institute of Material Science of Barcelona, Barcelona, Spain.

In a relatively short time, 3D technology has become a new method for manufacturing prototypes and is occupying a first place in terms of research in multiple universities across the world, as well as the searching of new materials with advanced properties suitable for the development of prototypes with 3D printing. In this sense, layered graphene represents one of the most impressive materials for this purpose, due to the combination of its properties like high electrical and thermal conductivity or high mechanical strength. The main objective of the present research work is to study the impact that graphene has over the properties of the selected polymer when they are integrated in a unique compound forming a nanocomposite. In order to facilitate the integration of both components, graphene and polymer, chemical and structural modification of the layered graphene has been necessary. These modifications of the graphene lead to an improvement in the dispersion of both components, which has shown to be a critical parameter for the stress transfer from the nanoparticles to the matrix. In this way, modified graphene has been synthesized through different chemical processes, what first includes the synthesis of graphene oxide (GO) from graphite and its subsequent chemical reduction with different chemical reducing agents to obtain the reduced graphene oxide (rGO), which has similar properties to graphene. Lyophilization of the resulting graphene samples has been also carried out in order to increase the distance between graphene layers and improve the dispersion. Two different strategies has been employed during the synthesis of the nanocomposites: direct integration of the reduced graphene oxide (rGO) into the matrix of the polymer through solution in proper solvents (DMF and THF), and reduction in situ of the graphene oxide already integrated into the polymer structure. In both cases it is necessary the complete elimination of the solvent to ensure that the electrical and mechanical properties of the nanocomposite are not affected by the presence of traces of solvent. Polymers most commonly used in 3D printing have been used in this work, including ABS, PCL and PLA filaments. Nanocomposites were prepared with several loads of graphene between 3% and 15%, in order to compare the mechanical and electrical properties before being used in 3D printing. Graphene loading is also an important factor to take into account since too much loading could hinder the printing process due to the formation of graphene agglomerates. Characterization techniques employed to evaluate the samples have shown that the mechanical reinforcement of the polymeric structures is possible by addition of both GO and rGO. It also been establish that a well dispersed rGO into the matrix not only improves properties in relation to strength and fracture toughness, but also electrical conductivity of the nanocomposite, which is not possible to get by adding only GO.

NM01.04.12
Mesoscopic Simulations of Cross-Linked Carbon Nanotube Materials—Quasi-Static Mechanical Loading, Wave Propagation and Shear Lag Effect
Md Abu Horaira Banna, Arun B. Thapa and Alexey N. Volkov; University of Alabama, Tuscaloosa, Alabama, United States.

Individual carbon nanotubes (CNTs) are one of the strongest materials in nature. Networks of pristine CNTs, however, do not show similar superior mechanical properties due to weak load transfer between individual CNTs via van-der Waals interaction. Shear load transfer between CNTs can be improved by introducing covalent cross-links between nanotubes by means of ion or electron beam irradiation or chemical functionalization. The goal of this work is to quantify the effect of cross-links on quasi-static and dynamic mechanical properties of CNT network materials like CNT films, fibers, and aerogels in large-scale mesoscopic simulations. In our mesoscopic computational model, every nanotube is represented by a chain of stretchable cylinders. Mesoscopic force field accounts for stretching, bending and buckling of individual nanotubes, van-der Walls interactions, and cross-links between nanotubes. In order to account for the load transfer on individual CNTs, we developed a novel effective bond model. This model is parameterized based on results of atomistic simulations of pulling out of a central CNT from a seven-tube bundle performed in a range of CNT diameters and cross-link linear densities. The developed model is first applied to study the shear load transfer in long CNT bundles. The simulations reveal extremely strong shear lag effect, which sets limits on the ability of cross-links to reinforce nanotube bundles. Next, we perform simulation of quasi-static and dynamic wave loading of CNT films, aerogels, and fibers. The equilibrium networks structures in these materials are obtained in preliminary mesoscopic simulations as a result of self-assembly of dispersed nanotubes into networks of entangled bundles. The cross-links are distributed inside these in-silico generated CNT material samples in order to simulate the process of irradiation or chemical functionalization of pre-existing networks of nanotubes. The simulations show that the dominant mechanisms of non-reversible structural changes in CNT networks under an applied mechanical load strongly depend on the deformation rate. The elastic and inelastic properties of CNT materials, as well as the acoustic speed, are found for materials with various degrees of anisotropy, density, CNT length, and density of cross-links. This work is supported by the NSF CAREER award CMMI-1554589 and NASA Early Stage Innovations program (project NNX16AD99G).

NM01.04.13
The Interaction of Carbon and Boron Nitride Nanotubes with Metals
Christoph Rohmann1, 2, 3, Zwolak Michael1 and Searles Debra1; 1Center for Nanoscale Science and Technology, National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 2The Institute for Research in Electronics and Applied Physics, University of Maryland, College Park, Maryland, United States; 3Australian Institute for Bioengineering and Nanotechnology, The University of Queensland, Brisbane, Queensland, Australia.

The interaction of carbon and boron nitride nanotubes with metals is significant for a wide variety of applications. For example, the binding of tubes to transition metal nanoparticles plays a role in their catalytic growth, as well as in their nucleation. Similarly, the strength of nanotube-metal composites crucially depends on the interaction strength between the tube and the metal matrix. We performed quantum chemical calculations to investigate the binding strength and geometry of a variety of metals with carbon and boron nitride nanotubes. We examined both, binding by individual metal atoms and the interaction with metallic surfaces to identify possible candidates for the creation of novel metal matrix composites.
Ricin (MW~64 KDa) is one of the most toxic proteins, with LD₅₀ varying from 10 μg to 20 mg/kg depending on the uptake pathway. Being soluble in water, it's quite easy to extract from castor bean seeds. Ricin belongs to Ribosomal inhibiting protein (RIP) family and was classified by CDC (Centre of disease and control and prevention) as a category B bioterrorism agent. Detection of Ricin before or even after being assimilated may be critical to survival, as there is no efficient counter-measure against its poisoning. Ricin is composed by two chains, one bearing the enzymatic activity (chain A, RNA glycosidase) and the other one acting as a recognition/transportation moiety (chain B, galactose-binding lectin). Current methods for its detection are essentially based on SPR, ELISA, colorimetric and Raman (SERS) techniques.¹

SALDI-MS (surface assisted laser desorption ionization mass spectrometry) concerns the use of nanostructured materials (mainly carbon and semiconductive ones) that will absorb energy from UV laser helping the desorption/ionization of the analytes (with no use of organic matrix in the contrary to MALDI) followed by their subsequent detection by MS. Among their known properties, they should be anti-reflective, have low photoluminescence and low thermal conductivity. They have been shown to be very salt tolerant and highly sensitive to small compounds.² Recently, we have demonstrated that vertically aligned boron doped graphene sheets (known as carbon nanowalls, CNWs) are suitable nanomaterials for SALDI-MS detection of various small compounds including carbohydrates, lipids, peptides etc.³ However, detecting larger compounds by SALDI-MS such as proteins is still challenging. Indeed, only few examples of protein detection by SALDI-MS have been reported so far.⁴

Here, we propose, for the first time, to use CNWs for the SALDI-MS detection of the Ricin B chain (32 KDa) from buffered solutions and blood serum. A systematic study was conducted to optimize our interface by varying the dimensions of the nanowalls and the boron doping level. Other important parameters such as thermal conductivity, electrical resistivity, morphology, internal energy deposition, optical properties were also studied and discussed in correlation with the protein detection performances. Finally, the detection of Ricin was achieved and a limit of detection (LoD) found to be 8 ng/0.5 μL, meaning that for an average person weighting 70 kg, the lowest ricin’s LD₅₀ can still be detected. The ability of our CNWs to detect proteins via SALDI-MS paved the way and opened new opportunities to matrix-free LDI-MS, still limited to small compounds detection so far.

Micro-Fabricated Individual CNT Point Cathode Field Emission Electron Source for Focused Electron Beam Applications
Xiuyuan Shao, Amit Banerjee and Anjam Khursheed; Department of Electrical and Computer Engineering, National University of Singapore, Singapore, Singapore.

There is remarkable interest and potential for field emission technology for the development of cold field emission sources for ultra-high-resolution scanning electron microscopes, lithography and other applications. However, some inherent problems have prevented the widespread practical usability of these sources, e.g. inherent ultrahigh vacuum condition requirement (10⁻¹⁰ torr), relatively poor current stability and rapid emission decay. The current report presents a cold field emission electron source which overcomes these problems based upon using a resist-assisted patterning process fabricated carbon nanotube (CNT) electron emitters. The CNT emitter was grown on a silicon (Si) substrate by direct current plasma-enhanced chemical vapor deposition (DC-PECVD), using nickel (Ni) catalytic layer patterned by a conventional photolithography process, which provided several micron-scale CNT seeds and photoresist required for CNT growth. The patterned sample was formed at 600°C over 30 min under ambient argon (Ar) in DC-PECVD. The resulting CNT emitter featured unique structural properties and the geometry is determined by the temperature, total pressure, gas ratio, and in optimized process conditions for one individual CNT emitter growth. Preliminary experiments on one free-standing CNT emitter electron beam properties with tip radii ranging from 5 nm to 60 nm demonstrate to be promising in terms of current stability, high brightness, coherence, low energy spread, and small virtual source sizes, comparable to state-of-the-art conventional cold field emission sources. The freestanding CNT emitter cold-cathode electron sources have promising application possibilities to a variety of electron microscope or lithography devices, fabrication of compact glass-sealed x-ray tubes and cold cathodes for high-resolution imaging.

NM01.04.16
Towards Pure and Large-Scale Hexagonal Boron Nitride 2D Layers—A Unique Combination of PDCs Route with SPS Process
Yangdi Li,¹ ² Catherine Journet-Gautier², Bérangère Toury², Vincent Garnier¹ and Philippe Steyer¹; ¹MATEIS, INSA Lyon, Villeurbanne, France; ²LMI, Université Lyon, Villeurbanne, France.

Since graphene's properties are strongly linked to the substrate on which it is deposited, it is clear that the promising future development of practical graphene devices will necessarily go through the development of insulating substrates on which graphene can be deposited without changing its intrinsic properties. As one of the most suitable substrates, hexagonal boron nitride nanosheets (BNNSs) are promising 2D materials for their exceptional chemical and thermal stabilities together with electrical insulating properties. These capabilities make it interesting as support for graphene in devices and also as clean, flat insulating environment for materials of heterostructure. However, in order to make h-BN relevant for real world applications, scalable synthesis routes are needed. As a consequence, the development of a novel source for highly crystallized h-BN crystals, suitable for a further exfoliation, is a prime scientific issue. We have developed a promising approach to synthesize pure and highly-crystallized h-BN crystals, which can be further exfoliated into high quality, ultrathin, uniform BNNSs. This new accessible production process represents a relevant alternative source of supply in response to the increasing need of high quality BNNSs. The synthesis strategy is based on a unique combination of Polymer Derived Ceramics (PDCs) route with Spark Plasma Sintering (SPS) process. Through a multi-scale chemical and structural investigation, it is clearly shown that obtained layers are large, defect-free and well-crystallized, which are key-characteristics for a subsequent exfoliation into relevant BNNSs.

Ultralow Platinum Carbon Electrodes by Cathodic Polarization Treatment for Efficient Hydrogen Peroxide Sensing
Muhammad Adil Riaz and Yuan Chen; School of Chemical and Biomolecular Engineering, The University of Sydney, Sydney, New South Wales, Australia.

Hydrogen peroxide (H₂O₂) is a widely used oxidizer, bleaching agent, and disinfectant in many fields, such as food processing, medicine, and environment. Thus, detecting the trace amount of H₂O₂ is essential for many industrial and biological applications. Electrochemical H₂O₂ sensors, especially nonenzymatic ones, have attracted significant interests because of their relatively simple operation, low cost and fast response. Platinum (Pt) based Electrochemical H₂O₂ sensors demonstrate superior sensing performances, i.e., higher sensitivity, wider detection concentration range and lower detection limit. However, the high mass loading and cost of Pt limits their practical applications. Here, we develop a cathodic polarization treatment method to deposit ultralow mass loading of Pt nanoparticles on a high surface area (385 m²/g) porous carbon composite substrate comprised of reduced graphene oxide (rGO) and carbon nanotubes (CNTs). Using multiple cyclic voltammetry (CV) cycles at the specific potential window (-0.8-0 V vs. standard caramel electrode) in 0.5 M H₂SO₄ electrolyte without Pt precursors, about 3.89 wt.% of Pt nanoparticles were anchored on the rGO-CNT composites with a
narrow size distribution around 1–2 nm from a Pt mesh anode. Furthermore, different Pt mass loadings on rGO-CNT composites were obtained by varying the CV cycles and their morphological and physicochemical properties were characterized by SEM/EDS, TEM, and XPS along with H$_2$O$_2$ sensing performance to understand the synthesis-structure-property relationships. The optimized Pt/rGO-CNT composite obtained at 3000 CV cycles shows superior H$_2$O$_2$ sensing performances with a detection limit of 10 µM, a wide linear range up to 15 mM, and the sensitivity of 2027 µA/mM·cm$^2$, which are one of the best among recently reported Pt/carbon composites and commercial 20 wt.% Pt/C catalysts. Further, the Pt/rGO-CNT sensor can also detect trace amount of H$_2$O$_2$ in milk and juice samples, demonstrating their excellent practical application potentials.

NM01.04.18
Selenium-Functionalized Graphene Oxide that Can Modulate the Balance of Reactive Oxygen Species Jiahao Xia and Huaping Xu; Department of Chemistry, Tsinghua University, Beijing, China.

Graphene oxide (GO) is an important two-dimensional material since it is water soluble and can be functionalized to adapt to different applications. Diselenide bond is a dynamic covalent bond and can respond to both redox condition and visible light irradiation in a sensitive manner. In this work, by combining the stimuli response of diselenide bond and the oxidative/radical attackable nature of GO, we achieved the in situ covalent functionalization of GO simply by stirring GO with diselenide-containing molecules in aqueous solution. The covalent functionalization was proven by FT-IR, Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS), Atomic Force Microscopy (AFM), etc. And the functionalization mechanism was deduced to involve both redox reaction and radical addition reaction according to the XPS, Atomic Emission Spectroscopy (AES), etc. Moreover, we found the selenium-functionalized GO could modulate the balance of reactive oxygen species (ROS). Specifically, GOSe could decrease ROS level by accelerating the reduction of peroxides when the ROS concentration is high while boosting the ROS level by in situ generating ROS when its concentration is relatively low.

High Aspect Ratio Nanomaterials in Corrosion Protection Composite Coatings David W. Johnson1, Alex Borak1, Carmen Espejo2, Simon Gibbon1, Steven Gourlay1, David James3, Jennifer MacKay3 and Jonathan Moghal1; 1Centre for Process Innovation, Sedgefield, United Kingdom; 2Crown Technology, Wantage, United Kingdom; 3Akzo Nobel, Northallerton, United Kingdom; *Akzo Nobel, Birmingham, United Kingdom; Thomas Swan, Consett, United Kingdom.

Anti-corrosion coatings are ubiquitous with an expected market value of $20 billion by 2025. Current innovation is being driven by both demand and regulatory restrictions. (Global Market Insights 2016) A promising option is the incorporation of high aspect ratio nanomaterials (HARNs), such as graphene and boron nitride, as polymer composite coatings. (Liu, et al. 2016)

It has previously been shown that platelet like materials can improve the performance of anti-corrosion coatings. This is typically thought to be due to the creation of a "tortuous path" in which corrosive media (typically water, electrolytes and oxygen) must follow a long path through a network of impermeable filler to reach the metal substrate. (Zheng, et al. 2017) This effect is maximised when the platelets are high aspect ratio and aligned parallel to the metal substrate.

While the concept of such a system is simple there are several complex factors to consider in the production of a working coating. In producing HARNs it is challenging to control morphology and achieve both the large lateral dimensions and the thin sheet sizes desired. Dispersing HARNs in resin also presents challenges as aggregates reduce the effective aspect ratio and risks creating porous structures through which electrolytes can penetrate. Once dispersed the nanomaterial must remain wetted by the resin throughout the cure process to avoid generating voids and an associated decrease in performance. Finally, the coating must remain adhered to the substrate and not delaminate.

In this work we present data on the effect of HARN morphology and surface energy on the barrier performance of a protective coating. Consideration is given to how these variables may affect nanomaterial dispersion quality, porosity and interaction with the metal substrate. Initial results indicate that dispersion quality and HARN surface chemistry both influence performance.

NM01.04.20
Heterogeneous Metal Oxide-Graphene Porous Single Fiber Derived from Engineered Graphene-Tunicate for Sensitive Chemiresistor Ji-Soo Jang and Il Doo Kim; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Graphene oxide liquid crystal (GOLC) behavior is very intriguing and powerful phenomenon, especially for simply achieving graphene-based fibers, which have ordered graphene alignments in fiber. Taking advantages of graphene based fiber such as high mechanical strength, electrical conductivity, and supercapacitive behavior, various applications such as energy storage, photovoltaic cell, and chemical sensing have been explosively exploited. Although graphene based fiber have opened up great opportunities for various researches, high graphene density in graphene based fiber is disadvantageous for the creation of pores on graphene based fiber. This effect is maximised when the platelets are high aspect ratio and aligned parallel to the metal substrate.

In this work, we propose a facile synthetic route for providing high density of pores in graphene based fiber by employing tunicate cellulose nanofiber (TCNF) engineering. For the first time, by using the liquid crystal (LC) behavior of graphene oxide (GO)-TCNF composite, we successfully develop the ultra-porous GO fibers due to the random distribution of TCNF in GO fiber. Furthermore, by using the super-hydrophilicity of TCNF, TCNF in GO fiber is also used as seed layer for growth of WO$_3$ nanorods (NRs), leading to formation of porous WO$_3$ NRs-GO thorn-bush like composite single fiber. Due to its high porosity and heterogeneous junction effect (WO$_3$ NRs-GO), porous WO$_3$ NRs-GO showed reversible NO$_2$ detection capability even at 1 ppm level of NO$_2$ chemicals.
Design of Microwave Absorption Structures Based on Magnetite Multi-Granule Nanocluster–Multiwall Carbon Nanotube Composite Materials

Boo Hyun An1, Bum Chul Park2, Sahith R. Madara1, Hamad Al Yass1, Jung-Rae Park4, Jong E. Ryu1, Mihai Sanduleanu1, Young Keun Kim1 and Daniel S. Cha1; 1Kaifila University of Science and Technology, Abu Dhabi, United Arab Emirates; 2Korea University, Seoul, Korea (the Republic of); 3Amity University, Dubai, United Arab Emirates; 4Minotech, Charlton, Massachusetts, United States; 5North Carolina State University, Raleigh, Indiana, United States.

Recently, reduction and cancellation technique of microwave has been widely studied in military and civil areas for various applications such as radar absorption, electromagnetic interference (EMI) shielding, reduction of electromagnetic wave pollution, and wireless communication fields. Research on microwave absorption materials is widely conducted by adopting dielectric and magnetic powder material to conductive matrix, because the conductivity, dielectric constant and permeability of the materials are contributing to the microwave absorption efficiency of the materials. [1-3]

Carbon nanotubes (CNT) are good candidate materials for the conductive matrix of microwave absorption composite structures due to their high electrical conductivity, light weight, and easiness to form thin layers. Ferrite nanostructures are generally used for microwave absorbing materials due to their magnetic and dielectric property. The electromagnetic properties of ferrites are different depending on microstructural and physical properties of the ferrites such as chemical composition, crystal structure, crystallite size, particle size. Such properties can be controlled by synthesis techniques and our novel synthesis method of multi-granule nanocluster (MGNC) of magnetite (Fe3O4) by controlling the cluster and granule size with the modified hydrothermal polyl process was previously reported [4].

In this study, we fabricated Fe3O4 MGNC – multiwall CNT (MWCNT) composites by using the surface-engineered tape-casting (SETC) method with various granule and particle size of MGNCs. The microstructural and microwave absorption properties in X-band (8.2 GHz – 12.4 GHz) with different granule size of the nanoclusters are investigated. Design and three-dimensional (3D) printing of the 3D metamaterials based on the nanocomposite materials made up of MGNC and MWSNT are also in progress.

Designing a Catalyst for Carbon Nanotube Growth by \textit{Ab Initio} Molecular Dynamics with Respect to the Carbon Source Molecule Dissociation Process Satoru Fukuhara1, Masaaki Misawa2, Fuyuki Shimjo2 and Yasushi Shibuta3; 1Department of Materials Engineering, The University of Tokyo, Tokyo, Japan; 2Department of Physics, Kumamoto University, Kumamoto, Japan.

For the application of carbon nanotubes (CNTs), a synthesis method which can control its property (e.g. length, diameter and chirality) is required. Catalytic chemical vapor deposition (CCVD) method is the standard way to produce CNTs. In this method, the quality and quantity of CNTs largely depends on the combination of the catalyst and the carbon source. For example when using ethanol as the carbon source, which C-O bond or C-C bond dissociates have effect on CNT growth. In order to develop a better catalyst, it is required to know the mechanism of the dissociation process. In this research, we clarify the difference of carbon atom dissociation reaction mechanism by catalysis element from the atomistic viewpoint, using the \textit{ab initio} molecular dynamics method (AIMD method) and clarify the advantages of using the alloy catalyst and give guidance to new catalyst design. The dissociation process of ethanol and carbon monoxide on Fe, Co, FeCo alloy catalyst is investigated by AIMD. 30 ethanol molecules and 30 carbon monoxide molecules are placed around the Fe12, Co12, Fe6Co6 clusters, respectively. The dissociation process of 5 ps for ethanol molecules and 2 ps for carbon monoxide molecules is analyzed at 1500 K. C-H bond and C-O bond of ethanol have been observed to dissociate on each catalysts, but C-C bond dissociation is only observed on Fe6Co6 catalyst. Regarding the calculation of carbon monoxide, C-O bond dissociation is only observed on Fe catalyst.

We have clarified that bond formation of oxygen and metal atoms is important in dissociation reaction mechanism. Specifically, strong bonds with oxygen as seen with Fe atoms are disadvantageous in C-C bond dissociation but are necessary for C-O bond dissociation in ethanol and CO molecules. From these results, it is possible to design a catalyst that dissociates both C-C bonds and C-O bonds by alloying elements that form strong bonds with oxygen.

The Effect of Heat Treatment on the Structural Development and Mechanical Properties of Carbon Fibers Jeong-Fum Lee, Sojeong Hae, Kyeonghun Choi, Sang-Ha Hwang, Youngho Eom and Han Gi Chae; Ulisan National Institute of Science and Technology, Ulisan, Korea (the Republic of).

Carbon fibers have been of great interest in many industrial applications due to their high specific mechanical properties. The tensile strength of the polyacrylonitrile (PAN)-based commercial carbon fiber is as high as 7 GPa, and the highest tensile modulus is about 600 GPa although the theoretical properties of carbon fibers are known to be 150 GPa and 1000 GPa, respectively. The property discrepancy is attributed to the defective structures including voids and structural heterogeneity. In addition, carbon fibers are often subjected to extreme environment such as high stress and high temperature, which may change their microstructure and properties. In this study, we have heat-treated commercial carbon fibers as high as 2400 °C without applying external stress, and traced the changes in microstructure using Raman spectroscopy, wide-angle X-ray diffraction, and X-ray photoelectron spectroscopy. The tensile testing and nano-indentation experiment were also conducted to examine the correlation between the microstructural variation and corresponding mechanical properties. The structure-property relationship of carbon fibers upon high temperature heat treatment will be presented.

Using Cell Membrane Models to Investigate the Toxicity of Carbon-Based Nanomaterials Juliana Cancino1, 2 and Valtencir Zucolotto3, 2; 1University of Sao Paulo, Sao Carlos, Brazil; 2Nanomedicine and Nanotoxicology Group, University of Sao Paulo, Sao Carlos, Brazil.

Single-wall carbon nanotubes (SWCNTs) and polyanidoamine dendrimers (PAMAM) have been proposed for a variety of biomedical applications due to their unique physico-chemical properties. However, toxicological studies have shown that these nanomaterials may exhibit high toxicity in biological environments. In this study we used C2C12 murine cells and membrane model systems to understand the interactions occurring at the bio-nano interface, as well as the possible toxicity exhibited by SWCNT-PAMAM conjugates against mamalian cells. The results showed that SWCNT-PAMAM and PAMAM inhibited the proliferation and caused DNA damage in C2C12 cells. Flow cytometry analyses revealed a less toxicity in C2C12 cells exposed to SWCNT compared to the other nanomaterials. The toxicity of SWCNT, SWCNT-PAMAM, and PAMAM in C2C12 cells are strongly correlated with the charge of the nanomaterials. The membrane model studies revealed a pronounced incorporation of SWCNT-PAMAM through dipalmitoylphosphatidylcholine (DPPC) monolayers even at high surface pressure values, ~30 mN/m. Therefore, the results confirm that the presence of the nanomaterial affects the packing of the synthetic membrane monolayers. The methodology introduced here may be of great importance for further nanotoxicity studies.

Detection of Acute Kidney Injury Biomarker Using Reduced Oxide Graphene Transistors Fabricio Santos1, 2, Nilton C. Vieira1, Naiara Zambianco1 and Valtencir Zucolotto1, 2; 1University of Sao Paulo, Sao Carlos, Brazil; 2Institute of Science and Technology, Federal University of Sao Paulo, Sao Jose dos Campos, Brazil, Brazil; 3Nanomedicine and Nanotoxicology Group, University of Sao Paulo, Sao Carlos, Brazil.

The early detection of biomarkers of renal damage is important because the glomerular filtration rate is reduced before the onset of the signs of renal failure. Cystatin C is a protein that has been identified as the most promising biomarker to acute kidney injury diagnosis in early stages. Here, we introduce a papain-modified graphene oxide field-effect transistor (rGOFET) for the detection of Cystatin C with enhanced sensitivity. The rGOFETs were fabricated using the layer-by-layer (LBL) technique, employing oppositely charged rGO onto interdigitated gold electrodes. Detection of Cystatin C occurred via electrical measurements upon monitoring output and/or transfer curves of rGOFETs. The detection mechanism is based on changes of the charge balance at the electrode surface after the formation of papain/cystatin C complex. Cystatin C could be detected at a concentration range from 5 ng/mL-1 to 100 ng/mL-1 with 0.13 mV/nmL-1 sensitivity, suggesting that the system may useful for clinical purposes.

Enhanced Conductivity and Thermal Stability of Carbon Nanotube Yarns via Densification and Chemical Doping Karen Soule1, 2, Colleen C. Lawlor1, 2, Andrew R. Bucoissi3, Cory D. Cress, Ivan Puchades1, 2 and Brian Landi1, 2; 1Nanopower Research Laboratory, Rochester, New York, United States; 2Electronics Science & Technology, U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

Carbon nanotube (CNT) based conductors are candidate light-weight and robust alternatives to conventional metal conductors for a variety of space, defense, and power transmission applications. Although the conductivity of bulk CNT materials is still an order of magnitude less than copper conductors, these demanding applications can benefit from the reduction in weight, increased flexure tolerance, and corrosion resistance provided by CNT conductors. Previously, CNT conductors have been produced from commercially available CNT sheet material, which is rolled into wires of varying diameter. Radial densification and chemical doping with aqueous KAuBr4 has been used to increase the conductivity of these rolled conductors by an order of magnitude.
These works demonstrated the possibilities of CNT conductors along with the effects of densification and chemical doping, but these techniques are limited in scalability due to the batch nature of CNT sheet production. Recently, continuous processes have allowed for the production of CNT yarns available in kilometer lengths, a breakthrough needed for the practical implementation of CNT conductors. With the synthesis of scaled CNT conductors, the operational stability of these materials along with the accompanying chemical doping procedures needs to be explored.

NM01.04.30
Polyacrylamide Covalent Grafted on Graphene Oxide (GO) Surface for Extraction of Chromium(VI) Pei P. Yang1, 2, Ruimin Li1, 2 and Jun Wang1. 2, 3, College of Materials Science and Chemical Engineering, Harbin Engineering University, Harbin, China; 4, Key Laboratory of Superlight Material and Surface Technology, Ministry of Education, Harbin University, Harbin, China.

With the rapid growth of industrialization, water pollution caused by heavy metals has become one of the most serious environmental problems, and attracted considerable attention. Heavy metals are non-degradable and can accumulate in living tissues, so they must be removed from wastewater. Extraction of heavy metals from wastewater embraces reverse osmosis, chemical precipitation, electrodialysis, organic−inorganic ion exchange, and adsorption. Among these methods, adsorption plays a significant role due to its simple operation and cost-effectiveness. Thus far, the most efficient adsorbent for the adsorption of heavy metals have not been suitable for application at wastewater pH. Currently, the design of a suitable wastewater adsorbent shows more promise for the extraction of heavy metals. In this report, we report a facile approach to construct a suitable wastewater pH and large surface area material that polyacrylamide (PAM) covalent grafted onto the surface of GO nanosheets. In the progress, transmission electron microscope (TEM), X-ray diffraction (XRD), X-ray photoelectron spectroscopy (XPS) and Fourier transform infrared spectroscopy (FTIR) were used to determine the effectiveness of the synthesis of GO-PAM composites. Meanwhile, the GO-PAM composites were investigated for adsorption of Cr(VI) from aqueous solution. It is clear that the GO-PAM composites have a high adsorption capacity (qm = 398.2 mg g⁻¹, t=298.15 K) at a suitable wastewater pH with a high removal rate (~90%). Based on the FTIR spectroscopy, Zeta potential, and X-ray photoelectron spectroscopy (XPS), a possible adsorption mechanism of Cr(VI) onto GO-PAM composites is revealed. Finally, the result also exhibited outstanding adsorption efficiency and adsorption capacity under the operating conditions for the adsorption-desorption of Cr(VI) from aqueous solution, which indicated a promising potential in the application of the absorbent in wastewater. (This paper is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.)

Are Carbon Nanotubes Intrinsically Hydrophilic? Grzegorz Stan1, Damian Łukawski2, Filip Lisiecki3 and Dawid Janas1; 1, Silesian University of Technology, Gliwice, Poland; 2, Faculty of Technical Physics, Poznan University of Technology, Poznan, Poland; 3, Institute of Molecular Physics, Polish Academy of Sciences, Poznan, Poland.

Although carbon nanostructures such as carbon nanotubes (CNTs) and graphene have shown promising properties on the electrical [1], thermal [2] and mechanical [3] fronts, their implementation is somewhat restricted because they are incompatible with the most of traditional polymer matrices. The problem is commonly explained by the nature of their surface, which has been considered as highly hydrophobic for many years. The employed main-stream solution is focused on chemical functionalization to introduce certain functional groups to make the surface hydrophilic. We have recently shown that carbon nanotube networks can have unexpectedly high hydrophilic character without any grafting if the films are briefly annealed at high temperature, which does not need to involve oxidation [4,5]. In this contribution, we would like to present an explanation of this effect and mark what are the most immediate applications of this high-performance material.

Enhancement of X-Ray Shielding Properties of PVDF/BaSO4 Nanocomposites Filled with Graphene Liliane A. Silva1, Adriana M. Batista2 and L.O. Faria3; 1Engenharia Nuclear, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2Anatomia e Imagem, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 3Materials, Development Center of Nuclear Technology, Belo Horizonte, Brazil.

Carbon nanotubes (NTCs) and graphene-based nanocomposites have been reported to enhance the X-ray shielding effects, for photons with energy below 17 keV [1,2]. The mechanisms behind this anomalous behavior cannot be interpreted by the already established X-ray absorption theory. In this work, we report additional evidences of the improvement of X-ray attenuation efficiency by the addition of a very small amount of reduced graphene oxide (4.0 wt %) in polymer composites made of poly(vinylene fluoride) (PVDF) homopolymer and barium sulfate (BaSO4) nanoparticles. The investigation was performed by using polycrystalline spectra produced by an X-ray tube energized with 20, 30, 40, 60, 80 and 100 kV. For the lowest voltage (20 kV), the beam attenuation for pure PVDF/BaSO4 nanocomposite (50%/50%) and the one with the addition of 4.0 wt % of rGO was found to be 9.14% and 24.56%, respectively. The respective linear attenuation coefficients (μ) were 39.9 cm⁻¹ and 54.4 cm⁻¹, respectively. The X-ray attenuation gradually decreases until 6.71% and 17.62%, respectively, for the highest energy spectrum (100 kV). Fourier transform infrared data revealed that, due to the lack of the bending vibration modes of CF₃ molecule at 656 cm⁻¹, 688 cm⁻¹, 723 cm⁻¹, 776 cm⁻¹ and 796 cm⁻¹, characteristics of the γ-crystalline phase of PVDF, the nanocomposites casted from solution are mostly in the β-ferroelectric phase of PVDF, besides the γ-paraelectric phase. SEM micrographs were used to
evaluate the dispersion state of graphene sheets and the BaSO4 nanoparticles into the polymeric matrix. UV-Vis spectrometry and Differential Scanning Calorimetry were also performed in order to complement the structural analysis. The results confirm that the addition of graphene sheets in PVDF polymer-based nanocomposites enhances the X-ray features. The phenomenon is discussed in terms of the reported anomalous negative thermal expansion coefficient of graphene sheets [3].

The Stability of Humidity Sensor Response in Graphene by Low Damage Plasma Chung-Huan Lin Lin1, Mingshiu Tsai1, Weitong Chen1, Chihsien Huang2, Weiyen Wong1 and Chiting Lin1; 1Graduate Institute of Electronics Engineering, National Taiwan University, Taipei, Taiwan; 2Materials Engineering, Ming Chi University of Technology, New Taipei, Taiwan; 3Physics, National Central University, Jangli, Taiwan.

Graphene has been recognized as a promising material for sensing applications, such as gas detection and biomolecular sensor. Although it has been demonstrated to have good sensitive characteristics, some essential aspects such as stability need to be improved for further applications. To conquer these obstacles, different kinds of surface functionalization, for example particle doping, chemical modification, and UV irradiation are used to demonstrate improvements of repeatability and stability with the cost of sensitivity degradation. Following surface functionalization idea, in this work, we used a low-damage oxygen plasma to functionalize a bilayer graphene sheet without high-energy ion bombardment and UV irradiation damage on the graphene structure. This leads to an improved stability of the developed bilayer graphene humidity sensor. Based on the experimental observation of Raman spectroscopy, the D/G ratio showed the result of the low-damage plasma functionalization and the integrity of graphene structure. Utilizing XPS spectra, at the same time, we found the fact that the compositional ratio of C-OH is increased with modified time. Similar observations can also be indicated by wettability enhancement by contact angle measurement. According to these experimental characterizations, one possible scenario is that the upper layer of the bilayer graphene is the one of the functionalization and the lower layer of the bilayer graphene keeps its original 2D structure. Then the developed low-damage bilayer graphene can be experimentally demonstrated as a humidity sensing material. Compared with traditional graphene humidity sensors, the developed low-damage bilayer graphene humidity sensor has less drifting. The drifting result is followed from the x electron adsorption, which can easily adsorb molecules, including the water molecule and the other air molecules. These adsorbed molecules are difficult to be desorbed from the surface and cause sensor degradations. In our low-damage bilayer graphene, there are high surface ratio of O-H bond introduced by the low-damage oxygen plasma. As a result, the surface with less x-electron help water molecule to be desorbed from the surface. This results in a stable sensitive response to humidity. This work raises a method which potentially helps to functionalize graphene-based sensing materials.

NM01.04.35

In this work, a partially reduced graphene oxide (GO) biosensor is presented. Mild thermal treatment is used to reduce GO drop-casted on a SiO2 substrate, after hydrophylization and functionalization. As a result of the reduction, the graphene sp2 lattice of GO is gradually restored and its electrical conductivity is enhanced. At the same time, the GO retains functional groups during the course of the reduction, thus facilitating the immobilization of proteins on its surface. To confirm this, Biotinylated Bovine Serum Albumin (b-BSA) was used as a model molecule in protein immobilization experiments. The immobilization of b-BSA was affirmed by inspecting the GO drops under a fluorescence microscope after reaction with the fluorescently labeled streptavidin. Reduced GO biosensors were then constructed by first drop-casting GO on APTES functionalized SiO2 substrates followed by a mild thermal treatment (heating for 1 h at 180°C) in order to achieve both protein immobilization and a conductive state. Silver paint conductive adhesive was then used to contact the GO drops. To test the sensor in the detection of b-BSA immobilization, a plastic frame was placed around the GO drops in order to contain the reaction fluids and prevent short-circuiting while resistance measurements were taken using the following procedure: a) inserting buffer solution in the frame and over the GO, b) adding different concentrations of b-BSA and monitor its immobilization, c) adding BSA blocking, and d) adding streptavidin at various concentrations. Using this procedure the sensor was capable to detect b-BSA concentrations down to 200 pM. Based on these initial results the sensor was then used in a medically relevant application which involves the detection of BRCA1 gene. For this experiment the characteristic gene sequence of BRCA1 is amplified and tagged during amplification with a biotin molecule at its end using Recombinase Polymerase Amplification (RPA) at 37°C for 30min. RPA was chosen as it possesses many advantages over other amplifications methods in terms of speed, portability, accessibility, sensitivity and specificity. Next, the GO sensor was prepared by drop-casting and immobilizing streptavidin over the reduced GO through non-covalent binding. Upon insertion, then, of the amplified DNA the biotin end interacts with the immobilized streptavidin. Using this scheme DNA concentrations down to 200pM was detected. These findings thus demonstrate the ability of the proposed sensor to detect on the one hand the immobilization of biotin on the sensor as well as its usefulness in a real world application. Further work will focus on further optimizing the sensor by introducing DNA probes for label free detection.

NM01.04.36
Doping of Boron or Nitrogen to Multilayered Graphene Grown on Copper by Simultaneous Thermal Chemical Vapor Deposition of Methane and the Vapor of Phenylboronic Acid or Melamine Ryoko Furukawa, Yuno Yamamoto, Yoji Nabe and Shunji Bandow; Meijo University, Nagoya, Japan.

Either boron or nitrogen doping was carried out while growing of graphene on a copper foil. For the boron doping, mixture of methane and the dopant vapor of phenylboronic acid, which was generated by heating between 393 and 433 K, was introduced to the furnace kept at 1273 K where the Cu foil was placed. For the nitrogen doping, we used the vapor of melamine generated at 473 K. Prior to grow of the doped graphene on Cu, the Cu foil was annealed at 1273 K for 8 hours under flowing of 20 sccm H2 at 3 kPa in order to improve the flatness of surface. Growth of the doped graphene was carried out for 2
hours at 1173-1273 K at the pressure of 3 kPa with a total flow of 100 sccm of the mixture of PR gas (10% CH₄ in Ar) and Ar gas for carrying phenylboronic acid or maleimide vapor by adding 2 sccm H₂. After growing the doped graphene, gas flow was switched to the mixture of 5 sccm H₂ and 50 sccm Ar at 3 kPa, then cooled. Cooling rate was ca. 40 K/min by 1073 K.

It was found that low pressure annealing of Cu foil was drastically improved the flatness of the surface, which would be a great benefit for growing graphene. From the Raman scattering, the number of the layers of the doped graphene was found to be excess of 5 layers which was evaluated by the intensity ratio of G'/G. Doping amount was evaluated by XPS, which was taken by an Al-Kα excitation, and was found to be in the range of a few at% for both B and N. In addition, rate of substitutional doping of B for C was increased when low level of phenylboronic acid vapor was mixed with methane by decreasing a vaporizing temperature of the dopant by 393 K. For the nitrogen doping, substitutional doping of N for C (quaternary N) was enhanced as decreasing growth temperature of graphene by 1173 K. In case of high temperature doping at 1273 K, pyridine-like (or pyrrole-like) N accompanying with atomic defect at the next of N became a major component for N-doped graphene. Electric conducting feature of B-doped and N-doped multilayered graphene would be opened as the results of sample characterization.

8:30 AM "NM01.05.01 Strategies for the Chirality Control During Carbon Nanotubes’ Growth Feng Ding1, 1; 1Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 2Center for Multidimensional Carbon Materials, Institute for Basic Science, Ulsan, Korea (the Republic of).

The formation of the cap structure determines the chirality of the consequent SWCNT and the addition of the last pentagon can turn the SWCNT into one with any possible chiral angle. Therefore, the random formation of the last pentagon during SWCNT nucleation explains the even distribution of chiral angles in most SWNT samples. During the cap formation, an external bias that affects the addition of the last pentagon may lead to the chirality-selected SWCNT growth. Detailed theoretical and experimental study suggests that the growth of (2n,n)-rich SWNT samples can be achieved by catalyst surface symmetry control. Besides the nucleation stage, varying the chirality during SWNT growth is predicted to be another route towards the chirality-specific SWNTs synthesis. Such a predication has been successfully realized by experimental studies and the synthesized SWNTs show exact chirality distribution as predicted theoretically.

9:00 AM NM01.05.02 Theory of Topological Phases and Topological Band Engineering of Graphene Nanoribbons Ting Cao1, 2, Fangzhou Zhao1, 2 and Steven G. Louie1, 2, 1Department of Physics, University of California, Berkeley, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Topological insulators (TIs) are an emerging class of materials that host highly robust in-gap boundary states while maintaining an insulating bulk. While most notable scientific advancements in this field have been focused on TIs and related topological crystalline insulators in 2D and 3D, we have shown that 1D symmetry-protected topological phases exist in graphene nanoribbons (GNRs) [1]. Using first-principles and model Hamiltonian calculations, we discover that semiconducting GNRs of different width, edge shape, and terminating unit cells can belong to electronic topological classes characterized by different values of an Z₂ invariant. Interfaces between topologically distinct GNRs characterized by different Z₂ are predicted to support robust in-gap topological interface states which can be utilized as a tool for material engineering.

The experimental realizations of these predictions and rational design of a topologically-engineered GNR superlattice synthesized from molecular precursors have been achieved [2,3]. Such GNR superlattice hosts a 1D array of topological interface states, which generates novel robust electronic bands with desirable properties. We present here the theoretical basis and calculations for these states. The band width and band gap of the topology-induced bands are tunable by the coupling between the adjacent topological interface states, which may be varied for example by varying the segment lengths. This novel manifestation of 1D topological phases presents a new route to band engineering in 1D materials based on precise control of their electronic topology, and is a promising platform for future studies of 1D quantum spin physics.

9:15 AM NM01.05.03 One-Third-Hydrogenated Graphene—The Fabrication and Anisotropic Electronic Properties Yuyang Zhang1, Hui Chen1, De-Liang Bao1, Shixuan Du1, Sokrates T. Pantelides3 and Hong-Jun Gao1, 1Chinese Academy of Sciences, Beijing, China; 2Vanderbilt University, Nashville, Tennessee, United States.

The hydrogenation of graphene is a powerful tool to change the carbon hybridization from sp² to sp³, which introduces a finite band gap and generates magnetic moments to make graphene functionalized. Large-scale periodically-hydrogenated graphene, namely with hydrogen atoms chemisorbed in a uniformly-periodic manner, can also be viewed as new kinds of two-dimensional (2D) crystalline materials, e.g. graphene, graphone, and 2D CₓHₙ. These new 2D crystals have been predicted to exhibit unique electronic structures beyond graphene, such as large band gap (graphane) and ferromagnetism (graphone). In hydrogenated graphene, however, the electronic properties strongly rely on the distributions of hydrogen atom. Thus, the fabrication of large-scale, periodically-hydrogenated graphene is critical important as the first step towards potential applications.
Here, in a combined investigation of scanning tunneling microscopy (STM), scanning tunneling spectroscopy (STS), low-energy electron diffraction (LEED), Raman spectroscopy, and density-functional theory (DFT) calculations, we present the formation and anisotropic electronic properties of the single-crystal, millimeter-scale, one third hydrogenated graphene (OPTH) on Ru(0001) substrates. Monolayer graphene (MLG) was firstly synthesized on Ru(0001). The as-fabricated monolayer graphene was then exposed to atomic hydrogen generated by a radio-frequency (RF) atom source for 20 minutes and subsequently annealed to ~1200 K for 20 minutes. After four cycles of hydrogen exposure and subsequent annealing, the sample was characterized by STM and LEED. STM images show that the sample exhibits a moiré pattern with a periodicity of ~2.6 Å. Based on atomic-resolution STM images and LEED pattern, a double-sided 3√3×3√3R30° hydrogen-adsorbed structure was proposed. Simulated STM images show excellent agreements with experimental observed STM images validating the atomic model. The size and uniformity of the fabricated OPTH were checked by taking LEED patterns and STM images on different locations of the sample. We demonstrate that the single-crystal OTHG sample has areas up to 16 mm² (the size of the Ru substrate). Raman spectra and STS measurement indicate that the interaction between the fabricated OTHG and Ru substrate is weak. DFT calculations using a high-level hybrid functional show that for the new 2D material, OTHG, there are Dirac cones at Fermi level along only one high-symmetry (Γ-M) direction. Edge states with energy gaps (~0.6 eV) are opened along other two Γ-M directions due to the hydrogenation, leading to an anisotropic electronic structure. Considering the significant anisotropic electronic structure, novel anisotropic physical properties, such as anisotropic Fermi velocity and directional conductance are expected in OTHG[1].

10:00 AM *NM01.05.04 Structural and Environmental Factors for Tuning Photoluminescence Properties of Carbon Nanotube sp3 Defects S. Dong1, Avishhek Saha1, Xiaowei He1, Brendan Gifford2,3, Geyou Ao4, Ming Zheng4, Kirill Voltzhanin1, Sergey Toetjaki1,3 and Han Hoon1; 1Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 2Center for Nonlinear Studies, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Theory Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 4Materials Science and Engineering Division, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

Photoluminescent defect states introduced by low-level covalent functionalization of single wall carbon nanotubes (SWCNTs) are of growing interest as routes to enhanced photoluminescence (PL) quantum yields and new functionality.1,2 In particular, exciton localization in deep traps at the defect sites gives rise to single photon emission at room temperature that is tunable to telecom wavelengths.3,4 Control over defect-state emission wavelengths and dynamics is essential for advancing potential applications of these unique emitting states. We present results exploring the role of nanotube structure in determining the range of binding configuration that can occur for functionalizing agents. We show that functionalization occurs at ortho-only binding configurations and that nanotube structural symmetry can lead to a 3-fold decrease in emission wavelength bandwidth for zigzag structural types. Strategies for tailoring the SWCNT environment to extend defect-state PL lifetimes (to nanoseconds) and optimize linewidths will also be presented. Environmental impacts on dephasing times will also be discussed, along with temperature dependent effects on relaxation dynamics.

10:30 AM NM01.05.05 Concentric Dopant Segregation in CVD-Grown Nitrogen-Doped Graphene Single Crystals Jinjun Lin1, Roland Yingjie Tay1, Hongling Li1, Lin Jing1, Shi Hon Tsang2, Asaf Bolker1, Cecile Sagny2 and Edwin Hang Tong Teo3; 1Nanyang Technological University, Singapore, Singapore; 2Solid State Institute, Haifa, Israel; 3Space Environment Department, Sorqeq NRC, Yavne, Israel.

Heteroatom doping in graphene leads to bandgap opening and tunable electronic, magnetic and optical properties, which are important for graphene-based electronics applications. In recent years, scalable fabrication of nitrogen-doped graphene (NG) by chemical vapor deposition (CVD) has been extensively studied because of its potential for practical application. A phenomenon that occurs exclusively for CVD-grown NG films is the segregation of doping concentration. However, most studies to date are conducted using highly polycrystalline NG films comprising N depleted regions as determined by Raman spectroscopy. Supported by scanning tunneling microscopy experiments, we propose that the segregation of N dopants is caused by a competing N attachment mechanism to either zigzag or Klein edges during growth; where the former should result in higher N concentration and the latter with lower N concentration. This work provides critical insights into the growth mechanism of CVD-grown NG and enables new opportunities to engineer the properties of graphene by fabrication of lateral heterostructures.

10:45 AM NM01.05.06 Symmetry Breaking in the Plastic Deformation of Coiled Carbon Nanotubes Under Torsional Stress/Strain Socrates O. Dantas1,2, Cristiano F. Woellner1, Alexandre F. Fonseca2 and Douglas S. Galvao1; 1Universidade Federal de Juiz de Fora, Juiz de Fora, Brazil; 2Applied Physics Department, State University of Campinas, Campinas, Brazil; 3Departamento de Fisica, Universidade Federal do Paraná, Curitiba, Brazil.

Since the discovery of carbon nanotubes (CNTs) [1], other carbon allotropes and/or morphologies were observed. One of these morphologies are coiled carbon nanotubes (CCNTs) [2]. It has been a continuous evolution in the study of the structures as well as properties (electrical, mechanical or thermal) of addition of nanostructured carbon materials (NCMs) to polymers and other host materials, forming all sort of composites. However, the molecular scale mechanisms by which the NCMs interact with the hosts are still not fully understood. Previous studies [3-5] used theoretical simulations to address the interaction of NCMs with polymers, and a recent review also illustrated the use of simulations on the study of graphene and hexagonal boron nitride polymer nanocomposites [6]. Inspired by these studies, we investigated the mechanical properties of pristine CCNTs as well as composites formed with CCNTs and hexagonal-shaped monolayer NG single crystals of ~20 µm on Cu substrates. The NG single crystals exhibit discrete concentric hexagonal rings comprising N depleted regions as determined by Raman spectroscopy. Supported by scanning tunneling microscopy experiments, we propose that the segregation of N dopants is caused by a competing N attachment mechanism to either zigzag or Klein edges during growth; where the former should result in higher N concentration and the latter with lower N concentration. This work provides critical insights into the growth mechanism of CVD-grown NG and enables new opportunities to engineer the properties of graphene by fabrication of lateral heterostructures.

to the one for pristine systems, but as expected, at different deformation rates and/or ranges. 

11:00 AM NM01.05.07 Covalent Molecular-Nanotube Heterostructures for Photonics Applications Antonio Setaro1, Mohsen Adeli1, Antoine Godin2, Mareen Glaeske1, Timo Bisswanger1, Rainer Haag3, Laurent Cognet2 and Stephanie Reich1; 1Department of Physics, Freie Universität Berlin, Berlin, Germany; 2LP2N - Institut d'Optique, Université de Bordeaux, Bordeaux, France; 3Institute of Chemistry, Freie Universität Berlin, Berlin, Germany.

Single-walled carbon nanotubes have outstanding electronic and optical properties including ballistic transport and tunable infrared light emission. These properties arise from the delocalized π electrons of the sp² carbon structure and confinement effects around the nanotube circumference. There has been a long-standing need to controllably tailor single-walled nanotubes through the covalent attachment of functional groups. We recently introduced a novel way of nanotube functionalization using triazine anchors that preserves the π electrons of single-walled carbon nanotubes. [1] Infrared light emission from the optically active E₁₁ exciton was observed even at high degree of functionalization (4%) of the carbon atoms).

Here, we present functional hybrids that are built using the triazine groups to anchor functional units on single-walled carbon nanotubes. We show how our platform provides routes toward controlled doping in carbon nanotubes. Nanotube luminescence is tailored by the attachment of molecular switches and enhancing plasmonic gold nanostructures. The molecular switch spiropyran reproducibly introduces blinking in single-walled carbon nanotubes after switching into its open merocyanine form. This makes carbon nanotubes that are covalently functionalized with merocyanine promising markers for ultra-high resolution imaging in the infrared.

11:15 AM NM01.05.08 Capillarity-Driven Water-Holey-Graphene Interactions Yanbin Wang, Kunal Ahuja, Shayandev Sinha, Parth Rakesh Desai, Haoyuan Jing and Siddhartha Das; University of Maryland, College Park, Maryland, United States.

Holey graphene (HG) is a particular form of structurally defective nanoporous graphene where the holes are introduced during the fabrication process. A HG matrix is a vertical stacking of multiple HG sheets with inter-stack separation of several nanometers. This structure affords generation of a massive ion-accessible graphene surface area and has been employed for applications such as fabrication of supercapacitors, oxygen reduction, nitrogen adsorption, Li-ion batteries, etc. Here we would present our research on the use of molecular dynamics (MD) simulation to probe the capillarity-driven interaction of a water drop with the HG. We consider appropriate functionalization of the edges of the holes of the HG. We recover highly interesting transportation behavior of water through the HG matrix where in presence of an applied force water is transported faster in HG with hydrophobic functionalization of the hole edges and Darcy’s law is violated at a weak force where capillarity dominates. Secondly for cases where the force is applied for a duration less than that needed to make the water escape the HG matrix, our simulations reveal a development of novel transient and equilibrated water-graphene wetting states that ensure an attainment of enhanced water-graphene wetted area in a most facile manner. Finally, we study the motion of ion-rich drop through the HG matrix, only to reveal that an appropriate analysis would necessitate addressing the hitherto unprobed problem of the role of ions in modifying the capillary waves at the air-water interface.

11:30 AM NM01.05.09 Pulsed Laser Synthesis and Optical Properties of High Quality Quantum Dots of Nitrogen Doped Graphene Quantum Dots Muhammad Shehzad Sultan1, Muhammad Sajjad2, Vladimir I. Makarov3, Frank Mendoza3, Wojciech M. Jadwiszczak2, Brad R. Weiner4 and Gerardo Morell1; 1Department of Physics, University of Puerto Rico - Rio Piedras, San Juan, Puerto Rico, United States; 2Department of Physics, Western Kentucky University, Bowling Green, Kentucky, United States; 3School of Electrical Engineering and Computer Science, Ohio University, Athens, Ohio, United States; 4Department of Chemistry, University of Puerto Rico - Rio Piedras, San Juan, Puerto Rico, United States.

The graphene quantum dots (GQDs), a zero-dimensional graphene quantum structure, have triggered an intense research worldwide. GQDs possess unique optical, chemical and physical properties as compared to conventional quantum dots (QDs), such as low toxicity, biocompatibility, optical stability, chemical inertness, high photostability and good water-solubility and therefore hold great application potential in biomedical, optoelectronics and energy storage devices. The doping of GQDs with heteroatoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this study, we developed a novel approach to synthesize high-quality Nitrogen-doped graphene quantum dots (N-QGDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-QGDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized NQGDs exhibit high quality crystalline structure of graphene with an average size of about 3.7 nm. A high quantum yield was exhibited by the obtained N-QGDs as compared to the pristine GQDs. The obtained N-QGDs with oxygen-rich functional groups exhibit a strong emission. These outcomes result in an ample opportunity for the biomedical and optoelectronic applications.

11:45 AM NM01.05.10 Studying the Growth of Single-Walled Carbon Nanotubes by Optical Means Vincent Jourdain1, Léonard Monniello1, Huy-Nam Tran4, Hugo Navas1, Matthieu Picher2, Théry Michel3, Rémy Vialia3, Said Tahir3, Eric Anglaret1, Amandine Andrieux-Ledier2, Frédéric Fossard2, Annick Loiseau2, Akinari Kozawa1 and Takahiro Miura1; 1University of Montpellier, Montpellier, France; 2Laboratoire d'étude des microstructures (ONERA/CNRS), Châtillon, France; 3Meijo University, Nagoya, Japan.

Controlling the structure and arrangement of single-walled carbon nanotubes (SWCNTs) directly during their growth constitutes a central bottleneck for the applications of SWCNTs in numerous fields including optics and microelectronics. Catalytic chemical vapor deposition (CCVD) is currently the most popular method for synthesizing SWCNTs because it offers more defined and versatile growth conditions, thus allowing to grow SWCNTs with a better control of their structure, orientation, surface density and purity. Although many groups reported catalyst systems and growth conditions yielding high
selectivity for specific diameters or chiralities, a profound understanding of the processes impacting the structural distribution of SWCNTs is still missing. Two main reasons can explain the difficulty to experimentally isolate growth mechanism and structural features: 1) monitoring the growth of individual SWCNTs still remain very challenging, 2) determining SWCNT structure is usually complex and requires a combination of methods.

In this contribution, we will show how optical methods of spectroscopy and microscopy can help addressing this issue. First, we will present in situ and ex situ Raman measurements used to study the dynamics of the different populations of SWCNTs during their growth by CCVD [1]. Importantly, this study reveals that the nanotube diameter distribution strongly evolves during SWCNT growth but in dissimilar ways depending on the growth conditions. The origins of these evolutions will be discussed. Second, we will show how polarization-based optical methods can be used to monitor the growth of individual SWCNTs on substrates [2]. We will notably show that individual SWCNTs on substrate can be imaged during their growth with time resolution of 5-50 ms. Third, we will propose a general modeling of the polarized optical spectra of individual SWCNTs including the influence of the multi-layer substrate and of coherent and non-coherent depolarization by the optics. We will show that this model allows one to extract both the real and imaginary parts of the nanotube susceptibility and to improve the methodology of chirality assignment [3].

Sheraton, 2nd Floor, Republic AB

1:30 PM *NM01.06.01  
Toxicity and Degradation of Carbon Nanotubes After Uptake by Macrophage Minfang Zhang1, Mei Yang2, Hideaki Nakajima2, Masako Yudasaka1, Sumio Iijima1, 2, and Toshiya Okazaki2; 1Meijo University, Nagoya, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan.

The public concern regarding possible toxicities of carbon nanotubes (CNTs) has attracted many attentions. Because CNTs would be mainly entrapped by macrophages when CNTs entered into the living body, the investigation of the degradation of CNTs and the resulted cytoxicity after uptake by macrophage would be crucially important. In this study, we quantitatively investigated the intracellular degradation of CNTs by macrophages using an optical absorption method [1] and studied the toxicity changes of CNT during degradation. We have found that the intercellular degradations of CNTs by both primary cells and cultured macrophages were happening in the beginning 3 days after uptake and almost no degradation by the longer period incubation. The cell viability and cell total protein amount did not change during the degradation, and the amount of ROS generated by macrophage decreased with the degradation. These results indicated that the degradation of CNTs by macrophages followed the oxygen-depended mechanism and the residues of un-degraded CNTs persisted in macrophages without toxicity. In addition, through investigation of over 8-types of CNTs, we have found that the degradation rates of CNTs were dependent on their diameters, which would be helpful to predict the degradation characteristics of CNTs from their physical and chemical properties.

2:00 PM NM01.06.02  
Electronic Structure of Electron-Irradiated Graphene and Effects of Hydrogen Passivation Asanka Weerasinghe1, Ashwin Ramasubramaniam2 and Dimitrios Maroudas1; 1Chemical Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Mechanical and Industrial Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Defect engineering through irradiation processes and chemical functionalization of graphene are promising routes for fabrication of carbon nanostructures and 2D metamaterials with unique properties and function. In previous computational studies, we reproduced experimentally observed structures of electron-irradiated graphene sheets through introduction of random distributions of vacancies in the graphene lattice and proper structural relaxation. We found that a vacancy-induced amorphization transition in graphene occurs for an inserted vacancy concentration between 5% and 10%. This order-to-disorder transition is accompanied by a brittle-to-ductile transition in the fracture mechanism upon uniaxial tensile straining as well as a transition in the lattice thermal transport mechanism in these irradiated graphene sheets.

Here, based on molecular-dynamics (MD) simulations in conjunction with first-principles density functional theory (DFT) calculations, we report results for the electronic structure of irradiated and irradiation-induced amorphized graphene. We find that localized states appear at the Fermi level upon irradiation and the corresponding local density of states increases with increasing inserted vacancy concentration. Furthermore, electronic band structure calculations show that band flattening occurs due to electron localization in the vicinity of irradiation-induced defects and reduces the charge carrier mobility. This band flattening effect becomes stronger with increasing vacancy concentration inducing an increasing number of flat bands near the Fermi level. Moreover, we present electron wave functions (as frontier orbitals) and charge density distributions, which provide clear evidence of carrier localization near the irradiation-induced carbon dangling bonds. Passivating these bonds with hydrogen atoms leads to delocalization of the charge density, hence increasing the carrier mobility, which also is seen in the reduced density of states observed at the Fermi level and the increased band dispersion with increasing inserted vacancy concentration. We find these spatially localized states to be spin polarized, which gives rise to a net local magnetic moment. We will show how polarization-based optical methods can be used to monitor the growth of individual SWCNTs on substrates [2]. We will notably show that individual SWCNTs on substrate can be imaged during their growth with time resolution of 5-50 ms. Third, we will propose a general modeling of the polarized optical spectra of individual SWCNTs including the influence of the multi-layer substrate and of coherent and non-coherent depolarization by the optics. We will show that this model allows one to extract both the real and imaginary parts of the nanotube susceptibility and to improve the methodology of chirality assignment [3].

scaling limits are completely unknown. In this talk, I will illustrate the electroburning approach for sub-5 nm nano-gap fabrication and subsequently define the fundamental limits to scalability. The phonon based nano-gaps which is associated to a carbon chain filamentation process (electric field driven formation of carbon chains). Using a phase change material in the nanogap as a demonstrator device, fabricated using a self-alignment technique, I will demonstrate that for gap sizes approaching 1 nm the switching is dominated by such carbon chain formation, creating a fundamental scaling limit for potential devices. These findings have important implications, not only for fundamental science, but also in terms of potential applications.

Defects Enable Dark Exciton Photoluminescence in Single-Walled Carbon Nanotubes
Amanda Amori1, Jamie Rossii, Zhentao Hou1, Brian Landi1 and Todd Krauss1
1University of Rochester, Rochester, New York, United States; 2Rochester Institute of Technology, Rochester, New York, United States.

Single-walled carbon nanotubes (SWCNTs) are fundamentally interesting and technologically relevant materials with size-tunable absorption and emission across visible and near infrared wavelengths. However, several important aspects of SWCNT photophysical properties defy even simple physical explanation. For example, we found using variable temperature photoluminescence excitation spectroscopy that a sideband located approximately 130 meV away from the bright S1 exciton peak relating to the K-momentum dark exciton state, called X1, decreased in intensity five-fold as the nanotubes were cooled. Direct optical excitation of this dark state is nominally forbidden, thus calling into question how the state is populated, why it is so prominent in the photoluminescence spectrum, and what causes its strong temperature dependence. Interestingly, the ratio of the integrated photoluminescence intensities of X1 to S1 scales with a Boltzmann factor completely unrelated to the phonon that is thought to be responsible for depopulating the K-momentum dark exciton state: an in-plane transverse optical phonon, A′. Furthermore, photoluminescence spectra from individual nanotubes show that only a small fraction exhibit the X1 feature, with varying oscillator strength, thus suggesting that intrinsic processes such as phonon scattering are not responsible for populating the dark state. Alternatively, we suggest that populating the K-momentum dark exciton state requires scattering from defects, which is consistent with the increased magnitude of the X1 feature for samples with increased sample purification and processing. Thus, the presence of an X1 peak in photoluminescence is an extremely sensitive spectroscopic indicator of defects on single-walled carbon nanotubes.

Thermoacoustic Generator from a Free-Standing Single Walled Carbon Nanotubes
Stepan Romanov1,2, Ali Aliev3, Albert Nasibulin2 and Boris Fme3; 1Skolkovo Institute of Science and Technology, Moscow, Russian Federation; 2University of Texas at Dallas, Dallas, Texas, United States.

Recent advances in material science provoked a new wave of researches in a thermoacoustic process induced by Joule heating. Mainly due to very low heat capacity per unit area (HCPUA) of the modern materials. Here, we present the state-of-the-art performance of free-standing single walled carbon nanotubes (SWCNTs) thin films as thermoacoustic sound generators. The SWCNT films synthesized by an aerosol chemical vapor deposition (CVD) method showed record sound pressure level of 101 dB with a frequency of 100 kHz at the distance of 3 cm and the input power of 1 W. Such performance was caused by extremely low HCPUA of the films 0.35 * 10^-3. The research was performed with the films of different thicknesses in the sound range from 1 kHz to 100 kHz. The importance of aerogel structure of the materials for thermoacoustic generator researches theoretically and with experiments of densification and vacuum annealing. Full theoretical model of thermoacoustic free-standing films, which included effects of diffraction and finiteness of heat capacity per unit area was derived. Theoretical model was checked numerically in 3D by solving full system of coupled Linearized Navier Stokes and Helmholtz differential equations. This work was supported by Skoltech NGP Program (Skoltech-MIT joint project).

Thermoelectric Materials Consisting of Doped Carbon Nanotubes
Yoshivuki Nonoguchi1,2; 1Nara Institute of Science and Technology, Nara, Japan; 2JST PRESTO, Kawaguchi, Japan.

Carbon nanotubes have recently been used as the building blocks of thermoelectric materials that enables the construction of wearable electronics and power modules. In this context, air- and thermally-stable doped, i.e. n-type materials are highly desired not only for the development of practical PN series thermoelectric modules but also for the optimal tuning of thermoelectric transport. In this presentation, I will talk about the preparation of air- and thermally-stable p- and n-type carbon nanotubes and their application in thermoelectric transport studies [1-6]. Supramolecular (electro-)chemistry is introduced to improve, and quantify doping efficiency and stability. A recent progress on the power factor enhancement is also presented.

4:00 PM NM01.06.07
Interlayer Charge Transport in 2D Molecular Structures
Elad Koren; Materials Science and Engineering, Technion–Israel Institute of Technology, Haifa, Israel.

Weak interlayer coupling in 2-dimensional layered materials such as graphite gives rise to rich mechanical and electronic properties in particular in the case where the two atomic lattices at the interface are rotated with respect to one another. A lack of crystal symmetry leads to anti-correlations and cancellations of the p6 orbital interactions across the twisted interface, which gives rise to low friction behavior and low interlayer electrical transport. Using our recent nanomanipulation technology1, based on atomic force microscopy, we studied the interlayer electrical conductivity as a function of twist angle between two misoriented graphene layers with unprecedented angular resolution of ~0.1 deg. The angular dependence indicates that the electrical transport across the interface is dominated by a phonon assisted channel which conserve the momentum of conduction band electrons, tunnelling across the twisted Dirac bands. Most intriguingly, the conduction is significantly enhanced within a narrow angular range of less than 0.5 deg at pseudo-commensurate angles of 21.8 and 38.2 degrees. This provides the first experimental evidence for the existence of a 2-dimensional interface state originating from the coherent coupling of electronic states in the twisted sheets due to commensurate superlattices2. Finally, we show that combined electro-mechanical characterization techniques of mesoscopic graphite structures can be uniquely address open fundamental question related to the dielectric interlayer interactions and electronic charge transport through stacking faulted structures3.
The physics governing the adsorption of ions onto metallic or semimetallic surfaces underpins future technological developments in many areas. Specifically for graphene-based technology new emerging applications for example in energy storage or water filtration require a precise understanding of the relative stability of ions at the graphene surface and surface wetting properties. [1] However, many questions about the atomic structure of the electrolyte/graphene interface remain challenging to answer since the characterization of the interface proved to be elusive largely because the experimental techniques have not allowed direct observation of the behaviour of the ions. [2]

The driving force for the ion interfacial adsorption is a complex mix of enthalpic and entropic contributions, but molecular dynamics (MD) simulations of the electrolyte interface with both air and unstructured hydrophobic surfaces have demonstrated that it is mainly related to the stability of the ion’s solvation shell and its propensity to dehydrate. [3] For a semi-metallic surface, such as graphene, the proximity of an ion induces a further effect associated with polarization of the surface itself, which strongly affects the interfacial attraction/repulsion of the ions. In order to capture these important phenomena, we recently developed a novel molecular model that can include the polarizability of all the species involved and allow the prediction of the specific relative adsorption of ions on the graphene surface for electrolyte concentrations comparable to the experimental ones. [4]

In this talk we will show that this new model predicts that in a 1 M electrolyte solutions, cations are adsorbed onto the graphene surface with a trend (Li+ < Na+ < K+ ) opposite to that predicted by the gas-phase calculations and different than from that obtained from the single-ion simulations and with an energy of adsorption now validated by microscopy and electrochemistry experiments. [5] We will discuss how these findings are relevant for the graphene exfoliation process and wetting properties of the surface.

Contactless Detection of Opto-Electronic Anisotropy and Real-Time Atmospheric Doping in Single Walled Carbon Nanotube Films

Maxwell Jundt, Adam B. Phillips, Rajendra R. Khanal, Michael J. Heben and Nikolas Podraza; Physics & Astronomy, University of Toledo, Toledo, Ohio, United States.

Thin films of single-walled carbon nanotubes (SWCNT) have many attractive opto-electronic features such as tunable conductivity and visible light transmission that make them of interest for a variety of applications. We present a characterization method that employs multi-angle spectroscopic ellipsometry spanning a wide spectral range from the ultraviolet to the terahertz (210 nm – 3 mm) that is capable of simultaneously determining a variety of opto-electronic properties in a contactless manner. In particular, SWCNT films are prepared in both “de-doped” (i.e. heat treated) and heavily nitric acid doped states and measured in both ex-situ and in-situ modes. The ex-situ measurements fully leverage the wealth of spectral features present in the wide spectral range while the in-situ mode allows for tracking of changes in real time as the film properties change due to atmospheric exposure. This frequency domain spectroscopic measurement is one of the only known techniques sensitive to the optical effects arising from electrical anisotropy between the in-plane and out-of-plane directions. Comparison to direct electrical measurements sampling the in-plane electrical properties confirms accuracy. Such electrical anisotropy arises from the fact that, despite no intentional alignment of the nanotubes being made, the nanotubes tend to lie flat on the substrate surface. Nitric acid doping is shown to decrease the film resistivity by factors of ~4 and ~100 in the in-plane and out-of-plane directions, respectively. This capability of determining electrical anisotropy is particularly relevant for incorporation of SWCNT films into devices where the desired direction for conduction is a consideration. Measurement of real-time changes to the film through the in-situ measurements are of interest for SWCNT films used in sensor applications. Additionally, the influence of doping on optical features arising from metallic and semiconducting transitions is determined.

4:45 PM NM01.06.10
Gapped Graphene Nanoribbons with Spatial Symmetries as One-Dimensional Topological Insulators

Kuan-sen Lin1,2 and Mei-Yin Cheu1, 3
1Institute of Atomic and Molecular Sciences, Academia Sinica, Taipei, Taiwan; 2Department of Physics, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 3School of Physics, Georgia Institute of Technology, Atlanta, Georgia, United States.

The Berry phase is a geometrical phase that is known to provide the essential physics behind several intriguing materials properties such as the electric polarization, anomalous Hall effect, orbital magnetization, etc. It is expected that this geometrical phase also reflects the intrinsic topological properties of one-dimensional (1D) insulators, because the 1D Brillouin zone (BZ) integral forms a natural loop in the k-space. In this work, we study the system of gapped graphene nanoribbons (GNRs) with spatial symmetries (e.g., inversion) and show that a symmetry-protected Z2 topological phase exists. Although the Berry phase turns out to be -quantized in the presence of the chiral symmetry, it does not provide the correct Z2 correspondence as expected. It is found that only the origin-independent part of the Berry phase gives the correct bulk-boundary correspondence by its -quantized values, with the relevant Z2 invariant dependent on the choice of the bulk unit cell (namely, ribbon truncation) and connected to the symmetry eigenvalues of the wave functions at the center and boundary of the BZ. Using the edge-dressed GNRs as examples, we demonstrate the existence of localized states at the end of some GNR segments and at the junction between two GNRs based on topological analysis. The current results are expected to shed light on the design of electronic devices based on GNRs as well as the understanding of the topological features in 1D systems.

References

Novel nanocarbon-metal composites called covetics have the potential to improve significantly upon the mechanical, thermal, and electrical properties of common metals and alloys, including Al. Electric current applied to the melt containing a C precursor is believed to ionize carbon atoms and cause nanoscale graphitic ribbons and chains to form within the resulting Al lattice. Despite the potential of nanocarbon incorporation to improve desirable properties of Al alloys, critical for aerospace, structural, and power transmission applications, the atomic-scale mechanism is not yet completely understood.

In this work, the effects of current density and residence time on the uniformity and extent of carbon conversion to nano-graphite are explored in order to provide further insight into the conversion process. We characterize the structural and chemical features of nanocarbon-Al covetics using Raman spectroscopy, TEM imaging, electron energy loss spectroscopy (EELS), and X-ray photoelectron spectroscopy (XPS). Raman and EELS spectra are localized to within a few μm of a selected region of interest, as guided by fiducial marks milled using a focused ion beam tool before collection of the spectrum images (SIs). The Raman and EELS SIs are subjected to nonlinear iterative fitting and hyperspectral decomposition using machine learning techniques to reveal features indicating nanocrystalline graphite embedded within the Al lattice. The Raman G and D peak intensities and shifts are found to depend on the current parameters, with greater exposure corresponding to greater graphitic order. Evidence of sp2 carbon bonding and Al-C bonding is seen by EELS and XPS. Local mechanical (nano-indentation) and electrical conductivity measurements will also be taken and related to processing conditions and local structure.

This work is based upon work supported by the U. S. Department of Energy under Award No. DE-EE0008313. Dr. David Forrest is the Project Technology Manager and Debbie Schultheis is the Project Officer/Manager.

Interfacial Detection with Carbon Nanotube Pipette Laden Graphene Quantum Dots Electrode
Hayley Richardson, N.N.N. Ahamed and K.S.V. Santhanam; School of Chemistry and Materials Science, Rochester Institute of Technology, Rochester, New York, United States.

Single cell analysis is an emerging technology that can provide a mechanistic understanding of the complex biological systems and cell heterogeneity. (1) Any disruption of its activity can be monitored through interfacial bioelectrochemistry. In this emerging technology it is necessary to have high spatial and temporal resolution over an extended period of time that has been seldom achieved in the adopted analytical measurements. This problem has been solved in the present work by using an electrochemical technique such as differential pulse voltammetry (DPV) carried out with carbon nanotube pipette electrode that is laden with graphene quantum dots (20 nm-50 nm) (2). This modification gives rise to a sensitive electrode material for high temporal resolution through idealizing the DPV parameters. The in-vitro experiments carried out in understanding oxidative stress produced by p-aminophenol (PAP) that
results in membrane disruption suggest that molecular attachment of PAP to graphene is higher than the pipette electrodes (amorphous carbon) as indicated by the signal strengths being several orders of magnitude higher than with amorphous pipette electrode. The shape and features of the current-voltage curves that are recorded can be idealized as nanotube electrode arrays acting as an ensemble in harmony. As the electric field known to influence the cells, the electric field produced during the detection of an electroactive species by this ensemble has been simulated for practical usage for in-vivo studies. The new electrode opens up an approach at observing the electroactive neurotransmitter during its functioning in chronic diseases.

Electrochemical (re)activity of graphene and graphene-based ‘hybrid’ nanomaterials is crucial for food, energy and water sustainability applications, which requires delicate control over its geometric and electronic structures. We demonstrate that precise control of the density of defects, hierarchical porosity, and topological interconnectedness, invoked in hydrothermally synthesized graphene aerogel integrated with multi-walled carbon nanotubes that can finely tune mesoporosity and enhance the electrochemical heterogeneous electron transfer rate (kTST). We prepared range of three-dimensional solid network of graphene-based ‘hybrid’ scaffolds (i.e. aerogel) and their nitrogenated counterparts with varying graphene-carbon nanotube compositions using two schemes (approach 1 and approach 2). This study allows us to correlate quantitatively between number defect density determined (via Raman spectroscopy; RS) and heterogeneous electron transfer rate (via scanning electrochemical microscopy; SECM). RS provides nanoscale phononics characterization revealing collective atomic/molecular motions and localized vibrations. The first- and second-order phonon modes are analyzed in terms of Raman intensity, band position (intrinsic mechanical strain) and intensity ratio (structural disorder, number defect density), distinct localized n electronic states were found in photoluminescence excitation (PLE) spectra reflecting carbon atoms around oxygenated and nitrogenated species. The role of carbonyl (C=O), epoxy (C-O-C) and nitrogen (pryridinic-N and graphitic/pyrrolic-N) surface functionalities and corresponding bonding configurations besides hierarchical mesoporosity are emphasized in view of understanding the improved physicochemical properties for electrochemical energy, water desalination and sensing applications. The engineered defect density induced increase in finite electronic density of states (DOS) near Fermi level revealed using density functional theory (DFT) calculations and decrease in room temperature electrical conductivity, heled in establishing optimal defect density for moderate heterogeneous rate as a critical state such that the whole system becomes electronically activated while maintained structural integrity. Moreover, it enlarges the overlap between DOS for graphene aerogels and redox probe couple, which signifies the experimental correlation estimates.

Fabrication of Bilayer Graphene Based Films as Hygromorphic Actuators Omkar S. Bhatkar, Sheikh Rasel, David Smith and Reza Rizvi; Mechanical, Industrial and Manufacturing Engineering, University of Toledo, Toledo, Ohio, United States.

Extensive research is being conducted on graphene-based composite films to explore their potential in actuation mechanisms stimulated by electrical, thermal, mechanical or optical energy sources owing to its extra-ordinary electrical and mechanical properties. In this study, we report the use of all graphene based functionally graded, bilayer free-standing films as mechanical actuators triggered by adsorption of moisture at the film interface. The bilayer films were fabricated by a single-step doctor blade coating technique and dried at controlled temperature and humidity conditions. The reduction mechanism of Graphene Oxide into rGO was implemented through metal substrate-assisted reduction, which involves coating GO paste on an active metal like Aluminum that possess a high oxidation potential. The internal architecture of the films was tuned as per requirement by changing the initial process parameters like the concentration and pH of GO and the surrounding humidity and temperature. Selective reduction of Graphene Oxide into desired intricate patterns was also demonstrated, through usage of masks during film coating and deposition. The functional grading of the films, where one side is electrically-conducting GO while the other being insulating rGO was confirmed by SEM, Raman, XRD, FTIR and XPS analyses. SEM revealed an overall understanding of the porous nature of the film throughout the cross section whereas Raman Spectroscopy showed an increase in (ld/lg) ratio from GO to rGO face, denoting gradual reduction of sp² hybridized hexagonal carbon structure. XRD, FTIR and XPS results also confirmed the functional grading throughout the thickness of the film post-reduction. The bilayer film, which is composed of Graphene Oxide and Reduced Graphene Oxide on either side, is shown to exhibit selective bending mechanism in humid environments, due to the affinity of Graphene Oxide towards polar molecules like water. Reduced Graphene Oxide being immiscible in water shows repulsive nature towards humidified surroundings, thus triggering a differential bending mechanism in the individual bilayer film. The Hygromorphic behavior exhibited by the robust and flexible functionally graded graphene films, can intrigue a variety of applications in mechanical actuation, robotics and gas sensing systems.

Mechanics of Triply Periodic Minimal Surfaces of Three-Dimensional Graphene Foams GangSeob Jung and Markus Buehler; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The mechanics of triply periodic minimal surfaces (TPMSs) with three-dimensional (3D) graphene foams are systematically studied to understand the effects of structure and size on the mechanical properties, e.g., elasticity, strength, and fracture. The design of lightweight open-shell porous solid materials with TPMSs has shown excellent and tunable load-bearing properties. However, subtle mechanics and their relations with surface topologies are largely unknown. Utilizing reactive molecular dynamics simulations, here we investigate the elastic and fracture properties of three different surface topologies with 3D graphene foams: P (primitive), D (diamond), and G (gyroid). Models with different lattice sizes are utilized to derive power laws, which can connect the properties along different sizes to shed light on the multiscale mechanics of 3D graphene with TPMSs. Our study provides a systematic understanding of the relation between TPMS topologies and their mechanical properties, including failure mechanisms of graphene foams, opening
opportunities to explore designable complex structures with tailored properties.

Thermal Conductivities of Triply Periodic Minimal Surfaces of Three-Dimensional Graphene Foams  
GangSeob Jung and Markus Buehler; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Graphene has excellent mechanical, thermal and electrical properties. However, there are limitations in utilizing monolayers of graphene for mechanical engineering applications due to its atomic thickness and lack of bending rigidity. Synthesizing graphene aerogels or foams is one approach to utilize graphene in three-dimensional bulk forms. The structures of graphene foams can be idealized with the triply periodic minimal surface (TPMS):P (primitive), D (diamond), and G (gyroid). Here, we investigate the thermal conductivity of three different surface topologies with 3D graphene foams by using full-atom molecular dynamics simulations. We derive a scaling law showing how the different TPMSs have different trends. Our analysis shows that the trend of the thermal conductivities can be attributed to defects and curvatures of graphene. Our study shows that three-dimensional porous graphene has potential that may be utilized in designing new lightweight structural materials with low and density-insensitive thermal properties and superior mechanical strength.

Enhancing the Thermal Conductivity of PBAT/Graphene Composites via Applying PLA as a Second Phase Reorganizer  
Xianhao Zuo, Yuan Xue, Miriam Rafailovich and Yichen Guo; Stony Brook University, Stony Brook, New York, United States.

In this study, we have designed and engineered polymer blends as an improvement of the thermal diffusion structure for polymer materials. In our system, poly (lactic acid) (PLA) was used as a second phase reorganizer of the Poly (butylene adipate-co-butylene terephthalate) (PBAT)/graphene composites. Two different types of graphene, H-5 and C-750, were used in this study to guarantee the thermal conductivity of the composites. According to the contact angle measurements and the calculation of the interfacial tension between polymers and graphene, we observed that graphene will be more stable in the PBAT phase than in the PLA one. Therefore, in our blends system, PBAT was designed as the polymer matrix, while the PLA was considered as the minor phase with a comparatively lower concentration. Because the size of H-5 (average around 5 nm) is larger than the PLA domain size (around 3 nm), H-5 can disperse perfectly in PBAT matrix and form continuous thermal diffusion paths. With 20% of graphene H-5, the thermal conductivity of PBAT/PLA blend can achieve a 26% enhancement, as compared with the sample without PLA. Moreover, we discovered that the incorporation of C-750, unfortunately, failed in promoting the thermal conductivity of the PBAT/PLA blend. Since the PLA domain size is much larger than the size of C-750 (average around 750 nm), it can hardly help drive the dispersion of the C-750 in a preferential orientation in the PBAT matrix and makes the formation of the thermal diffusion path even harder.

Quantifying Defects in Graphene for High Performance Conductive Ink  
Md Akibul Islam1, Sheikh Rasel1, Derek Keith Messer1, Wai Mak2, Reza Rizvi1,2 and Richard B. Kaner1; 1Mechanical, Industrial and Manufacturing Engineering, University of Toledo, Toledo, Ohio, United States; 2Chemistry and Biochemistry, University of California, Berkeley, Los Angeles, California, United States.

Over the past decade, comprehensive investigations have been conducted to develop graphene based two-dimensional (2D) materials to harness their excellent and unprecedented properties such as high electrical conductivity, optical transparency, mechanical strength, and flexibility. To fully utilize these functionalities, a number of methods including chemical vapor deposition, liquid shear exfoliation, sonication, ball milling, electrochemical exfoliation and polymerization can be used to produce high-performance conductive ink from exfoliated graphene. However, these methods can introduce significant defects during exfoliation into the graphene crystal structures that have a strong influence on their properties. This study is designed to compare the defect and flake quality between CFE and bath or probe sonication process for producing high-performance conductive ink from exfoliated graphene. In our CFE process, graphene is rapidly jetsonned through a small orifice using high-pressure gases without the need for any time-based treatment, unlike other shear-based liquid processes. Shear-induced exfoliation occurs due to the high velocities that expanding and accelerating gases can achieve in small orifices coupled with viscous friction effects resulting in a high shear rate (>$10^5$ s$^{-1}$) experienced by the graphite particles. In contrast, in the sonication methods, an ultrasonic transducer is used to induce unstable cavitation bubbles in a liquid medium, which upon their inevitable collapse emulate a shock wave. The energy of this shockwave is sufficient to fragment nearby bulk graphite powders into smaller lengths as well as thickness along the weak, secondary c-axis. But when the bulk particle is fragmented into smaller flakes, a good number of edge and basal plane defects are introduced into the flake. The defect population increases as the time for sonication rises. The occurrence of a disorder-activated D peak at 1330 cm$^{-1}$ in the Raman spectra of graphene is indicative of defects, in particular, those which disrupt the sp$^{2}$ hybridization. Such defects can be interpreted to be the creation of new edges, vacancies or substitutions, with the ratio between the peaks intensities of the D to G peak ($I_{D}/I_{G}$) providing a qualitative indication of their population. In our study, we found the ratio of D peak to G peak is significantly less in CFE than that of bath sonicated graphene ($I_{D}/I_{G}$=0.66 for CFE graphene and $I_{D}/I_{G}$=1.1 for bath sonicated graphene. In contrast, the bulk graphite powder had $I_{D}/I_{G}$ ratio of 0.62. The increased quantity of defects in bath sonication may be attributed to the prolonged sonication time which is well known to be responsible for reducing the flake length and hence, introducing more edges. The flake quality of exfoliated graphene was also verified using atomic force microscope (AFM) and transmission electron microscope (TEM).

3D Knitted Carbon Nanotube Fabric as Smart Textiles  
Javad Foroughi; University of Wollongong, Wollongong, New South Wales, Australia.

Highly stretchable, actuatable, electrically conductive knitted textiles based on Spandex (SPX)/CNT (carbon nanotube) composite yarns were prepared by an integrated knitting procedure. SPX filaments were continuously wrapped with CNT aerogel sheets and supplied directly to an interlocking circular knitting machine to form the three-dimensionally electrically conductive and stretchable textiles. By adjusting the SPX/CNT feed ratio, the fabric electrical conductivities could be tailored in the range of 870 to 7092 S/m. The electrical conductivity depended on tensile strain, with a linear and largely hysteretic-free resistance change occurring on loading and unloading between 0 and 80% strain. Electrothermal heating of the stretched fabric caused large tensile contractions of up to 33%, and generated a gravimetric mechanical work capacity during contraction of up to 0.64 kJ/kg and a maximum specific power output of 1.28 kW/kg, which far exceeds that of mammalian skeletal muscle. The knitted textile provides the combination of strain sensing and the ability to control dimensions required for smart clothing that simultaneously monitors the wearer’s movements and adjusts the garment fit or exerts forces or pressures on the wearer, according to needs. The developed processing method is scalable for the fabrication of industrial quantities of strain sensing and actuating smart textiles.

Electronically Tunable SPR Biosensor with Reduced Graphene-Oxide Thin Films as Functional Layers  
Xiaolong Liu1,2, Pavel Damborský1, Walid-Madhat Munief2, Jessica Ka-Yan Law4, Vivek Pachauri1,2, Jens-Uwe Neurohr6, Samuel Grandthyll6, Karin Jacobs6, Frank Müller6, Jaroslav Katrlík3, Xianping Chen5 and Sven Ingebrandt1; 1Department of Informatics and Microsystem Technology, University of Applied Sciences Kaiserslautern, Zweibruecken, Germany; 2Department of Informatics and Microsystem Technology, University of Applied Sciences Kaiserslautern, Zweibruecken, Germany; 3Department of Glycobiotechnology, Slovak Academy of Sciences; 4Department of Chemistry, The Chinese University of Hong Kong, Hong Kong; 5Department of Electrical Engineering, RWTH Aachen University, Aachen, Germany; 6Department of Chemistry, Technical University of Denmark, Lyngby, Denmark.
Academy of Sciences, Bratislava, Slovakia; 2R·AGroupDEGmbH,Zweibruecken,Germany; 3KeyLaboratoryofOptoelectronicTechnology&Systems,ChongqingUniversity,Chongqing,China; 4ExperimentalPhysics,SaarlandUniversity,Saarbruecken,Germany.

Graphene is bustlingly exploited as a linker layer in surface plasmon resonance (SPR) biosensing for advanced biomolecule-recognition due to its intriguing plasmonic properties. However, the chemical nature of pristine graphene limits the binding of receptor biomolecules to physisorption and π-π stacking. Therefore, chemically exfoliated graphene oxide (GO) and reduced graphene oxide (rGO) are used instead for covalent immobilization of receptor biomolecules, since they possess various functional groups on the carbon basal plane and concurrently preserve the carbon-lattice as pristine graphene within nanoscale size. In this work, we investigated the sensing performances of Au/glass SPR chips with GO and rGO thin films as functional layers. As a proof-of-concept we applied a lectin Concanavalin A (ConA) binding assay with prostate cancer-specific antigen (PSA) as receptors. The results demonstrated stronger surface plasmon resonance effects for biomolecule recognition with rGO functional layers, whilst the average intensity of surface plasmons and signal-to-noise ratio were 1.7 and 3 times higher compared to the GO as functional layers. More remarkably, taking advantage of the bipolar property of the rGO thin films, it was possible to further enhance the surface plasmon intensity by applying bias voltages to the rGO thin films. The limit of detection ConA target molecules was 0.01 μg/mL. Such tunable SPR platforms based on rGO thin films lighten up a wider road for diverse surface functionalization, adjustable sensing regimes and improved sensitivity in the field of SPR biosensing.

**Vertically Aligned Single-Walled Carbon Nanotube Growth from Ir Catalysts by Alcohol Gas Source Method**

Takuya Okada, Takahiro Saida1,2; Shigeya Naritsuka1 and Takahiro Maruyama1,2; 1Applied Chemistry, Meijo University, Nagoya-shi, Japan; 2Nanomaterials Research Center, Meijo University, Nagoya-shi, Japan; 3Materials Science and Engineering, Meijo University, Nagoya-shi, Japan.

Single-walled carbon nanotubes (SWCNTs) have been anticipated for applications in a lot of future nanodevices. However, there still remain several problems for realizing the SWCNT devices, and one of the most significant issues is high-yield growth of semiconducting SWCNTs. So far, to grow SWCNTs with high-yield, Al2O3 buffer layers are widely used, because they prevent migration of catalysts on the substrate surface at growth temperature and aggregation of catalyst particles are suppressed [1]. In this study, we attempted to grow SWCNTs using Ir catalysts without Al2O3 buffer layers, which have never been used as catalysts in SWCNT growth. After deposition of Ir catalysts on SiO2/Si substrates, SWCNT growth was carried out using alcohol gas source method in a high vacuum [2]. Growth Temperature and growth time were set at 800°C and 1 h, respectively. The ethanol pressure was varied between 1×10⁻¹⁰ and 1×10⁻⁹ Pa. The grown SWNTs were characterized by FE-SEM, TEM and Raman spectroscopy. SEM and Raman results showed that, as the ethanol pressure increased, the SWCNT yield became higher and the SWCNT diameter became narrower. When the ethanol pressure was 1×10⁻⁹ Pa, high-density vertically aligned SWCNTs were grown, whose lengths were about 2 μm. Raman measurement showed that SWCNT diameter were distributed between 0.83 and 1.13 nm. In addition, Raman spectra showed that semiconducting SWCNTs were dominantly grown from Ir catalysts. This study is the first report to grow SWCNTs from Ir catalysts, and our results indicated that Ir catalysts are effective to obtain high-density vertically aligned and small diameter SWCNTs using no Al2O3 buffer layers.

**Band Alignment Study of Locally Gate-Controlled Graphene/Carbon Nanotube Junctions**

Mao Shiomi, Takayuki Arie, Seiji Akita and Kuni Takei; Osaka Prefecture University, Sakai, Japan.

Heterojunctions of nanomaterials have attractive attention due to interesting electrical and optical characteristics. One of the interesting materials is graphene, which has Dirac-cone band structure. Utilizing this band structure and other contacting semiconductor nanomaterials, diode and transistor behaviors can be controlled by applying a global back gate voltage. However, due to vertical integration of this heterojunction, each band structure cannot be separately controlled to observe different functions. Furthermore, although the barrier height as a function of gate voltage has been studied, detailed band alignment has yet to be studied due to difficulties of gate voltage separation between graphene and other nanomaterial. To address these challenges, we demonstrate a graphene-carbon nanotube (CNT) junction device laterally integrated with local gate electrodes for graphene and CNT. Furthermore, barrier height dependence is also investigated as a function of local gate voltages. CVD-grown monolayer graphene was transferred onto a Si/SiO2 substrate with Au source and drain electrodes. After graphene was patterned by an oxygen plasma, semiconductor-enriched CNT networks were deposited by modifying the surface of graphene and SiO2 surfaces with poly-L-lysine. SiO2/Al2O3/SiO2/dielectric layers were deposited over the substrate, followed by Al gate electrode deposition. To apply the gate bias at graphene, CNT, and junction of them, multi-gate stack structure was fabricated by repeating the gate dielectric and electrode deposition. Uniform formation of graphene, CNT, and junctions were confirmed using Raman spectroscopy and AFM. Dirac point of graphene was about -3 V, and ambipolar behavior of CNT/graphene transistor was observed. When graphene voltage from -6 V to 3 V was applied, threshold voltage is modulated from 0 V to 0.28 V. These mobilities are 7.0±1.6 cm²/Vs and 1.1±0.2 cm²/Vs for p-type and n-type behaviors, respectively. After analyzing the device as a function of temperature, thermal and tunnel emission probabilities were calculated. At the transition between thermal and tunnel emission, barrier heights were extracted at different local gate bias of graphene. Based on the results, barrier heights were linearly changed by changing the gate voltage, which is in good agreement with our expectation due to the Fermi level movement. The barrier heights are varied from ~84.5 meV to ~69 meV for n-type and ~85.5 meV to ~71.5 meV for p-type depending on the graphene gate voltage. The values are slightly lower than that of vertically integrated graphene/TMD materials. This may be caused by the multiple junctions with defects to the Fermi level of graphene due to solution process of CNT network formation. In summary, we could successfully fabricate the locally gate controllable graphene/CNT junction transistor and analyzed the barrier height at different local gate voltage corresponding to the Fermi level movement.

**Local Structures of Polycyclic Aromatic Hydrocarbon Molecules Encapsulated in Single-Walled Carbon Nanotubes Studied by Molecular Dynamics Simulations**

Ryo Nagai, Hironori Ogata and Yosuke Karaoke; Hosei University, Tokyo, Japan.

Carbon nanotubes (CNTs) is one of the most promising material because of their superior electronic, thermal and mechanical properties. Single-walled carbon nanotube(SWNTs) have a hollow space of about several nm in diameter. It is possible to encapsulate various functional molecules in hollow space and expected new functions by encapsulation. One of the polycyclic aromatic hydrocarbon (PAH) molecules, coronene has been reported to exhibit interesting fluorescent properties depending on the local structure. The unique luminescence properties of columnar stacked coronene encapsulated in SWNTs have been also reported.In this study, molecular dynamics simulation was performed to clarify the local structure and properties of various kinds of PAH molecules encapsulated in SWNTs systematically. We will report the detailed results of SWNT chirality dependence of encapsulated structures of PAH molecules.
Effect of Carbonyl and Hydroxyl Groups on the Performance of ITO-Decorated MWCNT Based Electrochemical Capacitors Neftali L. Carreno1,
Matheus Krelow1,2, Guillerme Maron1, Bruno Norenberg1, Lucas Rodrigues1 and Jose H. Alano1; 1University Federal-Pelotas, Pelotas - RS, Brazil; 2Instituto Federal Sul-rio-grandense Caupolica-CAVG, Pelotas, Brazil.

Owing to the energy needs of the modern world, numerous studies have been performed in order to develop new materials with advanced electrical properties to be applied in energy storage devices, especially capacitors and supercapacitors. Accordingly, carbon-based materials such as carbon nanotubes (CNT) and reduced graphene oxide (rGO) are regarded as great alternatives to be used in the clean energy industry. Also, the possibility of the development of nanocomposites with carbon-based materials, metallic nanoparticles and metal oxides becomes interesting for electrochemical applications, such as energy storage devices, capacitors, gas sensors and others, and is the main focus of many researches in the last few years. A potential candidate to be used in the surface modification of CNT’s is the indium tin oxide (ITO), since it presents very interesting electrical properties and is studied for several applications. In the present work, nanocomposites of CNT/ITO have been prepared using a microwave-assisted hydrothermal synthesis (MHS), with posterior annealing of 400 °C and 600 °C, in inert atmosphere, to obtain crystalline ITO. Hydroxylated (CNTOH) and carboxylated (CNTCOOH) multiwalled carbon nanotubes-MWCNT (30% w/w), indium nitrate and tin chloride were used as precursors. The obtained powder was investigated by X-ray diffraction (XRD) and scanning electron microscopy (SEM). The electrochemical properties were evaluated by cyclic voltammetry, electrochemical impedance spectroscopy and galvanostatic charge-discharge, using a two electrode cell with current collectors made of 304 stainless steel, KOH 6 mol L-1 as electrolyte and filter paper as separator. The measurements were performed in a source meter Keithley model 2651A and a potentiostat IVIUM - Compactstat.e. XRD results showed that the sample annealed at 400 °C; the phase obtained was rhombohedral, while at 600 °C formed the cubic phase. Charge-discharge results showed values of 3.2 F/g and 1.4 F/g for CNTOH/ITO-400 and CNTOH/ITO-600, respectively, and 5.1 F/g and 0.3 F/g for CNTCOOH/ITO-400 and CNTCOOH/ITO-600, respectively. It is possible to observe that the specific capacitance of the samples with rhombohedral ITO was higher than for cubic, which can be explained by a degradation of nanotubes structure when submitted to higher temperatures. However, these findings require further characterization, such as Raman spectroscopy and FEG-SEM images, for example.

NM01.07.16
Fabrication of Gate Tunable Graphene Lateral Tunnel Diodes Takashi Uchino1, Kanako Shiga1, Kenta Sugawara1, Hirokazu Fukidome1, Akira Satou2 and Taichi Otsuiji2; 1Tohoku Institute of Technology, Sendai, Japan; 2Tohoku University, Sendai, Japan.

Two-dimensional materials have attracted attention in recent years because of their excellent electrical properties and can develop innovative devices [1-3]. In particular, single-layer graphene with the higher mobility and saturation velocity could push the limit of high-frequency devices [4]. In this work, we focus on fabrication and electrical characterization of gate tunable graphene lateral tunnel diodes to realize optical rectennas which receive and convert optical frequency electromagnetic radiation into DC output with high-efficiency and low-cost [5].

The gate tunable graphene lateral tunnel diodes were fabricated using monolayer graphene grown by chemical vapor deposition (CVD) on Cu foil and later transferred to 83-nm-thick SiO2 on Si substrates. Tunnel regions were formed by using electron beam lithography, and the tunnel length ranged from 60 to 150 nm. Tunnel dielectric consists of Si3N4 and Al2O3. The Al2O3 layer was formed by atomic layer deposition on the negative oxide of Al thin film. Metal electrodes (anode and cathode) were formed by electron beam evaporation of Ti/Pd/Au (0.5/20/100 nm) right after an oxygen plasma treatment to reduce contact resistance between graphene and electrodes. Top and back gate electrodes were formed by Ti/Au (20/80 nm) and Al (100 nm), respectively. Typical current-voltage (I-V) characteristics of the fabricated devices showed rectifying characteristics at a low voltage below 1 V. The on-state current of the lateral diodes increased with reducing the tunnel length. The lateral diodes have p-type rectifying characteristics for positive gate voltages and n-type rectifying characteristics for negative gate voltages. This result indicated that the tunnel barrier height could be controlled by applying gate voltage. We also measure the rectifying characteristics as a function of the back gate voltage to confirm the tunneling transport. The devices exhibited steep subthreshold slope (SS) of 40 mV/decade, which was lower than the theoretical limit of MOSFETs at room temperature indicating the devices were tunnel diodes.

Importance of Electrical Current in Post-Synthetic Graphitization Process for Property Improvements of Single Walled Carbon Nanotubes and Graphene Sheet Naoyuki Matsumoto, Azusa Oshima, Kenji Hata and Don Futaba, National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Many papers have clarified that the healing of crystalline defects in materials improves various properties. In this study, we demonstrate a new approach for healing crystalline in single wall carbon nanotubes (SWCNTs) based on simultaneously applying electrical current and heat. In this way, we succeeded in improving the graphitization without inducing other changes to the structure, in particular diameter and wall number. To achieve this we designed and constructed a specialized treatment device capable independently applying current (~240 A cm-2) and heating (room temperature to 2000 °C). Our examination found that at 800 °C, 150 A cm-2 for 1 min, we could achieve a 3.2-times increase in crystallinity as indicated by an increase in Raman G- to D-band ratio, a 3.1-times increase in electrical conductivity (from 25.2 to 78.1 S cm-1), and a 3.7-times increase in thermal conductivity (from 3.5 to 12.8 W m-1 K-1). The simultaneous increase in electrical and thermal conductivities stems directly from defect healing, and importantly we observed no additional change in diameter or wall number. The simultaneous application of current is essential in maintaining the initial CNT structure (diameter and wall number) as demonstrated in a reference test where CNTs were treated without an applied current. Further studies have demonstrated the scalability of this process in achieving similar improvement (~3-fold) in both thermal and electrical conductivities, which results indicate the fundamentally scalable towards larger scale (i.e. gram-level or more) amounts of SWCNT. In addition to fundamental improvement in composition and structure, we applied this re-graphitization process to few-layer, free-standing exfoliated graphene. We achieved this by applying the electrical current (current density: ~900 A cm-2) in conjunction with heating (~900 °C) in-plane of an “exfoliated graphene sheet” with the original sample holder in an argon ambient. After treatment at 900 °C and 545 A cm-2 for 1 min, we observed a significant increase in graphitization as exhibited by a ~10-times increase in the Raman G- to D-band ratio (2.84 to 36.7) and no observed change in interlayer separation, i.e. (002) reflection by x-ray diffraction. Furthermore, we observed a ~2.0-times increase in electrical conductivity (from 1088 to 2275 S cm-1). These results demonstrate the use of a post-synthesis process to nanocarbon materials to improve crystallinity and the difference between its application towards SWCNTs and graphene. Therefore, we believe strongly that this process overcomes one of the major limitations of SWCNT and
graphene (other 2D-materials) toward real applications.

Damage Formation Due to Low-Energy He and Ne Ion Irradiation in MWCNTs
Sathana Eswara, Jean-Nicolas Audinot, Tom Wirtz and Patrick Philipp; Advanced Instrumentation for Ion Nano-Analytics (AINIA), MRT Department, Luxembourg Institute of Science and Technology, Belvaux, Luxembourg.

Targeted tuning of the structure and properties of carbon nanotubes (CNT) using ion irradiation is very attractive for technological applications. To understand the damage formation and evolution due to ion irradiation in multiwalled (MW) CNT, we used 25 keV Ne⁺ and He⁺ ion irradiation with controlled fluences in the range of 10¹⁴ to 10¹⁸ ions/cm² and subsequently investigated the irradiated areas by TEM imaging and Raman spectroscopy. A new methodology involving Au TEM grids was developed to ensure compatibility across the different techniques and to preclude the Raman contribution coming from the amorphous carbon support of typical TEM grids. The experimental results indicate a significant difference in the damage evolution between He⁺ and Ne⁺ irradiation. Furthermore, the sample thickness was found to play an important role in determining the extent of damage. TEM imaging suggests that the thicker areas are significantly amorphized, while thin areas (t < 10 nm) were found to be relatively undamaged with only very minor changes in comparison to pristine samples. For He⁺ and Ne⁺ irradiation, damage formation evolves differently, with a change in the trend of the ratio of D to G peak in the Raman spectra being observed for He⁺ but not for Ne⁺. The experimental results were then compared with the Monte-Carlo (MC) simulations of ion-solid interaction by approximating the sample to a thin carbon membrane. Due to the small thickness of the MWCNTs, sputtering has been observed for the top and bottom side of the samples. Depending on thickness and ion species, the sputter yield is significantly higher for the bottom than the top side.

In this presentation, we will describe the new methodology that was developed for this study and discuss the experimental results from correlative TEM-Raman analysis of MWCNT under He⁺ and Ne⁺ irradiation together with insights drawn from MC simulations using SDTRIMSP.

Organic Solvent-Induced Spectral Shifts of Near Infrared Photoluminescence of Locally Functionalized Single-Walled Carbon Nanotubes
Yoshiaki Niidome, Tomohiro Shiraki, and Tsuyohiko Fujigaya; Graduate School of Engineering, Kyushu University, Nishi-ku, Fukuoka, Japan; International Institute for Carbon Neutral Energy Research (WPI-I2CNER), Kyushu University, Fukuoka, Japan; JST-PRESTO, Kawaguchi, Saitama, Japan.

Semiconducting single-walled carbon nanotubes (SWNTs), which have one-dimensional cylindrical structures with a graphene wall, show near infrared (NIR) photoluminescence (PL). As an interesting feature of SWNTs, the PL properties are sensitively changed by effects of microenvironments that are composed of surfactants and solvent molecules. Therein, physical properties of microenvironments such as polarity and polarizability could affect coulumb interactions between electron - electron or electron - hole in the tubes [1]. In recent studies, local chemical functionalization of SWNTs is reported to produce novel PL properties [2][3]. The locally functionalized SWNTs (lf-SWNTs) emit new PL (E₁₁*) whose wavelength are red-shifted over 100 meV from the original PL (E₁) of the pristine SWNTs and their quantum yields increase largely. These properties arise from electronic structure variation introduced by the functionalization and exciton trapping at the functionalized sites, respectively. Actually, we experimentally revealed that energy levels of the HOMO and LUMO shifted at the local functionalized sites with dependence on the chemical structures of the functionalized groups [4].

In this study, we examine microenvironment effects on the E₁₁* PL of lf-SWNTs in order to compare excitonic properties at the local functionalized sites and the pristine sites. Herein, we synthesized nitroaryl-functionalized SWNTs (lf-SWNTs-NO₂) that were solubilized in D₂O containing sodium dodecylbenzenesulfonate (SDBS). For microenvironment creation of an organic solvent [5], o-dichlorobenzene (oDCB), which was immiscible in water, was poured into the lf-SWNTs-NO₂ solution and vigorously shaken, then the separated aqueous layer was collected for measurements. After the experimental process, PL peaks of E₁₁* and E₁ were red-shifted, indicating that oDCB permeated into the hydrophobic regions between the nanotubes and the coating SDBS micelles. Interestingly, the shifted energy value of E₁₁* was larger than that of E₁; the result indicates that interactions of oDCB on the nanotubes might be varied at the local functionalized sites and the pristine sites. Details including the effects of other solvents will be discussed in this presentation.

Preparation of Size-Controlled Carbon Nanomaterials via Morphological Transcription from β-lactoglobulin Aggregates
Yoshifumi Orimoto, M Nuruzzaman Khan, Yutaka Kuwahara, Makoto Takafuli and Hirotaka Ibara; Department of Applied Chemistry and Biochemistry, Kumamoto University, Kumamoto, Japan.

Herein, we report a diverse and simple method that enables stabilization and transcription of protein - derived nano - sized superstructure. It is known that β-lactoglobulin used to forms aggregates by controlling specific protein concentrations and solution pH, ionic concentration and heating temperature, so it was thought that we succeeded in morphological transcription. Furthermore, CPNS after high temperature carbonization also maintained spherical shape with nano-sized carbon-shell. It was also possible to confirm the morphological stabilization of the superstructure before and after polymer coating under alkaline conditions. Prepared CPNS is expected to be used in fields such as nanosensor, drug delivery, and adsorbent. In addition, this method is expected to be used as a method for preparing and functionalizing carbon nanostructures, which is convenient and versatile than ever before.

NM01.07.21
Mechanism Study of Chemical-Vapor-Deposition Graphene Adlayers Pei Zhao, Xuewei Zhang and Hongtao Wang; Zhejiang University, Hangzhou, China.

In the past few years there have been many exciting achievements in the synthesis of large-size and high-quality monolayer graphene (MLG) using the chemical vapor deposition (CVD) method on Cu substrates. During the MLG growth, accompanying adlayers occur and remain a broad interest to researchers for a deep understanding of the graphene mechanism. When methane is used as the precursors, it is believed that the adlayers are grown underneath the previous layer, whereas when ethanol or other precursors with stronger reactivity is used, adlayer growth follows a layer-by-layer regime. In this work, we studied the growth mechanism of graphene adlayers using carbon isotope labelling of the precursors and Raman spectroscopy. Results show that when methane is used, the growth of the adlayers exhibits several different modes. For most of the adlayers, they maintain their AB-stacked or twist structures with the upper layer during the growth since their nucleation, but for some of them these stacking structures can suddenly change during the growth. Moreover, we also observed that the adlayers can nucleate tens of minutes later during the growth (not together with the first layer), with an AB-stacking with the upper layer. We also compared the results with previously reported work using ethanol, whose epitaxial nucleation of the second layer is mainly due to the active CH3 radicals with the presence of a monolayer-graphene-covered Cu surface. We believe that this study will help clarify more growth mechanism of graphene by CVD process, and lead to many new strategies for scalable synthesis of graphene with more controllable structures and numbers of layers.

NM01.07.22
Extraordinary Lithium Storage Property Form Transition Metal Oxide Electrodes by Introducing Porous CNT Sponges and Massive Oxygen Vacancies Mingchi Zou; College of Engineering, Peking University, Beijing, China.

Transition metal oxides (TMOs) are regarded as alternative anode materials due to their high theoretical capacity, nontoxic and low cost. However, it is unable to take into account of high capacity and stable cycling performance which hinder their practical applications. Here, we improve both specific capacity and stability of transition metal oxides by following two aspects: 1) composing with CNTs through a hierarchical coaxial nanostructure, and 2) introducing with massive oxygen vacancies. The synergistic reaction between TMOs (shell) and CNTs (core) through a hierarchical coaxial nanostructure can effectively enhance conductivity and reduce the Li+ diffusion distance, and consequently improve the rate performance, cycling stability and specific capacity. We develop an unique three-dimensional sponge-like CNT bulk material with excellent conductivity, high porosity and stable compressibility, which can be used as an ideal current-collector. Titanium dioxide (TiO2) is directly deposited onto the CNT sponge as a coaxial structure, forming a highly porous composite sponge electrode without any redundant additives (such as conducting agent and binder). As an anode for LIBs, TiO2@CNT sponge exhibit stable charging/discharging plateau voltages, higher capacity, better stability and rate performance comparing with pure TiO2 electrodes.

Moreover, due to the TMOs are directly deposited onto the CNT sponge, the morphology of electrodes are determined by the CNT sponge. We fabricate a 1D porous electrode by depositing CNT sponges on a single carbon fiber (CF) and then deposit manganese dioxide (MnO2) onto the CNT sponge and obtain a MnO2@CNT@CF fiber-shaped electrode for LIBs. Massive oxygen vacancies are introduced into TMOs to further improve the performance of LIBs. An unique electric field assistant annealing method is developed to treat TiO2@CNT sponges. Under the combined function of the temperature and electric field, oxygen vacancies are rapidly formed and migrated through TiO2, forming an amorphous TiO2@CNT sponge with a large number of oxygen vacancies (~45%) uniformly distributed in the hole TiO2@CNT exhibits a capacity as 604 mAh/g which is much higher than theoretical capacity of TiO2 (335 mAh/g). Even under high rate condition (10000 mAh/g), the capacity is stable as 110 mAh/g. This extraordinary performance is originated from the massive uniformly distributed oxygen vacancies which significantly enhance the conductivity and Li+ diffusion ability of TiO2. Using this electric field assistant annealing method, massive oxygen vacancies can be introduced into many other TMOs (such as MnO2 and SnO2).

In conclusion, we efficiently improve the lithium storage performances of TMO electrodes by composing CNT sponge with a coaxial structure and introducing massive oxygen vacancies uniformly. Our work has a prospect in achieving advanced LIB anodes with stable and high rate capacities for many practical applications.

NM01.07.24
New Carbon Allotropes—Novamene and Protomene as Future Advanced Carbon-Based Nanomaterials Daniel Choi1, Mohamed Alfahim2, Larry Burchfield2, Rashid Alfahim2, Kin Liao1, Abdel F. Isakovici1, Bao Huan An1, Tamador Elshohra1 and Nicola Manini2,3; Khalifa University of Science and Technology, Abu Dhabi, United Arab Emirates; 2Alfields, Inc, Abu Dhabi, United Arab Emirates; 3Universita degli Studi di Milano, Milano, Italy.

A new classification of carbon allotropes, called, Novamene is the first release in a series which fall into an entirely new class of carbon in 2016. As for the comparison with diamond and other carbon allotropes, thermal properties of Protomene can be differentiated. Since thermal expansion behaviors of Protomene are associated with interplane bonding, Protomene may experience structural phase change which can lead to a more rapid change in energy band gap and thermal expansion compared with diamond and silicon.

We will present our efforts of on-going development of fabrication techniques for new carbon allotropes including Novamene and Protomene based on both top-down and bottom-up approaches and modeling activities by means of Density Functional Theory (DFT) simulations.

References
Electronic properties including work function, carrier type, and conductivity were measured and correlated with their ORR catalytic activity for post-doping process and high-temperature annealing treatment, and evaluated their ORR catalytic activities in an acid electrolyte. In addition, their temperatures (> 1000 K). The obtained ultimate strength and ultimate stress show an anisotropic material; the highest ultimate strength was obtained for x simulations. We used the ReaxFF force field as available in the LAMMPS code. Our results [2] show that the protomene are very stable, up to very high temperatures (> 1000 K). The obtained ultimate strength and ultimate stress show an anisotropic material; the highest ultimate strength was obtained for x directions, with a value of ~102 GPa. As for the ultimate strain, the highest one was for z direction (27% of strain) before protomene mechanical failure (fracture).

References:
onset potential, oxygen reduction current density at half-wave potential, and numbers of electrons transferred per oxygen molecule in the ORR, the AN-SWCNTs exhibited superior ORR catalytic activity to the N-SWCNTs. The work function of the AN-SWCNTs was lower than that of the N-SWCNTs, and the carrier type of the AN-SWCNT film was obviously n-type even in air. The conductivity of the AN-SWCNT film was higher than that of the N-SWCNT film. These results suggest that the low work function and high conductivity observed in the AN-SWCNTs can promote the ORR catalytic activity.

NM01.07.28
Towards Single Crystal Monolayer Films—Catalyst Engineering for High Quality CVD Graphene Oliver Burton and Stephan Hofmann; University of Cambridge, Cambridge, United Kingdom.

Chemical Vapour Deposition (CVD) has become the dominant technique for the growth of graphene and related 2D materials, driven by the emerging industrial demand for ‘electronic-grade’ materials that are consistent over large areas. Significant progress has been made using heterogeneous catalysis,[1] and using the most widely used substrates is polycrystalline copper foil. A fundamental challenge in devising a CVD process that consistently results in homogeneous single crystal graphene is the initial substrate: which has varying concentrations of different trace impurities that can affect the growth process. It has been shown that a simple oxidative pre-treatment of the Cu catalyst to remove residual carbon results in a significant reduction in nucleation density, allowing for a much larger graphene domain size to be achieved.[2] There is still a compromise between fast growth rates and reducing sources of defects such as grain boundaries. Further to this, adequate characterisation of large area monolayer graphene films has become a significant challenge on its own.

Here we report how these compromises in controlled graphene growth can be addressed by systematically studying modifications of the Cu catalyst. The effects of adding oxygen to the Cu bulk on graphene nucleation density, morphology, growth rate and quality are closely examined. The epitaxial relationship of graphene on different Cu textures is quantitatively analysed and the capability to significantly enlarge Cu grains and recrystallize the foil is demonstrated. By leveraging the epitaxial alignment seen on specific Cu facets, single crystal graphene films can be rapidly grown, paving the way for films with improved homogeneity. In addition, a novel method to characterise graphene quality on a larger scale is introduced based on a modification of established Raman characterisation strategies.

NM01.07.29
High-Performance Magnetorheological Suspensions of Fe3O4-Deposited Carbon Nanotubes with Enhanced Stability Hoyeon Kim, Junseok Choi and Yongseok Seo; Seoul National University, Seoul, Korea (the Republic of).

The magnetorheological (MR) performance of suspensions based on the Fe3O4-deposited carbon nanotubes (CNTs) was investigated by using a vibrating sample magnetometer (VSM) and a rotational rheometer. The Fe3O4-deposited CNTs were synthesized by the reduction process in which nano-Fe3O4 nanoparticles were generated and adsorbed on the surface of CNTs. All tested suspensions displayed excellent MR behaviors with high yield stress. The important parameter which determined the MR performance was the surface density of Fe3O4 on the CNT surface. The morphology was observed by scanning electron microscope (SEM) and transmission electron microscope (TEM). Most Fe3O4 particles adsorbed on the surface of PS/Fe3O4 particles to make the surface topology bumpy and rough which decreased the particle sedimentation velocity. Finally, Turbiscan apparatus was used to examine the sedimentation properties of Fe3O4-deposited CNTs suspensions. The suspensions showed excellent stability against sedimentation, much better than bare Fe3O4 particle suspension due to the inherent low density of CNT and its inside pore which can reduce the density mismatch between the nanoparticles and the carrier medium as well as the surface topology change due to the adsorption of Fe3O4.

NM01.07.30
Fabrication of Nanoporous Ultrathin Membranes by Cluster Ion Irradiation Ar dak Ain abay ev1, Aid yn Shaik ho v3, Ab at Zhuld ass ov1, Sean Kirkpatrick1, Michael Walsh3, Mititaka Terasawa4 and Zin et u la Z. Insepov1,2,3; 1School of Nuclear Engineering, Purdue University, West Lafayette, Indiana, United States; 2Condensed Matter Physics, National Research Nuclear University MEPhI, Moscow, Russian Federation; 3Nazarbayev University, Astana, Kazakhstan; 4Laboratory of Advanced Science and Technology for Industry, Kouto, Japan; 5Exogenesis Corp., Billerica, Massachusetts, United States.

Gas Cluster Ion Beams (GCIB) is a powerful tool for surface modification of various materials and theoretically and experimentally demonstrated the ability to create defects in ultrathin graphene-like films. In this study GCIB of Ar with acceleration energy  E = 30 kV (Exogenesis, MA, USA) and total fluences ranged from 1x1019 to 1x1021 ions/cm² is used to produce defects in ultrathin films such as graphene, graphene oxide, MoS2 and Si, HOPG as a reference. GCIB irradiated ultrathin films were characterized by NEXAFS and Raman spectroscopy, scanning electron and atomic force microscopy. The Raman spectroscopy (Horiba) study of the irradiated samples was conducted by a 632 nm laser wavelengths and 100x objective with a laser spot size of ~1 μm, 2 mW power and atomic force microscopy (AIST NT) measurements were carried out in a tapping mode by SUPERSHARP SILICON™ AFM probes for high resolution. NEXAFS spectroscopy measurements were carried out at the NewSUBARU BL09A beamline of the NewSUBARU SR LATTI facility at the University of Hyogo, using total-electron yield (TEY) method and without uncompleted correction of energy. Density functional theory (DFT) calculations have been performed to study the Raman spectra of pristine and graphene with vacancy defects. Large-scale parallel molecular dynamics (MD) simulations (LAMMPS) were employed for studying interactions of accelerated cluster ions with ultrathin films, such as graphene, MoS2, HOPG, and BN. The MD results showed formation of uniform holes, with the diameters of 10-20 nm, in the ultrathin films, and were used for optimization of the experimental fabrication of holes in 2D-films.

The DFT and MD simulations provides fundamental understanding of the argon bombardment of ultrathin films and its influence on Raman spectra of graphene.

Study of the Interfacial Interaction Between Carbon Nanotubes and Catalyst—The Effects on the Tube Diameter Mauricio Carvajal Diaz and Perla B. Balbuena; Artie McFerrin Department of Chemical Engineering, Texas A&M University, College Station, Texas, United States.

Single-walled carbon nanotubes (SWCNTs) are seamless cylinders of graphene that have been at the forefront of nanotechnology research for the past two decades. While mass-produced SWCNT powders are adequate for some applications, many emerging applications require stricter control over SWCNT properties and architectures, necessitating targeted growth, i.e. tailoring the physical properties of the SWCNTs (diameter, orientation/architecture, etc.). This work attempts to prove the key role of the graphene properties and the metal - catalyst interaction in the relation between catalyst size and nanotube diameter. We work on the assumption that the curvature energy is one of the most influential factors in the graphene film formation and a crucial constraint...
to determine the stable diameter of the nanotube during the growth. The calculation of interlayer binding energies using density functional theory (DFT) and pseudopotential functions has been valuable to find the transition diameter between fullerene and tube. Additionally, we propose a new model that links statistical mechanics theory with the possible strain energy states and allows the calculation of the expected or most probable diameter. This is just the first step to bring light to the yet undiscovered reigning principle for the nanotube’s diameter stability during nucleation.

NM01.07.32
Segregated rGO/P(MMA/PA) Bilayer Composite Systems with Improved Electrical Features Tajamal Hussain, Sidrah Ishaq, Adnan Mujahid and Azeem Intissar; University of the Punjab, Lahore, Pakistan.

Poly(methylmethacrylate) (PMMA) based reduced graphene oxide (rGO) and reduced polyaniline (rPA) segregated bilayer composites (rGO/PMMA/rPAI) with different compositions have been designed as high performance nanocomposites. Synthesis process of the rGO incorporated PMMA (rGO/PMMA) and rPAI incorporated PMMA (PMMA/rPAI) and rGO/PMMA/rPAI composites have been monitored by UV-visible and FTIR spectroscopy. Performance of the synthesized segregated bilayer composites has been studied by analyzing the electrical features measured at wide range of frequencies starting from few Hz to 1MHz. Substantial enhancement in the electrical properties was observed at relatively lower filler contents. Almost 15 times increase in value of dielectric constant was observed at just 0.7 wt% of rGO. Impressive increase in the electrical conductivity was achieved and percolation threshold value was observed as low as 0.06 wt%. Electrical features determined for these segregated bilayer composites are more outstanding than those of simple tri components PMMA based composites.

NM01.07.33
Organic Field Effect Transistors Incorporating Ultrapure Semiconducting Single-Walled Carbon Nanotubes Nicole Rice1, William Bodnaryk2, Brendan Mirka, Owen Melville1, Alex Adronov2 and Benoit Lessard3; 1University of Ottawa, Ottawa, Ontario, Canada; 2Chemistry, McMaster University, Hamilton, Ontario, Canada.

Printed electronics is a burgeoning field that has received intense research interest and is beginning to experience commercial successes. Single-walled carbon nanotubes (SWNTs) are a unique and promising building block for incorporation into next generation superfast electronic devices. SWNTs have very high carrier mobilities, with band gaps compatible for integration into logic circuits. Their excellent mechanical flexibility allows for potential incorporation into flexible printed electronics, enabling fully-printed transistors and circuits with performances that support low cost, large area fabrication. Progress in incorporating SWNTs into commercial devices has been hindered by the presence of metallic SWNTs, which are produced alongside semiconducting SWNTs during synthesis, and negatively impact device performance. Fabrication of ambipolar SWNT organic thin film transistors (OTFTs) with high carrier mobilities and high on/off ratios remains particularly challenging; many examples in the literature required high temperature, expensive and energy-demanding processes.

Since the initial discovery of conjugated polymer-assisted dispersion and purification of SWNTs in 2008, several polymer families have been successfully shown to selectively disperse semiconducting SWNTs. However, only a relatively small number of these supramolecular complexes have been incorporated into OTFTs. We used a novel conjugated polymer to exclusively disperse semiconducting SWNTs. The dispersion procedure requires a simple sonication and centrifugation, during which the metallic SWNTs sediment out. Solution purity was evaluated using UV-Vis-NIR and Raman spectroscopies. The resulting dispersions are amenable to solution processing techniques such as spin coating and drop casting, allowing for the potential for large area device fabrication at room temperature. Ambipolar OTFTs were fabricated under ambient conditions using this solution and tested in both air and under inert atmosphere. The presence of excess conjugated polymer, solution deposition techniques, SWNT density, surface treatment, and post-fabrication treatment were all investigated to determine which parameters facilitated the production of OTFTs with high mobilities (>20 cm2V-1s-1), high on/off ratios (106-108), negligible hysteresis, controlled threshold voltages, and high bias stability.

NM01.07.34
Bubble Tunable Novel Vibration Damping PDMS-Graphene Soft Nanocomposites Tong Zuo1, Kuangyu Shen1, Xiaoliang Li1, Isaac Macwan1, Prabir Patra1, Chandra S. Tiwari2, Peter S. Owuor2 and P. M. Ajayan2; 1Biomedical Engineering, University of Bridgeport, Bridgeport, Connecticut, United States; 2Materials Science and Nanoengineering, Rice University, Houston, Texas, United States.

Constrictions inclusions or other accidental cases occur very regularly. Often times constrictions leads to chronic traumatic encaphalopathy (CTE) and eventual death. Polydimethylsiloxane(PDMS)-based nanomaterial are gaining widespread attention in this regard. Here we report a unique bubble tunable graphene reinforced PDMS nanocomposites as a vibration dampening and possibly concussion resistant material. PDMS based nanocomposite was prepared by solvent swelling of the PDMS (Sylgard 184 from Dow Crowing Company) in chloroform/TEOS (4:1 ratio) mixture followed by ultrasonication of the graphene nanoplatelets in the solvent that swells the polymer. Various nanocomposite structures with and without bubbles were prepared. We studied the mechanical properties of PDMS-graphene nanocomposite as a function of temperature, pressure, nanoparticle size, solvent percentage, curing agent and filler concentration. The effect of different concentrations of graphene in the nanocomposite with and without bubble formation were measured and analyzed using dynamic mechanical analyzer (DMA) and impact testing. Physical interaction of PDMS adsorptions on the graphene were computed using molecular dynamic (MD) simulation. The influence of a well controlled bubble structure on the energy absorption behavior of the nanocomposite was explored. Stiffness of the nanocomposites increased with the loading of graphene. The role of bubble and bubble-graded nanocomposites is underway.

NM01.07.35
Intrinsic Wettability of Graphitic Carbons and Its Implication on Double Layer Capacitance Lei Li and Haitao Liu; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Graphitic carbons have been considered as hydrophobic for nearly eighty years. However, recent works in our lab1,2 showed that graphitic surfaces are much more hydrophilic than previously thought. Since the water-graphitic interface is critical to many important applications including electrodes, adsorbents, catalyst support, and solid lubricants, this unexpected finding could completely change the way graphitic materials are made, modeled and modified.

In this presentation, we will discuss on the intrinsic water wettability of graphitic carbons and its implication on double layer capacitance. First, our recent experimental results, e.g., contact angle, XPS, ATR-FTIR and ellipsometry, will be presented showing that pristine graphene and graphite are mildly hydrophilic and airborne hydrocarbons make the surfaces appear to be hydrophobic. Second. The implication of contamination will be illustrated through comparing the electrochemical activity and double layer capacitance of pristine and contaminated graphite. Lastly, future research directions to address a few important unanswered questions will be presented.

**Intercalation of Fullerenes Between Graphene/Cu Interfaces**

Alexandre F. Fonseca1, Socrates O. Dantas2, Douglas S. Galvao2, Difan Zhang3 and Susan B. Sinnott4; 1State University of Campinas, Campinas SP, Brazil; 2Universidade Federal de Juiz de Fora, Juiz de Fora, Brazil; 3University of Florida, Gainesville, Florida, United States; 4The Pennsylvania State University, State College, Pennsylvania, United States.

Investigation of the structure and properties of the intercalated molecules between interfaces of two-dimensional layers or of a layered material and a substrate is a subject of great interest. Formation of crystalline patterns as well as induction of chemical reactions under two-dimensional covers are two of the main drivers behind this interest. One recent study by Reineke and collaborators [Nano Letters 15, 7421–7430 (2015)], showed the formation of amorphous and crystalline structures of C60 intercalated between graphene and a copper substrate. They further reported the existence of more or less strained graphene wrinkles, as well as detached graphene from substrate depending on the concentration or distance between the intercalated C60 molecules. Motivated by this work, we investigated the formation and thermal stability of graphene wrinkles as well as graphene attachment and detachment from substrate on previously distributed C60 and carbon nanotube molecules on copper substrate. We performed fully atomistic reactive molecular dynamics (MD) simulations using the third generation of the charge optimized many-body potential as available in the LAMMPS computational package. As the timeframe of spontaneous intercalation of C60 molecules between graphene and the substrate is too high to be feasibly simulated by MD methods, we simulated the “blanketing” of graphene on different concentrations of C60 and carbon nanotubes previously laid on the substrate. We tested both fixed and non-fixed structures, i.e., we predicted the change in the height of graphene, fullerene, and substrate when the fullerenes are not fixed. We then verified that graphene attaches to the substrate when the distance between the fullerenes is at least 6 nm. Below that distance, graphene becomes locally suspended and low strain is verified. While such studies of intercalation of molecules on interfaces formed by graphene-substrate are motivated by finding out ways to control wrinkling and strain in graphene, this work reveals the role of stability and wrinkling as well as the shape and structure of intercalated molecules under the action of graphene on the final structure and properties.

**Double Charge Neutrality Point Induced by H2 Exposure in Graphene Devices**

Cintia L. Pereira, Alisson R. Cadore, Natália P. Rezende, Leonardo C. Campos and Rodrigo G. Lacerda; Departamento de Física, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

In this work, we present a study regarding the interaction between molecular hydrogen (H2) and graphene field effect transistor with different metals and contact geometries. We demonstrate that this interaction is strongly dependent on the characteristics of the graphene-metal contact interface. Three different contacts were probed: pure Au, Au/ Cr and Au/ CrO2 contacts. Interestingly, we observed that only for Au/CrO2 contact devices the emergence of a second charge neutrality point (CNP) in the resistance as function of gate voltage curves (“M-shape”) due the H2 exposure. This is the first time that such behavior (“M-shape”) is found due to a gas interaction with graphene devices. This effect was observed for different conditions of temperatures (25°C-200°C) and H2 concentrations (0.5%-50%) and it is totally reversible. Previous works about graphene-contact interaction, demonstrated that the difference of the work function between both materials generates a local p-type or n-type doping [1]. Added to the electrostatic doping generated by the back gate voltage, a pn junction is formed. Also, Cadore et al. verified that the H2 can modulate these pn junctions in graphene devices with Au/ Cr or Au contacts [2]. Thus, the formation of the two CNP that appear on devices with Au/CrO2 contacts can be explained by the fact that the charge density of the graphene under the electrodes and in the channel can be modulated by back gate voltage application. This, in two CNP appear without pinning the work function, and the difference between the Fermi level in both regions generates the two CNP [3]. Also, we believe that the thin layer of oxide formed (Cr2O3) may be responsible for a catalytic process and facilites the hydrogen flow inside the interface contact-graphene, hence increasing the influence from such regions of the electrical measurements. In other words, our findings suggest a way of inducing the decoupling of the work function between the metallic electrodes and graphene by the use of contacts Au/CrO2 and hydrogen gas exposure. Additionally, we demonstrate that the high variation of the resistance generated by the emergence of the second peak and the low time of response to hydrogen provides a system that is very promising for H2 sensor applications. This work was supported by CAPES, Fapemig (Rede 2D), CNPq and INCT/Nanomaterias de Carbono. References:

**Flexible CNT-Decorated PDMS Foams Enable Unprecedented Detection of Ultralow Strain and Pressure Coupled with Large Working Range**

Rossella Iglio1, Stefano Mariani2, Valentina Robbiano2, Luccano M. Strambini2 and Giuseppe Barillaro3; 1University of Pisa, Pisa, Italy; 2National Research Council, Pisa, Italy.

Low-cost piezoresistive strain/pressure sensors with large working range, at the same time able to reliably detect ultralow strain (≤0.1%) and pressure (≤1 Pa), are one of the challenges that have still to be overcome for flexible piezoresistive materials towards personalized health-monitoring applications. Here, we report on unprecedented, simultaneous detection of ultrasmall strain (0.1%, i.e. 10 µm displacement over 10 mm) and subtle pressure (20 Pa, i.e. a force of only 2 mN over an area of 1cm2) in compression-mode, coupled with a large working range (i.e., up to 60% for strain – 6 mm in displacement - and 50 kPa for pressure) using piezoresistive, flexible three-dimensional (3D) macroporous PDMS (pPDMS) foams decorated with pristine multi-walledCNTs1. pPDMS/CNTs foams with pore size up to 500 µm (i.e. twice the size of those of commonly used foams, at least) and porosity of 77%, decorated with a nanostructured surface-network of CNTs at densities ranging from 7.5 to 37 mg/cm2 are prepared using a low-cost and up-scalable process, through replica molding of sacrificial sugar templates and subsequent drop-casting of CNT ink. A thorough characterization shows that piezoresistive properties of the foams can be finely tuned by controlling the CNT density, and reach an optimum at a CNT density of 25 mg/cm2, for which a maximum change of the material resistivity (e.g., ρ2/ρ0=4 at 50% strain) is achieved under compression. Further static and dynamic characterization of the pPDMS/CNTs foams with 25 mg/cm2 of CNTs highlights a detection limit for strain and pressure of 0.03% (3 µm displacement over 10 mm) and 6 Pa (0.6 mN over an area of 1 cm2), respectively; moreover, good stability and limited hysteresis are apparent by cycling the foams with 255 compression-release cycles over the strain range 0-60%, at different strain rates up to 10 mm/min. Our results on piezoresistive, flexible pPDMS/CNT foams pave the way towards breakthrough applications for personalized health care, though not limited to, which were not fully addressable to date with flexible strain/stress sensors.

Photoluminescence Modulation of Single-Walled Carbon Nanotubes by Meta-Linked Bis-Aryldiazonium Modifiers

Boda Yu, Tomohiro Shiraki, and Tsuyoshi Fujigaya

1Department of Applied Chemistry, Graduate School of Engineering, Kyushu University, Nishi-ku, Fukuoka, Japan; 2International Institute for Carbon Neutral Energy Research (WPI-I2CNER), Kyushu University, Nishi-ku, Fukuoka, Japan; 3JST-PRESTO, 4-1-8 Honcho, Kawaguchi, Saitama, Japan.

A small amount of chemical modification of single-wall carbon nanotubes (SWNTs) has been reported to create modified sites with narrower band gaps on the tubes. The resultant locally functionalized SWNTs (IF-SWNTs) show new photoluminescence (PL) with red-shifted wavelengths and high quantum yields. The used SWNTs were (6,5) chirality-rich tubes (CoMoCAT) and they were solubilized in D2O containing sodium dodecylsulfate through sonication followed by ultracentrifugation. Chemical modification of SWNTs was conducted by mixing the solubilized SWNTs and synthesized meta-linked bis-aryldiazonium salts. When the meta-linked bis-aryldiazonium salt having the spacer of five methylene units (mC5-Dz) was reacted with SWNTs (mC5-IF-SWNTs), very slight changes were observed in the UV/vis/NIR absorption spectrum in comparison to that of pristine SWNTs, indicating that local chemical functionalization occurred. In sharp contrast, in the PL spectrum of mC5-IF-SWNTs, a new PL peak appeared at 1246 nm that was largely red-shifted from typical E1* and was the different wavelength value from the E2* of the previously reported IF-SWNTs using the para-linked bis-aryldiazonium salts. These results indicate that the structural difference between meta- and para-linked bis-aryldiazonium salts may induce unique spectral changes of E1, E2* for the IF-SWNTs. Other structural factors will be discussed in the meeting.

Experimental and Theoretical Study of Aqueous Dispersions of Graphene-Based Materials

Shan Jiang and Karl Coleman; Department of Chemistry, Durham University, Durham, United Kingdom.

Since the first reports of its isolation in 2004, graphene has received unprecedented interest from the scientific community. This is due to its remarkable properties such as high electron mobility, thermal conductivity and mechanical strength. However, in spite of this huge potential, a number of hurdles have existed which hinder graphene’s wholesale uptake by commercial applications. One of these is the need to improve the processability of graphene materials by improving their dispersibility in a range of aqueous and non-aqueous solvents. A wide range of approaches have been employed to try to improve the dispersibility of graphene in many solvents such as covalent functionalization of graphene sheet, aiming to enhance dispersibility by improving interaction with the solvent. The downside to all covalent modification techniques is that the presence of additional chemical functionalities disrupts the sp² matrix of the graphene sheets by introducing defect sites which can have a significant negative effect on the properties of the material. Surfactants have been used which adsorb non-covalently to the surface of the graphene sheets improving their dispersibility. However, residual surfactant molecules can have a negative impact on the properties of the graphene prepared and can be difficult to remove.

Herein, we have developed a method for improving the dispersibility of graphene and its related materials in commonly used, and low boiling solvents by making use of prior dispersion in good solvents (such as N-methyl-2-pyrrolidone (NMP) and dimethylformamide (DMF)). This method allows reduced graphene oxide (rGO) to be dispersed in water at concentrations of up to 20 μg ml⁻¹ which is over a six-fold improvement compared to dispersion of untreated rGO prepared under the same conditions. Predispersion of rGO in NMP can produce NMPrGO which forms a stable dispersion in water, with less than 0.3% residual NMP, confirmed by the experimental characterizations. Furthermore, molecular dynamics (MD) simulations have been used to exploit how the dispersion process is facilitated by the organic solvent treatment (NMP and DMF in this study), and investigate graphene and solvents interactions, and solvent geometry and orientation with respect to the graphene sheet. Additionally, DFT calculations have been used to study the electrical properties and charge distribution upon organic solvent adsorption on the graphene surface, in order to rationalize the improved dispersibility in water and ethanol.

from the channel as long as the electrode is bridged with the channel through the electrolyte—which we refer to as the remote gating. For effective remote gating, the distance between the gate and channel must be less than 200 μm. As the distance increases, the remote gating effect becomes weaker. The results demonstrate that the dynamic characteristics of the remote-gated graphene transistors can be maintained even if the gate electrode is located 1700 μm apart from the channel, which is comparable to the dynamic characteristics of a device using a direct-gated graphene transistor. Overall, the present results demonstrate the potential of Joule-heating-driven CVD towards fabricating remote-gated graphene transistors that can operate promptly even when they are gated from a distance. We confirmed that the effective current modulation of graphene transistor can be achieved at 1 kHz, even when the gate electrode is located 1700 μm apart from the channel, which were comparable to the dynamic characteristics of a device using a directly contacted gate electrode. The results indicate that the distance-dependence degradation on the dynamic characteristics of the remote-gated graphene transistors can be eliminated. The new device architecture provided here shows new opportunities to exploit graphene transistors for applications requiring long-range control.

Quantum Confinement Effect in the Absorption Spectra of Graphene Quantum Dots

Leon Yang and Kofi Addu-1, 2

Graphene quantum dots have emerged as functional material for myriad applications due to their unique properties such as deep ultraviolet and blue to green luminescence, two-photon induced fluorescence, minimal to no toxicity, chemical- photo-stability, and biocompatibility. These attractive properties of graphene quantum dots are mainly due to the bandgap opening of two-dimensional graphene quantum confinement effects, edge effects, surface functionalization, and doping. We present our results on the effect of both p- and n-doping on the absorption properties and correlate the results with the diameters to explore electronic and phonon confinement effects.

Antifouling and High-Permeation Mechanisms in Reverse Osmosis Nanocomposite Membranes made of Carbon Nanotubes and Aromatic Polyamide

Rodolfo Cruz-Silva1, 2, Aaron Morelos-Gomez1, 3, Josue Ortz-Medina1, 2, Yoshishiro Takizawa1, Ayaka Yamanaka1, 3, Michio Katouda1, 3, Syogo Tejima1, 3, Kenji Takeuchi1, 2, Takuya Hayashi1, 3, Mauricio Terrones1, 2 and Morinobu Endo1, 2, 3

1. Institute of Carbon Science and Technology, Shinshu University, Nagano, Japan; 2. Research Organization for Information Science & Technology, Tokyo, Japan; 3. Department of Physics, Department of Materials Science and Engineering, and Department of Chemistry, The Pennsylvania State University, State College, Pennsylvania, United States.

Nanocomposite membranes made with multiwalled carbon nanotubes (MWCNTs) and aromatic polyamide (PA) have been studied to improve their superfiltration performance, that combines high permeation, high salt rejection, good chlorine resistance, and low-fouling behavior. We have used a combination of experimental techniques, such as cross-flow filtration, microscopy and spectroscopy, whereas molecular dynamics studies were carried out to understand the membrane at the atomic level. The MWCNT-PA nanocomposite membranes were prepared by interfacial polymerization using an aqueous phase containing MWCNTs and an organic phase. Membranes were then evaluated under cross-flow and studied by x-ray photoelectron spectroscopy, Fourier transformed infrared spectroscopy, and electron microscopy. Organic fouling was studied using a protein (bovine serum albumin) solution, whereas scaling was produced using a mixture of calcium chloride and sodium bicarbonate that precipitates calcium carbonate. During these studies, the fouling of the membrane was followed in situ using fluorescence optical microscopy using an acrylic-made transparent cross-flow cell. The protein was labeled with fluorescein while calcite was added in the scaling study to render the calcium scales fluorescent. MWCNT-PA nanocomposite membranes showed considerably lower organic fouling and less scaling. Our findings show that the observed antiscaling and antifouling nature of the MWCNT-PA membranes is the result of several factors, among them: a smooth membrane surface morphology, a lower surface charge, an interfacial layer of water, and lower mobility of the membrane molecules. These results are important for the design and development of promising low-fouling RO membranes for water treatment. Regarding the water diffusion across the membrane, our studies show that instead of flowing inside the MWCNTs, an oriented diffusion mechanism explains the high water permeation of these membranes. MWCNTs reduce the diffusion path of water molecules across the membranes by providing a lower energy path. The proposed water diffusion mechanism offers an alternative and most likely explanation for the high permeation phenomena observed in CNTs and PA nanocomposite membranes, and its understanding is key to improve the performance of the nanocomposite reverse osmosis desalination membranes.

Coplanar Floating Gates Connected with Ionic Bridges for Remote Gating Graphene Transistors

Hyunwoo Jo1, Jong Ik Lee1, Hyeunseung Jung1, Wonwoo Lee2, Hojin Lee2 and Moon Sung Kang1

1. Department of Chemical Engineering, Soongsil University, Seoul, Korea (the Republic of); 2. School of Electronic Engineering, Soongsil University, Seoul, Korea (the Republic of).

Exploiting an electrolyte-based gate dielectric that relies on direct migration of ions allows design of unconventional transistor architecture. For example, the current density of a transistor channel can be modulated using a gate electrode that is not located directly on top/below the channel but placed apart from the channel as long as the electrode is bridged with the channel through the electrolyte—which we refer to as the remote gating. For effective remote gating, the electric double layer at both the electrode/channel and the electrolyte/gate interfaces has to be formed promptly. However, the promptness of the electric double layer formation relies on the distance between the channel and the gate. This indicates that the dynamic characteristics of a remote-gated transistors degrades with this distance. Here we present new device architecture to maintain the dynamic characteristics of a graphene transistor, even if its channel is gated remotely. The new structure employs multiple coplanar floating gates bridged through short ionic dielectric layers. Unlike the dynamic characteristics of a remote-gated graphene transistor employing a single, extended electrolyte layer, the devices with multiple, short electrolyte layers could operate promptly even when they are gated from a distance. We confirmed that the effective current modulation of graphene transistor can be achieved at 1 kHz, even when the gate electrode is located 1700 μm apart from the channel, which were comparable to the dynamic characteristics of a device using a gate located 200 μm apart. The results indicate that the distance-dependence degradation on the dynamic characteristics of the remote-gated graphene transistors can be eliminated. The new device architecture provided here shows new opportunities to exploit graphene transistors.

Hierarchically Structured Large Area Carbon-Nanosheets for Shape Deformable Electrochemical Capacitors

Jong Han Jun1, Hyeonjun Song2, Changsoo Kim3, In-suk Choi1, Youjin Jeong4 and Ji-Hoon Lee5

1. Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of); 2. Department of Information Communication, Materials, and Chemistry Convergence Technology, Soongsil University.
The energy storage systems applied on wearable electronic devices should exhibit mechanical robustness, high cost efficiency, and high electrochemical activity in various human body motion. To solve these requirements, we introduce all-carbon-based large-area nanocomposites for freely-deformable electrochemical capacitors. Three-dimensionally incorporated all-carbon-based self-supported nanocomposites are composed of activated carbons (ACs) dispersed in carbon nanotube (CNT) sheets by direct spinning method without additives such as conductive agents and polymeric binders. On account of the synergetic effects from immensely porous AC particles providing large number of active sites, high electrical conductivity of CNTs, and facile ion accessibility in aqueous electrolyte solution utilized by the acid treatment, the nanocomposites show a greatly improved specific capacitance compared to that of conventional electrodes used metallic current collectors in terms of total mass of the electrodes. We also fabricated the deformable all-carbon-based electrochemical capacitors that showed excellent durability and electrochemical performances under extreme mechanical deformations of bending, folding, twisting, and stretching.

Fast Solution-Based Catalyst Preparation for Fluidized-Bed Synthesis of Submillimeter-Long Carbon Nanotubes

Risa Maeda¹, Toshio Osawa¹, Hisashi Sugime¹ and Suguru Noda¹; ¹Waseda University, Department of Applied Chemistry, Tokyo, Japan; ²Waseda Institute for Advanced Study, Waseda University, Tokyo, Japan.

Carbon nanotubes (CNTs) have attracted great interest for many potential applications. To realize such applications, low-cost production of high quality CNTs is highly demanded. Fluidized-bed chemical vapor deposition (CVD) is one of the candidates for the realization of mass production [1]. We previously reported fluidized-bed CVD synthesis and easy separation of submillimeter-long CNTs on/from ceramic beads with smooth surface [2]. Our previous reports revealed that the preparation of catalyst is important for CNT growth. Two methods have been examined for the preparation: ex situ sputtering and in situ CVD methods. Fe/Al₂O₃ catalyst by ex situ sputtering yields single-wall CNTs [3]. On the other hand, in situ CVD method enables the fast catalyst deposition in a few minutes [2,4]. Other methods including impregnation have been introduced for the catalyst preparation [5]. However, all these methods still have limitations. For the ease of sputtering and impregnation, they take long time. In situ CVD is quick but uneasy to make fine control of catalyst for single-wall CNTs. Therefore, in order to increase the productivity, it is required to find a method which realizes both the easy control of the catalyst and the short preparation time.

Here we report a fast solution-based catalyst preparation on ceramic beads for CNTs. We coated catalyst on beads by gas-pressurized filtration of ethanol solution of Fe(CH₃COO)₂ and Al(OC₃H₇)₃ in a vertical tube for a few minutes. We then synthesized CNTs on the beads. The beads yielded CNTs with submillimeter length but on a part of the bead surface due to the non-uniform catalyst deposition. After the separation of CNTs from the beads, the beads were reused to reduce the cost. The beads with re-coated catalyst yielded CNTs with higher coverage with increasing number of reuse, resulting in improved yield of CNTs. We will discuss the catalyst condition on the structure of the resulting CNTs.

In Situ TEM Studies on Phase Transition Mechanism of TMDs by Alkali Metal Intercalation

Xuedong Bai; Institute of Physics, Chinese Academy of Sciences, Beijing, China.

In-situ transmission electron microscopy (TEM) method is powerful in a way that it can directly correlate the atomic structure with physical and chemical properties. By using the homemade in-situ TEM holders, the properties at nanoscale under various physical stimuli have been studied, including mechanical, electrical, and optical properties. For example, the physical properties of individual carbon nanotubes with known chirality have been reported previously. For this work, the real-time imaging of solid state electrochemical processes at atomic scale has been carried out by in-situ TEM. In this presentation, we will review our progress on the studies of phase transition mechanism of the two-dimensional layered transition metal dichalcogenides (TMDs) by alkali metal intercalation.

**9:00 AM **NM01.08.02

Controlling the Inner Dielectric Environment of Carbon Nanotubes to Tune Their Optical Properties

Sofie Cambré¹, Jochen Campo¹,², Bea Botka¹, Wouter van Werveke¹, Jan Obrazt², Wim Wenseleers¹ and Jeffrey Fagan³; ¹University of Antwerp, Antwerp, Belgium; ²Materials Science and Engineering Division, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

The optical properties of single-wall carbon nanotubes (SWCNTs) are extremely sensitive to their external and internal environment. For example, filling the endohedral cavity with water molecules results in characteristic shifts and broadening of both the SWCNTs' radial breathing mode vibrational frequency and their optical (electronic) transitions, as well as a quenching of their emission.[1] Although mostly ignored in literature, solvent ingestion effects are substantial, and can also be used to passivate the nanotube interior, by controlled manipulation of the endohedral environment prior to dispersion.[2]
In this work, specific and tunable modification of the optical properties of SWCNTs is demonstrated through the direct encapsulation of guest molecules with widely varying dielectric constants. Over 30 different compounds with static dielectric constant varying from 1.8 to 109 have been encapsulated inside the SWCNTs and their spectroscopic analysis, in comparison to unfilled (empty) SWCNTs, demonstrates for the first time experimentally that the general effect of filler static dielectric on the nanotube optical properties corresponds to a monotonic energy reduction (red-shifting) of the optical transitions with increased magnitude for higher dielectric constants.

Systematic two-dimensional fitting of the fluorescence-excitation spectra enables the direct comparison of this red shifting as a function of nanotube diameter, modulus and chirality. In addition to these spectral shifts, the filling with dielectric molecules also reveals a general increase of fluorescence intensity with lower dielectric constants, with some fillers approaching the emission efficiencies of empty SWCNTs.

Our investigation hence demonstrates a new degree of modulation of the SWCNTs’ optical properties by simple endohedral ingestion of various guest molecules.

High-quality channel layer is required for next-generation flexible electronic devices. Graphene is a good candidate due to its high carrier mobility and unique ambipolar transport characteristics but typically shows a low on/off ratio caused by gapless band structure. Here we propose a graphene/MoSe₂ channel layer with high-k ion-gel gate dielectric. The graphene/MoSe₂ device shows both high on/off ratio and carrier mobility. Most importantly, it reveals ambipolar behaviors which are controlled by external bias, although such ambipolarity has never been previously reported in graphene/semiconductor barristor structures. Therefore, our graphene/MoSe₂ barristor with ion-gel gate dielectric can offer various high performances. Here we make a contact of graphene and MoSe₂. The graphene/MoSe₂ barristor exhibits high on/off ratio of 10⁶ and high mobility. The modulation of graphene’s Fermi level (E_F) by applying gate voltage (V_g) is confirmed by the change in Schottky barrier height at the graphene/MoSe₂ junction. Such field effects including ambipolar behaviors are locally investigated by using scanning photocurrent microscopy (SPCM).

In this work, a low temperature sol-gel technique was used to prepare graphene aerogels from graphene oxide (GO) nanosheets. Through this method, GO nanosheets simultaneously undergo reduction and crosslinking in presence of ammonia to form a hydrogel. The Critical point drying was performed on the hydrogels, and they were annealed at higher temperatures to produce graphene aerogels. Our studies indicated that the GO/ammonia ratio affects the reduction and crosslinking of the nanosheets, which in turn determine the packing density and pore size distribution in the final aerogels. The nature of the covalent bonds and the inter-sheet “bridges” observed in the SEM images were investigated using various spectroscopic techniques. These aerogels possessed considerably high surface areas in the range of 900-1500 m²/g and electrical conductivities comparable to those of copper and silver.

Nanosheets morphology and aspect ratio is another factor that determines the morphology and properties of GO aerogels. To study the effect of theses parameters, we have used semi-spherical crumpled graphene oxide (cGO) particles as the precursor for aerogel preparation. cGO particles were produced by spray drying aqueous GO dispersions. During this process, the 2D nanosheets are crumpled into 3D semispherical particles. Usage of these cGO particles instead of flat GO nanosheets led to a higher degree of crosslinking and packing density in a 100% cGO aerogel. A slight increase in the surface area (~1600 m²/g) was also observed in this sample. The synergistic effects of mixed GO/cGO precursors on the structure and properties of aerogels were also explored and characterized.

Establishing a 3D electrically percolating network in an insulating matrix is key to numerous engineering and functional applications including energy storage and conversion, sensing devices, and telecommunication. To this end, using hydrophobic carbon nanofillers like graphene or carbon nanotubes is tempting, but still results in suboptimal performance due to processing challenges including colloidal instabilities in aqueous media. Here, we demonstrate how natural cellulose nanofibers (1) can be in situ transformed into graphene-like sheets connected to a 3D network enhancing both electrical and mechanical properties, depending on their preparation method, chemical composition, and morphology. We envisage that our results can advance the processing science and technology to provide the improved hierarchical graphene composite materials needed for advanced applications in fields like energy and telecommunications.

Thermal and Electrical Conductivity of High Volume Fraction Aligned CNT/Polymer Composites Yoko Inoue, Kenta Ishigami, Motoyuki Karita and Takayuki Nakano; Shizuoka University, Hamamatsu, Japan.

Most of good material properties of carbon nanotube (CNT), including thermal and electrical conductivities, and tensile strength and modulus, appear in the direction of long axis of CNT. Therefore, to derive CNT properties into applications, alignment degree is one of the important structural parameters. In this study, aligned CNT sheet preforms were prepared by dry spinning from CNT forests. The aligned CNTs were mixed with epoxy or polyamide resin. A hot-melt method of the CNT sheet with the resin film enabled high CNT volume fraction up to 49 %. We investigated thermal and electrical conductivity of the high CNT content composites. Spin-capable CNT array was synthesized by chloride mediated thermal chemical vapor deposition (CM-CVD). Dimensions of CNT are 30 nm in diameter and > 1mm in length. By stacking the CNT webs, a CNT sheet was formed. Then, aligned CNT/polymer composite films were prepared by hot-pressing the CNT sheet and a polymer sheet simultaneously. We used a thermosetting polymer of B-stage epoxy and ZrO₂ (YSZ) matrices, respectively. The microstructure of the resulting materials was characterized by electron microscopy and spectroscopy (STEM/EELS), while the electrical and dielectrical properties were analyzed by impedance spectroscopy. The materials showed high electrical conductivity at only 2 % initial CNT content, while the FLG-YSZ nanocomposites exhibited mixed ionic-electronic conduction at ≤1% CNF, which is interesting for electrode materials in solid-oxide fuel cells. Besides the transport properties, the incorporated cellulose nanofibers largely improve the mechanical properties and also enable the use of technologically important machining methods for electro-conductive ceramics.

We envisage that our results can advance the processing science and technology to provide the improved hierarchical graphene composite materials needed for advanced applications in fields like energy and telecommunications.

Conformal Printing of Graphene Inks and Multilayered Devices onto Arbitrarily Shaped 3D Objects  
Leonard Ng, Xiaoxi Zhu, Guohua Hu and Tawfique Hasan; University of Cambridge, Cambridge, United Kingdom.

Printing has drawn a lot of attention as a means of low per-unit cost, high throughput and additive patterning of graphene inks for scaled-up functional thin-film factor device manufacturing. However, the traditional printing processes typically require a flat surface and hence the current graphene printing methods are incapable of achieving patterning onto arbitrarily-shaped objects such as 3D printed parts and even on human skin.

Here, we present a conformal printing method to deliver conductive graphene patterns on to arbitrarily-shaped 3D objects using a sacrificial layer. We first formulate a water-insoluble conductive graphene ink and print it on to an ultrathin polyvinyl alcohol (PVA) film using conventional printing processes. The printed graphene patterns are then floated onto water, allowing the dissolution of PVA, while retaining the graphene patterns. This allows transfer of the conductive graphene patterns directly onto arbitrarily-shaped 3D objects with high resolution. I will present the formulation process and the parameters vital to achieving this and demonstrate this process onto a variety of irregularly-shaped 3D objects. Using this approach, I will also demonstrate multilayered device fabrication/transfer, including simple 2D material based electric circuits and components as well as resistive and capacitive strain sensors, without requiring post deposition processing.

Perylene-Based Functionalization of Carbon Nanotubes  
Antonio Setaro, Mareen Glaeske, Katharina Huth, Mohsen Adeli, Rainer Haag and Stephanie Reich; Freie Universität Berlin, Berlin, Germany.

Functionalization aims at granting compounds with additional features. This is achieved by typically attaching novel groups to the original systems. The aftermath of such process yields complexes whose characteristics often result in more than just the mere sum of the initial products. The specific character of the functionalized structure, moreover, depends upon the way the functionalization strategy has been pursued.

We will focus on the carbon nanotubes functionalization through perylene, an aromatic molecule emitting in the excitation window of most single-walled nanotubes commercially available. We have previously shown that the perylene core of custom surfactants was able to attach through pi-pi stacking interactions onto the sidewall of CNTs while ensuring efficient excitation transfer to the tubes. Here we will show how starting from the same elements (perylene and nanotubes) and pursuing different functionalization routines, we achieve systems with different features and functions. In particular, we will compare the characteristics of perylene-comprising polymers wrapped around the tubes with the peculiarities of perylene covalently attached to the nanotubes following a novel conjugation-preserving routine we recently developed. We will highlight the difference among the properties of the final products as well as the applications they would be suitable for.

**2:15 PM NM01.10.03**  
Molecular Recognition of Carbohydrates using Alternating Phenyl Boronic Acid Co-Polymers as Carbon Nanotube Corona Phases  
Minkyung Park, Jiyoung Ahn, Pingwei Liu, Daichi Kozawa, Volodymyr Koman, Song Wang, Gili Bisker, Seomyeong Kwak, Naveed A. Bakh, Michael A. Lee and Michael Strano; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The molecular recognition of carbohydrates remains a major challenge due to their inherent structural complexity and low affinity for most substrates despite its importance in biological systems. Natural and synthetic lectins have been broadly studied and comprised the majority of molecular recognition strategies to date. However, in this work, we explore a class of specific polymers that adopt a unique 3D configuration and exhibit highly specific carbohydrate binding when adsorbed at the surface of a carbon nanotube. A compositionally diverse polymer library based on reversible addition-fragmentation chain-transfer (RAFT) polymerization of *ortho*, *meta*, and *para*-phenyl boronic acids (PBA) with acrylic, methyl acrylic, vinyl benzoic, and maleimidopropionic monomers, forming alternating, random, and block co-polymer variations is evaluated for the ability to selectively bind various monosaccharides and sugar alcohols. When adsorbed as a solubilizing corona phase onto single walled carbon nanotubes (SWNT), we demonstrate several examples, including a *meta*-PBA maleic anhydride) co-polymer that enables dulcitol over mannitol and sorbitol recognition despite differing by only one or two cis/trans hydroxyls. We also identify a *meta*-PBA 3-maleimido-propanic acid) co-polymer selective for D-(-)-arabinose over all other aldopentoses including L-arabinose. This corona phase molecular recognition represents the first synthetic systems capable of specific, chiral saccharide recognition, which satisfies the demand for high precision assays, chemical sensors, catalysts, and biological probes for difficult to detect carbohydrates.

---

**2:30 PM BREAK**
We propose a conceptually new structure, in which mono- or few-layer hexagonal BN seamlessly wrap around a single-walled carbon nanotube (SWCNT), and result in an atomically smooth coaxial tube consisting two different materials, SWCNT@BNNT. The structure is synthesized by chemical vapor deposition (CVD), and the length of the coaxial tubes can reach up to micrometers. As the reaction occurs on outer surface of the existing SWCNTs, we name this process conformal CVD. Various SWCNTs, e.g. vertically aligned array, horizontally aligned arrays, suspended SWCNTs, random networks and films, are employed as the starting material, and successful coating are achieved on all of them. TEM-EELS clearly demonstrated the BN-SWCNT coaxial structure in individual tube scale, while Raman, optical absorption, and cathode luminescence spectra clearly confirm the existence of this structure in large scale. After coating, the SWCNTs can be fully coated and thermal stability significantly increases. Our characterizations confirm that the outside BN coating started locally on the wall of a SWCNT and then merged into a BN nanotube on the curved surface of the SWCNT which served as a template. The thinnest inner SWCNT that can support the BN layer growth is found to be 0.6-0.7 nm. The number of walls can be tuned from 1 to few by controlling the CVD condition. The structure of inside SWCNTs are almost not effected by the conformal CVD, as evidenced by Raman and many other characterizations. The crystallization and cleanness of the starting SWCNT template are believed to be critical for the successful fabrication of outside walls. This structure is expected to have a broad interest and impact in many fields, which include but not limited in investigating the intrinsic optical properties of environment-isolated SWCNTs, fabricating BN-protected or gated SWCNT devices, and building more sophisticated 1D material systems.

Part of this work was supported by JSPS KAKENHI Grant Numbers JP25107002 and JP15H05760.

4:00 PM NM01.10.05 Thermal Conductivity Measurement of Single-Walled Carbon Nanotubes by Photoluminescence Imaging Spectroscopy Kazuki Yoshino1, Kazuma Nagano1, Makoto Horiguchi1, Yuichiro Tanaka1, Shohei Chiashi2 and Yoshiyuki Homma2; 1Tokyo University of Science, Tokyo, Japan; 2The University of Tokyo, Tokyo, Japan.

Single-walled carbon nanotubes (SWCNTs) are expected to have high thermal conductivity along the tube axis. However, experimentally obtained values of the thermal conductivity vary widely because of the difficulties in the thermal conductivity measurements as well as the characterization of SWCNTs. We have recently developed a novel method for measuring thermal conductivity using photoluminescence (PL) imaging spectroscopy [1]. We use a long SWCNT individually suspended between quartz pillars, and evaluate the chirality of SWCNT by PL and crystallinity by Raman spectroscopy. Because the measurements are done for chirality-assigned and isolated (not bundled) SWCNTs, the obtained conductivities are highly reliable. For (9,8) SWCNTs with 10–12 μm in length, the thermal conductivity was 1166 ± 243 Wm-1K-1 at 400 K. We can also obtain the temperature dependence of thermal conductivity from the temperature distribution along the tube axis. We will discuss the accuracy of the measurement based on the data for multiple chiralities.

This work was partially supported by a MEXT Grant-in-Aid for Scientific Research on Innovative Areas “Science of hybrid quantum systems” (grant no. 15H05869).

4:15 PM NM01.10.06 Scalable Fabrication and Characterization of Vertically Aligned Carbon-Nanotube/Polymer Membranes Richard J. Castellano1, Eric R. Meshot2, Francesco Fornasiero3, Robert Praino3 and Jerry Shan1; 1Rutgers University, Piscataway, New Jersey, United States; 2Lawrence Livermore National Laboratory, Livermore, California, United States; 3Chasm Technologies, Canton, Massachusetts, United States.

Membranes incorporating vertically aligned carbon nanotubes (CNTs) as through-pores have been shown to transport fluids at rates orders-of-magnitude faster than predicted by theory, offering promise as highly permeable membranes for applications as diverse as breathable yet protective garments, desalination membranes, and highly efficient filters. However, there is a need for cost-effective and scalable solutions for fabricating large-area vertically aligned nanotube membranes, ideally starting from bulk nanotubes. Here, we describe a new, solution-based fabrication technique for creating polymer composite membranes using electric-field alignment and electrophoretic concentration of CNTs initially dispersed in a solvent. The solvent is then replaced with a UV-curable oligomer, which is cured to controlled thickness to form a membrane with vertically aligned carbon nanotubes. After etching to open CNT pores, the pore size and total open area are assessed with He-N2 flowrate ratios, size-exclusion tests and aqueous KCl conductance measurements. By comparing to theory, a pressure-driven gas flow-enhancement factor of 200 - 300 is found for flow through the small-diameter nanotube pores, which is consistent with reports in the literature for membranes fabricated from CVD-grown aligned nanotube forests. We conclude by describing recent progress in significantly increasing nanotube number density and membrane permeability, and the remaining challenges for ultimate roll-to-roll fabrication of vertically aligned nanotube membranes.

To evaluate the influence of the synthesis temperature and the flux of the carbon precursor gas, experiments were performed between 600 and 800 °C, with hetero-atoms, like the nitrogen, in the electrical conductivity of the NC-CNTs-N is shown. Non-crystalline carbon nanotubes (NC-CNTs) were synthesized by chemical decomposition in vapor phase using nanoporous anodized aluminum oxide.

The proto-type graphene Hall sensor array shows the extremely high current-normalized sensitivity of ~ 2000 V/AT [1] by the employment of large-area hexagonal BN as a substrate for graphene. This sensitivity could be improved to almost 3000 V/AT [2] by the replacement of large-area synthesized graphene with exfoliated MoS2 flake, but the level of applied current for such a high sensitivity regime is too small. Therefore, we further examine the possibility of electrolyte gating in the graphene Hall sensor configurations with the usage of commercially available chemical-vapor-deposition grown graphene layer without hexagonal BN. Due to the suppressed charge-impurity scattering in the electrolyte, the current-normalized sensitivity can reach to the value of > 3000 V/AT with moderate current levels and noises. In addition, the choice of operating conditions for the source-drain and gate voltage biases is to be systematically discussed, while the way of predicting it without a real test under the magnetic field is introduced from the analytical model. Low voltage operation (~ 0.5V) of the electrolyte-gating graphene Hall sensor is the additional advantage for the applications in the mobile devices.

Carbon nanomaterials have been promising elements for a variety of future applications in electronics. Since the contact interfaces between carbon nanomaterials and metal electrodes influence the properties of assembled structures, the extensive studies on the interfaces have been conducted. The atomic configuration and electrical properties of the interfaces have been investigated to elucidate the conduction mechanism [1]. In situ transmission electron microscopy (TEM) using nanotip operation techniques allows the simultaneous observation of the structures and electrical properties of the junction of a carbon nanocapsule (CNC) and metal electrodes [2]. In this study, we applied in situ TEM to investigate the relationship of the structure and electrical resistivity of the interfaces between a CNC and metal electrodes. CNCs were dispersed in ethanol and were dropped on the edge surfaces of a gold (Au) nanotip. This nanotip and another bare nanotip were inserted in a transmission electron microscope. Single nanoparticle junctions (SNPJs) were assembled using the CNCs and the two Au nanotips (electrodes) by piezomaneupulation inside the microscope. After the preparation of SNPJs, their configuration was controlled by using piezomaneupulation and was observed in situ at an atomic scale. Simultaneously, the conductance of SNPJs was measured by a two-terminal method while applying bias voltages. These process of observations and electrical measurements were performed at room temperature in a vacuum of $1 \times 10^{-5}$ Pa. The observed high-resolution TEM images and currents were analyzed. We could observe several interfaces and measure their contact resistivity. Consequently, it was found that the contact resistivity depended on the orientational relationships of the interfaces.

**NM01.11.06**

**Structure and Electrical Properties of Interfaces Between a Carbon Nanocapsule and Metal Electrodes Studied by In Situ Transmission Electron Microscopy**

Manabu Tezura and Tokushi Kizuka; Division of Materials Science, Faculty of Pure and Applied Sciences, University of Tsukuba, Tsukuba, Japan.

Carbon nanomaterials have been promising elements for a variety of future applications in electronics. Since the contact interfaces between carbon nanomaterials and metal electrodes influence the properties of assembled structures, the extensive studies on the interfaces have been conducted. The atomic configuration and electrical properties of the interfaces have been investigated to elucidate the conduction mechanism [1]. In situ transmission electron microscopy (TEM) using nanotip operation techniques allows the simultaneous observation of the structures and electrical properties of the junction of a carbon nanocapsule (CNC) and metal electrodes [2]. In this study, we applied in situ TEM to investigate the relationship of the structure and electrical resistivity of the interfaces between a CNC and metal electrodes. CNCs were dispersed in ethanol and were dropped on the edge surfaces of a gold (Au) nanotip. This nanotip and another bare nanotip were inserted in a transmission electron microscope. Single nanoparticle junctions (SNPJs) were assembled using the CNCs and the two Au nanotips (electrodes) by piezomaneupulation inside the microscope. After the preparation of SNPJs, their configuration was controlled by using piezomaneupulation and was observed in situ at an atomic scale. Simultaneously, the conductance of SNPJs was measured by a two-terminal method while applying bias voltages. These process of observations and electrical measurements were performed at room temperature in a vacuum of $1 \times 10^{-5}$ Pa. The observed high-resolution TEM images and currents were analyzed. We could observe several interfaces and measure their contact resistivity. Consequently, it was found that the contact resistivity depended on the orientational relationships of the interfaces.

**Fabrication of Polyamide/Polyethersulfone Reverse Osmosis Membranes Containing Functionalized Carbon Nano-Onions Having Antibacterial Activity**

Somin Lee, Eun Yeob Choi, Jeongung Nam and Chang Keun Kim; Chung-Ang University, Seoul, Korea (the Republic of).

Polyamide/polyethersulfone (PA/PES) membranes containing carbon nano-onions (NOs) were fabricated for the application in reverse osmosis (RO) membrane with enhanced antibacterial properties. The PA/PES membranes were prepared by interfacial polymerization between m-phenylenediamine (MPD) and trimesoyl chloride (TMC) on the surface of PES as support membrane. Then, the resulting PA/PES membranes were incorporated with the NOs to give antibacterial activities and use as RO membrane. The PA/PES membranes containing NOs were prepared in two variants; one contains aminated NO (NO-NH2) and another contains acyl chloride-terminated NO (NO-COCl). Each functional group in both NOs was reacted with MPD or TMC in the PA membranes, resulting in grafting NO with PA membrane. The formation of PA membranes containing NOs was confirmed by some analyses including FT-IR, XPS, FE-SEM and TGA. The PA/PES/NO-NH2 membrane exhibited better antibacterial properties compared with the PA/PES/NO-COCl composite membrane. In addition, the PA/PES/NO-NH2 membrane showed high water flux without a loss in salt rejection. Thus, the excellent performances of PA/PES/NO-NH2 membrane make its potential applications as an effective RO membrane.

**NM01.11.08**

**Fabrication of Polyketone/Polyketone Grafted Multi-Walled Carbon Nanotube Composites Using a Grignard Reagent Containing Pyrene Derivative**

Jeongung Nam, Eun Yeob Choi, Somin Lee and Chang Keun Kim; Chung-Ang Univ., Seoul, Korea (the Republic of).

Aliphatic polyketone (PK) composites containing PK grafted multi-walled carbon nanotubes (PK-g-MWCNTs) were prepared and their physical properties containing interfacial adhesion between PK and multi-walled carbon nanotubes (MWCNTs) and mechanical strength of the composite were examined. To fabricate PK-g-MWCNTs, 1-pyrenylmethylmagnesium bromide (PMgBr) was absorbed on the MWCNTs surface by physisorption and then reacted with PK. During this procedure, Grignard reagent in the PMgBr reacted with ketone groups in the repeat unit of PK, resulting in grafting PK with MWCNTs. The formation of PK-g-MWCNT was explored by spectroscopy, electron microscopy, and thermal analysis. The interfacial adhesion energy between PK and PK-g-MWCNT was the highest value that can be achieved with PK and modified MWCNTs. The PK/PK-g-MWCNT composite exhibited better performances of PK/PK-g-MWCNT membrane make its potential applications as an effective RO membrane.

**Covalently Connected Graphene/Carbon Nanotube Hybrid Structure and Their Application**

Nam Dong Kim1, Yilun Li2, Yingchao Yang2, Caitian Gao1 and James M. Tour1; 1Korea Institute of Science and Technology, Bodong-eup, Korea (the Republic of); 2Mechanical Engineering, University of Maine, Orono, Maine, United States; Chemistry, Rice University, Houston, Texas, United States.

Carbon materials have great potential for advanced nanotechnology. They exist in various allotropes in several dimensions, such as 0D of C60 family and graphene quantum dots, 1D of carbon nanotube (CNT), graphene nanoribbon (GNR) and carbon fiber (CF), and 2D of graphene relate materials. Each of these allotropes shows unique and interesting properties making them representative nano-materials. Recently, hybrid system of those different carbon allotropes has great attentions to achieve an improved and synergetic properties. Making 3D hybrid structure gives many enhanced properties, such as high integrity, interconnectivity, porosity, conductivity and mechanical strength. New strategy to connect different carbon allotropes with covalent bonding allows us to fabricate more advanced structure which was not possible previously and to understand novel properties of materials. After first research about seamlessly connected graphene and carbon nanotube hybrid structure (G/CNT) has been reported, it has attracted great attentions due to its high surface area, excellent electrical and mechanical properties. In this presentation, several researches derived from G/CNT structure will be introduced. such as patterning, mechanical strength at the junction and energy storage application, and its powerful possibility will be discussed.
Use of environmentally friendly solid polymer electrolytes is important for battery technology. This work aims at investigating effect of lithium in chitosan-graphene films which can be useful for energy storage applications. Lithium ions are small in size. Lithium salts conduct electricity under electric field due to the mobile lithium ions which can easily migrate. Chitosan is an abundantly available biopolymer. It has good film forming ability. However chitosan films do not have good conductivity. Graphene-based functional materials have caused great interest in electronic, medical, environmental applications due to its large surface area, high electrical conductivity and high mechanical strength. H5 Graphene was purchased from XG Sciences, USA. The graphene platelets have approximate thickness of 15 nm and length of 5 micro meter. Chitosan solution was prepared by adding 1% (w/v) of chitosan powder, 1.5% (w/v) of acetic acid and 100ml of double distilled water. The solution was stirred for 30-40 minutes to form a transparent thick solution. A part of this solution was transferred to a plastic dish to form a film at room temperature. To proportionate amount of chitosan solution 33, 66 and 100% (weight with respect to chitosan) of lithium perchlorate (LiClO4) was added. To a part of the chitosan lithium solution 5% of graphene (weight with respect to chitosan) was added. The solution was stirred and heated for 30 min. This solution was poured on a plastic dish and dried at room temperature in order to obtain chitosan–graphene-lithium nanocomposites. The thickness of the nanocomposite films varied between 50-200 micro meter. Dielectric studies such as conductivity, dielectric constant, dissipation factor and impedance were measured using impedance spectrometer. The conductivity ranges from 10^-8 to 10^-4 S/cm for graphene-chitosan lithium system. The conductivity of chitosan was lowest. In the absence of graphene the conductivity increases with increasing LiClO4 concentration. Conductivity (at 100 Hz) for Chitosan, Chitosan 33% LiClO4, Chitosan 66% LiClO4, Chitosan 100% LiClO4 films are 6x10^-7, 2x10^-6, 2x10^-7 and 3.5x10^-7 S/Cm respectively. Conductivity (at 100 Hz) for Chitosan 5%LiClO4, Chitosan 5%LiClO4, Chitosan 5%LiClO4, Chitosan 5%LiClO4, Chitosan 5%LiClO4, Chitosan 5%LiClO4 are 3.5x10^-7, 5x10^-7, 1.5x10^-6 and 3.5x10^-7 S/Cm respectively. The conductivity measurements show that incorporation of graphene decreases the conductivity for films with 66 and 100% LiClO4. This indicates that graphene induces crystallization of Lithium salts thereby reducing the conductivity. SEM image shows that graphene affects the crystallization of LiClO4. Both LiClO4 and graphene increased the dielectric constant of the nanocomposites. Dissipation factor analysis showed that the relaxation behavior is affected due to incorporation of graphene. The dissipation was also relatively low (similar to chitosan), indicating that the nanocomposites do not have much heat loss.

Graphene, a one-atomic-thick material with honeycomb structure built from carbon atoms, which can be considered as a monolayer of graphite, is the most representative two-dimensional material. It has drawn tremendous attention due to fascinating electronic and mechanical properties. Graphene with no defect is believed to be the strongest material. Through all synthesis methods, chemical vapor deposition (CVD) is a facile approach to grow large-scale monolayer graphene, which is polycrystalline with inevitable defects and boundaries. Thus, the study on mechanics of graphene, particularly fracture behavior, is essential from both fundamental interest and technological importance. Numerous studies on fracture mechanics of graphene are emerging. The fracture toughness and crack propagation of graphene have been investigated by means of in situ methods and simulations. In these studies, fragmentation of graphene tends to initiate randomly at pre-existing defect locations, resulting in irregular morphology and is considered as a limitation in applications.

However, ordered fragmentation can be utilized in nanstructuring. Here, our works propose and demonstrate a facile method on controlling the fragmentation of graphene to fabricate ordered graphene nanoribbon arrays with sharp edges by taking advantage of the strong localized strain existing at the neck front during polymer cold-drawing process. For the thermoplastic polymer, a neck will form locally during a stretch. This necking phenomenon results from the mechanical instabilities of the polymer and will propagate along the entire length of polymer, which is called cold-drawing. The neck front moves uniaxially with strong localized strain while the deformation of after-necking areas ceases. We harness this strong localized yet moving strain to fragment graphene and show the fabrication of finely ordered graphene nanoribbons. The CVD grown monolayer graphene is transferred to polycarbonate substrate and then mounted on a linear travel stage. After the following cold-drawing process of the polycarbonate substrate, monolayer graphene nanoribbon arrays are fabricated. The structure and morphology of obtained monolayer graphene nanoribbons are systematically investigated using various microscopic and spectroscopic measurements. The potential applications for both chemical and physical sensing are explored. Future work will be conducted to investigate the fragmentation via polymer cold-drawing on multilayer graphene.
demonstrated to show its practical application in identifying the position of various objects. This study reveals its application prospect in areas such as motion tracking and small force application.

NM01.11.14
Malic Acid Carbon Dots—From Super-Resolution Live-Cell Imaging to Highly Efficient Separation Bo Zhu1, Yi Cui2, Shengyang Wang3, Ben P. Frank1, Denise Williams4, Richard P. Brown5, Eric S. Melby6, Robert J. Hames6, Zeev Rosenzweig1, D. H. Fairbrother1, Galya Orr1 and Christy L. Haynes6; 1Chemistry, University of Wisconsin-Madison, Madison, Wisconsin, United States; 2Environmental Molecular Sciences Laboratory, Pacific Northwest National Laboratory, Richland, Washington, United States; 3Chemistry, The Johns Hopkins University, Baltimore, Maryland, United States; 4Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore County, Maryland, United States; 5Columbia Basin College, Pasco, Washington, United States; 6Chemistry, University of Minnesota Twin Cities, Minneapolis, Minnesota, United States.

As-synthesized malic acid carbon dots are found to possess advanced photobleaching properties compared to conventional dyes. Considering their excellent biocompatibility, malic acid carbon dots are suitable for super-resolution fluorescence localization microscopy under a variety of conditions, as we demonstrated in fixed and live tritium epithelial cells. In addition, during imaging experiments, the so-called “excitation wavelength-dependent” emission was not observed for individual as-made malic acid carbon dots, which motivated us to develop a time-saving and high-throughput separation technique to isolate malic acid carbon dots into fractions of different particle size distributions using C18-reversed phase silica gel column chromatography. This post synthesis separation allowed us to determine how particle size distribution influences the optical properties of malic acid carbon dot fractions, i.e., optical band gap energies and photoluminescence behaviors.

NM01.11.15
Electrically Probing and Tuning of Physisorption for Both Polar and Non-Polar Molecules on Graphene Wenzhe Zang1, Girish S. Kulkarni2, Karthik Reddy3, Hongbo Zhu4, Kyoungmoon Lee5, Xuadong Fan2 and Zhaozhong Zhong1; 1Department of Electrical Engineering and Computer Science, University of Michigan--Ann Arbor, Ann Arbor, Michigan, United States; 2Department of Biomedical Engineering, University of Michigan--Ann Arbor, Ann Arbor, Michigan, United States.

Nanoelectronic systems are perfect testbeds to study and mimic the physicochemical nature of noncovalent interactions which, though weak in nature (~100s of meV), form the bedrock of most biological and cellular processes. Furthermore, the ability to electrically tune the charge density (hence the chemical potential) in nanomaterials via electrostatic gating provides another knob to control such interaction. Unfortunately, nearly all existing electronic sensing methodologies are based on charge transfer (covalent interactions) which does not fully represent the interaction between the adsorbed vapor molecules and a pristine nanosurface. Here we present results of electrical probing and tuning of the noncovalent physisorption of both polar and nonpolar molecules on graphene surface by using two different sensing techniques — heterodyne sensing and µCmbFET sensing. Temperature-dependent molecular desorptions for six different polar molecules and five non-polar species were measured in real-time to study the desorption kinetics and extract the binding affinities. Furthermore, we demonstrate electrical tuning of molecule-graphene binding kinetics via electrostatic gating of graphene. Our results not only provide insight into the non-covalent interaction dynamics between both graphene and both polar and non-polar molecules, but also pave the way to electrically tailor physisorption dynamics at nanoscale interfaces.

NM01.11.16
Non-Linear Current-Voltage Behavior of Epoxy-CNT Composites Toshiyuki Sato1, Yoshitaka Kamata1, Hui Li2, Jian Song2, Howard E. Katz2 and Pawel Czubarow3; 1NTC, NAMICS, Niigata-City, Japan; 2Department of Materials Science and Engineering, Johns Hopkins University, Baltimore, Maryland, United States; 3EM-TECH, Southborough, Massachusetts, United States.

The electronics industry is always looking for new ways of protecting devices from over-voltage, or over-current scenarios. In the present work we will introduce novel low-voltage epoxy-carbon nanotube composites with high non-linearities in resistive devices. Plots of current versus voltage can be fit to powers of voltage > 2. Devices of different dimensions were made on single substrates by photolithographic patterning of interdigitated electrode pairs. These devices were tested at different speeds over different voltage ranges, and I-V relationships are compared. From the resulting data, the limiting resistances can be apportioned between injection barriers and bulk nanotube connectivity.

NM01.11.17
Effects of Graphene Oxide-Carbon Nanotube Hybrids as Nanofiller on the Interfacial Interaction in Nylon 6,6 Prepared by In Situ Interfacial Polymerization Beom-Gon Cho1, Seonghwan Lee1, Sang-Ha Hwang2, Jong Hun Han3, Han Gi Chae2 and Young-Bin Park4; 1Department of Mechanical and Aerospace Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 2School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of); 3School of Chemical Engineering, Chonnam National University, Gwangju, Korea (the Republic of).

Nylon 6,6 nanocomposites including well-dispersed graphene oxide (GO) and carbon nanotubes (CNTs) were successfully fabricated via in situ interfacial polymerization between two immiscible phases: organic phase assisted by poly(vinylpyrrolidone, PVP) surfactant containing adipoyl chloride with dispersion of GO and CNTs; aqueous phase containing hexamethylenediamine. Prior to the polymerization, GO was functionalized with thionyl chloride, resulting in acyl chloride-functionalized GO (AGO). The effects of incorporation of AGO and PVP on the state of dispersion were investigated. It was observed that the addition of AGO and PVP reduced particle flocculation, leading to a well-dispersed suspension as verified through dispersion stability analysis and UV–Vis spectroscopy. The interfacial interaction between the carbon nanofillers (AGO, CNTs) and nylon 6,6 chain can be induced via electrostatic interactions. These devices were tested at different speeds over different voltage ranges, and I-V relationships are compared. From the resulting data, the limiting resistances can be apportioned between injection barriers and bulk nanotube connectivity.

Nonuniform strain fields in graphene have received much attention due to the tight relation between its morphological and electronic properties. In addition to the well-known pseudomagnetic field, another recognized effect induced by a nonuniform strain is the position-dependent Fermi velocity (PDFV) [1]. Pioneering experiments [2], through scanning tunneling spectroscopy (STS), have revealed the existence of a PDFV, but its effects on the graphene physics have been scarcely explored [3].

In this work, we present analytical and numerical studies of the local density of states (LDOS) measured by STS for graphene under a nonuniform strain, either in the absence or in the presence of a uniform magnetic field [4]. The analytical expressions of the LDOS, derived from an effective Dirac model in term of a PDFV, were verified by tight-binding numerical calculations. In consequence, such expressions can be useful to quantify appropriately nonuniform strain effects on STS experiments of strained graphene, including those of Landau level spectroscopy. Finally, our results demonstrate that PDFV effects should be considered in a full description of transport signatures of strain-induced pseudomagnetic fields in graphene.

Structural and Electronic Characterization of the Ripples in Single-Layer Graphene on Ge by STM/STS

Cesar A. Diaz Mendoza, Marcelo Eduardo Huguenin Maia da Costa and Fernando Lazaro Freire Jr; Physics, Pontificia Universidade Católica do Rio de Janeiro, Rio de Janeiro, Brazil.

The graphene’s growth directly on germanium surface can be a good route to integrate graphene into nanoelectronic-devices. Several works deal with the syntheses and characterization of the graphene on Ge [1-3]. Graphene/Ge interface interaction is not fully understood. A remarkable aspect that we found was the presence of ripples. The ripples and their characteristics can modify the electronic structure, electron/hole puddle formation and carrier transport in graphene. The objective of this work is to identify and study how these ripples can modify the local density of states (LDOS) of the graphene growth by CVD on two different germanium crystalline orientations. The samples were characterized by the Raman Spectroscopy and Scanning tunneling microscopy and spectroscopy (STM/STS). Our experimental data shows that the graphene on Ge is strained of compressive biaxial type and such strain is related to the graphene’s growth directly on germanium surface. Nonuniform strain fields in graphene have received much attention due to the tight relation between its morphological and electronic properties. In addition to the well-known pseudomagnetic field, another recognized effect induced by a nonuniform strain is the position-dependent Fermi velocity (PDFV) [1]. Pioneering experiments [2], through scanning tunneling spectroscopy (STS), have revealed the existence of a PDFV, but its effects on the graphene physics have been scarcely explored [3].

In this work, we present analytical and numerical studies of the local density of states (LDOS) measured by STS for graphene under a nonuniform strain, either in the absence or in the presence of a uniform magnetic field [4]. Structural Changes in Carbon Nanotube Yarn Exposed to Actual Space Environment

Motovuki Kariya1, Takayuki Nakano1, Yoku Inoue1, Yasuhiro Fuchita2, Takashi Hitomi2, Yoji Ishikawa2 and Naoko Baba2; 1Department of Electronics and Materials Science, Shizuoka University, Hamamatsu, Japan; 2Obayashi Corporation, Tokyo, Japan; 3Japan Manned Space Systems Corporation, Tsukuba, Japan.

Carbon nanotubes (CNTs), which have excellent thermal and mechanical properties, are promising materials as ground or space structures. Although there have been many ground-based characterizations of the influence of radiation on CNT, no work has been performed on effect of space radiation. In this study, multi-walled CNT (MWCNT) yarns fabricated by dry spinning method were exposed to the actual space environment on the international space station (ISS) for one or two years. During the flight, ground-based comparison tests, including irradiation of atomic oxygen (AO), electron beam and ultraviolet individually, were performed. For the ground-based comparison tests, significant deterioration in tensile strength was found for AO irradiated MWCNT yarns. Transmission electron microscopy and Raman spectroscopy observations revealed that crystal structure of MWCNT was damaged with showing sharp open edges of graphene. For the actual space test, quite similar damages and decrease of tensile strength were observed. This study was carried collaborative research project with Obayashi Corp. and Japan Manned Space Systems Corp., which is adopted by project using Exposed Experiment Handrail Attachment Mechanism of Japan Aerospace Exploration Agency.

Gilding with Graphene—Rapid Chemical Vapor Deposition Synthesis of Graphene on Thin Metal Leaves

Kaihao Zhang, Charalampos Androulidakis, Mingze Chen and Sameh Tawfick; Mechanical Science and Engineering, University of Illinois-Urbana Champaign, Urbana, Illinois, United States.

Gilding is the ancient process of coating intricate geometries with precious thin metal films. Fascinating Egyptian and Chinese sculptures, coated with <
200 nm thin metal leaves by this process, have resisted corrosion and other environmental degradations for thousands of years. Similarly, palladium (Pd) is used as gilding material for its excellent corrosion properties, mechanical performance and of course its silver color. This is the reason that the 150 nm thick Pd leaves by doping with a single layer of graphene via low pressure chemical vapor deposition (CVD) processes. Pd leaves are made by hammer forgem of micrometer thick foils. During this process, their thickness is reduced to 150 nm while the average grain size exceeds 20 μm. The Pd leaves made by high strain beating are stable at high synthesis temperature, resisting solid state dewetting owing to their extremely low grain triple junctions.

Using nanoindentation, we demonstrate the graphene’s ability to significantly strengthen Pd leaves by constraining dislocation motion and bridging grain boundaries and cracks in Pd leaves. The as-grown Pd-Gr composite leaves are indented by a diamond-coated atomic force microscope (AFM) probe with diameter of 100 nm. We found that the effective surface modulus of the Pd-Gr composite leaves is 223 ± 23.4 GPa, which is over 2.5-fold of that of the pristine Pd leaves (83.7 ± 14.2 GPa) by coating less than 0.05 wt. % Gr. Moreover, indentation on edge-notched doubly-clamped nanostrip enables the measurement of the critical stress intensity factor in mode I fracture of ultra-thin film materials. We will describe the several systematic experiments on Pd leaves and Pd-Gr composites to reveal the strengthening and toughening mechanisms operating in this new materials. This new nanocomposite material could open exciting opportunities in utilizing high quality 2D materials to coat large structures.

Size-Controlled Single Crystalline Graphene Quantum Dots—Synthesis, Luminescence Properties and Application in Electroluminescence Seek Hwan Lee and O Ok Park; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Graphene Quantum Dots (GQDs) is one kind of graphene nanostructure, and it has enormous attention because of their excellent properties originated from the existence of energy bandgap. For synthesizing GQDs, the bottom-up method is required over the top-down approach on synthesis step because it has more potential to control the size and edge status, which is directly related to their optical properties. However, preparation of GQDs using the bottom-up method requires very stringent conditions with specific organic materials after complicated reaction steps. Until now, generating uniform lateral sized GQDs at the synthesis step has not been much successful, although separation of GQDs according to the diameter size have shown marginal success such as stepwise dialysis.

Synthesis of high-quality GQDs with well-controlled size, shape and surface functionalization needs to be further explored. It is still challenging to synthesize the GQDs with clear hexagonal shaped graphic structure via solution chemistry because the conventional bottom-up processes exhibit low crystallinity and they exhibit broad photoluminescent (PL) spectrum and low quantum yield compare with the top-down method. Here, we report a novel bottom-up approach not just for the synthesizing single-crystalline graphene quantum dots (GQDs) with hexagonal shape but also discover a new phenomenon that constructing graphic carbon structure from an understanding of nitrogen site role on graphitization and inducing the catalytic reaction intermediate. In details on selected analysis data, 5 nm lateral sized sample has ~350 pm thickness, and 70 nm lateral sized sample has ~700 pm from atomic force microscopic data and both samples consist of more than 90% carbon species from x-ray photoelectron spectroscopic data. Furthermore, we investigated the origin of luminescence via exciton decay profile through femto-second pulsed laser excitation on various size-controlled GQDs. We discuss the size effect on decay profile to elucidate the origin of luminescence on GQDs by difference core and edge-generated exciton behavior. As the application, we fabricated deep-blue emissive GQDs-light emitting diodes. It shows 2.5 V as turn-on voltage, ~450 cd/m² as max brightness and (0.16, 0.06) as CIE 1931 coordinates.

Spatial and Energetic Correlations of Workfunction for Doping Level and Hysteresis in Gate-Tunable Reduced Graphene Oxide Hwiji Woo and Young Jae Song; SAINT, Suwon, Korea (the Republic of).

The graphene grown by chemical vapor deposition method (CVD) has been widely studied for device applications due to scalable growth of CVD. The reduced graphene oxide (rGO) also has attracted huge scientific and industrial interests since it can be easily synthesized in massive quantities. Even CVD-grown graphene as well as rGO show clear hysteresis in IV curves of the devices, mostly due to the inherent or inevitable defects of graphene, which originate from the CVD synthesis itself or the wet process of graphene transfer from the metal substrate to a dielectric substrate. In this work, we have measured workfunction of the graphene and rGO on SiO2 with varying the gate voltage and the distance of the probe from the source electrode. A spatial dependence mapping of workfunction in graphene and rGO layers from the source electrode (ground) showed different carrier injection with showing the hysteresis similar with that of graphene-based device. The energy shift of Dirac point and the amount of hysteresis in the graphene or rGO devices can be correlated with a crossing point (a neutral point) and the width in spatial and electric mapping of workfunction. Further details will be discussed in the presentation.

NM01.11.24
Coulomb Drag Effect in Graphene/MoS2 Heterostructures Youngjo Kim1, Min-Kyu Joo2, Byoung Hee Moon1, Hyun Kim1, Sanghyub Lee1, Hye Yun Jeong1 and Young Hee Lee2; 1Center for Integrated Nanostructure Physics, Suwon, Korea (the Republic of); 2Sookmyung Women's University, Seoul, Korea (the Republic of).

Two-dimensional heterointerfaces often provide extraordinary carrier transport as exemplified by superconductivity or excitonic superfluidity. Recently, double-layer graphene separated by few-layered boron nitride demonstrated the Coulomb drag phenomenon: carriers in the active layer drag the carriers in the passive layer. Here, we propose a new switching device operating via Coulomb drag interaction at a graphene (Gr)/MoS2 heterointerface. The ideal van der Waals distance allows strong coupling of the interlayer electron-hole pairs, whose recombination is largely suppressed by the vertical energy barrier at µ-Gr/n-MoS2 interface via dual-gate, whereas the lateral carrier transport is constructed via Coulomb drag. This device exhibits a high mobility (up to ~3,700 cm²V⁻¹s⁻¹) even at room temperature, while maintaining a high on-off current ratio (~10⁶), outperforming those of individual layers. In the electron-electron drag regime, graphene-like Shubnikov-de Haas oscillations are observed at low temperatures. Our Coulomb drag transistor could provide a shortcut for the practical application of quantum-mechanical 2D heterostructures at room temperature.

NM01.11.25
Catalytic Degradation of 4-Nitrophenol by Three-Dimensional Au/rGO Microspheres Hua Wang and Shifeng Hou; National Engineering and Technology Research Center for Colloidal Materials, Shandong University, Jinan, China.

Microspheres as catalysts or catalyst supports have attracted a great deal of attention over the last two decades. Here, gold nanoparticles (Au-NPs) encapsulated within the reduced graphene Oxide microspheres (rGO microsphere) were prepared by using a spray-drying method. The mass content of
Au-NPs in the rGO microsphere composite reached 46.5%, and the average size of the Au-NPs was (10±2.5) nm, which was distributed evenly through the rGO microsphere composite. The morphologies and structural characteristics of the materials were determined by scanning electron microscopy (SEM), transmission electron microscopy (TEM), high-resolution transmission electron microscopy (HRTEM) and X-ray diffraction (XRD) patterns. The as-prepared composite was used to catalyze the reduction of 4-nitrophenol to 4-aminophenol in the presence of excess sodium borohydride and exhibited high catalytic activity. The catalysis process was monitored by UV spectroscopy, and the first rate constant of the catalytic reaction \( k \) was 3.05 × 10^{-3} s^{-1}, and the activation energy \( E_a \) was found to be 2.1710 J/mol.

NM01.11.26
Soft Aerogels Supported by ~1 wt% Carbon Nanotubes for Thermal Interface Materials
Satoru Kawakami, Shunji Kobayashi, Hisashi Sugime, Junichiro Shiomi and Suguru Noda; Applied Chemistry, Waseda University, Tokyo, Japan; The University of Tokyo, Tokyo, Japan; Waseda Institute for Advanced Study, Waseda University, Tokyo, Japan; Advanced Science and Engineering, Waseda University, Tokyo, Japan.

Thermal interface materials (TIMs) are used for enhancing heat transfer between solid surfaces by creating thermal paths. Their important characteristics are high thermal conductivity and softness for filling the air gaps. Many conventional TIMs consist of the thermal conductive fillers dispersed in polymer matrix, which has disadvantages of low thermal conductivity and poor thermal stability.

Here we propose aerogel TIM replacing polymer matrix with air matrix. Air matrix is released upon pressing and conductive fillers are in direct contact with each other. A soft sponge like self-supporting film can be fabricated using carbon nanotubes (CNTs), and this structure is able to support fillers 100 times larger in weight compared with their own weight [1]. In the case of hybridization with graphite particles, the porosity of the aerogel can be controlled in the range from 20 % to 70 % by changing the amount of CNTs [1]. Moreover, the CNTs do not disturb heat conduction between fillers because CNTs have high thermal conductivity, and the CNT has high thermal stability (500 °C in air). We selected silver having the highest thermal conductivity among metals as conductive filler. The aerogel TIM was fabricated by hybridizing Ag particles with CNTs. The TIM was self-supporting even when the amount of fillers were 200 times larger than that of CNTs. From the result of steady-state thermal resistance measurement, the thermal resistance of 99.5 wt% Ag-0.5 wt% CNT-TIM between two Cu rods was 60 mm² K/W under 0.8 MPa. Too thick TIM had high bulk thermal conductivity and a too thin one had high contact resistance. In addition, TIM showed lower thermal resistance with lower CNT content. Optimization of the structure is now underway, and the latest results will be reported.

NM01.11.27
Capitalizing on the Molybdenum Disulfide/Graphene Synergy to Produce Mechanical Enhanced Flame Retardant Ethylene-Vinyl Acetate Composites with Low Aluminum Hydroxide Loading
Yuan Xue, Xianghao Zuo, Yichen Guo and Miriam Rafailovich; Stony Brook University, Stony Brook, New York, United States; Pall Corporation, Port Washington, New York, United States.

We have engineered a flame retardant ethylene-vinyl acetate (EVA) composite which has the similar mechanical properties as polyvinyl chloride (PVC) and therefore may prove to be an alternative material for cable sheathing. Four composites were studied, EVA with aluminum hydroxide (ATH), EVA with ATH and molybdenum disulfide (MoS2), EVA with ATH and graphene nanoplatelets (GNPs), and EVA with all three components. Tensile testing showed nearly identical results for the EVA/ATH and EVA/ATH/MoS2 compounds, while the EVA/ATH/GNPs compound had higher mechanical properties. The compound containing all three components showed further enhanced mechanical properties, indicating that a synergy was established. This was further confirmed using Scanning Electron Microscopy (SEM) where GNPs were seen to increase the dispersion of the MoS2 and ATH components within the polymer matrix. Cone calorimetry test clearly showed a large decrease in heat release rate when GNPs were added, which was further enhanced by adding GNPs and MoS2 together. Application of the UL-94 test showed that only the compound containing 36 wt% of ATH and 2 wt% each of MoS2 and GNPs can achieve the UL-94 V0 rating.

NM01.11.28
Direct Ink Writing of Multi-Walled CNT Reinforced Alumina Matrix Composites for Conductive Ceramics
Chao Liu and Junjun Ding; New York State College of Ceramics at Alfred University, Alfred, New York, United States.

Alumina is a widely used ceramic material in due to its good chemical and thermal stability, light-weight and wear resistance [1-3]. However, the low fracture toughness and conductivity of alumina limit its broader application to build various devices [2]. Carbon nanotubes (CNTs) obtain good mechanical strength and electrical conductivity to reinforce ceramics [4]. Direct ink writing (DIW) is an ideal additive manufacturing method to build ceramics green bodies with the advantages of low cost and free design [5, 6]. In this work, we fabricate CNT-alumina composites to improve the mechanical strength and electrical conductivity. Multi-walled CNT (MWCNT) (6 and 10 wt %), alumina powder (90 and 86 wt %) and Ferro 3134 (4 wt%) were mixed together. 3.7 wt% ammonium polyacrylate (NH₄-PAA) of whole slurry was used as a dispersant and 3.3 wt% polyvinylpyrrolidone (PVP) was used as a binder. 25.9 wt% of deionized (DI) water was used to modify the viscosity of slurry. After 12 hours of ball milling, the well-dispersed slurry ink was used to build the CNT-alumina composites using a modified DIW 3D printer. After drying out for 24 hours, samples were sintered at 1400 °C for 3 hours in a high vacuum. Scanning electron microscope (SEM) was used to observe the microstructure of the cross section in both green bodies and sintered samples. SEM images showed the dispersibility of CNT in sintered samples was better than that in green bodies, indicating the effect of sintering to microstructure of ceramics. The density of sintered samples was measured using Archimedes' Method. The density of the composite containing 6 wt% MWCNT was 3.065 g/cm³ (80.29% of theoretical density); the density of composite containing 10 wt% MWCNT was 2.875 g/cm³ (77.10% of theoretical density), confirming that the density decreased with an increasing amount of CNT [7]. Further study will be focused on the measurement of fracture toughness, compression strength and electric conductivity. We will study the percolation theory for electrical conductivity of composites with different fractions of MWCNT. We will also study various sintering methods, such as spark plasma sintering and hot isostatic pressing.

Growth Temperature Dependence of Low-Pressure CVD Graphene Directly Grown on R-Plane Sapphire
Yuki Ueda, Junpei Yamada, Taishi Ono,
Graphene has attracted much attention as a next-generation electronic material for its excellent properties such as ultra-high mobility. Large-size single-crystalline graphene is usually obtained on copper based catalyst with chemical vapor deposition (CVD). However, the property of the graphene is largely deteriorated by the transfer process for device fabrication. Therefore, the direct growth of graphene on the dielectric substrate is studied to overcome the problem. C-plane sapphire is conventionally used as a substrate for the direct growth of graphene [1]. There are very few studies about the optimization of crystalllographic plane of sapphire for the direct growth. In this study, we focus on the use of c-plane sapphire as a substrate, which is sometimes used for the growth of horizontally-aligned carbon nanotubes [2].

Graphene was directly grown on r-plane sapphire using low pressure CVD without metal catalyst. C-plane sapphire was also used for the comparison. Mixture gas of nitrogen (N$_2$), hydrogen (H$_2$), and diethylacetylene (C$_6$H$_{10}$: 3-Hexyne) was flown to a reactor for the growth of graphene. Growth temperature was systematically changed between 1090 °C and 1210 °C. In the case of c-plane sapphire, graphene was found to grow only in the pits of sapphire, which was formed during CVD. This is very similar to the result that Saito et al. reported [3]. They reported Al-rich surface appeared inside the pits and had a catalytic effect. In our experiment, the size of pits enlarged with increasing growth temperature. Also, the growth rate of graphene increased with growth temperature and, then, decreased over 1170 °C. On the contrary, in the case of r-plane sapphire, the surface was fully covered with single-layer graphene in all samples. D/G peak intensity ratio and wrinkle density of graphene decreased with increasing growth temperature. On r-plane sapphire, the graphene was found to grow simply in 2D nucleation mode. This is probably because the surface of c-plane sapphire has catalytic effect and enhances the decomposition of growth species. Therefore, the use of r-plane sapphire brings a faster growth rate and smoother surface than those on c-plane sapphire.

NM01.11.30 Reinforcement of CNT Yarn by Graphitization and Cross-Linking CNTs Taichi Kita, Motoyuki Karita, Takayuki Nakano and Yoku Inoue; Shizuoka University, Hamamatsu City, Japan.

Carbon nanotube (CNT) has been reported to have high tensile strength of 150 GPa [1]. Since the discovery of dry spinning phenomenon from a CNT forest [2], a dry-spun CNT yarn has been an attractive material as the structural material. One of good things of the dry-spinning is that large-scale and highly aligned CNT structures are uniformly formed. However, since the CNTs are connected by van der Waals force, the spun yarn fails by relative sliding of CNTs, and its mechanical properties are far inferior to those of individual CNT. Moreover, even the relative sliding is suppressed by cross-linking CNTs in the yarn, tensile strength of individual CNT is not so high as expected because of crystal defects, resulting in moderate improvement of strength in the yarn. In this work, in order to reinforce the CNT yarn, CNTs were graphitized at high temperatures. Then CNTs were cross-linked by binder materials. Dry-spin capable MWCNT forests were grown by chlorine mediated CVD using FeCl$_3$ as catalyst [3]. The yarns were prepared by twisting drawn CNT webs [4]. The yarns were annealed at higher than 2500 °C in inert ambient. The highly graphitized CNT yarns were further reinforced by introducing azide-group cross-linker agent that makes covalent bonding in between CNTs. Mechanical and electrical properties of the reinforced CNT yarns will be reported.

NM01.11.31 The Mechanics of Reinforcement in Graphene-Based Nanocomposites Robert Young, Dimitrios Papageorgiou and Ian A. Kinloch; University of Manchester, Manchester, United Kingdom.

Although there has been a rapid growth of interest in polymer-based nanocomposites, the mechanics of reinforcement in such materials is still not yet fully understood. It has been established by the authors that stress transfer from the matrix to the reinforcement in nanocomposites reinforced by graphene nanoplatelets (GNPs) can be followed from stress-induced Raman band shifts. A detailed study has been undertaken of the mechanisms of stress transfer in a polymer of polymeric matrices with very different levels of Young’s modulus, $E_m$, reinforced by graphene nanoplatelets. The matrix materials studies have been natural rubber ($E_m$ ≈ 1 MPa), thermoplastic elastomers ($E_m$ ≈ 10-100 MPa) and polypropylene ($E_m$ ≈ 1000 MPa). The microstructure of the nanocomposites has been fully characterised using a range of different advanced analytical techniques that include, Raman imaging, x-ray computer tomography (CT) scans and polarized Raman spectroscopy that give an unprecedented level of information upon their microstructures. It is found that the addition of the GNPs leads to significant increases in stiffness in each polymer showing high levels of reinforcement are obtained. For each material the effective Young’s modulus of the graphene, $E_{eff}$, has been determined using the rule of mixtures and it has been found that this scales with the value of $E_m$. Additionally the stress-induced Raman bands shifts show different levels of stress transfer from the polymer matrix to the GNPs which again scale with the Young modulus of the matrix. For example, shifts of the order of 1 cm$^{-1}$/100% strain are found in the natural rubber matrix nanocomposites compared with ~10 cm$^{-1}$/1% strain for the polypropylene matrix nanocomposites with a value of $E_m$ three orders of magnitude higher. Studies of the mechanics of stress transfer in model composites consisting of single graphene flakes in polymeric matrices have also been undertaken by using Raman spectroscopy to map the strain distribution in the individual flakes. A unifying theory has been developed to predict the stiffness of the bulk nanocomposites from the mechanics of stress transfer from the matrix to the GNP reinforcement based upon these studies of deformation of the individual flakes. Excellent agreement has been found between the measured and predicted values of $E_{eff}$ and hence composite Young’s modulus for the bulk nanocomposites. It will be shown that the theory also enables factors such as interfacial bonding, reinforcement geometry and orientation to be taken into account.

Overall it is found that it is only possible to realise the theoretical Young’s modulus of graphene of 1050 GPa for discontinuous flakes as $E_m$ approaches 1 TPa; the effective modulus of the reinforcement will always be less for lower values of $E_m$. In general it is found that the highest levels of reinforcement will be obtained in nanocomposites with strong graphene-polymer interfaces and optimised reinforcement geometries and orientation.

NM01.11.32
Carbon based nanomaterials are currently in the limelight for their potential to replace expensive noble metal based electrocatalysts. Noble metal electrocatalysts (Pt, Pd, Au, Ru) suffer from monofunctionality (hydrogen evolution reaction (HER)/oxygen reduction reaction (ORR) or oxygen evolution reaction (OER) favoured). As such, their use in electrocatalytic devices i.e. fuel cells, Zn-air batteries etc. is limited. Carbon based materials with controlled level of defects and high specific active surface area, can be tuned to serve as multifunctional materials. The overall oxygen electrochemistry towards ORR and OER is significantly lower than the noble metal group based electrocatalysts. Doping of nitrogen (or other heteroatoms) in the carbon structure also significantly improves their activity. In this context, a simple one-step pyrolysis route is used to synthesize exotic carbon based materials, especially core-shell nanostructures and nanotubes, using various transition metal precursors. It is observed that transition metal based alloy nanoparticles, in the vicinity of the carbon matrix significantly increases the cyclic stability and effective electrochemical window required for total water splitting or metal-air battery systems. Furthermore, the involvement of metal centres and their interaction with carbon and nitrogen in the generated carbon materials is investigated, which provides useful insights into the tunability and progress in such systems.

**Graphene Oxide-Templated Synthesis of Crumpled Holey Metal Oxide Nanosheets via Spray Pyrolysis for Enhanced Gas Sensor**

Rheehyun Kim, Ji-Su Jung, Dong-Ha Kim, Won-Tae Koo and Il Doo Kim; Material Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Two-dimensional (2D) metal oxides have widely been studied in various applications due to their intriguing properties, such as super high surface-to-volume ratio, ultra-thin thickness, high meso-porosity and small grain size. However, 2D nanostructures have the tendency to restack, so they can induce the decrease of surface area and amounts of accessible mesopores. In this work, crumpled SnO₂ nanosheets (NSs), crumpled ZrO₂ NSs, and crumpled SnO₂-ZrO₂ composite NSs (C_MO NSs, MO = SnO₂, ZrO₂ or SnO₂-ZrO₂) were successfully synthesized by using graphene oxide (GO) sheets as a sacrificial template and used as highly effective 2D oxide gas sensing layers. In detail, GO/metal ion composites were synthesized by dissolving metal precursor and GO in absolute ethanol to allow bonding between 2D GO and the metal oxide (GO in absolute ethanol to allow bonding between 2D GO and the metal oxide). Then, by conducting spray pyrolysis of the solution which is composed of dispersed GO/metal ion composites in DI water at 400 °C, the crumpled GO/metal oxide composites were fabricated. After calcination of them at 500 °C for 1 h, GO were thermally decomposed to form C_MO NSs. Crumpled metal oxide NSs have high surface-to-volume ratio and high distribution of macropores as well as mesopores, which are essential for efficient surface reaction and high gas permeability. Also, ultra-small grain size affects to form complete electron depletion layer for effective modulation of resistance. Additionally, n-n heterojunction from C_SnO₂/ZrO₂ NSs can induce the energy band bending to enhance the gas sensing capability. The gas sensing properties were proceeded to VOCs (volatile organic compounds) gas species, e.g., CH₃COOH, NO, C_H₄, C_H₃O, HCHO, H₂S and NO₂. The sensing test results demonstrated that C_MO NSs exhibited enhanced gas sensing performance toward formaldehyde (2.5 times higher response (R_p/R_u) than that of 2D metal oxide NSs) with high selectivity and fast response/recovery speed. Also, C_SnO₂/ZrO₂ NSs induced the improvement of gas sensing properties due to the creation of heterojunction (3 times higher response (R_p/R_u) than that of C_MO NSs). This work suggests the facile and effective synthesis method of C_MO NSs templated by the GO for enhanced gas sensor.

**High Electrical Conductivity of Carbon Nanotube/Poly(Acrylonitrile) Composite Fibers Fabricated via Current-Assisted Wet Spinning**

Yong-min Kim, Ho-Sung Yang and Woong-Ryol Yu; Seoul National University, Seoul, Korea (the Republic of).

Wet spinning process is one of the most common methods of producing polymer microfibers. Wet process has been used in particular for the polymers which can decompose near their melting temperature and thus defy melt spinning process. Poly(acrylonitrile) (PAN), a representative precursor of carbon fibers, belong to this kind of polymers. On the other hand, due to high thermal conductivity and electrical conductivity, carbon nanotubes (CNTs) have been used in PAN fibers to improve the conductivity of carbon fibers. Well-aligned CNTs are known to contribute high electrical conductivity. In this study, we developed high conductive CNT/PAN composite microfibers using a new process, so called current-assisted wet spinning. The current-assisted wet spinning is different from electrosprinning which utilizes the electric field to fabricate nanofibers from a charged solution. For the current-assisted wet spinning, the electrical current is applied to the spinning nozzle of wet spinning system, inducing the interaction of PAN and functional group of CNT and also more packing and alignment of PAN molecules via controlled diffusion between CNT/PAN and coagulation solutions. The electrical and mechanical properties of CNT/PAN fibers fabricated using current-assisted wet spinning were measured by the two-probe method and single fiber tensile test. 2D wide angle X-ray diffraction (WAXD) and transmission electron microscopy (TEM) were used to characterize the microstructures of CNT/PAN fibers. Nuclear magnetic resonance spectroscopy (NMR) and X-ray photoelectron spectroscopy (XPS) analysis were performed to characterize the chemical bonding of CNT/PAN solutions and fibers. Finally, a mechanism behind high conductivity of CNT/PAN composite microfibers via current-assisted wet spinning was investigated and will be presented in detail at the Conference.

**Quasi-Freestanding Graphene on SiC by Argon Mediated Intercalation of Antimony**

Susanne Wolff¹, Florian Speck¹, Martina Wanke¹, Felix Timmermann², Manfred Albrecht³ and Thomas Seyller¹; ¹Institut für Physik, Technische Universität Chemnitz, Chemnitz, Germany; ²Institut für Physik, Universität Augsburg, Augsburg, Germany.

The intercalation of various elements under the buffer layer is an elegant method to produce so-called quasi-freestanding graphene (QFMLG) on SiC substrates. The modification of the graphene/SiC interface changes the electronic properties of QFMLG depending on the choice of the intercalant. Hence, intercalation represents a promising technique to tune graphene’s properties according to the specific application. So far, three methods for intercalation have been successfully demonstrated to work for different elements. Gaseous species like, e.g., hydrogen [1] or oxygen [2] can be intercalated by annealing in the respective atmosphere. Solids with low vapor pressure such as gold [3] or germanium [4] were intercalated by first depositing the material on top of the buffer layer followed by annealing at a certain temperature in ultra-high vacuum (UHV). On the other hand, solids with high vapor pressure require a different method. Recently it was shown that implantation [5] allows the intercalation of bismuth. In this presentation, using the example of antimony (Sb), we introduce another method to intercalate solid elements with high vapor pressure. The method is based on a reduced rate of sublimation of Sb from the surface when the sample is annealed in argon (Ar) atmosphere rather than in UHV.

To that end, Sb with a thickness of approx. 50 nm was deposited by molecular beam epitaxy on top of the buffer layer and the samples were annealed in 1 bar Ar at an optimized temperature of 550°C. X-ray photoelectron spectroscopy (XPS) and low-energy electron diffraction (LEED) confirmed the intercalation and formation of quasi-freestanding graphene. Both, elemental Sb as well as oxidized Sb were observed at the interface. The latter is caused by the transport of the Sb-covered samples in air which leads to a thin oxide layer on top of the Sb. A two-step annealing process in 1 bar Ar where (i) the oxide is removed by annealing at 400°C and (ii) the intercalation is performed at 550°C leads to the intercalation of purely elemental Sb. Angle-resolved photoelectron spectroscopy (ARPEMS) reveals a moderate n-type doping of the samples which were intercalated with pure metallic Sb.
The aim of this study is to promote the ultra-fast, sensitive and real-time monitoring of different clinical cardiac Biomarkers (Myoglobin and Cardiac Troponins) for the diagnosis of the cardiac diseases like Acute Myocardial Infarction (AMI) using the 3D network of 2-ABA functionalized carbon nanotubes in a the Lab-on-a-chip configuration. The development of a rapid and practical immunosensor for detecting Cardiac markers in serum samples (standard as well as spiked) is desirable due to its roles in cardiacspecific diagnosis, risk stratification, and assessment. The main objective is to develop a biosensor exploiting microfluidics allowing in-situ self-functionalization. The sensitivity can be adjustable and the device can be used for detection of different cardiac biomarkers. The functionalization takes place in situ and selectively, just before the sensing, keeping the sensing area dry and inactive until the test starts, and conserving the functionality of the device. Also, the reagents and chips are stored separately and may be used before testing, without the need of overnight functionalization process or complex fabrication methods. The monitoring of the signal is performed in real-time and changes in impedance modulus (label-free electrochemical changes) are equivalently recorded by using an alternative and simpler voltage measurement. The label-free electrochemical biosensors are an attractive choice for fast, early diagnostics and monitoring of biological markers due to the direct conversion of a biological event into an electronic read-out signal.

Since the discovery of single-walled carbon nanotube (SWNT), SWNT has attracted with great interest because of their outstanding mechanical and electrical properties. For these reasons, researches for implementation of their electronic applications such as field-effect transistors (FETs), thermoelectric devices and biological imaging have been substantially promoted. However, the co-existence of metallic (m-) and semiconducting (sc-) SWNT have disturbed the effective use for electronic applications. In the recent, conjugated polymer wrapping of SWNT has specially aroused great attraction as a method for separation of SWNTs due to their advantages of high selectivity toward sc-SWNT and simple polymer sorting process. Although the π-π interaction between conjugated polymer and wall of SWNTs is related with the selective dispersion of SWNTs, the mechanism how to separate the sc-SWNTs remains as issues. In this research, we introduce the pyrene moiety as main chain of conjugated polymer to increase the π-π interaction with sc-SWNTs. New pyrene-based conjugated polymers were carefully designed and synthesized via suzuki polymerization. Their dispersion selectivity and diameter of sc-SWNTs enriched by pyrene-based conjugated polymers were characterized by various measurements such as UV-vis absorption spectra, Raman spectroscopy and Photoluminescence excitation/emission analysis. Finally, the sc-SWNTs were employed into FETs as an active layer.

Single-wall carbon nanotube(SWNT) is excellent material for many applications. Especially, SWCNTs with small diameter and high crystallinity are expected to have better property, however they are more difficult to synthesize which results in high cost (2-100 USD/g). One of the best synthesis methods for high quality CNT is floating catalyst chemical vapor deposition (FCCVD) [1-4]. However, the yield of CNT is still low which stems from the low efficiency of the formation of active catalyst nanoparticles. In the conventional CVD, because the gas which contain the catalyst source is heated gradually by the furnace, most of the catalyst nanoparticles aggregate and deactivate before the nucleation of the CNTs.

In this report, to generate more active catalysts, we designed a new process to control the gas temperature. The catalyst sources (ferroocene and sulfur) are rapidly (i.e., ~5 ms) heated to 1300 °C in the narrow flow path (Φ4 mm) to pyrolyze and vaporize efficiently. Then, the iron vapor is mixed with carbon sources (e.g., CH4, C6H6, etc.) and cooled down rapidly to 1150 °C in wide flow path (Φ40 mm), which enables the formation of the catalyst nanoparticles followed by the immediate nucleation and synthesis of the CNTs. The CNT yield was 2.5 mg/mm. The TEM observation showed 90% SWCNTs with 10% efficiency of the formation of active catalyst nanoparticles. In the conventional CVD, because the gas which contain the catalyst source is heated gradually by the furnace, most of the catalyst nanoparticles aggregate and deactivate before the nucleation of the CNTs.

Modified Tour Method for Synthesis of Graphene for Solar Cell Applications Dulce K. Becerra Paniagua1, Merida Sotelo Lerma2 and Hailin Zhao Hu1; 1Instituto de Energías Renovables, Universidad Nacional Autónoma de México, Temixco, Mexico; 2Universidad de Sonora, Hermosillo, Mexico.

Graphene products are obtained by reduction of graphene oxide (GO). A recently chemical procedure for GO synthesis is the Tour method [1]. In this method the GO was synthesized by the oxidation of graphite powder, using KMnO4 and a 9:1 mixture of H2SO4/H3PO4, the latter as a protective agent. In this paper a modified Tour method is designed to looking for a simple, easily controlled and an alternative approach for large scale production of GO for solar cell applications. We find that if a mixture of H2SO4/H2O2 is used instead of H2PO4, then the oxidation time of graphite can be reduced under the same reaction conditions: two hours of oxidation is enough for produce the equal amount of hydrophilic oxidized graphene material as compared to Tour method that requires about seven hours. The reduced graphene oxide (rGO) was prepared by the thermal and chemistry reduction of GO by employing ascorbic acid and ammonia solution at high temperature [2]. The GO and rGO samples were characterized by UV-Visible spectroscopy, FTIR spectroscopy, Raman spectroscopy, SEM, TEM and EDS. It is found that the GO prepared by modified Tour method yields a higher fraction of well-oxidized carbon material and could have the same advantageous in quality for achieving few-layers of graphene sheets for large-scale production than the
original Tour method. On the other hands, the results of XRD, EDS and UV-Vis of GO products reveal that the oxygenated groups that were present in GO products have been widely removed, this can be seen reflected in the atomic ratio C/O of rGO (3.7), it increase close to 70% with respect to the GO (1.3), so that almost 50% of the oxygenated groups were removed. Finally, thin films of GO and rGO were prepared by spin coating method with GO and rGO solutions. Optical and electrical properties of the films are analysed and their potential use as electron or hole transporting layers in perovskite solar cells are discussed. In particular, the presence of the remaining oxygenated groups in rGO reduces the electrical conductivity of the GO films, and, consequently, the power conversion efficiency of the solar cells. The removal of a higher percentage of oxygenated groups remains as a challenge in the synthesis of graphene products.

NM01.11.40
Electrical Performances of Carbon Nanotube Webs and Yarns Yoann Dini1,2, Jean Dijon1,2 and Jérôme Faure-Vincent1,3; 1Commissariat à l’energie atomique, Grenoble, France; 2Isère, Université Grenoble Alpes, Grenoble, France; 3Centre National de la Recherche Scientifique, Grenoble, France.

In electrical wiring, metal substitution by high conductivity materials like carbon nanotubes (CNT) is a near future challenge for high-end aeronautic and aerospace applications1,2. Several techniques exist to make CNT yarns. The most suitable, eco-friendly process for large-scale production is to directly dry spin CNTs grown by fixed- or floating-catalyst Chemical Vapor Deposition (CVD). For the last ten years, all published works on CNT yarns from CNT arrays made by fixed-catalyst CVD have faced the same resistivity limitation of around 1 mΩ.cm3. The basic reasons for this limitation are unclear. Is it the intrinsic CVD carbon nanotube quality or the disorganization of the CNTs inside the yarn induced by the CNT array? We recently developed a new carbon nanotube yarn production process based on a low temperature (630°C) and low pressure (1.2 mbar) hot filament CVD system. It allows us to produce small carbon nanotubes (7 nm average diameter) and yarns from our CNT arrays with state of the art resistivity (1.07 mΩ.cm). Our work answers the previous questions through extensive electrical transport studies of CNT webs and CNT yarns. Resistivity measurements from 3 K to 350 K are analyzed within the frame of known electronic transport models. The effects of the densification, the CNT lengths and the dopants on the yarn will be presented. Contrary to the typical explanation, we will show that the electrical contacts between carbon nanotubes in the yarn are good and do not limit the electrical transport at room temperature. Those contacts only hinder the yarn’s electrical transport at temperature below 70 K. We performed unique carbon nanotube web resistence measurements at room temperature. A careful scanning electron microscope image analysis of the CNT web reveals the fractal arrangement of the CNTs (fractal dimension of 1.75). Hence, we found that the average resistivity is 0.7 mΩ.cm for the CNT bundle and 0.5 mΩ.cm for the individual CNT. The CNT yarn resistivity is therefore similar to that of the CNT bundle. It appears that the 1 mΩ.cm resistivity limitation faced by yarns made from CNT arrays is mainly due to the individual CNT resistivity. Our work emphasizes that drastic enhancement of CNT yarn electrical resistivity can only be achieved by doping or by increasing the CNT quality.

NM01.11.41
Preparation of Carbon-Black/Polymer Composite Fibers Sang Young Yeo; Korea Institute of Industrial Technology, Ansan, Korea (the Republic of).

With the development of the wearable device industry, there is an increasing interest in conductive textiles, and research on conductive fiber manufacturing is actively being reported. Because carbon black has a high specific surface area, a composite is prepared by mixing with a polymer then a conductive network is formed in a small amount to improve electrical conductivity. In this study, carbon-black/polymer composites composed of polypropylene, polyester, and nylon matrix were prepared and their electrical properties were analyzed. The carbon-black/polyester composite film with good dispersibility showed the highest electrical conductivity and the lowest threshold value among 3 types polymer composites. The nylon composites with high polarity had dependent CL and compared to that diamond and ZnO [6]. The luminescence of hBN is confirmed to be unusually high and is found to remain constant from 10 to 300K. Enlightening analysis of this behaviour is provided by ab initio calculations of the excition dispersion in bulk hBN. First, the lowest-energy excition (X) is found at 5.97eV and to be indirect, as expected for an indirect band gap, with a binding energy equal to 300 meV. This dispersion behavior accounts for an assignation of the luminescence to phonon assisted recombinations of the indirect excition as proposed in [7] and for the assignation of the

Understanding Optical Absorption and Luminescence in hBN—From Bulk to the Monolayer Annick Loiseau; LEM, CNRS-ONERA, Chatillon, France.

hBN layers meet a growing interest for deep UV LED [1], and have become a strategic material for the fabrication of van der Waals heterostructures. Stacked with any other 2D material it can reveal the best of their physical properties [2]. However, hBN optoelectronic properties remain much less characterized and understood than other 2D materials.

In this talk, we review recent advances made thanks to the development of appropriate spectroscopies in the UV range - cathodoluminescence (CL) at 4K and Raman [3,4], combined with ab initio simulations [5]. Thanks to these tools, a h-BN characterization metrics has been developed on the basis of their original optical properties, governed, in the energy range 5.5 – 6 eV, by strong excitonic effects easily trapped at structural or chemical defects [3]. We shall discuss the interplay between structure, defects and spectroscopic properties and how these properties can be further exploited for sample benchmarking [3].

Beyond this effort, the talk will also address the recent advances made for the understanding of the high luminescence observed although bulk hBN is an indirect band gap material [1,6]. To that aim, the efficiency of radiative recombinations has been measured on a reference single crystal using temperature dependent CL and compared to that diamond and ZnO [6]. The luminescence of hBN is confirmed to be unusually high and is found to remain constant from 10 to 300K. Enlightening analysis of this behaviour is provided by ab initio calculations of the excition dispersion in bulk hBN. First, the lowest-energy excition (X) is found at 5.97eV and to be indirect, as expected for an indirect band gap, with a binding energy equal to 300 meV. This dispersion behavior accounts for an assignation of the luminescence to phonon assisted recombinations of the indirect excition as proposed in [7] and for the assignation of the
tiny peak observed in CL spectra at 5.956 eV to the zero-phonon radiative recombination of IX [6]. Further IX high binding energy is consistent with the temperature behavior of the luminescence, the high yield being the signature of a strong exciton phonon coupling. Second, calculations also confirm the direct exciton (dX) with a binding energy of 670 meV [6], an energy which turns to be only 100 meV above the indirect one. It comes out that bulk hBN displays a peculiar behavior where luminescence and optical absorption are due to different excitons. This situation totally evolves in the layer, the gap being direct and we could identify the dX line in the CL spectra recorded on very thin hBN layers [6].

9:15 AM NM01.12.03

Despite their similar crystallographic structures, boron nitride nanotubes (BNNTs) exhibit a range of physical and chemical properties distinct from carbon nanotubes (CNTs), which are mainly attributed to the partial ionic bonding character of BN. Here we present two markedly different properties between BNNTs and CNTs: interlayer mechanics [1] and reduction chemistry [2]. Firstly, we show using van der Waals (vdW) parameterized density functional theory (DFT) that the strong mechanical coupling between the buckled lattices of small-diameter BNNTs greatly elevates the threshold forces and internal friction with respect to the relative motion of BNNT walls. Unlike for CNTs, large differences between relaxed and unrelaxed energy corrugations of BNNTs could yield energy dissipation via the strain-induced anelastic relaxation of interlayer locking, resulting in the experimentally observed ultrahigh interlayer friction of BNNTs. Secondly, through DFT calculations and experimental studies of the covalent alkylation of BNNTs using 1-bromohexane, we demonstrate that the chemical reactivity of BNNTs towards radical molecules can be significantly enhanced via reducing the nanotubes (i.e., negatively charging). Our study predicts that the localization characteristics of the BNNT π electron system lead the excess electrons to fill the empty p orbitals of boron sites, which promote covalent bond formation with an unpaired electron in radical molecules.

Boron and Metal Boride 2D Sheets and Nanotubes Sohrab Ismail-Beigi; Yale University, New Haven, Connecticut, United States.

Compared to carbon, bulk and reduced dimensional forms of pure boron present more complex bonding patterns and atomic-scale geometries. An underlying reason is that boron has the same number of valence orbitals as carbon but has one fewer valence electron (i.e., is “electron deficient”). This means that standard two-center bonding motifs between neighboring atoms in familiar structures, such as hexagonal or triangular networks, are not energetically favorable. This leads to complexity and richness in the phase space of boron structures. This situation has attracted significant scientific attention over the last two decades. While the initial literature consisted of primarily of first principles theoretical studies and predictions, the last few years have witnessed experimental fabrication and characterization of 2D boron sheets which in turn has greatly enhanced interest in these materials.

This talk will provide a brief overview of the initial theoretical predictions in this field followed by a summary of some of the more salient experimental and theoretical performed recently, including some of our work on 2D and nanotubular boron and metal boride nanomaterials. In the process, we will discuss the challenges and opportunities this field may face when attempting to fabricate and use boron nanostructures.

10:30 AM *NM01.12.05
Carbon and Beyond: A Colorful Palatte of 2D Materials Boris I. I. Yakobson; Department of Materials Science and Nanoengineering, Department of Chemistry, and the Richard E. Smalley Institute, Rice University, Houston, Texas, United States.

From our theoretical insight into evolutionary selection in synthesis of monocrystal graphene [1], into the paths of back-diffusion in growth of its bilayers [2], and into their possible conversion to monocrystal diamond films like diamond [3,4], we envisage a platform to emerge for design of the point (0D) defects in 2D-media as effective single-photon emitters (SPE) [5]. More diverse basic optics of numerous 2D materials [6] further expands possibilities for SPE realization, where theoretical assessment can guide experimental choices and tests.

11:00 AM *NM01.12.06
Recent Advancement in Boron Nitride Nanotubes and Nanosheets Yoke Khin Yap; Michigan Technological University, Houghton, Michigan, United States.

Hexagonal boron nitride (h-BN) is structurally like graphite and has continued to gain research interest from synthesis, characterization, to application. Mono and few layered h-BN are now commonly known as boron nitride nanosheets (BNNSs), as one of the emerging two-dimensional (2D) materials. On the other hand, seamless rolls of BNNSs are known as boron nitride nanotubes (BNNTs). BNNTs are meaningful as a role model of materials by design, as they are first predicted by theory and then experimentally realized. Due to the difficulty on the synthesis of BNNTs and BNNSs, their research progress is far slower than the structurally similar carbon nanotubes (CNTs) and graphene. In this invited talk, recent advancement of BNNTs and BNNSs will be discussed, in particular for their application in advanced electronic and biomedical applications. These advancements suggest that BNNTs and BNNSs are important nanomaterials that complement the application of CNTs, graphene, and 2D materials.
Integration of atomic force microscopy and laser spectroscopy traditionally makes possible to obtain more complex information about the studied object: whether it is a living cell, a polymeric composite, or nanotubes. In the report are given various examples of combined AFM and Raman microscopy NTGERA Spectra (NT-MDT Spectrum Instruments Co) applications to study both physical properties of the surface (topography, surface potential, magnetic or piezoelectric properties, conductivity, local stiffness) and structural properties measured by Raman spectroscopy will be reported. Normally combined study is done by means of Si cantilevers of top-visual shape to provide optical access to the tip from above by high-resolution objective (100x, 0.7 NA). It is also possible to use metal needles for scanning tunneling microscopy or tuning fork-based feed-back. Measurements can be carried out in a controlled gas or liquid environment, which may be important to maintain the properties of the sample or to eliminate the background low-wavenumbers Raman peaks from the N\textsubscript{2} and O\textsubscript{2} molecules present in air. The design of the spectrometer allows to use either edge filters or notch filters to suppress laser radiation and provide both Stokes and anti-Stokes scattering, including the THz range down to 10 cm\(^{-1}\) from Rayleigh scattering.

The most intriguing possibility that appears when integrating atomic force microscopy and Raman spectroscopy is to overcome the diffraction limit due to local amplification of the field near the tip apex [1]. To achieve strong enhancement of Raman signal in the Tip Enhanced Raman Scattering (TERS) mode, it is necessary to keep the tip at the surface of the sample as close as possible. The mode of nonresonant intermittent-contact microscopy, also known as Hybrid mode [2] allows the probe to be held in contact with the surface up to 70\% of time, while eliminating lateral forces during scanning and minimizing the pressure force. In addition, this method is also applicable to keep feedback in the liquid and when the sample is heated, when a significant drift of the cantilever bending is observed.

The presented results, using the example of graphene oxide flakes, show that HybriD mode allows to effectively enhance Raman scattering and, at the same time, significantly reduces the mechanical probe-sample impact during scanning process.

11:45 AM AM01.12.08
Broad Spectra Absorption of Boron Nitride and Molybdenum Disulphide Quantum Dots for Photovoltaic Devices Amit Acharya, Dongyan Zhang and Yoke Khin Yap; Michigan Technological University, Houghton, Michigan, United States.

After the discovery of semi-metallic graphene, layered materials such as hexagonal Boron Nitride (h-BN) and molybdenum disulphide (MoS\textsubscript{2}) have attracted a lot of attention. For example, h-BN sheets have become the indispensable underlayers for two dimensional (2D) devices with high electron mobility despite being electrical insulating. On the other hand, the indirect to direct band gap conversion in MoS\textsubscript{2} is due to the quantum confinement effect along the thickness axis of the 2D materials. Here, we present the synthesis and properties of h-BN and MoS\textsubscript{2} quantum dots (QDs) by creating quantum confinement in axes perpendicular to the thickness axis. These QDs offer unique and broad spectra absorption bands for effective photoelectron generation for use in QD-sensitized photovoltaic devices.

A top-down approach was employed to convert h-BN and MoS\textsubscript{2} particles into QDs by using sonication, and solvo-thermal in Dimethylformamide (DMF). The MoS\textsubscript{2} are 2-40 nm in dimension, while the BN QDs are 2-8 nm in dimension. We show that the fluorescent emission from these polydisperse QDs are excitation wavelength dependent. These MoS\textsubscript{2} QDs could absorb a wide spectrum range of light from 320-520 nm to produce fluorescence emission from 385-569 nm. The h-BN QDs can absorb a broader spectra from 300-580 nm with fluorescence emission of 380-620 nm. The broad absorption wavelength range of these QDs would meet the peak of solar irradiation spectrum to enable effective production of photoelectrons from the sun for the applications of photovoltaic devices. Detailed of these results will be discussed in the meeting.

Harnessing the Versatility of Carbon Nanotubes for Printed Electronics Aaron D. Franklin; Duke University, Durham, North Carolina, United States.

Single-walled carbon nanotubes (CNTs) are one of the most versatile electronic materials ever discovered. Electronically, they can be semiconducting or metallic; mechanically, they are flexible yet have a tensile strength greater than steel; and physically they can be centimeters long to just a few nanometers. For nearly two decades, these diverse properties have excited and motivated researchers pursuing CNTs for electronic applications. However, thus far the versatility of CNTs has also been their greatest obstacle in terms of purification, precise positioning, and so forth. In this talk, I will discuss how the inherent versatility of CNTs can be appropriately harnessed for enabling certain applications. The tremendous progress in solution-phase processing of nanotubes has opened a path for their most suitable, near-term use as printed thin films. Recent advances will be presented in using printed thin films of CNTs for print-in-place additive electronics, sensors for harsh environments, and highly sensitive biosensors. Each of these is made possible by drawing from distinct properties of thin-film CNTs; properties unavailable from any other printable material. Perspectives on stability, reproducibility, and yield will also be offered, with evidence of the impact that printed silver contact morphology has on printed CNT thin-film transistor performance. The unique and reproducible behavior of printed CNT thin films suggests they be given greater consideration from the printed electronics community. In the company of organic semiconducting inks, and even that of non-printed metal-oxide semiconductors, printed films of CNTs are a standout with significant advantages and opportunities.

Low-voltage Operable, Highly-stretchable Carbon Nanotube Thin-Film Transistors with Novel Local Strain Control Structure Yuya Nishio2, Jun Hirota1, Shigeru Kishimoto1 and Yutaka Ohno1; 1; Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya, Japan; 1; Department of Electronics, Nagoya University, Nagoya, Japan.
Stretchable devices have intensively been studied towards a realization of wearable electronics for continuous monitoring of human activity and health condition. Recent works have demonstrated that carbon nanotube thin-film transistors (CNT TFTs) have excellent mechanical flexibility and stretching ability. [1-3] However, they still exhibited a degradation of drain current with applied strain. Another issue to be addressed is high-voltage (a few ten V) operation due to the polymer-based gate dielectric which is flexible and/or stretchable, but of low-dielectric constant. [3] wrinkled Al2O3 gate insulator was proposed for realizing low-voltage and stretchable CNT TFTs, but the degree of tensile strain was limited up to 20%. [2] Here, we have realized low-voltage operable and highly-stretchable all-carbon CNT TFTs by introducing a novel local strain control structure.

We fabricated CNT TFTs composed of a channel of a semiconducting-CNT thin film, transparent electrodes of a CNT thin film, and a 50-nm-thick Al2O3 gate dielectric layer on a stretchable poly(dimethylsiloxane) (PDMS) film. The device may exhibit some degree of stretching ability, however, in order to fully suppress the influence of strain on the device characteristics, we formed a local strain control structure with a rather hard polymer material on top of the channel region of a CNT TFT. We also performed the numerical analysis based on the finite element method to design the strain control structure.

The fabricated devices exhibited typical p-type transistor characteristics with a carrier mobility of 7.2 cm2/Vs and on/off ratio of about 104, and was operable at gate voltage of less than 5 V. By introducing the local strain control structure, only 14% of externally applied tensile strain was introduced in the channel region, whereas the CNT electrodes and the other field of the PDMS film were directly stretched. No significant degradation of drain current was observed against tensile strain up to 35%.

Fully-Printed Flexible Dual-Gate Carbon Nanotube Thin-Film Transistors with Tunable Ambipolar Characteristics for Complementary Logic Circuits Haochuan Wang1, Min Yu2 and Chuan Wang3; 1Electrical and Systems Engineering, Washington University in St. Louis, St Louis, Missouri, United States; 2Institute of Microelectronics, Peking University, Beijing, China.

Semiconducting single-wall carbon nanotubes (sSWCNTs) have been widely used as the channel material for high-performance printed flexible thin-film transistors (TFTs). Due to the absorption of moisture and oxygen in air, the printed sSWCNT TFTs generally exhibit p-type characteristics only. In this paper, we report fully-printed dual-gate sSWCNT TFTs that exhibit almost symmetric ambipolar characteristics. With the applied control gate voltage varying from -60 V to 60 V, a threshold voltage tuning range of 27 V is achieved, allowing the device to be effectively tuned into either predominantly p-type or predominantly n-type. The tunable ambipolar characteristics are found to be very stable over long period of time (4 months). By integrating two printed dual-gate TFTs biased with different control gate voltages, a complementary metal oxide semiconductor (CMOS) inverter with close to rail-to-rail output voltage swing is demonstrated. The use of dual-gate structure for achieving n-type printed carbon nanotube TFTs is much more controllable and repeatable compared to other methods such as chemical doping. Our work shows the feasibility of implementing more sophisticated complementary logic circuits using printed flexible carbon nanotube transistors.

Spectrally-Resolved Photoresponse in a Graphene-Based Gate Tunable Phototransistor Dehui Zhang1, Gong Cheng1, Zhen Xu1, Che-Hung Liu1, Meisi Guo2, Thomas Beechem3, Michael Goldflam1, François Leonard2, Steve Young1, David Peters1, Zhe Liu1, Audrey Rose Gutierrez2, Wenzhe Zhang1, Theodore B. Norris3 and Zhaohui Zhong1; 1University of Michigan, Ann Arbor, Michigan, United States; 2Institute of Microelectronics, Peking University, Beijing, China; 3CentraleSupelec, Gif-sur-Yvette, France; 1Sandia National Laboratories, Albuquerque, New Mexico, United States.

Graphene has a unique broadband absorption from visible to microwave due to its gapless nature. Integrating graphene with microcavities, photonic crystal or surface plasmonic structures can not only increase the strength of light-matter interaction, but also achieve some degree of spectral selectivity for enhanced light absorption around the designed wavelengths. However, the above-mentioned spectral selectivity results from some forms of resonance structures; therefore once the device is fabricated, the spectral response is fixed at the resonance wavelength for such devices. In our work, we demonstrate an electrically tunable, spectrally distinguishable photoresponse in a graphene-based phototransistor. The device is composed of a 6-nm amorphous silicon tunneling barrier sandwiched by two layers of graphene, one used as the channel and the other as the gate. By applying a sweeping voltage on the graphene gate layer while recording channel layer current, we discover gate-dependent photoresponse curves for different excitation wavelengths. Importantly, this electrical tuning of photoresponse offers a new mechanism for spectrally resolved photodetection with graphene detectors. As a proof-of-concept, we build a responsivity matrix of gate voltage and excitation wavelength by measuring the gate-dependent photoresponse curves for a finite number of wavelengths. Photodetection and spectral reconstruction for mono-color lights were then successfully demonstrated. More detail will be presented at the conference. Our results open the door for on-chip spectrometers free from complex optical setups and may find its applications in technologies such as hyperspectral imaging.

2:45 PM NM01.13.05

Aligned Carbon Nanotube Sheets Integrated in Liquid Crystal Device Cells M. A. Rahman1, Hakam Agha1, Meenu Murali1, Ji Hyun Park1, Kieu Truong2, Dongseok Suh2 and Glusy Scalia1; 1University of Luxembourg, Luxembourg, Luxembourg; 2Sungkyunkwan University, Suwon, Korea (the Republic of).

Sheets of unidirectionally oriented carbon nanotubes (CNTs) [1-2], among the various attractive applications, can be employed as transparent and conductive layer for switching but also, interestingly, for aligning liquid crystals (LCs) [3]. Even a single layer, tens of nanometers thick, can be used for applying electric fields strong enough to reorient LC molecules and, at the same time, for serving as an alignment layer for LCs. The successful implementation of new materials in LC cell geometries is a pre-requisite for future applications in device technology. CNT sheets as aligning electrodes are a relatively new entry that are showing very good performances for LC switching but also, present challenges to face. CNT sheets do not completely adhere to the substrate surface and methods to promote the adhesion, such as chemical treatment of the surfaces or polymer coatings, are needed. As it will be presented, the adhesion of CNTs on different types of underlying polymer films is indeed improved by ethanol treatment but the orientational order parameter of CNT sheets is affected at different extends [4]. The evaluation of the CNT sheet characteristics such as the degree of orientational order of the strands, the film thickness and its uniformity in properties like the electrical conductivity are of importance for the LC passive and active behavior. However, there are other characteristics that we will discuss here, that influence the LC behaviour, connected to the peculiar nature of the CNT sheets being formed by discrete elements, the nanotubes, even if connected in anisotropic networks. To understand the different aspects we investigate the CNT sheets using different techniques. For evaluating the morphology and the uniformity in properties we use electron and atomic force microscopy, profilometry and optical absorption. The electrical characteristics are investigated with and without LCs using DC as well as AC electric fields while monitoring the samples under a polarized optical microscope.

Energy Transport in Polymer-Free Semiconducting Single-Walled Carbon Nanotube Networks

Here we demonstrate an approach aimed at replacing the strongly-bound polymers with variants that can be removed using simple solution-based chemical strategies, resulting in networks with vastly improved energy transport properties. We show that removal of the polymer results in a significant enhancement of the charge carrier mobility and electrical conductivity. Finally, we extend the approach to samples strongly enriched in a single chiral SWCNT species, which allows us to employ transient spectroscopic techniques to probe energy transfer and exciton transport through the SWCNT network with high spectral fidelity. We show that the efficiency of exciton transport is subtly dependent on the complex interplay between polymer removal and carbon nanotube bundling. Our studies highlight a methodology by which high-performance SWCNT thin films can be prepared that could realize their potential for electronic and optoelectronic applications.

SESSION NM01.14: Structure and Properties V
Session Chairs: Ranjit Pali and Yoke Khin Yap
Thursday Afternoon, November 29, 2018
Sheraton, 2nd Floor, Republic AB

Electron Microscopy Studies on Single-Walled Carbon Nanotubes Hua Jiang1, Ying Tian1,2, Yongping Liao1, Qiang Zhang1, Nan Wei1 and Esko Kauppinen1; 1Department of Applied Physics, Aalto University School of Science, Espoo, Finland; 2Physics Department, Dalian Maritime University, Dalian, China.

With the aid of advanced electron microscopy, we have established an approach using ED as a means to evaluate the validity of Raman spectroscopy for quantification of concentrations of metallic SWNTs (M%) or of semi-conducting tubes (S-SWNT%) [1]. We have proved that the Raman RBM intensities depend largely on the resonant conditions at certain wavelengths, rather than simply on concentrations. Up to the resonance conditions, some majority nanotube species revealed by electron diffraction measurements induce relatively weak, or even missing RBMs, and vice versa. This certainly leads to an uncertainty over Raman spectroscopy for quantitative assessment of metallic tube concentrations calculating from the relative peak intensities.

Chirality distribution maps of SWNTs produced by CVD methods with Fe nanoparticles as catalysts at various synthesis conditions have been analyzed by electron diffraction technique. As a recent advance [2], we have successfully achieved direct synthesis of single-walled carbon nanotube thin films with various colors using a novel floating-catalyst-CVD process with ferrocene-based iron catalyst particles and CO as the carbon source. The color is tunable by adjusting the reactor conditions, i.e. the temperature and especially the addition of CO2. Based on unique electron diffraction analysis of individual SWCNTs in our colorful SWCNT thin films, we were able to attribute the colors of the SWCNT thin films to their narrow diameter in certain ranges which give rise to absorption peaks in the visible region. It is demonstrated that the narrow (n, m) chirality distribution also accounts for the display of certain color of a SWCNT thin film.

Energy Transport in Polymer-Free Semiconducting Single-Walled Carbon Nanotube Networks Andrew J. Ferguson and Jeffrey Blackburn; National Renewable Energy Laboratory, Lakewood, Colorado, United States.

The chemical structure of semiconducting single-walled carbon nanotubes (SWCNTs) results in optical and electronic properties of promise for a wide variety of applications. Until quite recently the presence of metallic SWCNT impurities has hampered efforts to gain a deeper understanding of their true potential, with the additional complication that most commercially available materials contain tens of different chiral species. Significant effort has been devoted to elegant enrichment strategies aimed at extracting tailored semiconducting SWCNT species from the raw soot, from the use of subtly tunable surfactant interactions to the exploitation of specific DNA sequences. However, conjugated polymers, typically based on the fluorene moiety, appear to show the greatest promise with regards to their high selectivity and viability for scalable manufacturing approaches.

Unfortunately, the van de Waals forces between the pi-electron systems of the polymer and SWCNT that enable the selective extraction of semiconducting SWCNTs with high purity also make removal of the polymer difficult. Since these polymers typically have a wide bandgap they act as an insulating coating on the surface of the individual SWCNTs within polymer networks, inhibiting the transport of energy in the form of excitons and/or charge carriers.

Here we demonstrate an approach aimed at replacing the strongly-bound polymers with variants that can be removed using simple solution-based chemical strategies, resulting in networks with vastly improved energy transport properties. We show that removal of the polymer results in a significant enhancement of the charge carrier mobility and electrical conductivity. Finally, we extend the approach to samples strongly enriched in a single chiral SWCNT species, which allows us to employ transient spectroscopic techniques to probe energy transfer and exciton transport through the SWCNT network with high spectral fidelity. We show that the efficiency of exciton transport is subtly dependent on the complex interplay between polymer removal and carbon nanotube bundling. Our studies highlight a methodology by which high-performance SWCNT thin films can be prepared that could realize their potential for electronic and optoelectronic applications.

Atomistic Modeling of Nanostructured Printed Graphene Coating Srilok Srinivasan1, Ganesh Balasubramanian2 and Suprem Das3; 1Department of Mechanical Engineering, Iowa State University of Science and Technology, Ames, Iowa, United States; 2Department of Mechanical Engineering and Mechanics, Lehigh University, Bethlehem, Pennsylvania, United States; 3Department of Industrial and Manufacturing Systems Engineering, Kansas State University, Manhattan, Kansas, United States.

Functional coatings have numerous properties, including anticorrosion, anti-icing, and self-cleaning leading to number of applications in future electronics, sensing, and energy. Although graphene has shown extraordinary properties that are demonstrated in past decade, scalable manufacturing and control of graphene’s structure could potentially transform the coating technology. Key to its function is the ability to tune local structure and understand its surface
energy evolution. Direct pulsed laser writing (DPLW) has been shown recently an efficient technique to surface nanostructure graphene coating to tune the contact angle of graphene from hydrophilic to superhydrophobic, leading to manufacturing of multifunctional graphene surface. In this work, using molecular dynamic (MD) simulations we show that the physical orientation of graphene flakes as well as its surface chemistry in a coating influence its wettability. We show that using DPLW the contact angle of graphene coating can be tuned significantly, starting from a hydrophilic (contact angle (CA) ~47.7°) to superhydrophobic (CA ~157.2°) nature. Since the cohesive interactions between water molecules remain invariant for degree of graphene orientation on a surface, the wettability of the surface is driven by the net attractive energies ($U_{h2o,c}$) between water molecule and carbon atoms in graphene due to the adhesive forces that changes with the petal orientation. Furthermore, the dangling bonds on the edges of the graphene ‘petal-like’ structures affect the wettability of the sample. Molecular dynamics (MD) simulations show that the –H termination induces hydrophobicity due to hydrogen repulsion whereas –CO termination makes the substrate hydrophilic due to the polar nature of the bonds. Additionally, we model the evaporation process of water droplets on these coatings that show delays in the water evaporation. Non-equilibrium molecular dynamics (NEMD) simulations reveal that the changes in Kapitza resistance and contact area with increasing contact angle results in a slower evaporation rates in the case of superhydrophobic graphene surface.

Probing on the Molecular Bonding of DMSO-DiI-MWCNT—A Route to Biological MWCNT Surface Modification Examined Through Synchrotron Spectroscopies—Theory and Experiment Wudmir Y. Rojas¹, Allen D. Winter¹, Torsten Bossing², Daniel Fischer², Sarbajit Banerjee³, David Prendergast⁴ and Eva M. Campo⁵; ¹Bangor University, Bangor, United Kingdom; ²Institute of Translational & Stratified Medicine, Plymouth, United Kingdom; ³National Institute of Standards and Technology, Gaithersburg, Maryland, United States; ⁴Department of Chemistry, Texas A&M University, College Station, Texas, United States; ⁵Molecular Foundry, Lawrence Berkeley National Laboratory, Berkeley, California, United States; ⁶National Science Foundation—Division of Materials Research, Alexandria, Virginia, United States.

Supramolecular chemistry of carbon nanotubes (CNTs) investigates the non-covalent functionalization of CNTs to preserve their pristine physical properties typically by p-pstacking with aromatic compounds, dispersion of CNTs with surfactants and polymer wrapping surrounding the CNTs for applications such as identification coating for biological sensing based on fluorescence and the use of CNTs for drug delivery. In this context, feasibility to use polymeric spacers as dispersant agents to reduce intratubular van der Walls forces requires adequate comprehension of nature and dynamics of the CNT-polymer interaction that will pave the way to inform on pharmacological carrier ability and biocompatibility linked with specific CNTs functionalization procedures.

In this work, a physico-chemical description of non-covalently functionalized multi wall carbon nanotube (MWCNT) with DiI and dimethyl sulfoxide through high-resolution electron microscopy, Raman and Near Edge X Ray Absorption Fine Structure (NEXAFS) spectroscopy has been employed. NEXAFS is a synchrotron tool capable to reveal molecular sensitivity description at interfaces, therefore, suitable to study non-covalent interactions. Furthermore, combination of experimental and constrained density functional theory simulations of NEXAFS spectra to propose a molecular model to analyze charge exchange at CNTs-dispersants (or loaded biomolecules) interfaces has been also applied.

Our findings suggest that incorporation of fluorescent markers does not change the morphological structure on MWCNTs. CH-p bonding with nearby molecules and Hydrogen bonding with external defects and graphitic lattice has been identified as well. Theoretical modelling suggests non-covalent interaction between dimethyl sulfoxide and CNTs.

4:45 PM NM01.14.05
Microfluidic Pathways Made from Alumina Nanotubes within Hydrophobic Carbon Nanotube (CNT) Barriers Cemile Aksu; North Carolina State University, Raleigh, North Carolina, United States.

An understanding of fluid transport within porous micro-and nanostructured materials is important for their use in microfluidic devices. In this paper we investigate the microfluidic behavior of alumina nanotube-based pathways within hydrophobic CNT barriers. These hybrid systems provide unique benefits toward the potential liquid transport control in porous structures with real-time sensing of those fluids. Specifically, we examine how the alignment of the alumina nanostructures with high internal porosity enables increasing the capillary action. Based on the Lucas and Washburn model (LW) and modified LW models, the microfluidic behavior of these systems is discussed. The predictions from the models for the time exponent for capillary transport in porous media are ≤ 0.5. The experimental results show that the average capillary rise in nanostructured media driven by capillary force followed the L(t)$^0.7$ law. Integration of electronic and microfluidic functions is also presented, taking advantage of the periodic hydrophobic/electrically insulating (pure alumina part) and hydrophobic/electrically conductive (CNT part) microlayers of the structure.
characterization of a hybrid aerogel based on reduced rGO decorated with silver nanoparticles (AgNPs) exploitable for the SERS detection of biomolecules at low concentration. Several synthesis conditions were approached by exploiting a one-pot hydrothermal process, starting from commercial GO and adding either AgNO₃ as silver precursor with different additives (such as trisodium citrate) or directly a pre-synthesized Ag colloid. The resulting 3-D porous sponge-like nanoarchitecture provides both a high surface area and a homogeneous spatial distribution of AgNPs arranged in order to maximize the Raman hot spots density and thus allowing to concentrate and adsorb biomolecules from highly diluted solutions. By decorating GO with AgNPs, the synergy of the EM field and CT enhancements can be exploited. The synthesized AgNPs/rGO aerogels were characterized by means of ARD, BET, XPS, FESEM, and TEM in order to single out the best performing aerogels to be processed for biosensing applications. Promising results were obtained in terms of SERS efficiency by using, as probe molecules, Rhodamine 6G in the 10⁻⁶ M - 10⁻⁵ M concentrations range, and 4-Mercaptobenzonic acid, in the 10⁻⁶ M - 10⁻⁵ M concentration range. Optofluidic chip were fabricated by coupling the optimized AgNPs/rGO aerogels to Polydimethylsiloxane (PDMS). Then the devices have been successfully functionalized both by thiol-ended oligos and porphyrin-ended biomolecules. These bioreceptor immobilization routes permit the application of the substrates as versatile SERS biorecognition bioships.

NM01.15.02
Functionaized Nano-Graphene Oxide as Multi-Modal Clinic for Effective Drug Delivery Manisha Chatterjee¹, Somensh Mahapatra² and Soumitra Satapathi²; ¹Lala Lajpat Rai Memorial Medical College, Meerut, India; ²Indian Institute of Technology Roorkee, Roorkee, India.

Nano-materials based drug delivery modalities to specific organs and tissue have become one of the critical endeavors in pharmaceutical research. Recently, two dimensional graphene has elicited considerable research interest because of its potential application in drug delivery systems. Here we report, the drug delivery applications of PEGylated nano-graphene oxide (nGO-PEG), complexed with a multiphoton active and anti-cancerous diarylheptanoid drug curcumin. Specifically, graphene derivatives were used as nano vectors for the delivery of the hydrophobic anticancer drug curcumin due to its high surface area and easy surface functionalization. nGO was synthesized by modified Hummer’s method and confirmed by XRD analysis. The formation of nGO, nGO-PEG and nGO-PEG-Curcumin complex were monitored through UVvis, IR spectroscopy. MTT assay and AO/EB staining found that nGO-PEG-Curcumin complex afforded highly potent cancer cell killing in vitro with a human breast cancer line mCF7.

NM01.15.03
Stable, Temperature Dependent Gas Mixture Permeation and Separation Through Suspended Nanoporous Single-Layer Graphene Membranes Zhe Yuan, Jesse D. Benck, Yannick Eatmon, Daniel Blankschtein and Michael Strano; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Graphene membranes with nanometer-scale pores could exhibit extremely high permeance and selectivity for the separation of gas mixtures. However, to date, no experimental measurements of gas mixture separation through nanoporous single-layer graphene (SLG) membranes have been reported. Herein, we report the first measurements of the temperature-dependent permeance of gas mixtures in an equimolar mixture feed containing H₂, He, CH₄, CO₂, and SF₆ from 22 to 208 °C through SLG membranes containing nanopores formed spontaneously during graphene synthesis. Five membranes were fabricated by transfer of CVD graphene from catalytic Cu film onto channels framed in impermeable Ni. Two membranes exhibited gas permeances on the order of 10⁴ to 10⁵ mol m⁻² s⁻¹ Pa⁻¹, as well as gas mixture selectivities higher than the Knudsen effusion selectivities predicted by the gas effusion mechanism. We show that a new steric selectivity mechanism explains the permeance data and selectivities. This mechanism predicts a mean pore diameter of 3.0 nm and an areal pore density of 5.5×10¹³ m⁻², which is validated by experimental observations. A third membrane exhibited selectivities lower than the Knudsen effusion selectivities, suggesting a combination of effusion and viscous flow. A fourth membrane exhibited increasing permeance values as functions of temperature from 27 to 200 °C, and a CO₂/SF₆ selectivity of > 20 at 200 °C, suggestive of activated translocation through molecular-sized nanopores. A fifth membrane exhibited no measurable permeance of any gas above the detection limit of our technique, 2×10⁻⁶ mol m⁻² s⁻¹ Pa⁻¹, indicating essentially a molecularly impermeable barrier. Overall, these data demonstrate that SLG membranes can potentially provide high mixture separation selectivity for gases, with CVD synthesis alone resulting in nanometer-scale pores useful for gas separation. This work also shows that temperature-dependent permeance measurements on SLG can be used to reveal underlying permeation mechanisms.

NM01.15.04
Encapsulation of Metallic Nanoparticles Near the Surface of Graphite Ann Li-Riosales and Patricia A. Thiel; Iowa State University and Ames Laboratory, Ames, Iowa, United States.

Graphite, in the bulk, is known to form graphite intercalation compounds (GICs) with certain elemental metals, for example, rare earth and alkali metals. These metals can insert between graphene sheets and alter the magnetic or transport properties of graphite. While intercalation in the bulk of graphite has received much attention, considerably less has been paid to intercalation near the surface of graphite, underneath only one (or a few) graphene layers. First of all, can one embed metals just beneath the graphite surface? Do the surface-intercalated metals adopt different structures compared to their bulk counterparts? What is the driving force for such surface intercalation? These are questions we seek to address.

The presentation will encompass strategies for achieving surface intercalation of metals in graphite. In short, embedding metal atoms just beneath the graphite surface requires two specific conditions: (1) ion-induced defects on the graphite surface, and (2) deposition of metals while holding the graphite substrate at elevated temperature. We find that this synthetic route works for a variety of metals, and the growth temperature is metal-specific. Results on dysprosium, copper and ruthenium will be presented. We use scanning tunneling microscopy to probe and characterize the surface intercalation. Based on experimental results and density functional theory, we find that the intercalated metal atoms at the graphite surface adopt very different structures compared to those in bulk GICs. Furthermore, metals that are not known to form bulk GICs can be encapsulated at the graphite surface. Finally, we find that some of the metals are well protected from atmospheric oxidation by the graphene overlayer. Our synthetic strategy opens up a new avenue for metals to interact with the graphite surface, and to create novel graphene-based nanomaterials.

NM01.15.05
Highly Conductive Copper Coated Reduced Graphene Oxide Fibers for Electromagnetic Shielding Fabrics Mingxin Li and Jie Lian; Mechanical, Aerospace, and Nuclear Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.

Despite no apparent evidence that the electromagnetic exposure to household mobile communication and other emitting devices poses harm to the general public, excessive electromagnetic radiation is of genuine concern for roentgenologists, radar engineers and pacemaker implanted patients. To alleviate such a concern, electromagnetic shielding clothing for these personnel made with thin steel wires are densely woven into cotton fibers. Here, we report a new method of producing copper-reduced graphene oxide core-shell fibers for the fabrication of lightweight electromagnetic shielding fabrics. Based on a simple electroplating process, a thin layer of copper oxide is coated onto the grooved surface of reduced graphene oxide fibers. After subsequent reduction, copper-coated reduced graphene oxide fibers with high electrical conductivity and high flexibility are obtained. A fabric woven with such fibers can provide comparable electromagnetic shielding to fabrics woven with metal wires, yet is appreciably lower in density.
The liquid phase exfoliated graphene nanoflakes are a high-yield and low-cost synthetic method, but the quality of the graphene nanoflakes is not high due to the presence of functional groups and structural defects. Therefore, the ability to improve the crystal structure of the graphene nanoflakes with excellent electrical properties is desirable for its applications in the field of flexible and printed electronics.[1]

In this talk, I will introduce an approach to structure repairing in electrochemically-exfoliated graphene flakes based on annealing with Ni thin film, accompanied by the laterally stitching of the isolated parts to form a continuous and monolithic film.[2,3] After annealing with Ni film, the graphene flakes-derived film has lower defect density, demonstrating that such a process for the crystal structure improvement is extremely effective. At the same time, the newborn-graphene in the space of the isolated flakes would stitch to form a continuous and monolithic film. After the structural repair, the electrical properties of graphene have been greatly improved, and the carrier mobility of graphene is more than 1000 cm² V⁻¹ S⁻¹, nearly 10 times higher than that of the process with Cu or 100 times higher than that of graphene via mere annealing. First-principles calculations on the adsorption of Ni and C atoms on different kinds of H-saturated graphene edges reveal that the binding energy depends upon the adsorption site, and the Ni case always gives a value 1.5 eV larger than that for the Cu case which is thus beneficial to the removing of edge saturates and allowing for a faster re-growth process. This approach for the graphene with structural design is promising for electronic and flexible applications. [4]

NM01.15.06 High-Quality Monolithic Graphene Films via Solid-Phase Coalescence and Structural Repair of Exfoliated Flakes Xinning Li1,2, Cheng-Te Lin2, Ying Fang3, Renzhi Ma4 and Takayoshi Sasaki3; 1International Center for Materials Nanoarchitectonics (WPI-MANA), National Institute for Materials Science (NIMS), Tsukuba, Japan; 2Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, Ningbo, China; 3National Center for Nanoscience and Technology, Beijing, China.

Since its discovery in 2004, graphene has received enormous scientific interest due to the remarkable two-dimensional structure, making it highly promising for numerous applications. Electrodes in lithium-ion-batteries (LIBs) are one of these applications that could benefit from mechanical strength, high surface area and electrical conductivity of graphene. For the integration in commercial LIBs, it is important to develop simple, cost effective and scalable methods for the production of graphene-like structures. Due to the good dispersibility in water and other polar solvents, graphene oxide (GO) easily forms multi- and monolayers and therefore offers advantageous properties for a green and simple wet-chemical synthesis.

In this study, GO was synthesized and further processed by liquid and gas phase approaches to obtain GO films via pressure filtration with superior mechanical properties and adjustable thicknesses. These paper-like structures of regularly arranged GO flakes were mechanically stable, scalable to mass production and could be used as flexible ultrathin separators in LIBs given their high electronic insulation. Additionally, the sheet-like structure of GO is expected to suppress the polysulfide shuttle effect in lithium sulfide batteries. Moreover, films of its reduced form (rGO) could additionally be incorporated as cathode or anode material, providing several advantages over traditionally used materials. For instance, if used as anodes, these films facilitated an increased volumetric energy density due to a reduction in weight, as additional battery paste components such as current collector, carbon black and binding agent, were no longer necessary. This was supported by the low preparative effort of the freestanding electrode design. Moreover, nitrogen doping of these graphene-like structures via different approaches has been proven successful to increase the electrical conductivity and storage capacity of anodes. Further investigations focused on the influence of nitrogen-integration in the carbon structure on electrical and electrochemical properties. In terms of the electrical properties of graphene have been greatly improved, and the carrier mobility of graphene is more than 1000 cm² V⁻¹ S⁻¹, nearly 10 times higher than that of the process with Cu or 100 times higher than that of graphene via mere annealing. First-principles calculations on the adsorption of Ni and C atoms on different kinds of H-saturated graphene edges reveal that the binding energy depends upon the adsorption site, and the Ni case always gives a value 1.5 eV larger than that for the Cu case which is thus beneficial to the removing of edge saturates and allowing for a faster re-growth process. This approach for the graphene with structural design is promising for electronic and flexible applications. [4]
cathodes, rGO films served as a highly conductive backbone for lithium sulfide/rGO-composites, in which the active material was well-distributed within the carbon matrix. This prevents the agglomeration of lithium sulfide, buffers the volume change during cycling and offers a good accessibility for charge carriers. In this work, the integration of GO and rGO films into LIB half-cells thus demonstrated their exceptional versatility and high application potential.

Investigating the Frictional Behavior of Copper-Graphene-Copper Laminates Shruti Rastogi, Amirali Zangibadi, Katayun Barmak and Jeffrey W. Kysar; Columbia University, New York, New York, United States.

Reducing energy and material losses in moving mechanical systems due to friction and wear still remain a significant challenge. A monatomically thin layer of graphene deposited onto a surface is known to reduce friction significantly, but graphene is a brittle material so its wear properties are limited. This study investigates the friction and wear of a lamellar metal-graphene-metal composite. We demonstrate a transfer-free material design comprising of monolayer CVD graphene sandwiched between a Cu substrate and a thin Cu film deposited via physical vapor deposition (Cu-Gr-Cu). A series of scratch tests performed on the free surface of the Cu film shows a considerable decrease in coefficient of friction from 0.4 to ~0.12 and an improved wear resistance for the Cu-Gr-Cu laminate. The reduction in coefficient of friction is proposed to be associated with a lower degree of plastic deformation in the Cu-Gr-Cu laminate suggestive of graphene’s ability to impede the propagation of the plastic zone from the copper film to the underlying copper substrate. Weak Beam Dark field Imaging technique (in TEM) confirm lower density of dislocations present in Cu-Gr-Cu laminate when compared to the Cu-Cu laminate thus indicating the effectiveness of graphene in blocking the propagation of the plastic zone.

NM01.15.11

The mechanical properties of graphene oxide/poly(lactic acid) (GO/PLA) composites were studied to analyze the effect of GO sheet addition on PLA. GO was synthesized through chemical exfoliation and characterized by using FTIR, Raman spectroscopy and SEM. GO/PLA filaments with various compositions were formed using extruder and the mechanical test specimens were prepared from these filaments by two different methods: injection molding and 3D printing. The mechanical properties of polymer/GO composites which were formed through different techniques and with different compositions were compared.

NM01.15.12

Graphene Production by Mechanical Milling Testing Different Solvents Sergio E. Mancillas and Eddie Lopez Honorato; CINVESTAV Unidad Saltillo, Ramos Arizpe, Mexico.

One of the main challenges in the exploitation of nanomaterials is their production in large volumes. One possibility in the production of graphene is the use of attrition. This work presents the effect of different solvents on the production of graphene by mechanical milling of graphite flakes. Methanol, ethanol, acetone, hexane, toluene and xylene were used in the milling process without the use of any other additive. Our results indicate that the solvent used is important in the particle size distribution, the final microstructure and the graphene produced. The solvent used was also important during ultrasound separation as it affected the number of graphene layers obtained.

NM01.15.13

Electrical Properties of N-Doped Graphene Cu(In,Ga)Se2 Schottky Junctions Jesse Claypoole and Harry Efthathiadis; SUNY Polytechnic Institute, Albany, New York, United States.

While doping graphene P type is relatively easy, the typical methods of N doping graphene including electrostatic or chemical methods do not achieve high or persistent N doping of graphene when exposed to air. Diffusion of alkali from a semiconductor onto graphene offers a scalable and low cost way of tunably doping graphene N type and has the potential to improve the electrical properties a large range of devices including solar cells, photodetectors, and supercapacitors. The amount and type of alkali diffused from the semiconductor can be varied which can then tune the Fermi level of graphene which alters the graphene semiconductor junction's electrical properties. In this study, we investigate the effect of the diffusion of alkali from the semiconductor Cu(In,Ga)Se2 onto graphene on the electrical properties of a graphene Cu(In,Ga)Se2 schottky junction.

NM01.15.14

Computing Modeling of the Graphene-Water Interaction and Its Applications Jatin Kashyap1, Priyanka Solanki2 and Dibakar Datta1; ‘New Jersey Institute of Technology, Newark, New Jersey, United States; 2Montville Township High School, Montville, New Jersey, United States.

Ever since its discovery in 2004, graphene has been extensively investigated for various applications such as energy storage, environmental barrier, biomedical, electronics, etc. The planar graphene sheet is hydrophobic. However, with the change in topology, i.e., defects, wrinkling, etc., we can tune its interaction with water. By performing Molecular Dynamics (MD) simulation, we discovered that water microdroplets containing graphene nanosheet spontaneously segregate into sack-cargo nanostructures upon drying. These cargo-filled nanosacks are promising for many potential applications where nanoscale materials should be isolated from the environment or biological tissue. Besides this, we considered another situation where water diffuses in between graphene and the underlying substrate during its growth process. The diffused water tends to occupy the empty space of the pre-existing wrinkling of small height and keeps pushing the wrinkling to make it bigger. Upon drying, the wrinkling becomes sharper. Our results show that we can tune the density of diffused water and the magnitude of the initial wrinkles to obtain various wrinkled structures after graphene growth. Our simulation results provide guidelines for the experimentalists for efficient design of the graphene-water systems.

NM01.15.15

Energetic Stability and Electronic Properties of Graphene Bilayer over GaN Maria G. Moreno-Armenta1 and Jairo A. Rodriguez-Martinez2; ‘CNyN, Univ Nacional Autonoma de Mexico, Ensenada, Mexico; 2Fisica, Universidad Nacional de Colombia, Bogota, Colombia.

In previous work1 we have calculated the growth of a graphene monolayer, two models emerged as the most favored: for Ga poor conditions a 3sqg3x3sqg3 graphene structure on top of a 4x4(0001) GaN surface and for Ga rich condition a sqg21xsqg21 graphene structure on top of a 2sqg3x2sqg3 GaN(0001). Gallium double bilayer2 with a -1.10% and -0.72% mismatch respectively. The gallium rich model exhibit a magnetic moment of 0.19 Bohr magnetons/cell whereas the stable structure for Ga poor conditions does not presents magnetic behavior. Later we added a second graphene layer with the goal to find defects free epitaxial growth, which could serve as a basis to introduce defects or doping it with the best suited elements in such a way that we will be able
to fine tuning a band gap. We also made simulations of scanning tunneling microscope (STM) that revealed a long distance buckling interaction between both layers. Our calculations were based on the plane wave density functional theory and the Born-Hamann formalism for simulating STM images. In this work we are analyzing what is happening when a graphene monolayer approach to the GaN surface and then when a second graphene layer comes closer to the first one, we plot the energy as a function of the interlayer separation distance and the kind of GaN surface. In this fashion we get potential energy surfaces (PES), which allow us to simulate how the graphene monolayer behaves when it is growth in a less than ideal substrate and what happens to the graphene buckling in the grain frontier. The electronic properties of these systems are studied by calculating the band structure and the density of states. The calculations are performed by Density Functional Theory as implemented in the PWscf code of the Quantum ESPRESSO package. The data are not fully analyzed yet as the work is still in progress. Acknowledgments: DGAPA project IN114817. The authors are grateful to A. Rodríguez for his technical assistance. Calculations were performed at the DGCTIC-UNAM under project LANCAD-UNAM-DGTIC-150.

Continuous Langmuir-Blodgett Deposition and Transfer by Controlled Edge-to-Edge Aggregation of Floating 1D and 2D Nanomaterials Luzhu Xu, Hadi K. Khaligh, Adam Tetreault, Irene Goldthorpe, Shawn Wettig and Michael A. Pope, University of Waterloo, Waterloo, Ontario, Canada.

The Langmuir-Blodgett technique is one of the most controlled methods to deposit monomolecular layers of floating or surface active materials but has lacked the ability to coat truly large area substrates. In our work, by manipulating single layer dispersions of graphene oxide (GO) and other 1D or 2D materials (ex. molybdenum disulfide, reduced graphene oxide, CNTs etc.) into water-immiscible spreading solvents, unlike traditional Langmuir-Blodgett deposition which requires densification achieved by compressing barriers, we demonstrate the ability to control the 2D aggregation and densification behavior of these floating materials without the use of moveable barriers. This is done by controlling the edge-to-edge interactions through modified sub-phase conditions and by utilizing the distance-dependent spreading pressure of the deposition solvent. These phenomena allow substrates to be coated by continuous deposition and substrate withdrawal - enabling roll-to-roll deposition and patterning of large area substrates such as flexible polyethylene terephthalate. The aggregation of GO sheets into 2D domains under various sub-phase conditions were examined by in situ Brewster angle video microscopy. Moreover, by measuring the local spreading pressure using a Langmuir-Adam balance we conclude that the densification phenomenon of deposited sheets is induced by the spreading solvent acting on the floating materials. This allows us to engineer the film density by easily changing the spreading solvent. As an example, the performance of films deposited in this way are assessed as passivation layers for Ag nanowire-based transparent conductors.

NM01.15.17
Gas-Phase Synthesis of Substrate-Free Graphene—A Comparison of Different Hydrocarbon Precursors Adrian D. Munoz,1 Hartmut Wiggers2 and Christof Schulz2;1 Institute for Combustion and Gas Dynamics - Reactive Fluids, University of Duisburg-Essen, Duisburg, Germany; 2CENIDE, University of Duisburg-Essen, Duisburg, Germany.

Graphene is regarded as a potential material for many application fields due to its unique electrical, mechanical, and thermal properties. Since its first isolation in 2004, growing interest has evolved in the development of facile and scalable synthesis routes. So far, some groups already investigated synthesis techniques towards environmentally-friendly and catalyst-free graphene production from methane or ethanol based on plasma technology, however, the variation carbon precursors is only rudimentarily investigated so far.

In this paper, we present a facile synthesis method for preparing free-standing few-layer-graphene (FLG) by gas-phase pyrolysis carried out in a microwave plasma reactor. This scalable synthesis route can produce highly pure carbonaceous nanostructures with production rates up to several g/h, depending on the precursor used. However, it is still unclear which precursor requirements have to be fulfilled for the formation of high-purity graphene avoiding the formation of byproducts.

Five gaseous and eleven liquid hydrocarbons have been tested in order to identify prerequisites for graphene formation. The materials have also been processed to investigate the growth process and the microstructure of the respective products. The samples have been characterized by X-ray diffraction, Raman-, four-point conductivity measurements, XPS, TEM and BET. The results indicate that the gas-phase generated samples show either FLG, or graphitic particles or soot-like particles or composites containing two or all of them following no straight dependency. However, it was observed that only precursors with certain C:H:O-ratios like ethanol, acetone and isopropanol can deliver graphene in a good quality while oxygen-free precursors with a relatively high C:H-ratio like toluene and acetylene lead primarily to soot-like particles.

All other used precursors with different or same C:H-O- and C:H-ratios tend to produce composites containing besides graphitic particles, FLG and soot-like particles at the same time. The best samples made from ethanol show highly pure surfaces and highly ordered FLG with superior electrical conductivity of more than 4000 S/m.

NM01.15.18
Liquid Phase Exfoliation of Nanoscale Organic/WS2 Heterojunctions for Organic Electronics Abdus S. Sarkar1,2,3 and Suman K. Pal1,2,3;1 School of Basic Sciences, Indian Institute of Technology, Mandi, India; 2Advanced Materials Research Center, Indian Institute of Technology Mandi, Mandi, India; 3Energy Center, Indian Institute of Technology Mandi, Mandi, India.

Since, the discovery of single layer graphene in 2004, great attention has been paid to other two dimensional (2D) layered materials from the academic to industrial research. Recently, beyond graphene, the emerging 2D transition metal dichalcogenides (TMDs), such as semiconducting (2H-phase) tungsten sulfide (WS2) have drawn most vibrant areas of nanoscience research because of direct energy gap and fascinating optical and electrical properties in their low dimensional structure. However, most of the preparation (chemical) methods do not preserve the semiconductive properties of WS2. Here, we have prepared a novel two-dimensional semiconductor heterojunction of few layer WS2, which is exfoliated in the presence of an organic semiconductor (OS) in a chloroform solvent and characterized by various experimental techniques. Our AFM, SEM, TEM and Raman spectroscopy results suggested that the few hundred nanometer size, few layer (4-5 layers) thick WS2 sheets were exfoliated in chloroform solvent and grafted with the OS. Hexagonal pattern in HR-TEM image intimates the presence of 2H-phase WS2. Significant changed in the electrical behavior in the heterojunctions are presented. Insight spectroscopic analysis indicate the possible hybrid optoelectronic applications. Highly dispersed WS2 sheet with prior little aggregation after 180 days.

NM01.15.19
Synthesis of Ramified Porous Graphite Foams with Diverging Microtubes with Enhanced Electrical Properties and Surface Areas Weigu Li, Jianhe Guo and Donglei (Emma) Fan; The University of Texas at Austin, Austin, Texas, United States.

3-D graphene or graphite foams (GFs) have received immense research attention owing to their superior electrical, mechanical, and thermal properties. Extensive applications of such 3-D GFs have been demonstrated in energy, environment, health, and biomedical research. This work presents an innovative
mechanism, the Kirkendall effect, in creating 3-D microporous catalysts with tunable pore sizes for the growth of multilevel porous graphite foams (MPGFs) that offer higher stability, electric conductivity, larger surface area as well as electrocatalytic performance. In addition to conventional GFs. Based on MPGFs, another new type of ramified porous graphite foams (RPGFs) made of strategically created superstructures with covalently-attached diverging microtubes have also been synthesized. Such RPGFs exhibit even higher surface areas than MPGFs, which allows for efficient loading of active pseudocapacitive materials when applied as supercapacitor electrodes. We also integrate the RPGF-based flexible supercapacitors with a nanomotor manipulation system into a portable and self-powered device, which readily compels Au nanomotors to transport along arbitrary trajectories, e.g., tracing letters of “U” and “T”.

NM01.15.20
Gas Selective Permeability of Graphenelyne Membranes
Jesse Paulino, Daiane Damasceno Borges and Douglas S. Galvão; State University of Campinas, Campinas-SP, Brazil.

Biphenylene carbon (BPC), also called graphenelyne, is a hypothetical porous two-dimensional (planar) allotrope carbon [1] that can be obtained from selective dehydrogenation of porous graphene [2]. The BPC molecular geometry consists of an one-atom thickness sheet with regular dodecagonal pores of diameters of 3.2 Å. Its pores resemble typical sieve cavities and/or some kind of zeolites. An open question is if the BPC natural porosity gives a selective permeability property that can lead to promising technological applications, such as gas separation. In this work, we have investigated the permeability and selectivity of natural gases such as CO2, H2, N2, CH4, and CO though BPC membrane. Fully atomistic Molecular Dynamics simulations were performed to predict the gas adsorption and the gas permeability of single components, and separation mechanism of binary gas mixtures. The simulation system is composed of single BPC sheet into contact with a gas reservoir under different thermodynamics conditions (e. g. T, P). We have systematically analyzed the permeability of each gas and the molecular layers on the adsorbed layers after the flux is stabilized. The selectivity is also quantified for CO2/H2 (50:50), CO2/N2(15:85), CO2/CH4 (50:50), and CO2/CO (50:50) mixtures and the mechanism of gas diffusion is also discussed. The BPC porosity can be exploited to pressure tune gas selectivity. Our results show that BPC exhibits high H2 selectivity, ideally for hydrogen purification.

Multiplexed Superbioelectronic Nose Using Olfactory Receptors Conjugated-Graphene Field-Effect Transistor for Mimicking the Human Sense of Smell
So Jung Lee and Oh Seek Kwon; KRIBB, Daejeon, Korea (the Republic of)

Human sensory-mimicking systems, such as electronic brains, tongues, skin, and ears, have been promoted for use in improving social welfare. However, no significant achievements have been made in mimicking the human nose due to the complexity of olfactory sensory neurons. Combinational coding of human olfactory receptors (hORs) is essential for odorant discrimination in mixtures, and the development of hOR-combined multiplexed systems has progressed slowly. Here, we report the first demonstration of an artificial multiplexed superbioelectronic nose (MSB-nose) that mimics the human olfactory sensory system, leading to high-performance odorant discriminatory ability in mixtures. Specifically, portable MSBnoses were constructed using highly uniform graphene micropatterns (GMs) that were conjugated with two different hORs, which were employed as transducers in a liquid-ion gated field-effect transistor (FET). Field-induced signals from the MSB-nose were monitored and provided high sensitivity and selectivity toward target odorants.

Broadband Optical Properties of Self-Assembled 3D Graphene Structures
Krity Agarwal, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota, Minneapolis, Minnesota, United States.

Recent progress in nanoscale self-assembly has led to the realization of 3D nanostructures with unique optoelectronic properties through a surface tension driven self-folding of diverse 2D graphene patterns. The self-assembly of 2D patterned graphene can yield 3D micro/nanoscale polyhedrons such as closed and open cubic structures with free-standing 2D materials (graphene or graphite oxide) acting as faces of the cube. Self-assembly is a versatile technique that can realize 3D graphene cube of dimensions ranging from 100 nm to 200 µm. Here, we present simulation and measurement results to study of the optical properties of nanocubes at their plasmon resonance as well as the off-resonance broadband properties of the micro and nanoscale graphene cubes. At a nanoscale, the uniform plasmon coupling in 3D graphene nanocubes gives rise to hybridized modes with strong enhancement of the incident electric (E)-field. The hybrid modes demonstrate large area hotspots of constant field enhancement with a much slower decay of the field away from the surface, giving rise to a volumetric field that is 2 orders of magnitude stronger than that in 2D ribbons. Moreover, in the absence of plasmon resonance such as in 200 µm sized 3D graphene cubes, the rippled geometry induces a strong absorbance of 2-40% over the entire measured wavelength of 1-10 µm. Fourier transform infrared (FTIR) spectroscopy of the 3D graphene microcubes and Cavcell Multiphysics simulations reveal that the angle of incidence, number of graphene layers, and the ripple geometry can be modified to tune the absorbance in 3D graphene over a wider range than in 2D graphene. Thus, the 3D free-standing graphene cubes offer an opportunity to overcome the weak ~3% broadband absorption in 2D planar graphene. The highly confined volumetric field within the nanocubes and strong tunable absorption in graphene microcubes provide an opportunity for the development of non-contact ultrasensitive 3D plasmonic sensors and devices with a larger active area and higher efficiency.

Geometrical Modification of Hybridized Plasmon Modes in 3D Graphene Nanostructures
Krity Agarwal, Chunhui Dai and Jeong-Hyun Cho; University of Minnesota, Minneapolis, Minnesota, United States.

A surface-tension driven self-folding mechanism has led to the realization of diverse self-assembled 3D architectures from patterned 2D ribbons, such as graphene-based pyramids, tubes, and cubes. The 3D graphene geometries exhibit distinct plasmon hybridization that cannot be excited in 2D graphene ribbons as a result of plasmon coupling over an extra spatial degree of freedom. However, a detailed systemic study of the plasmon coupling in 3D graphene geometries needs to be performed in order to efficiently utilize the hybrid plasmon modes for desired optoelectronic applications. We have investigated the plasmon coupling and found that the coupled plasmonic field enhancement in these 3D geometries is strongly dependent on the 3D shape, number of 3D edges, and surface angle of inclination. The uniform coupling in graphene nanocubes gives rise to large circular areas of constant field enhancement. Moreover, if the edges of the nanocubes are spatially separated by nanometer distances, circular field interference patterns are obtained with alternate rings for constructive and destructive coupling. The circular surface enhancement modes in 3D graphene nanocubes can be leveraged for novel optoelectronic applications. In contrast, the square graphene pyramids undergo a strong point enhancement at the apex of the pyramid arising from the inclined tapering faces meeting at the apex. The strong point enhancement propagates throughout the nanopyramid resulting in a volumetric field that is several orders of magnitude higher than in 2D graphene ribbons. Furthermore, as the number of faces and edges is increased to form pentagonal to octagonal pyramids, the point based enhancement can be transformed to uniform surface enhancement at the base of the pyramids. Thus, allowing geometrical parameters in the nanopyramids to be utilized for designing high-sensitivity plasmonic sensors that can assess low concentration analytes in the
bulk volume of targeted solution or the molecular surface binding properties at higher analyte concentrations. The graphene tube consisting of only 2 edges exists at the openings of the tube, a virtual hot-spot area of extremely high near-field enhancement is created due to radial plasmonic coupling at the small opening of the tube. The completely sealed tube demonstrates a strong hotspot, but, the hotspot covers only 13% of the volume of the tube. However, if the nanotubes are fabricated with small slits, the strongly coupled field exists throughout the tube structure giving rise to strong volumetric field. The volumetric field in nanotubes is especially desirable due to their open-ended geometry that can be leveraged for assessing targets flowing through the 3D tube. The self-assembled 3D graphene structures can be varied geometrically to achieve diverse point, edge, surface, and volumetric enhancement modes for achieving plasmonic devices exhibiting increased sensitivity and efficiency, and a high packing density.

**Carbon Nanoscrolls Formation from Bi-Layer Graphene Nanoribbons—A Reactive Molecular Dynamics Study**

Jose M. de Sousa, Vitor R. Coluci, Nicola M. Pugno and Douglas S. Galvao; 1State University of Campinas, Campinas-SP, Brazil; 2Instituto Federal do Piauí, Jose Raimundo Nonato, Brazil; 3University of Trento, Trento, Italy.

Carbon nanoscrolls (CNSs) are families of carbon-based nanomaterials, where unlike the closed carbon nanotubes, their geometrical aspect is like graphene layers rolling up into a spiral (papyrus-like) form. They have been extensively (theory and experiments) studied [1,2,3]. Due to its open-end topology, where the diameter can be easily varied make them ideal for applications such as hydrogen storage, actuators, tunable water channel, etc. Most of the theoretical works have considered single layer structures; there are only few works on multi-layered scrolls [4]. In this work we have investigated, through fully atomistic reactive (ReaxFF) molecular dynamics simulations, the dynamics formation and structural stability of scrolled structures formed from bilayer graphene nanoribbons. We have also considered these structures interacting with carbon nanotubes, which has been used as a ‘trigger’ to start the scrolling process [5]. Our results show that stable (up to high temperatures ~1000 K) structures can be obtained. We did not observe the formation of covalent bonds between layers and/or carbon nanotubes for the temperature range investigated.

**NM01.15.25**

**Properties of Bio-Inspired Low-Dimension Carbon Fiber and It’s Applications**

Seongwoo Ryu, 1,2 The University of Suwon, Hwaseong-si, Korea (the Republic of); 2Advanced Material Analysis Center, Hwaseong-si, Korea (the Republic of).

Over the past few decades, the fiber-based industry has achieved great progress in aerospace, military and many other industrial applications that require lightweight materials with high mechanical strength. As the demand for electronic devices has exponentially risen in recent years, the preparation of highly conductive fibers has become an important subject in the fiber industry. Low dimension carbon fibers such as carbon nanotube and graphene fibers may be an important material in advancing next-generation high-tech applications if their intrinsic mechanical, electrical and thermal properties can be maintained. By strategy of dopamine infiltration, oxidative polymerization and pyrolysis, we successfully fabricate low-dimension carbon composite fibers with remaining their intrinsic properties. The approach described herein presents a novel fabrication process that can enhance both the mechanical and electrical properties of low-dimension carbon based fibers.

**NM01.15.26**

**Dielectrophoresis-Based Fabrication of Carbon Nanotube-Based Electronic Devices**

Joevonte Kimbrough, Kenneth Davis, Sam Chance, Brandon Whitaker, John Elike, Roshawn Treadwell, JaTavia Cooper, Kayleb Hartage, Abram Jones, Alandria Henderson, Qunying Yuan and Zhigang Xiao; 1Department of Biological and Environmental Science, Alabama A&M University, Normal, Alabama, United States; 2Department of Electrical Engineering and Computer Science, Alabama A&M University, Normal, Alabama, United States.

We report the dielectrophoresis (DEP)-based deposition and alignment of semiconducting carbon nanotubes and the fabrication of carbon nanotube-based electronic devices. Semiconducting carbon nanotubes, which were dispersed ultrasonically in solutions, were deposited and aligned onto a pair of gold electrodes using the electric-field-directed dielectrophoresis method. The DEP-aligned tubes were further fabricated into carbon nanotube field-transistors (CNTFETs) and CNTFET-based electronic devices such as CNT-based inverters and ring oscillators using the microfabrication techniques. The aligned carbon nanotubes and fabricated devices were imaged using the scanning electron microscope (SEM), and the electrical properties were measured from the fabricated devices using the semiconductor analyzer. The semiconducting CNTs achieved higher yield in the device fabrication, and the fabricated electronic devices demonstrated excellent electrical properties.

**NM01.15.27**

**Multicolumn Gel Chromatography for Scalable Separation of Nanosheets Based on Size and Surface Chemistry**

Dorsa Parviz and Michael Strano; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Liquid-phase exfoliation of two-dimensional nanomaterials yields nanosheet dispersions with broad size distribution and varying surface chemistry. This polydispersity in size and surface chemistry of nanosheets becomes less desirable when their properties are to be precisely controlled for different applications. Hence, scalable separation methods are highly demanded to make this class of materials industrially relevant. Here, we use multicolumn gel chromatography to separate nanosheets of graphene family based on their size (later size and thickness) and surface chemistry (density of functional groups or defects). We demonstrate that various parameters such as stabilizer type, pH, and ionic strength of the solvent alter the binding affinity of nanosheets on the gel and tune the elution time of nanosheets of different size and surface chemistry. Single particle tracking analysis was used as a powerful tool for quick and precise evaluation of nanosheets size distribution in bulk. Other spectroscopic techniques such as fluorescence and Raman spectroscopy were applied to investigate the surface of the separated nanosheets.

**NM01.15.28**

**Graphene Oxide Polydispersity**

Harish V. Kumar, Chinthani D. Liyanage and Douglas Adamson; University of Connecticut, Storrs, Connecticut, United States.

Graphene oxide (GO) finds applications in variety of areas including, but not limited to, electronics, energy, biomedicine, and optics. Variations in oxidation of GO and its impact on various applications have not been much investigated even though these variations tend to effect the properties of GO. In order to universally understand this variation in oxidation, we have defined an oxidation dispersity number (OD) for GO samples. We divide a given GO sample in a number of different oxidized parts. The characterization of these differently oxidized GO samples enable us quantifying the OD for a given
batch and can be used to tune the density of oxygen functionalities in a GO sample. This emulsion based method is pH dependent and can also be used to isolate a reduced graphene oxide (rGO) like material with a reduced value of Raman defect density. This rGO like material has the capability of replacing the more expensive and topological defects inducing methods presently available. Further, we investigate the properties of different GO samples on the basis of their OD numbers. This number shows that the dispersity of oxidation in a given sample does have an impact on its properties and thereby performance of corresponding applications.

NM01.15.29 Wax-Enabled Graphene Transfer Wei Sun Leong, Jin-Yong Hong, Haozhe Wang and Jing Kong; Department of Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Charge carriers in freely suspended graphene can travel very fast (mobility ~200 000 cm²/V-s at 5K), but the reported values for large-area CVD graphene transferred on arbitrary substrate is several orders of magnitude lower, which has been attributed to the polycrystalline nature, surrounding medium, polymer residues, and wrinkles in graphene. The latter two factors were engendered by the polymer-assisted graphene transfer process. Here, we report a new wax-enabled graphene transfer technique that concurrently addresses the polymer residues and graphene wrinkles issues. Compared to poly (methyl methacrylate) (PMMA), the chemical structure of wax is much simpler and does not contain carbonyl (C=O) group, which is reactive to electrophiles or nucleophiles. Our density functional theory calculations further indicate that the adsorption energy of wax is 1.56 kcal/mol times lower than PMMA and wax radicals are not stable while PMMA radicals are stable enough to form covalent bonding with graphene. Remarkably, for graphene transferred with wax support layer, we observe not only much lesser polymer residues, but also a substantial wrinkle reduction in graphene surface, compared to that of PMMA, through atomic force microscopy studies. Field-effect transistors fabricated on wax-assisted transferred graphene shows the Dirac voltage is closer to zero and 2-fold higher electron mobility compared to that of PMMA. In short, wax-assisted transfer process opens a new avenue for the development of graphene-based electronics by minimizing charge carrier scattering centres in graphene (i.e. polymer residues and wrinkles in graphene).

NM01.15.30 Protection of Molecular Microcrystals by Encapsulation Under Single Layer Graphene Chris Bardeen, Elena Bekyarova, Wangxiang Li and Nathan Tierce; University of California-Riverside, Riverside, California, United States.

Microcrystals composed of the conjugated organic molecule perylene can be encapsulated beneath single layer graphene under mild conditions. Scanning electron and atomic force microscopy images show that the graphene exists as a conformal coating on top of the crystal. Raman spectroscopy indicates that the graphene is only slightly perturbed by the underlying crystal, probably due to strain. The graphene layer provides complete protection from a variety of solvents and prevents sublimation of the crystal at elevated temperatures. Time-resolved photoluminescence measurements do not detect any quenching of the perylene emission by the graphene layer, although nonradiative energy transfer within a few nanometers of the crystal-graphene interface cannot be ruled out. The ability to encapsulate samples on a glass surface under a graphene monolayer may provide a new way to access and interact with the organic crystal under ambient conditions.

NM01.15.31 First-Principles Investigation of a H₂O Molecule in a Heterogeneous Carbon/Boron Nitride (7,7) Nanotube Gwanwoo Kim and Gunn Kim; Department of Physics and Astronomy, Sejong University, Seoul, Korea (the Republic of).

We report behavior of a H₂O molecule inside a heterogeneous carbon nanotube/boron nitride nanotube (CNT/BNNT) structure. We have investigated energetic and electronic properties of our model system using density functional theory calculations. Considering the van der Waals interaction, we used Grimme’s DFT-D2 method implemented in the VASP package. For the model structure, the (7, 7) CNT and BNNT were chosen. The equilibrium distance between a water molecule and the CNT (BNNT) wall was calculated to be 3.3 Å (3.1 Å). In the CNT (BNNT), the energy of the water molecule was 103 meV lower (122 meV lower) at the center of the tube, and was 226 meV lower (257 meV lower) at the equilibrium position in the tube than in vacuum. The potential profile along the tube axis shows a dramatic change around the heterojunction. We plotted the projected density of states (PDOS) of hydrogen and oxygen atoms in the water molecule in the tube to check whether the orbital hybridization changes between the tube wall and the H₂O molecule, depending on the location of H₂O. The PDOS shows ~1 eV downshift in the DOS peaks of O and H atoms to the deeper valence bands when the H₂O molecule is in the (7, 7) BNNT than in the (7, 7) CNT.

NM01.15.32 Synthesis and Magnetic Properties of Metal-Free Nitrogen-Doped Graphene Quantum Dots Muhammad Sajjad1, Muhammad Shehzad Sultan1, Vladimir I. Makarov1, Frank Mendoza1, Wojciech M. Jadwisienczak1, Brad R. Weiner2 and Gerardo Morell1; 1Department of Physics, University of Puerto Rico - Rio Piedras, San Juan, Puerto Rico, United States; 2Department of Physics and Astronomy, Western Kentucky University, Bowling Green, Kentucky, United States; 3School of Electrical Engineering and Computer Science, Ohio University, Athens, Ohio, United States; 4Department of Chemistry, University of Puerto Rico - Rio Piedras, San Juan, Puerto Rico, United States.

Metal-free nitrogen doped graphene quantum dots (N-QGD) were synthesized and, for the first time to our knowledge, their magnetic properties were investigated. The results indicate that N-QGDs exhibit superparamagnetic behavior. The specific size, shape and zigzag edge structure of N-QGDs were considered to explain the origin of the observed magnetism. The magnetization dependence led to estimating the N-QGD material magnetic permeability for different ambient temperatures. From the zero-field-cooled (ZFC) and field-cooled (FC) magnetization measurements, carried out at 50 Oe magnetic field strength, we estimated the blocking temperature ƬB to be around 300 K. Based on the experimental data analysis, the magnetic permeability, number of correlated spins per single N-QGD, and number density of superparamagnetic N-QGD per gram of material were estimated. The excellent superparamagnetic properties together with optical properties manifested by N-QGDs have the potential to lead to high performance biomedical applications.

NM01.15.33 Effect of Non-Covalent Compatibilizers Agents in Mechanical and Thermal Properties of h-BN Nanosheets/Polymer Composites Sofia Vazquez-Rodriguez1, Eder I. Santos-Alvarado1, Luis E. Roman-Quirino1, Jose L. Aceval-Davila1, Angel A. Aguilar-Moriones2, Selene Sepulveda-Guzman2, Eduardo Arias2, Nora A. Garcia-Gomez2, Fernando A. Blanco-Flores3 and Rodolfo Cruz-Silva3; 1Universidad Autónoma de Nuevo Leon, San Nicolas de los Garza, N.L., Mexico; 2Centro de Investigación en Química Aplicada, Saltillo, Mexico; 3Shinshu University, Nagano, Japan.

Two-dimensional (2D) nanosheets such as those of transition metal dichalcogenides (TMDs) have become attractive due to the unusual properties associated with their ultrathin structure. Development of applications for these materials have been limited by the lack of a simple method to exfoliate them in single or few-layer flakes in large quantities. In this work, an exfoliation route of 2D materials such as graphene like boron nitride (hBN) using mechanical milling in solid state (cryomilling) and sonication was performed. Materials were cryomilled during 30 min and liquid sonicated. A reduction in particle
size of the powders materials after cryomilling was observed and a possible disorder of layers was evident because of the decrease in the intensity of the characteristic peak of the plane (002) in DRX patterns. After sonication process, the incorporation of 2D nanosheets in previously modified polymers by pyrolysis group, promoted changes in the optical, thermal and mechanical properties of i.e., polypropylene. The thermal diffusivity of thecomposite increased when the non-covalent compatibilizer was incorporated into the polymer even at low level of hBN concentration.

NM01.15.34 Structural Evaluation of Spin-Valves Comprising B-Doped Carbon Interlayers Hiroki Ishimoto1, Satoshi Takeichi2, Kazuki Kudo1, Ken-ichiro Sakai2 and Tsuyoshi Yoshitake1; 1 Applied Science for Electronics and Materials, Kyushu University, Kasuga-shi, Japan; 2 Control and Information Systems Engineering, Kurume College, Kurume-shi, Japan.

Spintronics is the fusion field of electronics and magnetics, and have attracted much attention from physical and practical viewpoints, because both electric charge and spin of electrons are utilized simultaneously. giant magnetoresistance (GMR) and tunnel magnetoresistance (TMR) effects have been the main principles of spintronics devices such as magnetic heads and magnetic random access memories (MRAM), which use changes in the electrical resistance accompanied by switching between parallel and antiparallel magnetization alignments. These phenomenon are occurred in trilayered spin-valve junctions composed of top and bottom ferromagnetic layers and a nonmagnetic interlayer. Therefore, spin-valves are suitable for investigating the spin-transport potential of interlayer materials due to the simple structure. It is expected that materials composed of light elements possess long spin-transport lengths due to weak spin-orbit interactions. Thus far, we have investigated structurally and electrically investigated ultrananocrystalline diamond (UNCD)/hydrogenated amorphous carbon (a-C:H) composite (UNCD/a-C:H) films. They comprise a large number of nano-sized diamond grains embedded in an a-C:H matrix, and have the following merits: (i) the production of p- and n-type conduction accompanied by enhanced electrical conductivities is possible by boron and nitrogen doping, respectively; (ii) they can be grown on foreign solid substrate; (iii) they can be grown at low temperature even on unheated substrates. Therefore, UNCD/a-C:H prepared by CAPD can be expected as a new candidate for a spin-transport material. Thus far, we have studied artificial lattices and spin-valve junctions comprising ferromagnetic Fe3Si and semiconducting FeSi2. In this study, based on experimental techniques in the previous studies, spin-valve junctions comprising B-doped UNCD/a-C:H interlayers and ferromagnetic FeSi and Fe layers were fabricated by a mask method, and they were structurally studied. Fe/B-doped UNCD/FeSi trilayered films were deposited on a p-type Si (111) substrate. The bottom FeSi layer and the top Fe layer were deposited by facing target direct sputtering (FTDCS) apparatus and B-doped UNCD/a-C:H was deposited by coaxial arc plasma deposition (CAPD) equipped with a 10 at. % B-blended graphite target. The microstructure was investigated by scanning transmittance electron microscopy (STEM). The magnetization curves of the junction measured at room temperature using a vibration sample magnetometer (VSM). From STEM image of the spin-valve junctions, it is confirmed that the UNCD/a-C:H interlayer exists in layer between the Fe and FeSi layers. From magnetization curves, it was observed the shape of the magnetization curve has clear two steps, which implies UNCD/a-C:H layers effectively act as interlayers between the Fe and FeSi layers without interdiffusion. The electrical properties of the spin-valve will be reported at the conference.

NM01.15.35 Optical, Electronic and Thermodynamic Properties of BN-Diamondoids Isomers—A DFT Study Marco d. Tavares1, Samir S. Coutinho1, Edvan Moreira1 and David L. Azvedo1,2; 1 Physics, Instituto de Física, Universidade de Brasília - UnB, Brasília, DF, Brazil; 2 Physics, Faculdade UnB Planaltina - FUP, Universidade de Brasilia, UnB, Área Universitária, Planaltina, DF, Brazil, Brasilia, Brazil; 3 Physics, Universidade Estadual do Maranhão-UEMA, São Luis, Brazil. 

We have systematically investigated the lowest-energy structures of boron nitride (BN) diamondoids, BnXn-based nanostructures (X = 4, 5 or 6), using the Density Functional Theory (DFT) and the Time-Dependent Density Functional Theory (TD-DFT) methods within the local density and generalized gradient approximations, LDA and GGA, respectively, were carried out to investigate the structural, electronic, thermodynamic properties and optical absorption of BN-diamondoids comparing to previous results for the adamantane (adc) and the sila-adamantane (sil) molecules, and even BN-adamantane proposed by Fyta [1]. The carbon atoms of the adamantane molecule have been substituted with Boron and Nitrogen atoms respecting the octet rule and considering homonuclear N-N or B-B bonds. Geometrical optimization of the nanostructures indicated that the BN-diamondoids exhibit good stability. The binding energy, HOMO-LUMO gaps and DOS were calculated to compare with the adamantane and sila-adamantane molecules. In addition, thermodynamical properties whose dependence with the temperature are discussed and indicating that all BN-isomers studied here could be synthesized, and its reaction should occur spontaneously in about 750 K. Finally, these BN-isomers have promising electronic and optical properties; in particular, the BnXn isomers (X = 4, 5 or 6) have an excellent optical absorption spectra in the range of ultraviolet radiation (UVA and UVB), and in particular, the 4BN-(196) isomer absorbs in the UV-Vis.
Advanced nanoengineered composites are a promising approach towards improving the mechanical performance of filamentary composites and adding multifunctionality to lightweight structures and vehicles. In particular, the integration of carbon nanotubes into composites through the circumferential growth of radially aligned carbon nanotubes (a-CNTs) onto microfibers has already demonstrated improvements in interlaminar fracture toughness, interlaminar shear strength, and electrical/thermal conductivities of alumina fiber composites. However, the implementation of this "fuzzy fiber" reinforced plastic (FFRP) architecture onto high performance carbon fibers (CFs) desired for demanding applications, has met with microfiber strength loss and effectively trades off in-plane strengths for through-thickness property improvements. This work presents an approach to growing high yields of CNTs on carbon fabrics to improve interlaminar properties while preserving the carbon fiber properties. Using a low temperature chemical vapor deposition (CVD) approach and a scalable method of catalyst deposition onto filaments, CNTs were directly grown on unidirectional (UD) carbon fabrics to form UD fuzzy CFs plies. Building on previous developments of woven fuzzy carbon fiber rein. The efficiency of the nanopumping effect triggered by Rayleigh travelling waves was predicted by FEMLAB and confirmed by experimental results. In present work, a large scale MD simulation package (LAMMPS) was used to verify that the nanopumping effect also exists in liquid water placed in pristine CNTs. Results of our simulations demonstrated that water molecules passed through CNTs and exited from the other CNT side. The efficiency of the nanopumping effect triggered by Rayleigh travelling waves was predicted by FEMLAB and confirmed by experimental results. Nevertheless, the implementation of this "fuzzy fiber" reinforced plastic (FFRP) architecture onto high performance carbon fibers (CFs) desired for demanding applications, has met with microfiber strength loss and effectively trades off in-plane strengths for through-thickness property improvements. This work presents an approach to growing high yields of CNTs on carbon fabrics to improve interlaminar properties while preserving the carbon fiber properties. Using a low temperature chemical vapor deposition (CVD) approach and a scalable method of catalyst deposition onto filaments, CNTs were directly grown on unidirectional (UD) carbon fabrics to form UD fuzzy CFs plies. Building on previous developments of woven fuzzy carbon fiber reinforced plastic (CFRP) laminates, vacuum assisted resin infusion was used to manufacture UD fuzzy CFRP laminates that have low interlaminar spacings (<15 μm) to increase the CNT fill fraction in the weak interlaminar region, and isolate CNT reinforcement effects. Both UD baseline CFRP and UD fuzzy CFRP were manufactured using a vacuum assisted resin infusion system with interlaminar spacings and laminate quality assessed through X-ray microcomputed tomography. Transmission and scanning electron microscopies reveal conformal CNT growth around carbon filaments prior to matrix introduction. Thermogravimetric data also shows the removal of the polymeric sizing layer on carbon fibers and the thermoplastic wet (that holds the CF tows together) through CVD processing and consequently informs matrix interface changes as well as process bounds for ensuring ply handleability. Further, short-beam shear testing data of UD fuzzy CFRP is presented, showing a 4% improvement in interlaminar shear strength. Thus, this work is an important step towards realizing hierarchical carbon fiber composites with improved interlaminar properties without compromising in-plane strengths, and provides a platform for future CNT growth optimization that may result in even larger property enhancements.
Applications of electromechanical probing for wafer testing progressively require smaller pitches, reliable and reproducible manufacturing and lower electrical contact resistances. Current electromechanical testing probes, for instance MEMS based vertical cantilever probes, have fundamental limitations in terms of the shortest pitch that can be achieved, cost and efficiency. The exceptional mechanical and electronic properties of carbon nanotubes (CNTs) make CNTs a promising candidate material for electromechanical probing applications. We synthesise vertically-aligned CNT structures by combining photo-thermal chemical vapour deposition (PTCVD) and photolithography and assemble them into a new type of metal-CNT-Polydimethylsiloxane (PDMS) composite structure for possible probing applications at both wafer-level chip-scale packaging (WL CSP) and wafer-level packaging (WLP) testing. Up to 600 μm tall, CNT-based vertical micro-spring type probes are demonstrated. We propose a design and architecture with a scalable approach, allowing for the assembly of thousands of probes in short manufacturing times, with easy pitch control that can facilitate testing at WL CSP and WLP packaging. Extra-long (~600 μm), vertically-aligned CNT probes are grown at high process temperatures and pressures, at rates up to 50 μm/min. The CNTs are metallic, multi-wall carbon nanotubes (MWCNTs) and are of good quality (I_d/I_g ~ 0.3). As-grown CNT probes are transferred to PDMS and metallised with Au, Pd and Cu to form a composite-like probe structure; with CNTs, acting as current carrying channels as well as micro-springs, providing good elasticity without compromising from the electrical conductance and a metal scaffold that stiffens the structure, whilst decreasing the overall contact resistance. Cyclic electromechanical characterisation of CNT-based probes showed reproducible contacts for up to 10,000 cycles, with a 50 μm compliance. For a 200 μm x 200 μm probe cross-sectional area, an average of 0.7 Ω contact resistance is achieved. Low contact resistance is realised by vertically-aligning CNTs, differing the combination of metallisation layers to obtain a good work function matching and wetting at the metal-nanotube interface. In addition, up to 16% compliance is observed and the mechanical failure mechanism is identified as micro-crack induced buckling in the plastic region. Overall, we demonstrate a scalable CNT-based micro-spring probe design as an alternative candidate to complex MEMS-based vertical cantilever probes for wafer probing applications at wafer level. Fabrication process can easily allow small pitch probes with minimal layout restrictions without compromising from electrical and mechanical properties. In addition, properties such as: stiffness, probe length and probe resistance are tunable via PTCVD deposition and metallisation processes allowing a wider range of probing applications.

NM01.15.41
Dynamic Mechanical Property of Multilayer Graphene Subjected to Supersonic Impact
Wanting Xie1,2 and Jae-Hwang Lee1; 1Department of Mechanical and Industrial Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Department of Physics, University of Massachusetts Amherst, Amherst, Massachusetts, United States.

Graphene is considered as one of the most promising anti-ballistic materials due to its high strength, stiffness, and low density. While its low-rate behavior has been studied for years, there are few experimental investigations at the high-strain-rate regime. By the observation of micro-spheres penetrating through free-standing graphene membranes in air, Lee and his colleagues (Science 346, 1092 (2014)) directly characterized mechanical properties of multilayer graphene at very high strain rates (~10³ /s). Their microscopic ballistic study demonstrated that the specific penetration energy of multilayer graphene was more than 10 times larger than that of steel for 600 m/s impact in the air. Independent numerical studies, however, predicted one order higher specific penetration energy than the experimentally measured value. A thickness effect was brought up to explain this discrepancy, as in modeling, a series of monolayer graphene was more efficient in energy dissipation than multilayer graphene with a same total mass. Moreover, aerodynamic effects of air were also suggested since the numerical simulations were carried out without introducing gases. For more precise quantification of the high-strain-rate properties of graphene, we have performed the micro-ballistic characterization in vacuum. Since the vacuum level is approximately 1/3,000 of the atmospheric pressure, undesired effects from air, including aerodynamic friction of a projectile and a membrane specimen, become negligible. As a projectile, 3.7 μm diameter silica sphere is accelerated and a suspended graphene membrane is subjected to projectile’s impact. With an ultrafast microscopic imaging system (up to 40 million frame per second), accurate velocities of the projectile before and after penetration are obtained. The specific penetration energy are directly calculated by the ratio of kinetic energy loss of the projectile and the mass of the membrane within the direct impact area of the projectile for different projectile’s velocities (100 – 1,000 m/s) and specimen’s thicknesses (10 – 100 nm). Post-mortem optical micrographs and electron micrographs are taken to measure the total crack length, crack number, and penetration area to explore their relationship with the penetration energy. The fine penetration features near the impact region are mainly examined by scanning electron microscopy.

Optical Visualization and Spectral Amplification of Single-Walled Carbon Nanotubes Through the Hygrosopic Salt Micro/Nanolenses
Yun-tae Kim and Chang Young Lee; Ulsan National Institute of Science and Technology (UNIST), Ulsan, Korea (the Republic of).

Micro/nanolenses of alkali metal halides are unique optical components that partially overcome the limitations of existing ones because of their hygroscopicity, solubility in water, tuneable refractive indices, excellent transmittance from UV to infrared, and high mobility of the constituent ions under an electric field. Forming such lenses and arranging them in a well-defined manner, however, remains a challenge. Here we demonstrate selective decoration of array of micro/nanolens along single-walled carbon nanotubes (SWNTs) using various salt species, which can be migrated along exterior of SWNT under an electric field. The lenses are promising for use in both the optical visualization and spectral amplification of underlying individual nanotubes. The lenses help detect molecular species located onto sidewall of a nanotube, such as amorphous carbon and diazonium that are not easily detectable using existing approaches. In addition, molecules dissolved in the solution can be captured within the lenses via exterior transport and then detected by Raman spectroscopy. Such lenses can be easily removed by a simple water rinse without degrading the properties of SWNTs. Thus, our approach will serve as a useful tool for the non-invasive visualization of nanostructures and spectral amplification of various molecular species.

NM01.15.43
The Exterior of Single-Walled Carbon Nanotubes as a Millimeter-Long Cation-Preference Nanochannel
Yun-tae Kim and Chang Young Lee; Ulsan National Institute of Science and Technology (UNIST), Ulsan, Korea (the Republic of).

In this study, the exterior of single-walled carbon nanotubes is shown to preferentially migrate cations over a millimeter length scale. Applying an electric field to drops of NaCl placed at both ends of the nanotubes causes transport of a cation-enriched solution counter-migrates along the adjacent substrate. This phenomenon is confirmed by Kelvin probe force microscopy and mass spectrometry imaging of individual nanotubes, as well as formation of bright and dark lines along the nanotubes in scanning electron microscopy (SEM). Blocking the exterior of the nanotubes prevents both the bright/dark lines in SEM and flow of current through the nanotubes, confirming the insignificance of interior ion transport and electron current. The cation-prefering transport results in the formation of positively charged salt crystals along the nanotubes (with a cation-to-anion ratio of 0.59:0.41 for KCl) followed by the subsequent shrinkage and growth of crystals in the direction of cation flux. Molecular dynamics simulations shows that cation–π interaction is responsible for such cation-preference observed during
transport. The loss of cation-preference upon covalent functionalization of the nanotubes further supports this mechanism. Utilizing the short-range cation-π interaction as a transport mechanism suggests broader applications in areas where charge-specific transport is desired.

NM01.15.44
Modeling the Bipolar Switching Effect in Graphene Oxide-Based Memristors
Andres Vercík and Luci C. Vercík; University of Sao Paulo, Pirassununga, Brazil.

The memory resistor, or memristor, was theoretically predicted by Chua in 1971 as the forth fundamental circuit element needed to complete the set of six mathematical equations relating four basic electrical variables: charge, current, voltage and magnetic flux. This idea remained as a missing element until its experimental realization in 2008 as TiO2-based memories. Since then, many researchers have directed their attention and efforts not only to the fabrication of memristors, using different materials, but also to understand the physics behind the switching mechanism, in order to control the processing and structural parameters that allow overcoming some drawbacks to obtain reliable and reproducible memory devices. Two-terminal devices, with the switching material sandwiched between two electrodes, are promising structures for the next generation of non-volatile resistive random access memory devices, with high speed, low-power consumption and excellent scalability. The two-dimensionality of the insulating graphene oxide sheets makes this material ideal for use in low-dimensional structures in nanoscale devices.

In this work, the transport properties of graphene oxide-based Metal-Insulator-Metal (MIM) structures are addressed. The graphene oxide (GO) was synthesized using an eco-friendly modified Hummers method. The obtained GO sheets were placed between gold electrodes, and the cycling current-voltage curves were measured by applying successive forward and reverse voltage sweeps in a range between -3 and 3V. When the absolute value of the measured current is plotted, in logarithmic scale, versus the applied voltage the typical butterfly-shaped curves are observed, which are better interpreted in terms of their first derivative, or differential conductivity, in order to understand the transport mechanism. A simple model is proposed, whose voltage dependence helps identifying the underlying physics responsible for the bipolar switching mechanism, such as bulk or electrode effects, conducting filament formation or tunneling. The analytical expressions used for the differential conductance for the low resistance state and the high resistance state (LRS and HRS respectively) leads to simple expressions for the I-V curves. The symmetry of the curves after several cycles is lost when compared to those measured on pristine devices, which might indicate the occurrence of filament forming effect, affecting the bipolar switching.

NM01.15.45
Rheological Characteristics of Chitosan - Gold - Graphene Gels
Radha Perumal Ramasamy; Department of Applied Science and Technology, ACT campus, Anna University, Chennai, India.

Gels are important class of materials and have wide applications. Gel polymer electrolytes is an interesting field and has gained much scientific attention in recent years. Controlling the rheological properties of gels can benefit its applications in fields such as batteries. In this research the effect of incorporation of graphene upon the rheological properties of chitosan-gold gels is explored. The chitosan solution was prepared by adding 1% (w/v) of chitosan powder of 1.5% (w/v) of acetic acid to double distilled water. The solution was stirred and heated at 60°C until a semitransparent thick chitosan solution was obtained. The solution was cooled to room temperature. To this solution, appropriate amounts of 1 M HAc/CH3OH were added to have 5 mM Au. Also graphene (grade H5 – XG Sciences) was incorporated in the gels to have 0, 10 and 20% of graphene (by weight compared to that of chitosan). The rheological and SEM measurements were made on these gels. The rheological measurements were made one day after the formation of the gels. The complex modulus for chitosan-5mM gold gels showed an increase from 100 Pa to 620 Pa as temperature increased from 25°C to 85°C. It then rapidly decreased to 36 Pa as temperature increased to 100°C. Chitosan-5Mm Au-20% graphene had a peak at 95°C. Hence the viscosity has maximum values at 85, 90 and 95°C for graphene concentrations of 0, 10 and 20% in chitosan-5Mm Au gels. Between 25 to 70°C the viscosity of chitosan-5Mm Au-10% graphene > chitosan-5mM Au > chitosan-5mM Au-20% graphene. Between 70 to 85°C the viscosity of chitosan-5mM Au > chitosan-5mM Au-10% graphene > chitosan-5mM Au-20% graphene. Phase angle measurements showed that chitosan-5Mm Au, chitosan-5Mm Au-10% graphene and chitosan-5Mm Au-20% graphene gels had lowest values at 80, 85 and 95°C respectively. These results indicate that the rheological properties are influence by the graphene incorporated in it. Interestingly, as graphene concentration increases to 20%, chitosan-5mM Au-20% graphene remains as a gel even at 100°C (as it has high viscosity) though chitosan-5Mm Au and chitosan-5Mm Au-10% graphene gels collapse at 100°C (as they have low viscosity). This indicates that graphene can be incorporated in gels to increase the temperature at which it can be operated. TEM images for graphene added to 5Mm Au solution (in room temperature) showed very less presence of gold nanoparticles. TEM images for chitosan-5Mm Au-10% graphene in room temperature (incubated for 10 days) showed presence of several sub-micron sized gold particles. Spherical, triangular and hexagonal shaped particles were observed. Some particles were as large as 500 nm. The particles were heterogeneous in sizes. TEM images for chitosan-5Mm Au-10% graphene heated to 30°C for 60 min (until the solution turned red in color) showed that uniform gold nanoparticles formed. Also gold nanoparticles attached to graphene indicating that graphene acts as nucleation site.

NM01.15.46
Interactions of Carbon Nanotubes with Magnetospirillum Magneticum via Carbon Nanotube/Polypyrrole Nanocomposite
Jake Dengelegi, Prabir Patra and Isaac Macwan; University of Bridgeport, Bridgeport, Connecticut, United States.

Being able to easily manufacture uniform chirality carbon nanotubes (CNT) is a difficult problem that we face today. There are many different ways that the carbon nanotubes orient themselves in making them either more metallic or semi-conducting in nature. Being able to separate these two types is very important to the semiconductor industry because semi-conducting carbon nanotubes are better suited for electronic devices such as transistors. Magnetospirillum magneticum (AMB-1) is a bacteria that can be used through magnetotaxis for controlled assembly tasks and it has also been shown that there are favorable interactions between the surface proteins, MSP-1 and flagellin of AMB-1 with glycine along with its flanking residues interacting only with metallic but not semi-conducting CNT. It has also been shown before that graphene, pyrrole, and carbon nanotubes can form a free standing film using cyclic voltammetry (CV) owing to the fact that the process of making the films containing only CNTs is extremely challenging because they are non-polar and cannot be polymerized independently. CV electro-polymerizes the pyrrole monomer into polypyrrole (Ppy) through a series of oxidation and reduction reactions along with CNT to be deposited on an electrode. In order to better study the interactions between CNT and AMB-1, this work is on the fabrication of a free standing nanocomposite CNT/Ppy film using CV with a specific aim to quantify such interactions using scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM), atomic force microscopy (AFM), electro-chemical impedance spectroscopy (EIS), and Fourier transform infrared spectroscopy (FTIR). In order to have large number of such interactions between AMB-1 and CNT only, we are working to find an optimum amount of pyrrole needed to make the film containing the most amounts of CNTs. We have been able to show that when 0.57mL of Ppy per 25mL of deionized water is polymerized, a free standing film (10 X 10 nm) with a greater percentage of CNT can be obtained. CV was used with a scan rate of 10mv/s, a low voltage of 800mV, a high voltage of 900mV, and 100 cycles. Based on the morphological characterization of the CNT/Ppy substrate along with AMB-1 using SEM and HRTEM as well as the data from FTIR and EIS, it is anticipated that AMB-1 does interact well with the CNT. The changes in the impedance in case of EIS with and without AMB-1 agree well with the AFM probing experiments and force distance data.

NM01.15.47
Enhancing Performance of Photovoltaic Solar Cell by P3HT:PCBM Doped Graphene Flakes as Photoactive Layer
Adnan Ali and Braham Alssaa;
Photoactive materials based on conjugated polymers are very promising candidates for Hybrid organic photovoltaic (OPV) cells. Conjugated polymers are inexpensive materials and therefore, their processing is very cost-effective and the ease of fabrication by solution processing make them more attractive. So far, OPV with modest efficiency are obtained. The low power conversion efficiency (PCE) of OPV is one of the main reason which has impeded large scale deployment. The low PCE of OPV solar cells is attributed to the low carrier mobility, which is closely correlated to the transport diffusion length of the charge carriers within the photoactive layers. 2D material like graphene which has huge carrier mobility, thermal and chemical stability and its compatibility of fabrication by solution processing techniques making it an excellent candidate for assisting charge transport improvement in the active layer of OPV cells. In this work, we report on the improvement of the optoelectronic properties and photovoltaic performance of photoactive blended layers i.e. P3HT:PCBM doped graphene flakes which was then integrated into a bulk heterojunction (BHJ) organic-photovoltaic-based device, using PEDOT:PSS on an ITO/glass substrate. Firstly, effect of graphene flakes content was studied in terms of the light absorption capacity which has shown increase with increasing concentration of graphene flakes. Besides this, quenching was observed through photoluminescence which is a clear indication of electron transfer between the graphene flakes and the polymeric matrix. P3HT:PCBM doped graphene flakes layer is incorporated into the BHJ as active layer. An increase in PV performance with respect to the reference cell was observed. The best PV performance was obtained for 3 wt.% loading of graphene flakes. The solar cell showed an open-circuit voltage (Voc) of 1.24 V, a short-circuit current density (Jsc) value of 6.18 mA cm⁻², a fill factor of 47.12%, and a power conversion efficiency of about 3.61%. It is obvious from the organic photovoltaic solar cell efficiency that sp² bonded carbon doping of photoactive conjugated polymer has strong role in its enhanced performance.

Mechanism Study of Graphene Adlayers in Chemical Vapor Deposition by Isotope Labeling

Xuewei Zhang, Zhenxing Zou, Yang Wang, Yunlu Wang, Le Mei, Zilong Zhang, Zehao Wu, Pei Zhao and Hongtao Wang; Zhejiang University, Hangzhou, China.

Bilayer graphene (BLG) has attracted enormous interest due to its outstanding mechanical, chemical, electrical and thermal properties with various potential applications. By applying a high ratio of H₂ to CH₄ in chemical vapor deposition (CVD) system, BLG can be synthesized with inverted-cake structures on polycrystalline Cu foils. Bilayer regions show distinct Raman spectra by carbon isotope labeling due to the different compositions of the graphene.

In this work, we studied the growth mechanism of BLG using carbon isotope labeling and Raman spectroscopy. Results show that the growth of BLG reveals several different modes. A new mode of “secondary” nucleation is firstly proposed in the growth of BLG, which means that graphene can be nucleated under the first layer tens of minutes later than the first layer. Moreover, during the BLG growth, the stacking structures of the two layers can suddenly change from AB-stacking to non-AB-stacking, while most of the BLG can still maintain their stacking structures during the whole CVD process. This work enables us to have a deep understanding of graphene growth mechanism as well as the layer control for large scale BLG using CVD.

LEEM Investigations of Polymer-Assisted Sublimation Grown Graphene on SiC

Philip Schädlich1, Florian Speck1, Georg Traeger2, Anna Sinterhauf3, Davood M. Pakdehi1, Klaus Pierz2, Martin Wenderoth2 and Thomas Seyller1; 1Institut für Physik, Technische Universität Chemnitz, Chemnitz, Germany; 2IV. Physikalisches Institut, Georg-August-Universität Göttingen, Göttingen, Germany; 3Physikalisch-Technische Bundesanstalt, Braunschweig, Germany.

Although much research has been conducted in the field of epitaxial graphene growth on silicon carbide (SiC), still new phenomena are discovered and need to be investigated in order to fully understand and control graphene synthesis and properties. Usually, during sublimation growth in argon at atmospheric pressure the substrate undergoes strong step bunching [1], which leads to relatively large step heights of multiple SiC unit cells. In contrast, the polymer-assisted sublimation growth (PASG) leads to flat and homogeneous graphene sheets on top of an SiC surface with step heights of mainly one or two SiC-bilayers [2]. This gives rise to a well-developed sequence of alternating SiC surface terminations underneath the graphene, which originate from different crystal truncations within the SiC unit cell at the surface [3].

Recently, scanning tunneling potentiometry measurements on graphene obtained by PASG revealed different values for the sheet resistance for graphene on different SiC terraces. Here, we present our results on PASG graphene investigated by low-energy electron microscopy (LEEM). The termination of the underlying SiC substrate is studied by LEEM bright field and dark field measurements as well as selected area low-energy electron diffraction (s-LEED) and atomic force microscopy. In addition low-energy electron reflectivity (LEER) spectra reveal slightly different electronic properties of the graphene on different SiC terminations. The relationship between the termination of the SiC substrate and the electronic properties of the PASG graphene as indicated by the LEER spectra is shown. Possible explanations for the local change in sheet resistance and the influence of the substrate are discussed.

Exceptional Multifunctional Properties of Non-Oxidized Graphene Aerogel/Epoxy Nanocomposite

Jin Kim1, Ne Myo Han2, Jungmo Kim1, Hyewon Yoon1, Minso Park1, Travis G. Novak1, AshrafalAzam1, Jinho Lee1, Kang-Kyo Kim1 and Seokwoo Jeon1; 1KAIST, Daejeon, Korea (the Republic of); 2MAE, HKUST, Hong Kong, Hong Kong.

Graphene aerogel, a three dimensionally interconnected porous structure, has gained significant attention due to its fascinating properties, such as high mechanical strength, electrical conductivity, thermal resistance, and ultra-light weight. Incorporation of graphene aerogel into a polymer composite is a promising route for fabrication of ultra-light multifunctional material, which is heavily demanded in various industries.

Recent studies have focused on optimization and alignment of graphene aerogel’s structure, in order to further improve the quality of the aerogel and the corresponding composite. Various methods have been developed for controlling the aerogel structure such as self-assembly, direct printing, and ice templating of graphene flakes. Initially, graphene oxide (GO) flakes was used for fabricating graphene aerogel with aligned structure, due to its abundant surface functional groups, which facilitate both aqueous dispersion and assembly of graphene aerogel. However, those functional groups also act as defects, which severely deteriorate the property of both GO flakes and its aerogel. Therefore, it is highly desired to fabricate graphene aerogel composed of graphene flakes with minimum damage.

Here we report a fabrication method to fabricate graphene aerogel composed only with highly crystalline non-oxidized graphene flakes (NOGFs). Bi-direction freeze casting technique was utilized in order to align the pore walls in two orthogonal directions, vertically and laterally. The graphene aerogel showed low defect concentration and oxygen content of 1.4 % according to Raman and XPS analysis. Due to the synergistic effect of both high quality of
Methods into Nano-Carbons and Fuels
A Comprehensive Study on Optimizing Conversion of Waste Plastics Using Diverse Catalysts, Carrier Gases, Flow-Rates and Pre-Treatment

Water splitting is one of the carbon-free hydrogen production methods. Electric power consumption of the hydrogen evolution reaction (HER) depends on the cathode materials. Although Pt is known as the most suitable cathode for HER under acidic conditions, identified resources of platinum are limited in the world. Hence, the development of alternative HER catalysts is required. Currently, MoS2 presents a promising alternative to Pt due to its low cost and high HER activity. The active sites of MoS2 are located at the edges, thus it is important to develop a simple synthesis process to obtain edge-rich MoS2. In previous research, edge-rich MoS2 of high crystallinity was synthesized under hydrothermal conditions, but the main problem of the process was the long reaction time (24-48 h). MoS2 synthesis via cathodic electrodeposition is one of the fast and facile processes because the deposited MoS2 can be applied directly for application. However so far, electrochemically deposited MoS2 showed low crystallinity and low purity with an amorphous structure. In order to realize high crystallinity MoS2 and short processing times, we propose a hydrothermal electrodeposition method to fabricate MoS2 electrodes. This method enables to synthesize crystalline thin films and to control the composition and morphology of the products by adjusting the operating temperature, pressure, and electrochemical conditions. In this research, we attempted to electrochemically deposit MoS2 on glassy carbon (GC) under hydrothermal conditions (200 °C, 10 MPa), and the MoS2/GC electrodes were then applied as HER cathodes. For the hydrothermal electrodeposition, a high-pressure vessel made of Hastelloy equipped with electrodes was used as a synthesis cell, and potentiostatic measurements were carried out at voltages of −1.5 V for 1-30 min. SEM and TEM images of samples synthesized by 1 min electrolysis revealed the formation of edge-rich MoS2 deposited on GC, while it seemed that the number of exposed edges of the products decreased with increasing reaction times. XRD patterns of working electrodes realized by electrodeposition for 1 min showed that crystalline MoS2 was deposited on the GC. From TOF-SIMS measurements, the product was mainly identified as MoS2, while compounds of molybdenum sulfides and oxides were observed in the case of the electrodes treated at ambient condition. HER catalytic activity measurements showed that products synthesized at hydrothermal condition exhibited higher HER performance than the samples synthesized at ambient conditions. Moreover, edge-rich MoS2 obtained for an electrolysis time of 1 min had higher activity compared to samples realized by longer electrolysis times, the higher HER activity being attributed to the edge-rich morphology of MoS2.

A Comprehensive Study on Optimizing Conversion of Waste Plastics Using Diverse Catalysts, Carrier Gases, Flow-Rates and Pre-Treatment

Fabrication of Edge-Rich MoS2 Cathodes for Water Splitting via Hydrothermal Electrodeposition

Water splitting is one of the carbon-free hydrogen production methods. Electric power consumption of the hydrogen evolution reaction (HER) depends on the cathode materials. Although Pt is known as the most suitable cathode for HER under acidic conditions, identified resources of platinum are limited in the world. Hence, the development of alternative HER catalysts is required. Currently, MoS2 presents a promising alternative to Pt due to its low cost and high HER activity. The active sites of MoS2 are located at the edges, thus it is important to develop a simple synthesis process to obtain edge-rich MoS2. In previous research, edge-rich MoS2 of high crystallinity was synthesized under hydrothermal conditions, but the main problem of the process was the long reaction time (24-48 h). MoS2 synthesis via cathodic electrodeposition is one of the fast and facile processes because the deposited MoS2 can be applied directly for application. However so far, electrochemically deposited MoS2 showed low crystallinity and low purity with an amorphous structure. In order to realize high crystallinity MoS2 and short processing times, we propose a hydrothermal electrodeposition method to fabricate MoS2 electrodes. This method enables to synthesize crystalline thin films and to control the composition and morphology of the products by adjusting the operating temperature, pressure, and electrochemical conditions. In this research, we attempted to electrochemically deposit MoS2 on glassy carbon (GC) under hydrothermal conditions (200 °C, 10 MPa), and the MoS2/GC electrodes were then applied as HER cathodes. For the hydrothermal electrodeposition, a high-pressure vessel made of Hastelloy equipped with electrodes was used as a synthesis cell, and potentiostatic measurements were carried out at voltages of −1.5 V for 1-30 min. A Comprehensive Study on Optimizing Conversion of Waste Plastics Using Diverse Catalysts, Carrier Gases, Flow-Rates and Pre-Treatment

Methods into Nano-Carbons and Fuels

As a result of China’s recent ban on the import of most plastic waste, the US and other industrialized countries that have been exporting their plastic waste to China for recycling will need to find new ways to handle the disposal of their wastes as much of it is already starting to pile up in landfills. In research conducted at Northeastern University, plastic wastes have been thermally recycled by pyrolytic gasification to nano-carbons and gaseous fuel. To achieve this conversion, a laboratory-scale pyrolytic gasifier was fed with waste plastics including (polyethylene, polypropylene, polyethylene terephthalate, polystyrene, etc., and combinations of the same) in inert (N2 or He or Ar or CO2) atmospheres with different flow rates (0.1-2 l/min). The plastic wastes were gasified in an electrically heated reactor at 600-800 C. Under these conditions, the pyrolyzate was pyrolyzed into a gaseous mixture of hydrocarbons and hydrogen. The pyrolyzate mixture was then conducted into a separate reactor where it was used as a carbon precursor for chemical vapor deposition process to synthesize carbon nanoparticles. The second reactor was set at 900-1000 C. Different grades of stainless steel wire cloths (SS-304, SS-316 and SS-316L) were used as catalytic substrates for the nanoparticle growth. The wire cloths were used either as-received or upon chemical etching by acid wash and/or heat-treatment in air, nitrogen or helium at 800 C, followed by rapid air quenching. In those cases, the yields were determined, by mass relative to the mass of carbon in the feedstock and ranged from 1% to 30%. With the purpose of purification and sorting, the catalysts and the produced Nano-materials were investigated for synthesis, structure and property characterization by SEM, TEM, AFM, TEM+EDX, HAADF and TGA. Results showed that the catalyst type, composition, and pre-treatment, as well as the type of waste plastic, are all influential on the yields and physical characteristics of the synthesized CNTs.

Investigation of Photocatalyzed Reduction of Technetium-99 Utilizing Titanium Dioxide, Graphene Oxide and Nanocomposites Thereof

Water contaminated with highly toxic long-lived radionuclides is a growing concern in the U.S. These contaminants are introduced into water sources from the legacy wastes of nuclear sites, and from nuclear reactors. Technetium-99 (99Tc) is one of the major nuclear waste contributors (~6% yield) generated from thermal neutron fission of uranium-235. It is considered a long-lived radioisotope with a half-life of 2.1x106 years and emits a weak beta with a max energy of 0.29 MeV. 99Tc is most prevalent in its oxidized form which predominantly exists as pertechnetate (Tc(VII)O4−). This contaminant is of concern in aqueous streams because of its inert nature that allows it to spread at nearly the same rate of water flow. To remediate 99Tc, reduction of pertechnetate has been the common approach because 99Tc is more reactive and less mobile when in a reduced state. The foundation of this work involved utilizing different functionalized nanomaterials as platforms to investigate the reduction and uptake of 99Tc. Titanium dioxide is a promising candidate as it has already shown to be a good material for removing toxic materials from the environment. Furthermore, it has a strong reducing potential and is found to be chemically inert in a variety of environments. Graphene oxide (GO) is an eco-friendly platform with a large surface area that provides tunability due to its chemically inert nature in a variety of environments. Graphene oxide (GO) is an eco-friendly platform with a large surface area that provides tunability due to its electrical conductivity of 122.6 S/m at 0.27 vol%. Both results are superior to those of epoxy composites based on GO aerogels, which demonstrate that incorporation of NOGFs is a promising approach for fabricating high quality graphene aerogel.

Influence of Contact Electrode in the Electrical Resistivity through Graphene Oxide Thin Films

Influence of Contact Electrode in the Electrical Resistivity through Graphene Oxide Thin Films
Graphene and their derivatives graphene oxide (GO) and reduced graphene oxides (rGO) have been of great interest in technological device applications in nanoelectronics and bio-sensors. The great flexibility of GO based thin films and its compatibility with existing technologies help in understanding the device physics and engineering of GO based thin film devices for their practical applications. The simplest structure for studying electronic properties includes sandwiching the thin film between two metal electrodes and study behaviour of charge flow. Motivated with the initial observation of bistable resistive switching behaviour in Al(200°C)/GO(T)/ITO structure, this work is extended to demonstrate the influence of various metal contacts in GO thin film is interpreted using X-ray photoelectron spectroscopy and the role of these electrode materials in the electrical resistance in metal(M1)/GO(T)/metal(M2) device structures [with M1 = indium tin oxide (ITO); gold (Au), or aluminium (Al), and M2 = Al or Au] have been analysed. GO is synthesised by modified Hummers method. Thin films of GO are prepared by spin coating the dispersed solution of GO (1mg/ml) on metal substrate (M1= ITO, Al, or Au) followed by annealing at different temperatures, T= 100, 200, 300, and 400 °C. The materials, optical, and electrical properties are characterized for the GO powders and GO(T)/M1 thin films [3]. The top metal electrode (M1 = Al or Au) is formed by thermal deposition technique through shadow masking. Temperature dependent current-voltage (I-V) characteristics of resulting devices M2/GO(T)/M1 are measured using Keithley-4200 Semiconductor Analyser system. The temperature dependent resistance coefficients (α) estimate values of 4.2 x 10^{-3} and 5 X 10^{-3} in Al(200°C)/GO(T)/ITO device structures, respectively. The presence of Au and Al contents in depth profile XPS spectra of GO(T)/Al or Au films and metallic behaviour in the temperature-dependent electrical resistance through M2/GO(T)/Al or Au structures with the R0 equivalent to the corresponding submetal, indicate migration of atoms from Al or Au electrodes through the defect sites of GO till the other electrode and connects both the top and bottom electrodes the with formation of metal filament. The electrical resistance values indicates R_{Al/GO(200°C)/ITO} < R_{Au/GO(200°C)/ITO} < R_{Al/GO(T)/Al} < R_{Au/GO(T)/Au}. In Al/GOT(A)/Au and Al/GO(T)/Al devices show more conducting compared to R_{Al/GO(T)/ITO} due to presence of more metal contents forming the filament within the GO layer between the top and bottom contacts. The Al/GO(T)/ITO device assists only the elemental metal atoms of Al to migrate through the GO and favors the provides uniform parameter during growth process, leading to growth of near identical filament structures between the electrodes and formation of contact interfaces at Al(200°C)/T and GO(T)/ITO with identical thermal and electrical behaviours for all the interconnecting filaments.

Mechanical Assembling and Structuring Graphene Oxide Based Materials Jing Zhong; Harbin Institute of Technology, Harbin, China.

Mechanical Assembling and Structuring Graphene Oxide Based Materials
Jing Zhong*,†
†School of Civil Engineering, Harbin Institute of Technology, Harbin 150090, Peoples’ Republic of China
‡Institute for Advanced Ceramics, Harbin Institute of Technology, Harbin 150080, China

As a building block, graphene possesses intriguing mechanical, electrical, thermal property and chemical stability. Assembling graphene into macrostructures is very appealing, if those unprecedented properties can be inherited. However, it is the physical interaction between graphene nanosheets mainly control the performance of the assembled materials. On the other hand, it should be noted that graphene is probably the most anisotropic material that has ever been discovered, as manifested by the prominent contrast of bending modulus (in the order of ~2kT) and tensile modulus (~1 TPa), as well as the ballistic electron transport in-plane and tunneling between-planes. Therefore, it is extremely important to improve the alignment of graphene nanosheets in the same direction and reinforce the interaction between them. Keeping this in mind, we propose to employ mechanical strategies, namely dead-end filtration and centrifugal casting, with the advantages of high efficiency, high yield and universal, to super-align and condense-compact graphene nanosheets, both of which result to materials with outstanding performance [1-3]. Finally, we will also illustrate that the combination of proper rheology properties of graphene oxide based ink and 3D printing technique, materials beyond 2D film with much more complex structures can be obtained.

Functionalization of Graphene Thin-Film Surface by Using 2- (dimethylamino) ethyl methacrylate by Plasma Enhanced Chemical Vapor Deposition Method Furkan Turgut and Mustafa Karaman; Chemical Engineering, Konya Technical University, Konya, Turkey.

The chemical reduction of graphene oxide is a promising route towards the large-scale production of graphene for commercial applications. Graphene is an atomic-scale honeycomb lattice made of carbon atoms. Due to its extraordinary mechanical, electrical, and thermal properties, graphene has potential applications in many fields. The reason of functionalize graphene with DEAEMA by using PECVD method is to enable the matrix to be form of composite with other chemicals. In this work, graphene oxide(GO) was synthesized from graphite by using modified Hummer’s method. Modified Hummer’s method according to other methods known in the literature; it is simpler and less costly in terms of processing steps. The synthesized graphene oxide(GO) was reduced with hydrazine hydrate to obtain a graphene. The obtained graphene was functionalized with amine group 2- (dimethylamino) ethyl methacrylate (DEAEMA) monomer by using plasma enhanced chemical vapor deposition (PECVD). Unlike other chemical vapor deposition methods, the PECVD method only polymerizes with the plasma that generated on the monomer surface without using an initiator in the system. To determine coating conditions; different reactor pressures, monomer flow rates, plasma powers and coating times were tested using PECVD method. Thickness of coating on surface was found by using profilometry, to characterize compounds FTIR and to determine GO surface morphology AFM analyses were used. As a result, the most efficient coating speed was determined as 69 nm/ min. Functionalization of graphene studies were carried out under the determined optimum coating speed condition. SEM, TEM and Raman analyses of the coated graphene oxides were carried out to investigate the morphological and chemical structure.

Elastic Properties of Bulk and Low-Dimensional Materials Using van der Waals Density Functional Kamal Choudhary; National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

In this work we present a high-throughput first-principles study of elastic properties of bulk and monolayer materials mainly using the vdW-DF-optB88 functional. We discuss the trends on the elastic response with respect to changes in dimensionality. We identify a relation between exfoliation energy and elastic constants for layered materials that can help to guide the search for vdW bonding in materials. We also predicted a few novel materials with auxetic behavior. The uncertainty in structural and elastic properties due to the inclusion of vdW interactions is discussed. We investigated 11 067 bulk and 257
monolayer materials. Lastly, we found that the trends in elastic constants for bulk and monolayer counterparts can be very different. All the computational results are made publicly available at easy-to-use websites: https://www.ctcms.nist.gov/~knx6/VASP.html and https://jarvis.nist.gov/. Our dataset can be used to identify stiff and flexible materials for industrial applications.

NM01.15.58 Hydrogen Storage in Ti Atoms Decorated Boron-Nitrogen Doped Graphene—Effects of Electric Field on Hydrogen Adsorption and Desorption Santhanamoorthi Nachimuthu and Jyh-Chiang Jiang; National Taiwan University of Science & Technology, Taipei, Taiwan.

In the last two decades, the significant efforts have been made to develop alternative energy sources instead of fossil fuels because of increasing CO2 emissions and the environmental impacts. Besides, hydrogen has been concerned to be an ideal clean energy carrier among the other renewable energy sources because of its environmental friendliness. However, some challenges have to be addressed before hydrogen will become a conventional and commonly available energy carrier. Carbon-based materials such as graphene and carbon nanotubes have been designed for hydrogen storage due to their large surface area, lightweight, and tunable properties. Recently, we proposed a new strategy in which we considered three pure transition metal (TM) atoms or/and a combination of two TM atoms and one alkali earth metal atom (AEM) with high, medium and low hydrogen adsorption energies. These different metal atoms are used to decorate the Boron doped graphene sheet (BDG) and investigated their performance towards hydrogen storage capacity through spillover mechanism using first-principles calculations. Our results indicate that the activation energies for H atom diffusion are much smaller, indicating that a fast H diffusion on this proposed surface can be achieved. These TM and AEM atoms decorated BDG surface can have the maximum hydrogen gravimetric capacity of 6.4% for double-sided adsorptions. To further achieve higher gravimetric density, in this study, we have considered Ti atoms decorated on the Boron and Nitrogen co-doped graphene surface (BNDG) because B–N pair is iso-electronic to the C–C pair. However, controlling the binding strength of metal atoms with that of the BNDG surface is an important issue in the application of hydrogen storage. The recent studies have shown that the binding strength between the metal atom and the substrate can be controlled by means of applying an external electric field. Thus, the effects of the external electric field, as well as the effects of applying point charges on the designed medium towards its hydrogen storage capacity, will be discussed. We have also explored the stability of the decoration of metal atoms on BNDG sheet at higher temperatures using molecular dynamics simulations.

NM01.15.59 Multifunctional Laser Induced Graphene Composite Surface Phu X. Luong, Kaichun Yang and James M. Tour; Rice University, Houston, Texas, United States.

Fabrication simplification and multi-functionalization are keys for universalization/popularization of current nanomaterials in many fields. Laser Induced Graphene (LIG) is one of the promising candidates in this topic by its one step production with laser ablation of commercial Polyimide (PI) Kapton film under ambient environment and many of its exploring applications.[1] However, LIG potential for realistic applications is limited by the PI substrate it attaches on and its weak robustness. Here, we present two facile methods to fabricate LIG composite (LIGC) compatible with diverse materials that are “Swiss army knife” for multi-purpose applications.

The first method is the materials infiltration. Herein, we are able to engineer the morphology of several LIGCS to superhydrophobic with contact angle > 160 degree. The LIGCS retain the conductivity of the LIG and is suitable for many Joule heating applications, including de-icing and thermal therapy. Stretchable and highly conductive LIGCS is used for resistive memory device substrate and strain sensor. Additionally, LIGCS in constructional materials also show anti-biofouling property.

The second method is mechanically pressing the LIG onto the material surface by sanding. The combination roughness induced by both sand paper and LIG result in a stable superhydrophobic composite surface. By this simple method, we have been able to produce a number of superhydrophobic surface on commercial polymer with roll-off contact angle down to less than 1 degree.

Keywords: laser induced graphene, nanocomposite, superhydrophobic, Joule heating, de-icing, thermal therapy, memory device, anti-biofouling.

NM01.15.60 Molecularly-Linked Gold Nanoparticle Films Across the Insulator-to-Metal Transition—From Hopping to Strong Electron Correlations Monique Teg and Al-Amin Dhirani; Univ of Toronto, Toronto, Ontario, Canada.

Strong electron-electron interactions are widely believed to play a key role in a range of remarkable phenomena such as high Tc superconductivity among others. Strongly correlated electrons are often described by the Hubbard model, which captures important gross features of phase diagrams of strongly correlated materials. However, open challenges include experimentally mapping correlated electron phenomena beyond those captured by the Hubbard model.

We use both film thickness and electrolyte gating to study a metal-insulator transition in a new class of strongly correlated material, namely, nanostructured materials, using 1,4-butanedithiol-linked Au nanoparticle films as an example. On the insulating side of the transition, we observe Efros-Shklovskii variable range hopping and a soft Coulomb gap, evidencing the importance of Coulomb barriers. On the metallic side of the transition, we observe signatures of strong disorder mediated electron-electron correlations. Films near the metal-insulator transition also reveal a zero-bias conductance peak, which we attribute to a resonance at the Fermi level predicted by the Hubbard and Anderson impurity models when electrons delocalize and experience strong Coulomb electron-electron interactions.

NM01.15.61 Biogas-Slurry Derived Mesoporous Carbon for Supercapacitor Applications—Harnessing Microorganisms to Circumvent Hydrothermal Treatment for Highly Porous Electrode Materials Ceril Kingondo1, Enock T. Kibona2 and Cecil King’ond1; 1Botswana International University of Science and Technology, Palapye, Botswana; 2Department of Physics, Mkwawa University College of Education, University of Dar es Salaam, Iringa, Tanzania, United Republic of.

Surface area, pore texture and pore distribution have been shown to have a strong influence on capacitance. Therefore, hydrothermal treatment (HT) of the most common carbon source, biomass, prior to carbonization and activation has recently received heightened interest owing to its ability to deliver high surface area carbon nanomaterials with remarkable pore texture via deconstruction of cellulose polymeric network in biomass. Nevertheless, hydrothermal strategies involve high pressure and temperature and thus expensive. This study reports on circumventing HT in preparation of the carbon materials with outstanding mesoporosity for supercapacitor electrodes by use of biogas slurry. The deconstruction of cellulose polymeric network in this case is achieved by bacteria while the carbon source is still in the biodigester for biogas generation. In the study, pore structure and surface chemistry have been modified by altering activation time, temperature and KOH/carbon mass ratio. Mesoporous carbon materials are successively developed as evidenced by type IV isotherms obtained in nitrogen sorption studies. The materials afford BET, micropore and mesopore surface area of 515, 350, and 165 m² g⁻¹, respectively as well as a narrow pore width distribution of 3-4.5 nm. X-ray photoelectron results confirms the presence of functional groups of oxygen and nitrogen in
the samples which facilitates the pseudocapacitance. The materials activated at 700 °C, 3:1 KOH to carbon mass ratio, and for 120 min exhibit high specific capacitance of 289 F g⁻¹ at a scan rate of 5 mV s⁻¹. Shortening activation time to 30 and 60 min increases specific capacitance to 163 and 182 F g⁻¹, in that order. Additionally, at 3:1 KOH to carbon mass ratio and 60 min activation time, specific capacitances of 170 and 210 F g⁻¹ at 600 and 800 °C, respectively are obtained. Moreover, specific capacitance increases with increasing the KOH to carbon mass ratio from 148 F g⁻¹ for 1:1 to 163 F g⁻¹ for 3:1 at 700 °C. Electrochemical impedance spectroscopy studies demonstrate that the materials have high conductivity. In addition; capacity retention of 96% after 20,000 cycles is attained at a scan rate of 30 mV s⁻¹. The study shows that high performance electrodes can be designed from biogas slurry thereby eliminating the need for HT to get electrode materials with high surface area and porosities from biomass.

NM01.15.62 Hierarchical Carbon Nanostructures for Energy-Efficient Water Purification Yuchen Liu, Shiren Wang and Zimeng Zhang; Texas A&M University, College Station, Texas, United States.

In this presentation, we demonstrate a hierarchical carbon nanostructures for energy-efficient water purification. Specifically, 2D graphene nanosheets were intercalated with zero-dimensional fullerenene nanocrystals, and a fixed interlayer spacing of ~1nm was achieved for tuning water passage. The resultant hybrids were stacked via epoxy adhesive and then the cross-sectional filtration of slaty water was investigated. The as-prepared GO/C60 membrane obtains a high water flux up to 10.85 L h⁻¹ m⁻² bar⁻¹ with a salty rejection of 89.66%, which is sufficient to purify brackish water into drinkable water. The energy consumption is as low as 0.775 KWh/L, more than 20-fold less than commercial desalination process. Such hierarchical GO/C60 membrane exhibits long-term stability, and thus provides a great potential for energy-efficient water desalination.

NM01.15.63 Molecular Detection at Ultra-Low Concentration Using Potential Gradient Traps and Interlayer Coupling of Few-Layers MoS2: Pavel San1, Dianjun Nandi2, Hiofan Hoi1 and Manisha Gupta2; 1Chemical and Materials Engineering, University of Alberta, Edmonton, Alberta, Canada; 2Electrical and Computer Engineering, University of Alberta, Edmonton, Alberta, Canada.

Single molecule detection has played an important role in monitoring of health and environmental conditions. Health monitoring efficiency depends upon detection of an immune response to pathogen, cell mutation, etc. at its early stages or low concentration. Traditionally, solid state nanopores are fabricated using silicon nitride (Si3N4) membranes. But 20-50nm thick Si3N4 membranes makes fabrication and reproduction of 2-5nm pores difficult, hampering detection sensitivity and accuracy. 2D materials with interlayer van der Waals forces, are a good choice for fabricating monolayer thin membranes. Molybdenum disulphide (MoS2) with surface charge (0.024 C/m²) similar to Si3N4 (-0.02C/m²) slows translocation without pore blockage, and also improves resolution. In this work, the advantage of using few layers MoS2 over monolayer MoS2 for low-concentration label-free detection has been demonstrated. The strong interlayers coupling creates a potential gradient along the van der Waals separated MoS2 layers, since the different layers feel different electric potentials. This causes trapping and detraping of the phosphate groups of DNA with the Molybdenum atoms at the nanopore. The increased negative-positive charge interaction pull providing platform for effective capture and detection at very low molecular concentrations, without the usage of any external trapping mechanism.

Here, we have conducted simulation and experiments to compare the detection efficiency of Si3N4 and MoS2 nanopores for dilute samples. We simulated translocation of nucleotide homopolymers in COMSOL Multiphysics. Our simulations show a 30-fold conductance improvement and three times lowering of translocation speed for a 5nm diameter pore on 4 layers (2.6nm) MoS2 compared to 50nm thick Si3N4, indicating a clear sensitivity improvement. Translocation experiments were conducted using 4E-4% IDT-ACTB1 and 60 mM KCl with Si3N4 and MoS2 pores, fabricated by photolithography, etching and TEM drilling. Here the concentration used for detection (4E-4%) implies a 10-fold sensitivity improvement when compared with detection demonstrated in literature (0.1-1%). MoS2 is seen to detect 102 molecules per minute whereas Si3N4 detected 20 molecules per minute at the ultra-low concentration without any external trapping mechanism. Moreover, the greatest dwell times obtained in literature for DNA sequencing using 100 mM KCl concentration is as low as 0.1-1 ms whereas our dwell times as large as 1100 ms were obtained in our study. MoS2 (0.3-1.4nA) demonstrates a significantly higher average blockade current as compared to Si3N4 (0.08-0.8nA). Simulation and experimental data for all nucleotides will be presented to show inherent capacity of few-layers MoS2 in improving molecular detection efficiency.

NM01.15.64 Complementary Dual Channel Gas Sensor Devices Based on Role-Allocated Heterostructure Garam Bae1,2, Woosook Song1, Sang Myung1, Jongsun Lim1, Sun Sook Lee1, Chong-yun Park1 and Ki-Seok An1; 1Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Department of Physics, Sungkyunkwan University, Suwon, Korea (the Republic of).

Intriguing electronic properties of graphene related with massless Dirac Fermions have enabled the applications in highly sensitive gas sensors. However, it is widely recognized that the poor gas desorption behavior because gas adsorption occurs defective sites of graphene only. To overcome this insurmountable hurdle, we rationally designed hybrid films including ZnO thin films and CVD-grown graphene in order to combine advantages of ZnO thin films with reliable gas adsorption/desorption related with their gas reaction mechanism and graphene with extremely high gas sensitivity originated from its exceptional electronic structure. The complementary dual channel gas sensor based on roll-allocated graphene-ZnO heterostructures, in which ZnO acts as a gas adsorption channel and graphene plays a role as carrier conducting path, was fabricated by combining atomic layer deposition, chemical vapor deposition, and polymer-assisted wet transfer techniques. The effects of ZnO top-layer thickness on the gas sensing properties of the hybrid films were explored. As a result, NO2 sensitivity improvement of the optimized hybrid film-based gas sensor was achieved unambiguously as ~40 times higher than that of graphene-based gas sensors. Additionally, we systematically explored the electrical interaction between thickness-controlled ZnO thin films and graphene before and after gas adsorption to explain the correlation between charge transfer and gas sensing properties.

NM01.15.65 Dispersion Control of Reduced Graphene Oxide and Application to Inverted Organic Solar Cells as a Hole Transport Layer Jong-Jin Park1,2, Jin-Mun Yoon1,2, Kyoungine Hwang1, Yeon-Ju Kim1, YeonSu Choi1 and Dong-Yu Kim1; 1Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 2Korea Atomic Energy Research Institute, Jeongeup, Korea (the Republic of).

Graphene-based materials have received tremendous attention due to their excellent mechanical and electrical properties. Among them, graphene oxide (GO), which chemically exfoliated from graphite, is possible to solution process in aqueous solutions owing to having oxygen-containing functional groups on its basal plane and edges. Moreover, they have active sites for reduction of GO and covalent functionalization of GO with small organic molecules or inorganic nanomaterials. For these reasons, GO have been researched in many applications such as polymer composites, biomedical, and energy-related
materials. In particular, reduced graphene oxide (rGO) reduced by functionalized hydrazine from GO is promising alternative material to poly(3,4-ethylenedioxythiophene)poly(styrenesulfonate) (PEDOT:PSS) as hole transport layer (HTL) in organic solar cells because it allowed the controllability of electronic properties through versatile functionalization and can improve the long-term stability of solar cells. However, rGO is difficult to apply in inverted organic solar cells because of limited dispersity in alcohol based solvent such as 2-propanol (IPA). The rGO is usually dispersed in dimethylformamide (DMF), which melt the organic active layer. Therefore, more research is required about controlling the dispersibility of rGO while maintaining their electrical properties in order that rGO apply to inverted organic solar cells as a HTL via solution process. In this study, we introduced trifluoromethoxy group on the rGO surface (FMrGO) for controlling the dispersibility of rGO while maintaining their electrical properties. FMrGO is well dispersed in IPA and 2-ethoxyethanol due to the flexible methoxy groups. The structural, optical, and thermal properties of FMrGO was characterized by Infrared spectroscopy, EA, XPS, UV-vis spectroscopy and TGA and their work function was estimated by UPS. Finally, we introduced the FMrGO film as a HTL on the active film through solution process and investigated the effect of FMrGO on device performance and long-term stability of inverted organic solar cells.

NM01.15.66
Self-Powered Motion Sensor Using Flow-Less CNT Sheet Nanogenerator Hyelynn Song, Usang Jeong and Yonghyup Kim; Seoul National University, Seoul, Korea (the Republic of).

Carbon nanotube (CNT), which has one-dimensional atomic structure, is highly accessible to external stimuli because of its high surface area to volume ratio. Thus, electronic configuration of CNT can be strongly influenced by tiny perturbations. The unique interaction between CNT and its surrounding stimuli has been of particular interest over the past decade. A thorough understanding of the interaction enables to develop a wide range of applications, such electrical bio/chemical sensors and actuators with unrivaled performance. Previous researches proved that CNT can generate electrical energy by converting mechanical energy of fluid into electrical energy. The transfer of momentum from the molecules in flowing fluid to the acoustic phonons in the CNT is induced, which in turn drag free charge carriers in the CNT. The driving of free carriers generates a potential difference along the CNT length, but this phenomenon is only realized in low dimensional nano carbon structures. The ability of generating electrical power can be enhanced in highly aligned structures of nanomaterial along the flow direction because this structural characteristic can decrease scattering of dragged charge carriers.

In this work, we investigated the effect of charge carrier drag in CNT by using more intuitive way of electrostatic induction. A highly aligned, free-standing structure of CNT sheet is used to enhance the charge dragging effect as well as to minimize peripheral influences from a substrate. Up to hundreds of microvolt can be generated, it is affected by sweeping speed, inter-distance between charged object and nanotube sheet, surface charge and number of nanotube sheet layers. Simple fabrication method of series connection is the most powerful aspect of continuously drawable nanotube sheet, which is simply completed by one-step winding of CNT sheet on the polyethylene terephthalate (PET)/copper foil/PET laminated substrate. As a practical demonstration of the CNT device, simple fabrication method of series connection is the most powerful aspect of continuously drawable nanotube sheet, which is simply completed by one-step winding of CNT sheet on the polyethylene terephthalate (PET)/copper foil/PET laminated substrate. As a practical demonstration of the CNT device, we have demonstrated CNT sheet based self-powered motion sensor for tracing finger movements. Coulombic interaction between finger and free charge carriers in CNT sheet induces efficient charge carrier transfer via electrostatic attractive force. Effective motion sensing for moving direction and speed is possible by detecting its electrical output. Motion sensing and energy harvesting are simultaneously available, thus external power source is not needed because of its ability to provide electrical power by itself. This fundamental studies has great significance in dry-state energy harvesting using nano carbon material which is quietly distinct from previously reported liquid-based energy harvesting studies. Furthermore, suggested self-powered motion sensor can read finger movements (just like a finger commend in a smart phone), requiring no need of touch panels.

Enhancement of Electrical Conductivity of Carbon Nanotube Fibers by Nitrogen Doping with Plasma Treatment Seunghi Hong1, Bon-Cheol Ku1, Yoong Ahn Kim2 and Jun Yeon Hwang1; 1Institute of Advanced Composite Materials, Korea Institute of Science and Technology (KIST), Wanju, Korea (the Republic of); 2Department of Polymer Engineering, Graduate School, Chonnam National University, Gwangju, Korea (the Republic of).

Carbon nanotube(CNT) fiber has been substantially realizing the outstanding property of the individual CNT (high strength, light weight, electrical conductivity...) in bulk materials. Due to superb intrinsic properties, CNT fibers are promising for alternative of metal wire. However, there is still challenging for commercialization of CNT fibers. One of major difficulties is CNT-CNT contact resistance, which decreases the electrical conductivity of CNT fibers. To overcome this drawback, nitrogen doping is an effective way to enhance the intrinsic conductivity of CNT fibers by increasing electron carrier density. As for typical doping process, not only quaternary N(NQ) electron donor but also pyridinic(Npy) and pyrrolic(NPyrr) nitrogen types are achievable. Since NQ and Npy, localize electrons resulting in increasing the electrical resistance, controlling the doping site of nitrogen is critical issue. In this study, NQ and Npy types were selectively removed by acidic reduction process without oxidation. The acid treated CNTs showed liquid crystalline behaviors, which can be directly spinning of CNT fibers without complex process. We have verified the improved electrical properties of CNT fiber related with bonding types of nitrogen in CNT fibers.

NM01.15.68

Perfect absorbers have many application in different fields including photovoltaic, antireflective rular absorption coatings for defence, energy harvesting and emissivity control. Here, we design and fabricate a near perfect optical broadband absorber, having absorption capacity of 99.4% from 300 to 2000 nm wavelength range. Etched Silicon wafer is used as base layer to fabricate multilayered optically graded assembly, while carbon nano tubes layer used as a top layer for impedance matching. Subsequent layers are selected as per increasing refractive index and varying micro/nano features for efficient light trapping. Less than 1% of reflectivity in entire range up to 50° beam angle has been observed. Moreover multilayered assembly shows contact angle of more than 160° with roll-off angle of less than 5° which showed that it is not only a near perfect absorber but also a self-cleaning superhydrophobic surface. Conclusionly, the properties of multilayered optically graded assembly impacts attractive applications of this superabsorber in the field of photovoltaic.

NM01.15.69
Spatially Resolved Solid-State Reduction of Graphene Oxide Thin Films for Anti-Fuses Maica Morant-Miñana1, Klaus Mullen1, Dago De Leuven2 and Karmel Asadi1; 1Max-Planck Institute for Polymer Research, Mainz, Germany; 2CIC energiGUNE, Miñano, Spain; 3Delft University of Technology, Delft, Netherlands.

The current paradigms at both the industrial and research level produce reduced graphene oxide (rGO), an imperfect form of graphene, only in the bulk form. For a wide range of applications, from microelectronics to water permeation, spatially resolved and controlled reduction of GO in (thin-) film is needed. Such applications require a paradigm shift in the reduction process, which should be free from intentionally used auxiliaries such as electrolytes and high temperatures.
Reestablishment of electrical conductivity in GO, is (partially) obtained by reduction through high temperature treatment in a reducing atmosphere, or using strongly reducing chemicals or electrolytic processes. The reduction methods are suited for bulk graphene oxide. Spatially resolved reduction of thin films of graphene oxide is important for wide range of applications such as in microelectronics, where an electrolyte-free, room temperature reduction process is needed. We present spatially resolved solid-state reduction of graphene oxide thin films. We show that the reduction mechanism is based on electrolysis of water that is adsorbed on the graphene oxide thin film. The RGO is obtained at room temperature with spatial resolution simply by application of voltage. The reduced graphene oxide thin-films show sheet resistance of only several kOhm, with weak temperature dependence. Graphene oxide can be produced on a large scale and processed using low-cost solution coating techniques. Spatially resolved reestablishment of conductivity in GO can be used in electrically controlled water permatation or in micro- and nanoelectronic applications for instance as an anti-fuses.

NM01.15.70
Study of the Vibrational Properties of Linear Carbon Chains Encapsulated by CNTs at Low Temperature Nathalia L. Coim1, Wellington Q. Neves2, Paulo T. Araujo2, Alexandre R. Paschoal2 and Antonio G. Souza Filho1; 1Physical, Univeersidade federal do Ceará, Fortaleza, Brazil; 2Instituto Federal de Educação, Ciência e Tecnologia do Ceará - IFECE, FORTALEZA, Brazil; 3Physics, The University of Alabama, Tuscaloosa, Alabama, United States.

Linear carbon chains, also known as carbones, are essentially one-dimensional (1D) systems that present carbon sp hybridization. The research involving linear carbon chains has been a hot topic in recent years mostly due to their unique properties and potential for technological applications. These chains are highly unstable under ambient conditions, but the internal volume of the nanotubes offers ideal conditions for stabilizing such systems. Techniques of encapsulation by DCWNTs and MWNTs have been successful to produce long linear carbon chains with lengths reaching several hundreds of nanometers. In this work, a systematic investigation has been conducted on linear chains of carbon encapsulated by double- (Cn@DWCNT) and multi-walled carbon nanotubes (Cn@MWCNT). Temperature studies in such materials are important for considering possible applications under extreme conditions (e.g. space and nuclear reactors). Our preliminary studies using low temperature Raman spectroscopy investigations of Cn@MWCNT-Bulk (300K at 20K) showed that the band frequency of the chains (~1,800 cm⁻¹) increased when the temperature was reduced. However the results seem to indicate an anomaly in the frequency behavior for temperatures below 60K, in which a decrease of the Raman frequency takes place with decreasing the temperature. We also observed that the frequency variations are reversible in the range of temperatures from 4K to 300K. To investigate this effect in detail, these studies will be conducted at the individual level. In other words, both Cn@DWCNTs and Cn@MWCNTs will be isolated and then investigated under low temperature. Dispersion of these materials has been successfully attained and isolated species have been confirmed by Atomic Force microscopy (AFM) measurements and Raman spectral features.

NM01.15.72

Graphene, a one-atom-thick sheet of carbon atoms arranged in a honeycomb-like pattern lattice, has attracted much attention owing to its potential applications in the fields of electricity, conductivity, energy generation, batteries. Intensive recent studies report the wetting transparency of graphene, suggesting that the wettability of graphene is partially governed by the underlying substrate and is more hydrophobic with increasing the number of graphene layers. This infers that its surface energy is decreased with increasing the number of graphene layers. Amongst those studies, the static contact angle measurement is a highly employed method for characterizing the graphene surface wettability; however, this technique requires large scale surface coverage of graphene to contact the milliliter size of water droplet at the solid-liquid interface. This is rather challenging since one cannot precisely control the number of graphene layers at the contact line. This challenge is often ignored despite being the origin of the uncertainty in the measurements that have led to contradictory interpretations. In order to shade light to this controversy, we combine bimodal atomic force microscopy [1] and micro-Raman spectroscopy to measure the surface energy of the graphene surface on different substrates. It is well-known that the number of graphene layers can be determined by the ratio of 2D to G peak in the Raman spectra. Therefore, the graphene sample is fabricated by using a designed two-step chemical vapor deposition method, which has large enough area of monolayer, bilayer and multilayer of graphene on the substrate, respectively. This deposition enables us to precisely measure the same area of graphene sample by using AFM and micro-Raman spectroscopy. Our experimental results show that in contradiction with graphene wettability transparency theory, the derived graphene surface energy increases with increasing the number of graphene layers. We also use density functional theory to directly predict the surface wettability of graphene on different substrate based on [2] and obtain results that qualitatively agree with our AFM experimental characterization.

NM01.15.71
Enhancing Thermal Conductivity and Mechanical Performance of PLA/PBAT Blends with Boron Nitride and Graphene Xianghao Zuo1, Yuan Xue1, Frederick Nitta2, Jinghan Tang3, Vicki Xu4 and Miriam Rafailovich1; 1Stony Brook University, Stony Brook, New York, United States; 2Henry M. Gunn High School, Palo Alto, California, United States; 3Mater Dei High School, Santa Ana, California, United States; 4Mission San Jose High School, Fremont, California, United States.

Thermal management is critical to the continually growing electronics industry to prevent devices from overheating and losing their functionality. As low-cost, lightweight, and highly versatile materials, polymers exhibit great potential for heat exchange applications, but their low thermal conductivity is a barrier to their effectiveness. Additive fillers are usually added into polymers to help enhancing the thermal conductivity.

In this study, we investigated the thermal conductivity of blends of PLA (polylactic acid) and PBAT (polybutylene adipate terephthalate) with graphene nanoplatelets (GNPs) and hexagonal boron nitride (hBN). It is hypothesized that the thermal conductivity of the PLA/PBAT nanocomposite would be elevated when adding the fillers compared to neat polymer blends. Contact angle measurements between polymer droplets on hBN and GNP layers deposited on a silicon wafers were used to determine the polymers’ relative affinities for the fillers. The calculation of the word of adhesion between fillers and polymers indicates that both hBN and GNP exhibited more affinity for the PBAT phase than the PLA phase, which means the fillers would be interspersed in the PBAT phase. PLA/PBAT blends with various concentrations of hBN powder and GNP were blended at 180 using a twin-screw mixer at 150 rpm. The thermal conductivity of PLA/PBAT and PBAT blends with hBN alone was tested at the beginning. Slow increase in thermal conductivity with increasing weight fraction of hBN was obtained. To better enhance the thermal conductivity, considering that we have demonstrated that with the larger size of the fillers which meet the size of the domain in the
polymer matrix, they will have a better arrangement, we decided to apply Graphene H-1-5 in the blends to make some new attempts. The results show that as the GNP content of the nanocomposite increased relative to the hBN content, the thermal conductivity increased significantly. Then, the samples were molded into different sizes to test the impact and tensile properties. The mechanical data indicates that although the combination of hBN and Graphene can help increasing the thermal conductivity significantly, it is difficult to maintain the mechanical properties. Therefore, to enhance the thermal conductivity of the polymer blends with relatively high mechanical performance is a new challenge. We did mechanical tests separately with PBAT/PLA/hBN and PBAT/PLA/GNPs and found that hBN can better maintain the mechanical properties. Thus, we tried different ratios of hBN and graphene and kept the total amount of the filler at 30 wt%. The results show that even 3% of hBN can help maintaining the impact toughness at 85.62 J/m, which is pretty high value that meets the demand for most of the applications.

SESSION NM01.15.73
A Novel Non-Enzymatic PEDOT:PSS/GO/MnO2 Based Biosensor for Hydrogen Peroxide Detection in Biological Samples Vedashree Sirdeshmukh1, Shreshita Mishra1, Indrayani Kadam1 and Amap A. Kale1; 1College of Engineering Pune, Pune, India; 2Applied Sciences, College of Engineering Pune (T.OEP), Pune, India.

Hydrogen Peroxide (H2O2) is a well-known reactive oxygen species produced in various biological phenomena. In various pathological and physiological conditions, higher concentrations of H2O2 can cause lipid peroxidation, DNA base modification, protein degradation etc. H2O2 present in quantities of about 20-50 µM or more can have deleterious effects as it can easily dissolve in aqueous solutions and penetrate biological membranes easily. Hence, sensitive and selective detection of H2O2 is important under physiological conditions.

In this work, we report on a non-enzymatic electrochemical method for the facile and sensitive detection of H2O2. We explored the approach of conducting polymer-nanocomposite as efficient transducer platform. We synthesized three-phase composite polymer system of PEDOT:PSS/GO/MnO2, comprising poly(3,4-ethylenedioxythiophene): poly(styrene-sulfonate) (PEDOT:PSS), graphene oxide (GO) and manganese dioxide (MnO2). On being exposed to H2O2, MnO2 undergoes a redox reaction which is responsible for the sensing ability of this material. The composite was prepared using the conventional solution mixing method and then used to modify screen printed electrodes. The physicochemical characterization was carried out using Scanning Electron Microscopy, UV-Visible Spectroscopy, Raman Spectroscopy and Fourier Transform Infrared Spectroscopy. Cyclic Voltammetry results showed that the nanocomposite showed high electrochemical activity for the detection of hydrogen peroxide (H2O2) in alkaline medium. The PEDOT/GO/ MnO2 based electrode exhibits high sensitivity and selectivity for electrochemical detection of H2O2 with a sensitivity of 0.5µM. The present study demonstrates that such a novel nanocomposite is promising for fabrication of non-enzymatic H2O2 biosensors. This method can further be explored for Point-Of-Care detection.

SESSION NM01.16.01
From Energy Harvesting to Living Plants—Concepts in Biosensing and Energy Conversion Using Carbon Nanomaterials Michael Strano; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Our lab at MIT has been interested in how the 1D and 2D electronic structures of carbon nanotubes and graphene respectively can be utilized to advance new concepts in molecular detection, as well as energy generation. By taking advantage of the exceptional electronic properties of these nano-structures, we continue to discover potential application spaces where carbon can play an important role. For example, we have pioneered a novel technique called Corona Phase Molecular Recognition, or CoPhMoRe, for discovering synthetic, heteropolymer corona phases that form molecular recognition sites at the nanoparticle interface. By screening libraries of synthetic heteropolymers chemically adsorbed onto single-walled carbon nanotubes (SWNT), we have engineered new optical biosensors that exhibit high selective recognition for bio molecules, such as riboflavin, L-thyroxine, dopamine, nitric oxide, sugar alcohols, estradiol, and fibrinogen. These results have significant potential for using SWNT-based sensors to interface to biological systems, allowing monitoring pathways at the sub-cellular, cellular, tissue, and whole-animal scale. I will also highlight our recent efforts in initiating an endeavor we call “Plant Nanobionics”. We use these techniques to deliver and transport functional nanoparticles into living plants to grant them non-native functions. Our goal is to engineer plants to take over many of the functions now performed by electrical devices. I will introduce the nanoparticle co-localization mechanism in a plant, and highlight some of our recent nanobiotic plant prototypes including a light-emitting plant. Lastly, I will briefly describe several applications of carbon nanomaterials in the energy space that have come out of our lab. There is a pressing need to find alternatives to conventional energy generation techniques, specifically those that rely on elements in finite global supply. We introduce Asymmetric Doping Cells (ADC), which convert chemical potential to electrical energy by means of spatially selective doping along a nanostructured conduit or particle. These ADCs have applications to energy harvesting from aqueous and organic solvents, as well as electro-catalysis for chemical synthesis. An inverse length-scaling of the maximum power as L−1.03 that creates specific powers as large as 30.0 kW kg−1 highlights the potential for microscale energy generation. We also introduce carbon materials for what we call thermal resonators that make use of thermal storage elements with high effusivity – the product of the thermal conductivity and heat capacity to the one half power. Thermal resonators base on carbon can harvest energy indefinitely from ambient thermal fluctuations of various frequencies, opening new possibilities for remote applications.

SESSION NM01.16.02
Overcoming Efficiency Limits of Carbon Nanotube-Laminated Metal-Free Perovskite Solar Cells Using 3D/2D FAPbI3 Will Jones1, Jin-Wook Lee2, Esko Kauppinen3, Yang Yang2, Yutaka Matsuo1, 4 and Maruyama Shigeo1; 1The University of Tokyo, Minato-ku, Japan; 2University of California, Los Angeles, Los Angeles, California, United States; 3Aalto University, Aalto, Finland; 4USTC, Hefei, China.

Perovskite solar cells (PSCs) have progressed remarkably through a heated power conversion efficiency (PCE) race. With a surge of research efforts, the certified PCE of the lab scale PSCs increased to 22.7% for last 5 years. Now the research efforts are being focused on enhancing the durability of the devices and reducing the production cost. PSCs typically require a metal electrode is thermally evaporated on top to serve as a counter electrode. These top metal electrodes, however, are known to substantially increase the process and material cost as expensive gold or silver layers are deposited under high vacuum. Furthermore, the metal electrodes are found to be not robust enough to render long-term stability of the PSCs as the metal ions migrate into the bulk of the device under an operational condition to react with the active materials, thus degrading the device.

As an alternative to the metal electrodes, researchers have incorporated single-walled carbon nanotubes (CNTs) into the PSC system. The CNT is a
favorable electrode material, owing to its hydrophobic nature, earth-abundance, and mechanical robustness. The application of CNT realizes CNT-based PSCs with good stability and versatility. Among the reported CNT-used PSC devices, aerosol-synthesized CNT top electrode (or back electrode) replacing metals in PSCs has shown the most promising potential. The application of CNT as the top electrode substantially enhances the stability of PSCs by removing the ion migration, and drastically reduces the fabrication cost as it can be easily deposited onto devices by a simple mechanical transfer. Despite such advantages, there are three factors limiting the PCE of the CNT top electrode-based PSCs that need to be addressed: 1) the work function of the CNT does not align with the perovskite, leading to loss in potential 2) CNT top electrode is less conductive than the metal counterparts, limiting the fill factor of the devices 3) the CNT back electrode is not reflective that the devices cannot maximize the light harvesting efficiency. In this work, we addressed those three issues by engineering CNT electrode and photo-active layer. We tuned the work function of CNT electrodes and increased their conductivity by using a vapor-assisted doping of trifluoromethanesulfonic acid (TFMS). Furthermore, by incorporation of Cs-based 2D perovskite-added low bandgap formamidinium perovskite, we enabled the harvesting of long-wavelength light, enhancing the photocurrent of the devices. By combining those technologies all into one device system, CNT electrode-based PSCs produced a PCE of 17.6% with a $J_{SC}$ of 24.21 mA cm$^{-2}$, $V_{OC}$ of 1.005 V, and FF of 0.72. The obtained PCE is the highest among the values reported from CNT top electrode-based PSCs. Moreover, the resulting CNT-PSCs exhibited higher high-temperature operational stability than those of the devices based on metal electrodes as well as conventional CNT electrodes.

Electricity Generation from Interface Between Flowing Water and Graphene 
Takeru Okada1, Golap Kalita2, Masaki Tanemura2, Ichiro Yamashita2, M Meyyappan1 and Seiji Samukawa1; 1Tohoku University, Sendai, Japan; 2Nagoya Institute of Technology, Nagoya, Japan; 3Osaka University, Osaka, Japan; 4NASA Ames Research Center, Moffett Field, California, United States.

Since the global energy demands are rapidly increasing, energy harvesting from the environment has received much attention. Environmental energy sources such as sunlight, wind, vibration, heat, and flow have been exploited to various extents for electricity generation. Among them, water flow exists in various forms and has potential for developing electricity generators. The interface between flowing water and graphene also shows potential of electricity generation. The energy harvesting by flowing water along the interface of graphene has been studied. The mechanisms proposed to date are still not deterministic, however, surface conditions are key factors for the understanding of the physical mechanism and maximizing the performance. The surface conditions include electric potential at the phase interface and wettability of graphene, both of which can be tuned by heteroatom doping. In this paper, the role of the surface condition of graphene on flow-induced electricity generation is investigated by heteroatom doping.

Nitrogen-doped graphene was used to investigate the role of surface condition on electricity generation. Characterization of the nitrogen doped graphene was carried out by x-ray photoelectron spectroscopy and Raman spectroscopy. In our typical experiment condition, at least 70 % of the doped nitrogen was graphic nitrogen. Atomic concentration of nitrogen was approximately 1 %. The electricity was studied with transferred graphene and deionized (DI) water droplets by manually dropping the droplets (0.1 ml). Pristine graphene shows approximately 80 mV and the highest voltage from nitrogen-doped graphene was approximately 380 mV, thus more than 3 times higher voltage generation was observed.

The enhancement of voltage generation by nitrogen doping is explained as follows. The electronic state of the nitrogen-doped sites is considered to have an important role. Nitrogen doping of carbon in various applications acts as an electron donor by providing the unshared electron pair of nitrogen in graphene. The local charge of graphic nitrogen is positive and that of the surrounding carbon atoms is negative. This is explained by the electron transfer from nitrogen atom. The inside of the droplet sitting on top of graphene is affected by the negative charge on the graphene surface, leading to potential formation at the interface. The induced negative charge reduces electric double layer at the interface, resulting in the formation of steep potential [1].

We have investigated the effect of graphene doping on flow-induced power generation between graphene and water interface and found that the nitrogen-doped graphene shows enhancement of power generation. The surface charge of the nitrogen-doped graphene reduces the electric double layer thickness, resulting in the formation of a steep potential, which contributes to higher power generation.

9:30 AM NN01.16.04
Advancement of High Conductivity Carbon Conductors Brian Landi; Rochester Institute of Technology, Rochester, New York, United States.

Macroscopic assemblies of carbon nanotubes (CNTs) in wire format have been proposed for a variety of applications including power and data transmission for both aerospace and terrestrial scenarios. Wires fabricated from CNTs have demonstrated superior flexure tolerance, weight savings, and corrosion resistance over their traditionally used metal counterparts. Current research is focused on translating the exceptional electrical properties of individual CNTs to bulk CNT wires through fabrication technologies like extrusion and densification, chemical doping, and metal-incorporated hybrids. In this talk, a summary of CNT conductors being advanced from high-purity laser-vaporized single wall carbon nanotubes (SCWNTs) as well as commercial CNT materials will be provided. Acid dispersion and extrusion of SCWNTs into a coagulant bath has been used to fabricate wires, with the coagulation dynamics shown to govern the resulting wire structure leading to electrical conductivities of 5-11 MS/m. Alternative approaches to enhance CNT electrical conductivity have been demonstrated using IBR chemical doping whereby low-dipole moment solvent systems favor the IBR-CNT interaction over the IBr-solvent and the solvent-CNT interactions. Recent work has also utilized densification and chemical doping with KAuBr4 to improve the conductivity of commercially scaled CNT yarns by 6x, while increasing the current density at failure by 67% to 35 MA/m2 in air. The thermal stability of KAuBr4 is proposed to provide the greater electrical stability at elevated current levels. Lastly, site-selective copper nanometal seeding through chemical vapor deposition (CVD) is demonstrated as a viable method in concert with solution electodeposition of bulk Cu to enhance the electrical conductivity of a low-density CNT rope. A Cu-CNT hybrid conductor has achieved a specific conductivity of 5632 Sm2/kg and electrical conductivity of 28.1 MS/m. A summary of high-current behavior and limitations to the current carrying capacity of these wires in air due to oxidative failure will be presented. Maximum current densities for SWCNT wires in a helium environment exceed fuse-law behavior for aluminum wires of equivalent diameter. The progress and opportunities for continued advancement of carbon conductors will be highlighted.

10:30 AM NN01.16.05
Tailoring Electronic Structure of SWCNTs for Transparent and Conductive Film Applications Alexey Tsapenko1, Daria Kopylova1, Alena Alekseeva2, Fedor Fedorov1, Evgenia Gilshetyn1, Vsevolod Iakovlev1, Pramod Rajanna1 and Albert Nasibulin1, 2; 1Skolkovo Institute of Science and Technology, Moscow, Russian Federation; 2Aalto University, Espoo, Finland.

Single-walled carbon nanotubes (SWCNTs) are among the strongest candidates for the replacement of commonly used transparent and conductive films (TCFs) based on doped metal oxides, such as indium tin oxide (ITO). SWCNTs possess unique multifunctional nature, which is based on their outstanding combination of mechanical strength and flexibility, chemical stability, exceptional electrical conductivity and optical properties [1]. However, to fully utilize these properties in modern transparent electrode applications, SWCNT-based TCFs have to demonstrate the optoelectronic performance at the level of high-end ITO-based TCFs. This has not been achieved for SWCNT films yet and as a result limit their practical usage. Using gold chloride as the most effective dopant for the SWCNTs, we improve their optoelectrical characteristics by optimizing the doping solvent and
Carbon nanotubes are widely regarded as very promising heat conductors. Although that is certainly true for individual carbon nanotubes [1-3], the situation is not that simple for carbon nanotube networks [4,5]. The way the heat is transported through the material is highly dependent on the carbon nanotube alignment, length, purity and other parameters. In fact, the influence is so strong that the spectrum of reported thermal conductivities for carbon nanotube networks ranges from thousands or hundreds of W/mK down to values lower than unity. In this contribution, we would like to show how careful surface modification enabled us to tune the thermal conductivity of the material. Free-standing carbon nanotube films of different composition and microstructure were manufactured and their thermal properties were measured by the previously reported method [6]. The results show a big potential of carbon nanostructures for a wide range of thermal management applications.

Conventional protective garments are passive protection systems that sacrifice breathability (i.e. inhibit water vapor transport) to prevent exposure to hazardous agents. This trade-off leads to overheating in extended wear of protective clothing and severely limits the duration of their active use. For in-the-field personnel protection from chemical and biological (CB) agents, smart dynamic materials are highly desirable that exhibit a reversible, CB-triggered, rapid transition from a breathable state to a protective state. Materials of this type are expected to be particularly effective in mitigating physiological burden because a less breathable but protective state can be actuated locally and only when needed.

To achieve adaptive protection and simultaneous thermal comfort, we have developed a chemical threat responsive material based on a surface-functionalized carbon-nanotube (CNT)-membrane, in which vertically-aligned CNTs function as the only pores in a polymeric barrier film. Upon exposure to a chemical warfare agent (CWA), responsive polymers grafted at the membrane surface collapse and close the CNT pore entrance to CWA permeation, thus enabling the membrane to switch from a highly breathable state to a protective state.

To demonstrate this concept, we first fabricated membranes with sub 5-nm CNT pores and quantified their breathability and rejection properties before functionalization with CWA-responsive polymers. Our results show that these membranes provide MVTR up to 11,000 gr/m²/day, thus exceeding state-of-art breathable fabrics (eVent, GoreTex, etc.) even if the moisture conductive pores are only a few nm wide. Measured water-vapor permeability in 1.9-nm CNT channels under a relative humidity gradient is ~100 times larger than Knudsen diffusion prediction, and this flow enhancement decreases for larger diameter tubes. Complete rejection of 3-nm charged dyes, 5-nm uncharged gold nanoparticles, and ~40-60-nm Dengue virus from aqueous solutions during filtration tests demonstrate that our CNT membranes provide a high degree of protection from bio-threats by size exclusion.

Then, we covalently grafted actuating polymers responsive to G-agent simulants to the surface of these CNT membranes. Upon exposure to simulants, these membranes switch from a breathable state with MVTR>4,000 gr/m²/day to a protective state with MVTR>1,000 gr/m²/day. Permeation tests reveal that simulant transport is reduced by 1-2 orders of magnitude in the protective state. Finally, we demonstrated that a simple base treatment reopens the CNT pores effectively and that regenerated membranes can be re-used for multiple cycles without performance loss.
Plasma Functionalized Defected Single-Walled Carbon Nanotubes as Promising Material for Gas Sensing Application

Alena A. Alekseeva¹, Fedor S. Fedorov¹, Daria S. Kopylova¹, Stanislav Evlashin¹, Anton Anisimov² and Albert Nasibulin¹; ¹Skolkovo Institute of Science and Technology, Moscow, Russian Federation; ²Canatu, Moscow, Finland.

Mobile gas sensors operating at room temperature with low power consumption, high sensitivity and selectivity are required in many industries as well as in everyday life namely for detecting explosive, combustible and toxic gases, food and air quality monitoring. The main element of the gas sensor is its’ sensitive material which determines sensors’ sensitivity, selectivity, response time and signal recovery, operation temperature and stability. Single-walled carbon nanotubes (SWCNTs) is a unique material for gas sensors application. Coupled with chemical, thermal and mechanical stability, SWCNTs have large specific surface area with all carbon atoms located on their surface making them exceptionally sensitive for adsorption of gases at room temperatures. In this work we propose a simple approach of SWCNTs low frequency plasma treatment, which on the one hand introduce defects into the structure of nanotubes, which increases gas adsorption and thus increase sensitivity. On the other hand, it allows to obtain different functional groups on SWCNTs surface depending on the plasma atmosphere to increase selectivity of the material. In this study we investigate SWCNTs conductivity upon adsorption of inorganic gases such like carbon monoxide, nitrogen dioxide and ammonia, and assess the optimal operation temperature and gas concentration detection limits. Particularly, we present the study of oxygen plasma treated SWCNTs with induced defects and oxygen containing groups on its surface which increase SWCNTs sensitivity to such gases as carbon monoxide (respond is 0,5%), nitrogen dioxide (respond is 15%), ammonia (respond is 1.5%), hydrogen disulfide (respond is 0.8%) at room temperature.

All Solution-Processed p-n Junction Diodes

Daisuke Yamamoto¹, Takayuki Arie¹, Seiji Akita¹ and Kuni Takei¹, ²; ¹Osaka Prefecture University, Sakai, Japan; ²JST PRESTO, Chiyoda, Japan.

Solution-based device fabrications are now of great interests due to attractive applications of printed flexible and stretchable electronics, which are required to form active components on an amorphous film using deposition and/or printing methods. However, due to difficulties of both p-type and n-type semiconductor formations on a film, most of the studies reported previously are based on Schottky diodes and transistors. To address this bottleneck and challenge, we here propose a solution-based p-n junction diode using developed IZO film and CNT network film formation and integration techniques as n-type and p-type semiconductor materials, respectively. Furthermore, barrier height between IZO and CNT films are also discussed based on the experimental results.

p-n junctions were formed by all solution process on Si/SiO₂ substrates. First, an IZO precursor was spin-coated on the SiO₂ surface with oxygen plasma treatment. After spin coating, it was cured at 300 °C in air ambient. After patterning the IZO film, semiconductor-enriched CNT solution was deposited by using van-der Waals interaction between the chemical-treated SiO₂/IZO surfaces and CNTs. After cleaning the substrate, Ag electrodes were painted on IZO and CNT films. Finally, the samples were annealed at 150 °C in N₂.

Transistor behaviors of IDS-VGS using Ag source-drain electrodes and a global back gate were measured. IZO and CNT transistors shows relatively good n-type and p-type behaviors, respectively, with high ON/OFF current ratio of >10⁴. Next, CNT/IZO p-n junction diode was characterized. Based on the results, good rectified behaviors with >10⁴ forward/backward current ratio were observed. After confirming the diode behaviors, barrier height of IZO and CNT was determined by measuring the diode characteristics as a function of temperature. From the experimental results and calculations, the barrier height of them was ~200 meV, which is in good agreement with the theoretical band alignment of CNT and IZO.

In conclusion, we developed p-n junction diode and analyzed the barrier height of CNT and IZO junctions. These material systems will be applied for the flexible devices in near future.
Nanoparticles play a central role in the rapidly growing nanoscience and nanotechnology fields. Atomic level tailoring of nanoparticles is of great importance in order to map out the structure-property relationships. Recent success in the synthesis of atomically well-defined nanoparticles has offered exciting opportunities to pursue many fundamental issues that were difficult to tackle with polydisperse nanoparticles. This talk will present several cases of single-atom, single-electron level manipulations of metal nanoparticles, such as doping a single Ag or Cu atom into a gold nanoparticle and site-specific “surgery” of surface motifs of a nanoparticle with controlled charge state. Such atomic-level manipulations provide unique opportunities for investigating how the structure and composition precisely impact the particle’s properties and functionality at the single-atom, single-electron level. New strategies for achieving such goals have been devised. Overall, the pursuit of single-atom level tailoring opens up new opportunities for controlling nanoparticles on an atom-by-atom basis.

Total synthesis, where desired organic- and/or bio-molecules could be produced from simple precursors at atomic precision and with known step-by-step reactions, has prompted centuries-lasting bloom of organic chemistry since its conceptualization in 1828 (Wöhler synthesis of urea). Such expressive science is also highly desirable in nanoscience, since it represents a decisive step towards atom-by-atom customization of nanomaterials for basic and applied research. Although total synthesis chemistry is less established in nanoscience, recent years have witnessed seminal advances and increasing research efforts devoted into this field. In this talk, I will discuss our recent work on introducing and developing total synthesis routes and mechanisms for atomically precise metal nanoclusters (NCs). Due to their molecular like formula and properties (e.g., HOMO-LUMO transition, strong luminescence and stereochemical activity), atomically precise metal NCs could be regarded as “molecular metals” (or metallic molecules / molecular-like metals), holding potential applications in various practical sectors such as biomedicine, energy, catalysis and many others. More importantly, the molecular-like properties of metal NCs are sensitively dictated by their size and composition, suggesting total synthesis of them as an indispensable basis for reliably realizing their practical applications.

In recent years, it has become possible to synthesize gold clusters, silver clusters, and alloy clusters with atomic precision using thiolate or phosphine (PR3) as a ligand. The electronic/geometric structures and size-specific physical/chemical properties of these metal clusters have also been investigated extensively. Similar to these metal clusters, platinum (Pt) clusters have also attracted much interest. An attractive feature of Pt clusters is their high catalytic activity in a variety of reactions. In the precise synthesis of these Pt clusters, carbon monoxide (CO) or PR3 is used as the main ligand. However, little information has been obtained on the electronic structure and physical/chemical properties of Ptn(CO)m(PR3) clusters to date. In this research, the final objective is to obtain experimental information about the largely unknown electronic structure of Ptn(CO)m(PR3) clusters. To this end, we precisely synthesized a Pt17 cluster ([Pt17(CO)12(PPh3)8]+; n = 1, 2) protected by CO and triphenylphosphine (PPh3) by a simple method and studied its geometric and electronic structure. Mass spectrometry, elemental analysis, and single-crystal X-ray structural analysis of the product revealed that the obtained Pt17(CO)12(PPh3)8 comprises positively charged [Pt17(CO)12(PPh3)8]+ and [Pt17(CO)12(PPh3)8]+; having a geometric structure similar to that of neutral Pt17(CO)12(PPh3). The optical absorption spectroscopy and electrochemical measurements of [Pt17(CO)12(PPh3)8][SbF6] (n = 1, 2) demonstrated that [Pt17(CO)12(PPh3)8][SbF6] (n = 1, 2) has a discrete electronic structure. Furthermore, the emission spectroscopy revealed that [Pt17(CO)12(PPh3)8][SbF6] (n = 1, 2) exhibits photoluminescence in the near-infrared region. In this presentation, I also talk about our recent results on the precise synthesis and one-dimensional structures of alloy clusters including Pt element.
space is further broadened, new cluster compositions, structures and interfaces can be discovered. We will provide an atomic-level view of alkynyl-protected gold nanoclusters. The syntheses of a series of gold nanoclusters with “direct reduction” method will be reported. The total structure determination of these clusters will be described. The stability and optical properties of these nanoclusters will be discussed based on electronic structural analysis. In addition, ligand effects on the catalytic performance of gold nanoclusters will be presented. We believe the success in these systems will stimulate more effort in discovering new aspects this class of gold nanoclusters with alkynyl groups in the protective layer.

11:15 AM NM02.01.06 Overview of the Ligand-Gold Interfaces and the Case of the N-Heterocyclic Carbenes De-en Jiang; University of California, Riverside, Riverside, California, United States.

Ligands play an important role in the stabilization and functionalization of Au nanostructures and in self-assembled monolayers. Despite the increasing number of organic groups capable of stabilizing gold in addition to the popular thiolate ligands and the emerging alkynyl groups, there has been no systematic comparison of organic ligands regarding their binding strength to gold. To facilitate the future experimental design of promising ligands for gold surfaces, nanostructures, and nanoclusters, we provide a comprehensive view of the ligand-gold interface for six types and 27 ligands from first principles dispersion-corrected density functional theory. We find a surprising contrast between simple and bulky N-heterocyclic carbenes (NHCs). The bulk NHCs benefit from greater van der Waals contributions and additional Au—H-R hydrogen bonds. In fact, we find that alkynyl groups and bulky NHCs demonstrate the strongest binding with the gold surfaces. We further explore the computational design and show the viability of NHC-protected gold nanoclusters of magic stability. The overall trend from the present work not only confirms the emerging role of alkynyl ligands but also predicts the very promising direction of using bulky NHCs to achieve stable gold nanoclusters and interfaces.

11:30 AM NM02.01.07 Structural Control of Quaternary Ammonium Cationic Gold Nanoclusters Tetsu Yonezawa, Yohei Ishida, Mai Thanh Nguyen, Kunihiro Narita and Ryan D. Corpuz; Hokkaido Univ, Sapporo, Japan.

Quaternary ammonium is a cationic group which is always show positive change at any pH conditions. Many reports have been published on thiolate-gold nanoclusters but almost all of them were covered by non-ionic or anionic thiol compounds. Only a few reports of amino-thiol-stabilized gold nanoclusters can be found but no report of quaternary ammonium thiolate-stabilized ones. For the first time, we prepared quaternary ammonium-stabilized fluorescent gold nanoclusters by sputtering processes. Furthermore, we have successfully prepared Au25 clusters stabilized by quaternary ammonium thiol. In this case, counter anion plays an important key. Bromides cannot well stabilize Au25 clusters and they decomposed rapidly. But after changing this counter anion to PF6- or other soft anions, very stable fully cationic Au25 nanoclusters could be obtained.

11:45 AM NM02.01.08 Tailoring the Atomic Structure of Gold Nanoclusters by Doping—Using an 23-Gold-Atom Nanocluster as an Example Qi Li and Rongchao Jin; Carnegie Mellon University, Pittsburgh, Pennsylvania, United States.

In this work, we demonstrate three different doping modes when an atomically-precise nanocluster: \([Au_{23}(SR)_{16}]^-\) is doped with different metals (Cd, Cu, Ag), including (i) simple substitution, (ii) surface reconstruction and (iii) total structure transformation. Both experimental and theoretical results demonstrate that the dopant concentration is critical: the original structure of \([Au_{23}(SR)_{16}]^-\) is retained under slight doping, but it starts to change under high concentrations of Cd and Ag dopants. Our results suggest that doping in nanoclusters is not just a simple substitution of original atoms or filling a vacant site; instead, it can be explored as a useful method to tailor the structure of nanoclusters partially (e.g., Cd doping of Au23) or totally (e.g., Ag doping of Au23). Overall, this work greatly expands doping chemistry for tailoring the structures of nanoclusters and is expected to open new avenues for designing nanoclusters with novel structures using different dopants.
Ultrasmall nanoparticles with a diameter below 2 nm are promising as specialized carriers for targeted drug delivery. Functionalized with specific binding motifs, they open up innovative opportunities in a wide range of applications, e.g., nanomedicine. A possible application is the specific targeting of protein-epitopes. A versatile approach to the functionalization with specific epitope-binding motifs, i.e., peptides and proteins, is covalent binding of the gold-surface with sulfur-containing molecules. NMR spectroscopy gives valuable insights into the characteristics of the binding situation on the surface.

L-cysteine as a typical sulfur-containing biomolecule was chosen to elucidate the binding of ligands to ultrasmall gold nanoparticles (d < 2 nm). Cysteine is the only thiol-containing amino acid and therefore an ideal model compound for the binding to gold nanoparticles. The nanoparticle preparation was carried out by reduction of HAuCl with NaBH₄. L-cysteine was directly attached to the gold nanoparticles via gold-sulfur binding. The purification of the cysteine-capped nanoparticles was performed by multiple centrifugation and washing steps.

To investigate the binding of L-cysteine to the gold nanoparticle surface, isotopically labeled L-cysteine (¹³C and ¹⁵N) was used. 2D ¹H-DOSY, ¹³C-DOSY and 3D ¹H-¹³C-HSQC-DOSY NMR spectroscopy of the gold nanoparticles enabled the determination of the hydrodynamic particle diameter in excellent agreement with the metallic core diameter by high-resolution transmission electron microscopy.

The binding of L-cysteine to the gold nanoparticles via the thiol group was confirmed by ¹H and ¹³C NMR spectroscopy and 2D-NMR spectroscopy (²H, ¹H-COSY, ¹³C-HSQC and ¹³C,¹³C-INADEQUATE). To exclude the binding of L-cysteine to the gold nanoparticles via the amino group, ¹⁵N NMR spectroscopy was carried out. Quantitative ¹³C NMR spectroscopy and atomic absorption spectroscopy enabled the calculation of a loading of approximately 100 L-cysteine molecules on each gold nanoparticle. By X-ray photoelectron spectroscopy, 95% elemental gold was identified whereas about 5% was oxidized. This confirms the existence of metallic gold nanoparticles, functionalized with L-cysteine as model compound.

We show that NMR spectroscopy is especially well suited to analyze ultrasmall gold nanoparticles due to their small particle size, leading to excellent spectra of dispersed nanoparticles that elucidate the binding situation of L-cysteine on the gold surface.

Polydopamine (PDA) is a nature inspired biopolymer that can be synthesized through self-assembly under mild controlled environment. Due to the catechol functional groups, PDA can form coordination bonding with various metallic ions. In our work, we utilized the strong affinity between PDA and various metal cations, including Cu²⁺, Ni²⁺, and Co²⁺, to obtain metal ion doped PDA (mPDA). The mPDA powders were irradiated under electron beam using a transmission electron microscope. As the electron beam intensity increased, nucleation and growth of nanoscale precipitates were observed.

Electron diffraction and EDX analysis indicated these precipitations were metal nanocrystals. The morphology of the metal nanoparticles varied depending on the metal specie. This discovery indicates electron and perhaps other irradiation sources can be used to induce nanoparticle in metal-doped PDA, which may be useful to modify the properties of PDA-based thin film materials. On the other hand, our study implies PDA can be used as a platform for growth of nanoparticles, which may have potentials in various engineering applications.
etching of gold nanocrystals in the graphene liquid cell was induced through a combination of pre-loaded iron chloride and oxidative species generated by electrodeposition. Control over the chemistry in the graphene liquid cell pockets allowed the nanocrystal dynamics and mechanisms to be related back traditional synthetic techniques. The electron beam dose rate controlled the rate of atom removal, and the initial concentration of iron chloride established the potential of the oxidative etching.

Pre-synthesized gold nanocubes and nano-rhombic dodecahedra (RDD), with \{100\} and \{110\} surface facets respectively, were oxidatively etched while monitoring the effect of chemical potential on the facet trajectories. Both the cubes and RDD transformed to intermediate tetrahexahedra (THH) shapes with \{hk0\} surface facets. When etching the cubes in this non-equilibrium regime, lower initial concentrations of iron chloride led to intermediate \{hk0\} facets with lower h/k values. However, etching the RDD at differing initial iron chloride concentrations led to same intermediate THH with \{hk0\} facets of h/k = 2.5. Monte Carlo simulations corroborated the role of chemical potential in controlling the facets for the cubes but not the RDD. Zero temperature kinetic models show that removing a 6-coordinated edge atom on the nanocrystals reveals 7-coordinate inner atoms for cubes but 6-coordinate inner atoms for RDD. Therefore, chemical potential controls the facets for cubes by modulating the probability ratio of removing inner versus edge atoms. This fundamental understanding of kinetically-driven shape transformations will aid efforts to make nanocrystals with high-energy facets.

These through in situ TEM studies, the formation of non-equilibrium nanocrystal structures were watched at the single particle level in solution, and the mechanisms of etching were elucidated. This mechanistic understanding of nanocrystal etching will hopefully inform future synthetic efforts to control facets and structures for energetically unfavorable shapes.

Hydrogen-Doped Gold-Based Superatom—Synthesis, Structure and Transformation Tatsuya Tsukuda1, 2; 1University of Tokyo, Tokyo, Japan; 2Elements Strategy Initiative for Catalysts and Batteries (ESICB), Kyoto University, Kyoto, Japan.

Gold clusters protected by ligands or stabilized by polymers are viewed as superatoms from the analogy of the electronic structures with those of the conventional atoms. It has been demonstrated that H atom mimics Au atoms in bare Au clusters: the electronic and geometric structures of Au clusters are retained after replacement of the Au atom with H atom \[1\]. A recent theoretical study proposed that an H atom behaves as an Au atom in the Au cluster Au2(3SR)6 (SR = thiolate) and contributes its 1s electron to the superatomic electron count \[2\]. Small nonplasmonic Au clusters stabilized by polymer exhibit localized surface plasmon resonance in the presence of NaBH4 due to electron donation from the adsorbed H atoms \[3, 4\]. These results suggest that structures and properties of gold superatoms can be tuned through doping H atoms. However, a molecular-level understanding has not been attained about the interaction between H and Au superatoms.

The present work focuses on the interaction of H with phosphine-protected Au-based clusters \[Au(AuPH)3]+ and \[PdAu(AuPH)3]+ which can be viewed as oblate gold superatoms with 6 electrons. We observed by mass spectrometry and NMR spectroscopy that a hydride (H−) was doped into these gold-based oblate superatoms upon the reaction with NaBH4. Density functional theory calculations of the products \[AuH(AuPH)3]+ and \[PdH(AuH)(PPh3)8]+ demonstrated that hydride is bonded to a coordinatively unsaturated site at the center and that the \[AuH2]+ and \[PdH2]+ core can be viewed as nearly spherical superatom with closed electronic shells. The hydride-doped superatoms \[AuH2]+ remained during the growth to \[PdH2]+. These hydride-mediated growth processes will provide a new atomically precise synthesis of Au clusters via bottom-up approach.

Stronger-Than-Pt Hydrogen Adsorption in a Au25 Nanocluster for the Hydrogen Evolution Reaction Guoxian Hu1, Zi Li Wu2 and De-en Jiang1; 1University of California, Riverside, Riverside, California, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Atomically precise metal nanoclusters have recently emerged as a novel class of catalysts for the hydrogen evolution reaction. From first-principles density functional theory, we show that the eight coordinatively unsaturated (cus) Au atoms in the Au25(L3)8 cluster \[L3 = 1,8-bis(diphenylphosphino)octane\] can adsorb H stronger than Pt, thereby being a potentially promising catalyst for the hydrogen evolution reaction (HER). We find that up to six H atoms can adsorb onto the Au25(L3)8 cluster and they have close-to-zero Gibbs free adsorption energies \(\Delta G_{H}\). From the HOMO–LUMO gaps, frontier orbitals, and Bader charge analysis, we conclude that H behaves as a hydride or electron-withdrawing ligand in the Au25(L3)8 clusters, in contrast to the metallic H in thiolate-protected Au nanoclusters. Our study demonstrates that ligand-protected Au clusters with cus Au sites will be the most promising candidates for realizing Au–H nanoclusters and can act as excellent electrocatalysts for the HER.

4:15 PM *NM02.02.08

Monolayer-protected clusters (MPCs) represent a class of nanomaterials that can be synthesized and isolated with structural (both compositional and geometric) specificity. Hence, MPCs provide model systems for understanding the nanoscale structure-function interplay. We have recently shown that femtosecond time-resolved two-dimensional electronic spectroscopy (2DES) can be used to isolate carrier dynamics of specific MPC electronic states.Here, 2DES studies of a family of MPCs in the 1-2 nm size range will be presented. These results show that the optical, electronic, and spin-state properties of MPCs are extremely sensitive to the electronic configuration of nanometal orbitals. For example, the magnetic properties of Au25(SR)18, where SR represents an alkanethiol, can be switched reversibly by oxidative opening of the eight-electron Superatom P orbital. Electronic interactions between assembled MPCs also exhibit spin-dependent magnetic phenomena not present in the isolated building blocks. Ultrafast spectroscopy on dimerized 20-atom MPCs reveal inter-partner spin-dependent dynamics not observed for the monomer. In contrast to the discrete carrier dynamics typical for MPCs, larger nanoparticles exhibit collective electronic behavior. I will provide a comprehensive description of how 2DES can be employed to describe the dynamics of metals spanning the non-metallic cluster and metallic particle domains.
Gold Treatment of Silver Nanoparticles and Their Enhanced Antimicrobial Activity

It has been known that silver ions released by silver nanoparticles have bactericidal effect against a wide spectrum of bacteria. Silver ions can induce redox reactions on the membrane transport proteins of bacteria thereby deactivating them. Silver ions are also capable of impairing the energy transfer mechanism of bacteria during respiration process. However, the nanoparticles are unstable and easily form aggregates, which decreases their antibacterial activity.

To improve the dispersion stability of silver nanoparticles in aqueous media, and to increase their effectiveness as antibacterial agents, we coated triangular plate-like silver nanoparticles (silver nanoplates, Ag NPLs) with one or two layers of gold atoms (Ag@Au1L NPLs and Ag@Au2L NPLs, respectively). These gold coatings improved the dispersion stability in aqueous media with high salt concentrations. Ag@Au1L NPLs showed stronger antibacterial activity on pathogenic bacteria than Ag NPLs and Ag@Au2L NPLs. Furthermore, the Ag@Au1L NPLs decreased the number of bacteria living in RAW 264.7 cells. The Ag@Au1L NPLs displayed no cytotoxicity towards RAW 264.7 cells, and the Ag@Au1L NPLs could be used as an antibacterial agent for intracellular bacterial infections.

Next, we prepared hollow-shaped alloy nanoparticles made of silver and gold atoms (Ag/Au NPs) by treating silver nanoparticles with gold ions, not core-shell type gold-coated silver nanoparticles as described in the previous section. The antibacterial activity of the hollowed Ag/Au alloy nanoparticles was stronger than the original silver nanoparticles. Additionally, the release of silver ions from the hollowed Ag/Au nanoparticles was higher than the original silver nanoparticles.

The gold atoms on the surface of silver nanoparticles or in the alloy nanoparticles made of silver and gold atoms affected the oxidation of the silver atoms in the nanoparticles. Since chloride ions can affect the migration of gold atoms on silver, in turn, the migration of gold atoms might affect the exposure of silver metals to the culture medium and the subsequent release of silver ions. These gold treatments are effective methods to improve the antimicrobial activity of silver nanoparticles.

Surface Architecting in Palladium Nanoparticle Synthesis

Morphology dependent properties of nanoparticles have been utilized in various applications and especially nanoparticles composed of high-index facets have attracted significant attention in catalysis with its high density of atomic steps serving as active sites for reactions. However, despite vigorous efforts for delicate control of nanoparticle morphology, controlled fabrication of specific surface structures within a few nanometer scale still remains as a big challenge due to instability of high-index facets. Previously, we demonstrated aqueous based seed-mediated two step growth method to synthesize high-indexed gold nanoparticles with morphological variations by control of reaction parameter and introduction of organo-thiol shape controlling additives. Strong interactions between the organo-thiol based additives and the metal surface induces directional growth depending on the shape-modifier structures.

Herein, based on this established system, we demonstrate precise surface structure control with organo-thiol additive during palladium nanoparticle synthesis. Resulting nanoparticles show multi-stepped surface structures which varies from cubic based planar step patterns to spiral step patterns composed of multiple high-index facets. We demonstrate superior catalytic activity of “multi-stepped” nanoparticles. Morphology variation is originated from collaborative interactions between kinetic modifiers and shape modifying additives during the growth step. Reduction kinetic was controlled by growth solution pH, where various types of acids were introduced to the growth solution. Higher proton concentration in the synthesis environment induced slower electron withdrawing of reducing agent to affect geometrical shape and uniformity. Additionally, dramatic change in nanoparticle morphology was observed respect to the acid type when shape modifying organo-thiol group was introduced to the reaction solution. These anion dependent morphology change is related to specific interactions between organo-thiol molecule and anions to modify growth directionally. Our study provides crucial design constraints for fine morphology tuning during nanoparticle synthesis which allows systematical control of nanoparticle surface structures for potential catalysis application.

Correlation Between Positive Surface Charge Density on Silver Nanoparticles and Separation Performances in Facilitated Olefin Transport Membranes

It has been accepted that the separation performance for olefin/paraffin mixtures has been improved through composite membranes containing silver nanoparticles (Ag NPs) dispersed in a common polymeric matrix when their surface is positively charged by electron acceptor. Here, a correlation between the surface positive charge density, represented by the binding energy, on Ag NPs and the separation performance was also obtained: the remarkably high mixed-gas selectivity above 150 for a 50/50 (v/v) propylene/propane mixture and the propylene permeance about 0.9 GPU. The correlation between the surface positive charge density and the gas separation performance was observed to be linear regardless of the electron acceptor used. This correlation thus suggests that the major determinant of the olefin/paraffin gas separation performance is not the chemical characteristics of electron accepting compounds, but the induced surface positive charge density on Ag NPs. Therefore, it is concluded that surface charge density of Ag NPs is a key factor in determining the separation performance of facilitated olefin transport membranes.

Micro/Nanostructured Lamella Phases Make 2205 Stainless Steel Have Superior Strength and Ductility

Strength and ductility are mutually trade off usually in steels and alloys. Grain refinement to nanoscale can make the conventional steels several times stronger, but invariably leads to poor ductility. Here we demonstrate a micro/nanostructured lamellar phases in 2205 stainless steel prepared by aluminothermic reaction and followed hot rolling that produced a superior yield strength of 780MPa, ultimate tensile strength of 979 MPa and elongation of 54%. The elongation is the highest in the reported steels with that level of strength. The product of tensile strength and elongation exceeds 50 GPa% and is the highest value that was reported in the literatures. The steel consists of micro/nanostructured lamellar ferrite phase and micro/nanostructured lamellar austenitic phase in which the dislocation free hard nano grains dispersed in soft coarse grains. The high strength is attributed to strengthening of dislocation...
free nano grains and interface between the two phases. The unusual high ductility originates from cracks propagation resistance by the nano grains and the two phase interfaces.

Highly Efficient Ni-B Amorphous Alloyed Catalysts on Ni Foam for Nitrobenzene Hydrogenation

Gang Chen,1,2 Xin Zhu,1,2 Rong Chen,1,2 Qiang Liao,1,2 Dengding Ye,1,2 and Biao Zhang1,2. Key Laboratory of Low-grade Energy Utilization Technologies and Systems (Chongqing University), Chongqing, China;¹ Institute of Engineering Thermophysics, Chongqing University, Chongqing, China.

In this work, Ni-B amorphous alloyed catalysts used for a gas-liquid-solid three phase reaction were synthesized on Ni foam by electroless plating method, which was evaluated by the reference reaction of nitrobenzene hydrogenation. Such design offered several advantages. First of all, the low-cost Ni-B amorphous alloyed catalysts showed superior catalytic activity and selectivity towards the hydrogenation reaction. Besides, the use of Ni foam as the support materials could increase the surface area for loading the Ni-B amorphous alloyed catalysts. Moreover, its interconnected macropore structure was beneficial for the transport of the gas/liquid reactants to the active sites. The morphologies and size distributions and the chemical composition of the prepared Ni-B amorphous alloyed catalysts were characterized by SEM, XRD and XPS, respectively. The actual loading of the Ni-B amorphous alloyed catalysts was analyzed using ICP-MS technology. The hydrogen chemisorption on the Ni-B amorphous alloyed catalysts was characterized by temperature programmed desorption of H₂ (H₂-TPD) analyses. Finally, the catalytic performance was evaluated by nitrobenzene hydrogenation in a continuous flow monolithic microreactor under various parameters. The experimental results indicated that the developed Ni-B amorphous alloyed catalysts deposited on the Ni foam was able to improve the catalytic performance.

Effect of Nanoparticles on Liquid State Dewetting of Bismuth Thin Films

Krishna Kumar, Mrudula Kavuri and Parasuraman Swaminathan; Indian Institute of Technology Madras, Chennai, India.

Metallic thin films are unstable in as deposited state. These films tend to break up and agglomerates when annealed. This is known as dewetting and driven by surface energy minimization of the film – substrate interface. Dewetting occurs in both solid and liquid state and while it can be detrimental, where high temperature performance is required, it can also be used to fabricate nanoparticles arrays on substrate for different applications [1].

Enhancing the thermal stability of metallic thin films is of importance, especially for high temperature applications. Recently, we reported that addition of silver nanoparticles on copper thin films suppresses the solid state dewetting of copper thin film [2]. In this work, we explore the effect of added nanoparticles on the liquid state dewetting behaviour of bismuth thin films. We study three system, copper, silver and gold nanoparticles deposited on bismuth thin films on amorphous carbon TEM grids. Transmission electron microscopy results shows that gold and silver nanoparticles accelerate bismuth dewetting, while copper nanoparticles suppress the process. A model is presented to explain these differences.

Inkjet Printed Encapsulation of Gold Nanoparticles inside Cell-Adhesive Chitosan Hydrogels

Álvaro Artiga1,2, Sonia García-Embid1,2, Inés Serrano-Sevillal, Gabriel Alfranca, Laura De Matteis1,2, Scott G. Mitchell1,2, Carlos Sánchez-Somolinos1,2 and Jesús M. de la Fuente1,2. 1Instituto de Ciencia de Materiales de Aragon (ICMA), CSIC/University of Zaragoza, Zaragoza, Spain; 2CIBER-BBN, Instituto de Salud Carlos III, Madrid, Spain; 3Instituto de Nanociencia de Aragon (INA), University of Zaragoza, Zaragoza, Spain.

The unique physicochemical properties of gold nanoparticles (AuNPs) make them highly applicable for drug release, optoacoustic imaging, biosensing and photothermal therapy, among others. This work highlights unique methodologies for the encapsulation of AuNPs in chitosan hydrogels to increase their applicability and efficacy in health-related applications, in particular for photothermal therapy (PTT).

In PTT, AuNPs are employed to convert light energy into heat for the selective ablation of target cells. Anisotropic AuNPs such as nanoprisms, rods and stars, are frequently employed because they absorb near-infrared light that is harmless for surrounding cells. In previous work, we have compared the heating capability, cellular internalization, toxicity and thermoablation capacity of two different types of anisotropic AuNPs: gold nanorods (AuNRs) and nanoprisms (AuNPs) [1]. Although both AuNRs were highly efficient photothermal converters, AuNRs possessed a more efficient heating capability. However, the in vitro thermoablation studies clearly demonstrated that AuNPs were more effective at inducing cell death by PTT due to their greater cellular internalization, while AuNRs could not be employed for this purpose due to their extremely low cellular internalization.

We succeeded in improving the PTT application of AuNRs by entrapping them inside a cell-adhesive chitosan hydrogel using anionic polyethelmetals (POMs) as gelling agents [2]. These functional nanocontainers remained non-cytotoxic and presented the ability to adhere to the cytoplasmic membranes of cells avoiding any need for cellular internalization, thus rendering them as highly efficient PTT agents. However, one key disadvantage of this entrapment methodology is the lack of control of the size and size-dispersion of the nanocontainers.

In order to improve these drawbacks, we have developed a novel strategy for AuNP microencapsulation in chitosan hydrogel by inkjet printing [3]. Inkjet printing, as a high-throughput, continuous and automatic technology poses relevant industrial potential for microencapsulation. In particular, our approach has showed a high degree of production, excellent control of the microcapsules size, high encapsulation efficiency and ease of scale-up, obtaining almost monodisperse chitosan microcapsules containing AuNPs. We are currently studying the use of these chitosan hydrogels for oral administration of gold nanoparticles in vitro and in vivo.

Fabrication and Morphological Control of Palladium Film with Three-Dimensional Nano-Network Structure as a Hydrogen Gas Sensing Material by Organic Acid Chelation

Takui Ube, Akizumi Kawamoto, Tomoya Nishi and Takashi Ishiguro; Department of Material Sciences, Tokyo University of Science, Tokyo, Japan.

The large specific surface area of nano-porous materials realizes both high catalytic activity and resource savings. Thin film materials have homogeneity in large areas and can be applied to sensor devices or electrode materials for batteries. The traditional and general method of fabricating a nano-porous noble
metallic thin film is the dealloying method, i.e., the selective corrosion of an alloy of a noble metal and a base metal by a strong acid, such as hydrochloric acid or sulfuric acid. In this study, we fabricated a palladium (Pd) thin film with three-dimensional (3D) nano-network structure (3DPdNNF) by the dealloying method without discharging any material with possibly high environmental impact, such as waste solution containing heavy metals or strong acids. The dealloying was conducted in aqueous solutions of organic chelating agents of citric acid and ethylene-diamine-tetraacetic acid (EDTA) and sodium carbonate. All agents are used as a food additive and have environmentally friendly characteristics. Furthermore, the base metal used was aluminum (Al). However, Pd has a hydrogen-storage property with hydrogen gas selective permeation, and it is expected to be useful for developing sensor devices to detect only hydrogen gas. However, pure Pd metal has low repetitive durability for hydrogen gas exposure due to irreversible deformation and destruction caused by its hydrogen-storage property. In this study, we aimed to fabricate a 3DPdNNF by the above method and utilize its stress relaxing action due to the nano-network structure to apply it to a hydrogen gas sensor with repetitive durability.

The thin film preparation was performed using the RF-sputtering method, and AI–Pd alloy (82at% Al–18 at% Pd) films were deposited on substrate (glass, Si wafer, and elastic carbon film) to a thickness of 70 nm. The dealloying process was conducted in mixed aqueous solution of organic chelating acid (100 μmol/L) and sodium carbonate for pH adjustment. The optimized pH value and temperature were 10.0 and 368 K, respectively.

The Al–Pd film was reformed to uniform 3DPdNNF with high Pd purity (> 99 at% Pd). The pore size of the network could be controlled to within the range of 2.90–12.5 nm by three parameters of the gas conditions during the sputtering deposition and the pH values and chelating agents in the dealloying processes. We evaluated the hydrogen gas sensing performance as a 3DPdNNF utilization of a high Pd purity and large specific surface area film. The fabricated 3DPdNNF showed a response to hydrogen gas by changing the electrical resistance in the kΩcm range with repetitive durability for hydrogen gas exposure.

Sputter Deposition onto Liquid to Prepare Pt and Pt Alloy Nanoparticles
Lianlian Deng1, Mai Thanh Nguyen1, Tomoharu Tokunaga2, Syo Matsumura1 and Tetsu Yonezawa1; 1Division of Materials Science and Engineering, Faculty of Engineering, Hokkaido University, Sapporo, Japan; 2Department of Quantum Engineering, Graduate School of Engineering, Nagoya University, Nagoya, Japan; 1Department of Applied Quantum Physics and Nuclear Engineering, Kyushu University, Fukuoka, Japan.

Platinum (Pt) and Pt-based (e.g., Pt/Cu, Pt/Au, Pt/Ag) alloy nanoparticles (NPs) have been demonstrated as high performance catalysts. Usually Pt and Pt-based alloy NPs have been synthesized via chemical reduction methods. However, impurity and incomplete removal of byproducts and toxic reductants can hinder catalytic properties. On the other hand, due to the difference in reduction potential of metal salts and/or difference in decomposition temperature of metal complexes, core-shell structure or phase segregation were observed in the formed bimetallic NPs. This is often seen in bimetallic NPs of immiscible elemental components in the bulk state such as Pt/Al. In our research, we have proposed to prepare highly uniform Pt and Pt alloy NPs, such as Pt/Cu and Pt/Au alloy NPs, by sputtering at room temperature onto a low vapor pressure liquid, polyethylene glycol (PEG, Mw 600). The method combines the advantages of sputtering to produce atoms and clusters for any metal from the bulk counterparts and the suppression and control of particle growth by the liquid medium in vacuum sputtering chamber. Thus varying the sputtering parameters allows for particle size control and tunable alloy NPs' composition. Sputtering was performed onto PEG and TEM grid. Sputtering current applied to each magnetron was separately controlled and varied in order to tune the composition in the resulting bimetallic NPs. Various characterization methods such as UV-Vis, XRD, XPS, TEM, HRTEM and STEM-HAADF and STEM-EDX mapping have been used to analyze the obtained NPs. TEM, HRTEM and STEM showed that Pt NPs with tunable sizes from 0.9 nm to 1.4 nm and narrow size distribution were produced. In addition, we found that negligible particle aggregation happened in PEG and Pt NPs were stable even after keeping in the dark at room temperature for several months. The slight growth of Pt NPs in PEG during storage was found accompanied with the consumption of free Pt atoms in PEG. The method was applied for a Pt/Cu alloy target and the effect of sputtering parameters such as sputtering time, the rotation speed of PEG on particle size has been studied. Pt/Cu alloy NPs have been synthesized by sputter deposition for the first time. Furthermore, we showed that we were able to produce Pt/Au alloy NPs using a double-target sputtering. The target design allowed us to finely control Pt/Au alloy NPs' composition via simultaneous sputter deposition onto PEG. The results showed that particle size and composition are strongly correlated and can be tailored by varying the sputtering current. Increasing Pt content resulted in smaller particle size and particles with same composition had similar sizes. Moreover, the agglomeration of NPs is dependent on the Pt content. Our findings in the relation among particle size, particle composition, and aggregation state of the formed NPs with respect to its composition can shed light into the formation mechanism of Pt-based alloy NPs.

The Role of Silver Nano-Particles/Colloids on Conduction Mechanisms of Current Through Ag Gridlines of Si Solar Cell
Kening Ren, Veyssel Unsur, Ahrar A. Chowdhury, Yang Ye and Abasifreke Ebong; Chemistry, University North Carolina at Charlotte, Charlotte, North Carolina, United States.

Fire through dielectric (FTD) contact is the dominant technology for contacting a commercial silicon solar cell because of its low-cost and high throughput attributes. During the FTD process, the glass frits in the Ag paste melt and etch the dielectric (anti-reflecting layer) first, to have Ag metal contact directly to the bulk Si. The redox reaction between the glass frits melting and dielectric etching leads to the formation of a recrystallized glass layer, which distributes within the Ag gridlines and bulk Si emitter surface, and silver nano-particles, which are mainly silver alloys (Ag2Te and PtTe) encapsulated in the glass layer. When without the Ag2Te and PtTe nano-particles/colloids, due to the existence of glass layer, silver gridlines rarely directly contact with the bulk silicon and electrons have to tunnel through the glass layer. However, in this work, Ag2Te and PtTe are semimetals which have very narrow bandgaps. The existence of Ag2Te and PtTe nano-particles/colloids in the glass layer can change the electrical property of the glass layer. Thus, the specific contact resistance of silver gridlines cannot be calculated based on simplified metal-semiconductor contacts. The possible electron transport on the silver/silicon interface includes: 1. through silver gridline contact directly with bulk silicon; 2. tunneling through an ultrathin glass layer; 3. through Ag2Te and PtTe nano-particles/colloids assisted tunneling; 4. through multistep tunneling. This suggests that the contact resistivity in the presence of Ag2Te and PtTe nano-particles/colloids is independent of the inverse square root of emitter peak surface concentration. Lower contact resistances were measured in the presence of Ag2Te and PtTe nano-particles/colloids with relatively low peak surface concentration.

Kinetics of Detwinning in Chemical Vapor Deposited Nickel—Critical Structures Determining the Stability of Nano-Twin Lamellas
Hao Sun; Mechanical and Industrial Engineering, University of Toronto, Toronto, Ontario, Canada.

Nickel carbonyl vapor deposition (CVD) is a novel metal-forming process used to produce thin-shell molds with a higher level of efficiency and a lower cost than traditional mold making techniques. Not only is the production process highly effective, but the deposited CVD Nickel shell is also both harder (a tensile yield strength of ~584MPa) than nanocrystalline electroformed Nickel (~4-7%) with a grain size of 21-30nm. The combination of high strength and high ductility of the CVD Nickel shell is attributed to its unique bi-modal grain structure with large columnar grains embedded in a nanocrystalline matrix. A high density of nano-twins in large columnar grains significantly improve the working hardening capacity and ductility of CVD Nickel, but they are thermodynamically unstable. Most coherent twin boundaries (CTBs) transform into dislocation cells during annealing at temperature higher than 400 degree centigrade. While the driving force for detwinning is well-known, the mechanism by which CTBs disappear is still puzzling. Based on both experimental observation and simulation analysis, we found that although the driving force for detwinning is determined by the density of nano-twins, the thermal stability of each CTB...
in CVD Nickel is only determined by incoherent twin boundaries (ITBs) and its intrinsic grain boundary dislocations (IGBDs). Driven by the tensile strain originated from grain growth in the nanocrystalline matrix of CVD Nickel, IGBDs detach from CTB planes during detwinning. The emerging dislocations rearrange into sub-grain boundaries which then remove some CTBs during their migration. Twin lamellas terminated by ITBs transform back to the matrix stacking by the migrating ITBs which can also release sessile grain boundary dislocations into the crystal. Our results suggest that replacement of the nanocrystalline matrix in CVD Nickel with nano-twin structure can eliminate the tensile strain originated from grain growth, so nano-twins in CVD Nickel without nanocrystalline matrix might have a much higher level of thermal stability than that in CVD Nickel with bi-model grain size distribution.

NM02.03.12
Electrochemical Synthesis of Ag-Cu Bimetallic Nanostructure for Oxygen Reduction Reaction (ORR) Junian Chen and Shien Ping Feng; The University of Hong Kong, Hong Kong, Hong Kong.

Highly active and economic catalysts for oxygen reduction reaction (ORR) are always important for renewable energy technique. Since more than half of the voltage loss in fuel cell comes from the cathodic ORR process, and most of the commercial available catalysts for ORR is Pt-based. Herein, a new Ag-Cu bimetallic nanostructure was developed by electrochemical method, the fabricated Pt-free material shows a great performance towards ORR, which is comparable to the Pt/C commercial catalyst. The selectivity of the catalyst was carefully studied by scanning electrochemical microscope (SECM). Result shows the ORR by Ag-Cu bimetallic nanostructure prefer a four-electron reduction process, with H2O as the main product and trace amount of H2O2 can be detected. However, similar pure Ag nanostructure presents a much lower selectivity, which indicates the introduction of Cu is essential. Possible model was established to explain the enhancement as well. This Ag-Cu bimetallic nanostructure suggests a potential to be developed as cathodes in fuel cell, with a highly active and relative low cost.

NM02.03.13
In Vitro and In Vivo Toxicity of Metal-Doped Titanium Oxide Nanoparticles Su-Eon Jin1, Seok Won Hong2 and Hyo-Eon Jin2; 1Inha University, Incheon, Korea (the Republic of); 2Ajou University, Suseon, Gyeonggi-do, Korea (the Republic of); 3Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Metal-doped titanium oxide (TiO2) nanoparticles were developed as enhanced photocatalysts with disinfection and purification potential. However, they can be hazardous to both the environment and human health. In this study, the toxicity of nickel (Ni) and platinum (Pt)-doped TiO2 nanoparticles (Ni-TiO2 and Pt-TiO2 nanoparticles) to skin and eye cells and a mouse skin model was evaluated. Physicochemical properties of nanoparticles were characterized using field emission-scanning electron microscopy, field emission-transmission electron microscopy, and X-ray photoelectron spectroscopy. Cytotoxicity was also evaluated at concentrations of 0.0001 to 10 mg/mL in HaCaT and ARPE-19. To investigate in vivo acute toxicity, 1 to 123 mg nanoparticles/1.5 cm² were applied to hair-removed dorsal skin in a mouse model, and skin tissues and body condition were monitored. Metal-doped TiO2 nanoparticles had a spherical crystalline shape with nanoscale sizes less than 100 nm. In nanoparticles, 1.0% Ni2p and 0.26% Pt4f were detected at 871.2 eV and 74.4 eV for Ni-TiO2 and Pt-TiO2 nanoparticles, respectively. Cell viability in HaCaT was higher than that in ARPE-19 at a range of 0.1 - 10 mg/mL nanoparticles. In ARPE-19, superior cell viability was observed at 1.0 mg/mL and more than 1.0 mg/mL Ni-TiO2 nanoparticles compared with Pt-TiO2 nanoparticles. In vivo, body weight and ALT/AST levels were not significantly altered by Ni-TiO2 nanoparticle exposure. Histology, skin thickness, and inflammation grade were also comparable to control mice. Thus, metal-doped TiO2 nanoparticles show minimal toxicity in skin cells and a mouse skin model, indicating their potential for various applications.

NM02.03.14
Morphological and Microstructural Evolution of Polycrystalline Thin Films Resego Phiri; Chemical, Materials and Metallurgical Engineering, Botswana International University of Science and Technology, Palapye, Botswana.

Modern thin film industries require precise tailoring of thin films properties to have excellent performance at specific applications intended. Atomic scale understanding of the microstructure of polycrystalline thin films is necessary for the control and manipulation of the film properties for a wide range of industrial applications. Thin film growth of thin films influence grain shapes, distribution of grains and the crystallographic orientation of the grains thereby affecting their reliability and performance. This article reviews the present understanding of the mechanism(s) determining the microstructural evolution of polycrystalline films and the related structure zone models. General trends in microstructural evolution, grain morphology and texture formation mechanisms are discussed in terms of their fundamental kinetic processes. The temperature dependency of the film microstructure is described using Thornton structure zone models.

NM02.03.15
Synthesis and Characterization of Redox-Sensitive Mixed Metal Complexes Joseph T. Race, Lauren Knappenberger and Scott Williams; Rochester Institute of Technology, Rochester, New York, United States.

A mixed metal inorganic complex which resembles redox sensitivity will be presented. Molecular switches experience a reversible physical change due to various external stimuli such as: high energy radiation, electrical current, heat, magnetic fields, and ultraviolet or visible light. We have synthesized a series of Group IVB and VB complexed to VIIIB metals that undergo intermolecular electron transfer upon high energy exposure resulting in a state change. In addition, we have found that substituting a Group IVB with selected Lanthanide metals results in fluorescently active compounds. We will present how the additional mechanism was enabled that resulted in the growth of highly crystalline Ni, Co and Ni-Co nanowires in addition to the nanostructured film. Excellent quality nanowires for high melting point metals are difficult to grow using the standard electrodeposition into nanoporous anodized aluminium templates method [2,3]. The new template-less growth conditions reported here indicate that an alternative method to produce highly crystalline nanowires...
for high melting point metals has been identified. Novel roles for oxygen, carbon and chlorine chemistries in the nanocrystallite and nanowire growth processes are identified. We identify specific growth models for both nanocrystal and nanowire from quantitative TEM, SEM, SAED, EDS and AFM results.

NM02.03.17 Fabrication of a Transparent Conducting Electrode Based on Silver Nanowires for Organic Photovoltaic Devices Heejeong Shin and Hyeosung Cho; Chemistry, Hanyang University, Seoul, Korea (the Republic of).

A solution-processed transparent conducting electrode was fabricated via layer-by-layer (LBL) deposition of graphene oxide (GO) and silver nanowires (Ag NWs). First, graphite was oxidized with a modified Hummer’s method to obtain negatively-charged GO sheets, and Ag NWs were functionalized with cysteamine hydrochloride to acquire positively-charged silver nanowires. Oppositely-charged GO and Ag NWs were then sequentially coated on a 3-aminopropyltriethoxysilane modified glass substrate via LBL deposition, which provided highly controllable thin films in terms of optical transmittance and sheet resistance. Next, the reduction of GO sheets was performed to improve the electrical conductivity of the multilayer films. The resulting GO/Ag NWs multilayer was characterized by a UV-Vis spectrometer, field emission scanning electron microscope, optical microscope and sheet resistance using a four-point probe method. The best result was achieved with a 2-bilayer film, resulting in a sheet resistance of 6.5 Ω sq−1 with an optical transmittance of 78.5% at 550 nm, which values are comparable to those of commercial ITO electrodes. The device based on a 2-bilayer hybrid film exhibited the highest device efficiency of 1.30% among the devices with different number of graphene/Ag NW LBL depositions.

NM02.03.18 Highly Sensitive Temperature Sensors with Ag Nanocrystal Thin Films Bang JunSung, Oh Soong Ju, Junhyuk Ahn and Ho Kun Woo; Nanocrystal Electronics Laboratory, Korea University, Seoul, Korea (the Republic of).

We introduce a strategy to design a highly sensitive temperature sensors using Silver (Ag) nanocrystal (NC) thin films. Resistive temperature sensors were fabricated on using poly(dimethylsiloxane) (PDMS) substrate through ligand exchange process [1] and interfacial engineering process. We take advantages of high thermal expansion coefficient of PDMS to control the interparticle distances of Ag NCs, and eventually to improve the sensitivity. We achieved a very sensitivity with temperature coefficient of resistance of 0.1/K. We discussed the origin of the high sensitivity by investigating structural, chemical, electrical, and electromechanical properties as well as the charge transport mechanisms. We also examine the stability, reliability, and sensitivity of our sensors. This work offers and effective way to design low-cost and high-performance sensors.

NM02.03.19 Designing Wearable Strain Sensors with Ag Nanocrystall Thin Film Through Halide Ligand Exchange Strategies Junhyuk Ahn, Soongju Oh, Bang JunSung and Ho Kun Woo; Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

Through all solution-processed methods, wearable strain sensors with high gauge factor are demonstrated using thin film of Ag nanocrystals (Ag NCs). Controlling of interval between Ag NCs enables to control a flow of electrons through hopping mechanism and/or tunneling effect, which can enhance gauge factor. In this study, halides ligand treatment is proposed to design interval between nanoparticles to obtain high performances at solid state. Higher sensitivity of ligand treatment with I- is demonstrated by comparisons of experimental results of halides: Br-, Cl-, I-. The origin of the higher performance is discussed with various characterization methods. Careful studies to further enhance the sensitivity is conducted by controlling various conditions in ligand exchange process. These high sensitivity thin film Ag NCs strain gauge sensors allow to measure a delicate movement or signal from various objects. This work provides a low cost and simple method to design high sensitivity wearable sensors for various field such as robotics, or healthcare systems.

NM02.03.20 Encoded Silver Nanoshells as Surface-Enhanced Raman Spectroscopic Nanoprobes for Diagnosis of Alzheimer’s Disease In-Jun Hwang, Jin-Kyung Yang, Sin Lee and Jong-Ho Kim; Hanyang University, Ansan, Korea (the Republic of).

Recently, early diagnosis of Alzheimer’s disease (AD) has attracted considerable attention in the field of nanomedicine and biosensing. In particular, detection of plasma biomarkers specific for AD, including amyloid beta (Aβ40 and Aβ42), is considered a promising, cost-effective, and non-invasive method for diagnosis of AD. Herein, we present a facile approach for designing a nanoprobe based on surface-enhanced Raman scattering (SERS) for the sensitive and selective detection of Aβ40 and Aβ42 in blood. To this end, Ag nanoshells (AgNSs) bearing Raman labels were synthesized in a single step under very mild conditions (25 °C and 60 min). As-prepared AgNSs had a uniform shell thickness and nanogaps of 2 nm, resulting in significant electromagnetic field enhancement. In addition, each AgNS exhibited a unique and intense SERS signal without overlapping, allowing the multiplex and sensitive detection of Aβ40 and Aβ42. The AgNSs conjugated with a specific antibody for Aβ40 or Aβ42 was able to detect each target protein at concentration as low as 100 fg/ml in a fast and simple manner.

NM02.03.21 Evaluation of Thin-Film Interfacial Properties Using Single Nanoindentation Test Jinwo Lee, Woojoo Kim, Ohmin Kwon and Dongil Kwon; Seoul National University, Seoul, Korea (the Republic of).
Nano technology is developed consistently in all kinds of industry like chemical, Bio, Energy. Especially thin-film process improvement and material changes is researching actively. Through variety material and processing, High quality thin film element must have clearly purpose for electric and optical ability and also request a reliable device which is over standard mechanical properties. A thin film’s reliable question is depend on interfacial characterization, so evaluating interfacial characterization is the most important things in this test. So far, Peel off test, 4 point bending test and scratch test are usually used among lots of test in order to evaluate a thin film’s feature. But those test is inconvenience to make sample, and hard to check a characteristic evaluation of characteristic interface because of mechanical properties. So, this research is introduced how to test a thin-film by indentation test, and confirmed availability of interfacial properties by nanoindentation test. Determination of the mechanical properties of thin films on substrates by nanoindentation has always been difficult because of the influence of the substrate and interface on the measured properties. In order to measure film-only properties, a commonly used rule of thumb is to limit the indentation depth to less than 10% of the film thickness. As the film gets harder, the substrates and interfacial effects appear at lower indentation depth. Many researchers derived the conclusion from the theoretical and experimental methods. In the case of thin films which have thickness under than from nanometers to micrometers, it has no choice but must include the substrates and interfacial effects. Owing to the quantitative consideration about interfacial effects was hard, modeling equations with no interfacial effects is used.

NM02.03.22
Stress-Induced Chemical Reaction of Ti/Si Multilayered Nano-Films
Hiroyuki Hirakata, Takashi Kawai, Yoshiyuki Kondo and Kohji Minoshima; 1Department of Mechanical Engineering and Science, Kyoto University, Kyoto, Japan; 2Department of Mechanical Engineering, Osaka University, Osaka, Japan.

When a sufficient energy is applied at a local point in multilayered nano-films composed of alternating layers with a thickness of 10 nm order, an exothermic reaction occurs and a compound is generated at the local region. The generated heat then spreads into an adjacent unreacted region. If the temperature in the neighboring region becomes high sufficient to cause additional mixing, a self-sustained propagating reaction (SPR) occurs. SPR is induced by not only by electrostatic discharge, electrical heating, and laser irradiation, but also by mechanical impact. SPR by mechanical impact can be divided into two phenomena: i.e., (i) initial reaction by mechanical loading and (ii) ignition and propagation of reaction wave. Many studies have been conducted on (ii) SPR properties such as the ignition threshold and the speed of propagation. On the other hand, for (i), the detailed mechanisms of the initial chemical reaction due to mechanical loading has been unclear. This chemical reaction occurs at well below melting points and eutectic temperature, implying that the chemical reaction can occur by solid-state reaction. The atomic mixing in the solid-state can be brought about by diffusion or plastic deformation. Since the reaction occurs in very short time, we focus the role of plastic deformation.

The purpose of the study is to clarify the mechanisms of initial chemical reaction of Ti/Si multilayered nano-films by mechanical loading. Since the multilayered nano-films have structural anisotropy, the deformation mechanism depends on the loading mode with respect to the stacking direction. In this study, we focus the deformation and chemical reaction under compression loading in the stacking direction as a basic mode. We fabricated truncated cone-shaped specimens by focused ion beam from a polycrystalline-Ti/1-2 nm thick amorphous-Si multilayered nano-films (biayer thickness: ~30 nm) deposited by electron beam evaporation, and then conducted compression experiments under in situ observation by field emission scanning electron microscopy. We evaluated the chemical reaction or change in crystal structure through transmission electron microscopy (TEM) observation and selected-area electron diffraction to the deformed specimens.

The specimens yielded at a true stress of ~3 GPa under compression, and showed gradual hardening behavior. TEM observation confirmed that each layer was plastically deformed or thinned, and then the mixing of Ti and Si occurred. The selected-area electron diffraction revealed that a new crystal structure, estimated to be Ti₅Si₄ or TiSi₂, was generated on the Ti/Si interface and in the Ti layer. These results indicated that the mixing of each layer was induced by plastic deformation due to compressive stress and the compound of Ti and Si was generated. The exothermic reaction can be controlled or generated at a desired site by the local mechanical loading, and so it can be used for various applications such as local heating in large-scale devices.

SESSION NM02.04: Growth and Interface of Nanostructures
Session Chairs: De-en Jiang and Mika Pettersson
Tuesday Morning, November 27, 2018
Sheraton, 3rd Floor, Commonwealth

8:30 AM *NM02.04.01
Confined Growth of Metal Nanostructures
Yadong Yin; University of California, Riverside, Riverside, California, United States.

Metal nanostructures have been studied quite extensively in the research area of heterogeneous catalysis long before the introduction of the concept of nanoscience and nanotechnology. The significant progress achieved in the past twenty years in chemical synthesis has enabled precise control over not only the size but also the shape of the metal nanostructures, and therefore attracted intense interest not only in catalysis but also optoelectronics due to the well-known effect of localized surface plasmon resonance. In this presentation, I will introduce our recent progress in the synthesis of colloidal metal nanostructures in confined spaces using various templating methods, and further manipulation of their secondary structures. By combining the confinement of templates with the seed-mediated growth strategy, we demonstrate the significant advantages of this general method over the conventional ones in creating a large variety of nanoplastics with novel plasmonic properties.

9:00 AM NM02.04.02
Near Surface Nucleation and Particle Mediated Growth of Colloidal Au Nanocrystals
Maria Sushko, Yingwen Cheng, Jinhui Tao, Guomin Zhu, Jennifer Soh, Elias Nakouzi, James J. De Yoreo and Jun Liu; Pacific Northwest National Laboratory, Richland, Washington, United States.

During non-classical growth of nanostructures via assembly of primary nuclei, nucleation and assembly are assumed to be distinct processes: nanoparticles nucleate randomly aggregate to form extended structures through Brownian motion in the presence of long-range attractive interactions. Here we investigate the relationship between these two processes by using in situ AFM, in situ, ex situ and cryo TEM and UV-Vis spectroscopy to observe growth of colloidal gold and simulations to develop a mechanistic model of the process. Our results reveal an inexorable link between nucleation and assembly with nuclei forming almost exclusively within a ~1 nm interfacial region of existing particles. The new particles immediately close the gap either through a diffusive jump or via growth of a neck between the seed and new particle, generating aggregates exhibiting features commonly attributed to oriented attachment of independently nucleated particles. In addition, pH was identified as a control parameter for manipulating crystallization pathway through shifting the balance of chemical potentials of solution species. The results demonstrate that creation of initial particle interfaces leads to local environments
that redirect growth towards non-classical processes.

9:15 AM *NM02.04.03
Controlling Absolute Dimensions of Gold Nanorods Catherine J. Murphy; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Gold nanoparticles of controlled size and shape display brilliant optical properties throughout the visible and near-infrared portions of the electromagnetic spectrum. Gold nanorods, usually 15-20 nm in diameter with tunable lengths of 20, 30, 40, 50, 60 nm, show two plasmon bands corresponding to transverse and longitudinal excitations. The length/width ratio (aspect ratio) of gold nanorods is well-known to dictate the relative positions of the two plasmon bands. Recently in my laboratory we have developed a synthesis of "mini gold nanorods" in which the particle diameters are 5-8 nm, and lengths are 10, 20, 30 etc. nm. These absolutely smaller nanorods display similar plasmon bands to their larger counterparts, but the relative proportion of light scattering compared to light absorption differs. This talk will describe the synthetic procedures to create mini-rods as well as comparisons of properties between mini-rods and "regular" rods.

9:45 AM NM02.04.04
Symmetry Breaking and Shape Control in Gold Nanorod Growth—From Conception to Old Age Joanne Etheridge, Wenming Tong, Michael Walsh, Hadas Katz-Boon and Alison Funston; Monash University, Monash University, Victoria, Australia.

Symmetry-breaking is the essential step required for an isotropic seed particle to grow into an anisotropic shape. Using specially designed electron microscopy methods and strategically-chosen synthetic routes, we investigate the mechanisms behind symmetry breaking and shape control in gold nanorod growth, from conception to old age [1-4]. We observe the symmetry-breaking event that triggers the formation of the embryonic nanorod; an asynchronous formation of new surface structures in the cuboctahedral gold seed particles [1,3]. We show that the size at which the seed particle breaks symmetry depends sensitively on the Au/Ag ion ratio and describe a mechanism as to how this, in turn, controls the initial nanorod aspect ratio [2,3]. After observing the initial symmetry breaking event, we investigate the evolution of the nanorod morphology over an extended timeframe, for periods up to 3 orders of magnitude longer than the conventional 1 - 2 hours [4]. Following initial rapid anisotropic growth, the nanorods grow isotropically, and over longer times (weeks), tend ultimately towards the same reduced aspect ratio, irrespective of the AgNO3 concentrations. Furthermore, we measure the orientation and stability of different facets [5,6] and show how the nanorod transitions from faceted to curved when allowed to grow for extended periods [4]. Collectively, these observations suggest that the ultimate final aspect ratio is dictated by the surface energetics of the cylindrical sides compared to the hemispherical tips, with little dependence on the initial AgNO3 concentration. In other words, the AgNO3 concentration mainly asserts control over aspect ratio at the symmetry breaking point, rather than during later growth. Altogether, these observations provide a rational framework for controlling width, aspect ratio and facet orientation in the growth of single crystal gold nanorods.

Quantitative Chemical Mapping of Soft-Hard Interfaces on Gold Nanorods Ilanka Janicek1, Joshua G. Hinman2, Jordan Himman2, Huei-Huei Chang2, Kenneth Suslick1, Catherine J. Murphy2 and Pinshane Huang1; 1Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Chemistry, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Soft-hard interfaces at the surface of nanoparticles (NPs) determine interaction potentials, including the mechanisms of growth, spatial reactivity, colloidal stability, and nanoparticle functionality [1]. For example, molecular ligands are thought to guide growth and symmetry breaking in anisotropic NPs. These ligands can also act as soft templates for site-selective deposition of functional coatings [2, 3]. Thus, quantitative details of the local attachment, distribution, and structure of soft-hard interfaces would enable the development of methods for high-yield, monodisperse NP synthesis.

Conventional techniques to characterize soft-hard NP surfaces—such as nuclear magnetic resonance, small angle x-ray scattering, and other bulk methods—lack the spatial resolution necessary to probe key details, including how the surface structure and chemistry varies within and between individual particles [1]. Yet in NPs, polydispersity is a defining characteristic, and surface energies and interactions vary widely based on local facet, curvature, and composition. While electron microscopy can address this challenge, an ideal approach requires a combination of: low-background substrates, the ability to quantify elemental distributions of small molecules, and the efficiency necessary to probe multiple NPs. Here we report a particle-by-particle analysis of soft-hard interfaces on gold nanorods (AuNRs) using aberration-corrected scanning transmission electron microscopy and electron energy loss spectroscopy (EELS) spectrum imaging on graphene substrates.

In order to demonstrate the ability of electron microscopy methods to probe soft-hard interfaces, we investigate anisotropic mesoporous silica functionalization of AuNRs. Mesoporous silica can be deposited with site selectivity to either the ends or the sides of AuNRs. Such growth is thought to be templated by the anisotropic distribution of capping ligand cetyl trimethylammonium bromide (CTAB) [2, 3]. We deposit AuNRs onto suspended graphene substrates and use EELS spectrum imaging to map the presence of carbon, silicon, and oxygen. We directly observe a mesoporous silica frame with carbon content indicating the presence of a residual CTAB shell surrounding the particle. Using graphene as a reference, we quantify the CTAB present before and after silica deposition. These results indicate that before deposition, AuNRs are coated with a few-nm thick CTAB layer corresponding to ~5,000 ligands/particle. This density is small when compared to the ~60,000 ligands/particle on silica-coated AuNRs. Our methods thus represent the first direct, quantitative chemical analysis of soft-hard interfaces of metal nanoparticles.

References:
A key way to impart specific function to metallic nanoparticles is to functionalize their surface with ligands, allowing a range of applications including chemical and biological sensing; theranostics; and catalysis. For gold nanoparticles, this typically involves incubating nanoparticles in solutions containing thiol-terminated ligands and allowing the ligands to self-assemble on the surface of the gold through the formation of gold-thiol bonds. However, the structure and organization of the resulting ligand shell at the metal-organic interface is difficult to visualize. This talk will describe how single molecule fluorescence and super-resolution microscopy provide insight into surface organization of DNA-functionalized gold nanorods as a function of different preparation strategies. In cases when the DNA binds in a collapsed, disordered configuration, plasmon heating facilitates dynamic surface reorganization to a more ordered, upright geometry. By understanding how changes in surface preparation protocols impact the resulting ligand shell, we will be able to synthesize more reproducible functionalized nanostuctures.

Amplification of Chirality Transfer to Nematic Liquid Crystals by an Enhancement of the Anisotropy Factor in Chiral Ligand-Capped Gold Nanorods

A new way to impart chiral function from metallic nanoparticles is to functionalize their surface with chiral ligands. The present approach significantly increases the chirality transfer efficiency from the chiral ligand to the nematic liquid crystal. This result is coherent with other data on the anisometric shape of GNRs with enhanced anisotropy or Kuhn’s dissymmetry factors.

A key way to impart specific function to metallic nanoparticles is to functionalize their surface with ligands, allowing a range of applications including chemical and biological sensing; theranostics; and catalysis. In Situ X-Ray Scattering Guides the Synthesis of Functional Nanocrystals

Synthesizing nanocrystals with precisely controlled size, shape, and structure is of great importance for understanding their properties. Although significant developments have been achieved in colloidal synthesis, it remains challenging to synthesize nanocrystals in a predictive way due to a lack of mechanistic understanding of the synthesis. In this talk, I will discuss my recent research efforts on precise syntheses of nanocrystals guided by *in situ* synchrotron X-ray scattering.

The first part of this talk describes using *in situ* small angle X-ray scattering (SAXS) under "realistic" synthetic conditions to elucidate the formation kinetics of monometallic Pd nanocrystals in the presence of different ligands, which enables precise synthesis of a broad library of monodisperse Pd nanocrystals with 1 nm size control. The real-time SAXS also allows us to observe an unprecedented rapid crystallization of nanocrystals into three-dimensional superlattices at high temperatures and their continuous growth within the superlattices, which provides new insights on interparticle interactions during colloidal synthesis. In the second part of the talk, I will demonstrate a mechanistic understanding of the formation of bimetallic PtSn nanocrystals at the atomic scale using simultaneous SAXS and wide angle X-ray scattering (WAXS). This type of *in situ* characterization can be readily extended to other nanocrystal systems to advance their rational synthesis.

Measuring the Facet-Selective Electrochemistry that Drives Anisotropic Growth of Metal Nanostructures

The number of applications for anisotropic metal nanocrystals in biomedicine, catalysis, and electronics has grown rapidly over the last decade. However,
the origins of anisotropic growth of metal nanocrystals in solution remain unclear due to the lack of experimental methods that can test previously proposed hypotheses. For pentagonally-twinned nanowires of Cu, Ag, and Au, researchers have hypothesized that organic capping agents selectively inhibit atomic addition to the \{100\} facets on the sides of nanowires, and thereby induce anisotropic nanowire growth through atomic addition to \{111\} facets on the ends of nanowires. However, there is little experimental evidence to support this hypothesis, and it does not explain why most syntheses require halide ions to grow Cu, Ag, and Au nanowires.

This presentation will show how electrochemical measurements on single crystals can be used to test hypotheses for how anisotropic growth of a metal nanocrystal occurs. In one study with Cu(100) and Cu(111), rather than acting as a capping agent, ethylenediamine (EDA) increased the rate of atomic addition to nanowire ends by keeping the Cu(111) surface relatively free of surface oxidation in the highly basic growth solution (>12 M NaOH). In another synthesis of Cu nanowires that involves the reduction of CuCl\(_2\) in the presence of hexadecylamine (HDA), we show that this capping agent passivates both Cu(100) and Cu(111) surfaces equally. However, the introduction of chloride ions in a narrow range of concentrations disrupts the alkylamine monolayer on Cu(111) but not Cu(100), causing Cu to preferentially deposit onto \{111\} facets on the ends of the nanowires. As in experiments, DFT calculations reveal there is an intermediate Cl coverage window in which HDA chemisorbs to Cu(111) but physisorbs to Cu(111), enabling the selective addition of Cu atoms to the less-protected \{111\} facets on the nanowire ends. This study shows single-crystal electrochemistry, in combination with DFT, can reveal unexpected mechanisms for how anisotropic growth occurs.

SESSION NM02.05: Plasmonic Structures
Session Chairs: Grant Johnson and Jianping Xie
Tuesday Afternoon, November 27, 2018

1:30 PM *NM02.05.01
Plasmonic Nanocrystals with High Refractive Index Sensitivity and Thermal Stability Sara E. Skrabalak; Indiana University, Bloomington, Bloomington, Indiana, United States.

Seed-mediated co-reduction is a versatile route to multimetallic nanocrystals with shape definition. This method has been used to achieve stellated Au-Pd nanocrystals with high symmetry, which is guided by the shape of the seeds used for bimetallic deposition. This presentation will highlight recent studies into the tunable optical properties of these nanocrystals for use as LSPR sensors and photothermal agents. As will be shown, compared to all-Au nanocrystals, the Au-Pd nanocrystals display higher sensitivity to changes in local refractive index as well as greater shape stability when heated. This presentation will be coupled with a detailed discussion of multimetallic nanocrystal synthesis by seeded methods and a broader discussion of the challenges associated with characterizing and modeling the composition of multimetallic nanostructures.

2:00 PM NM02.05.02
Peptide-Directed Synthesis of Chiral Plasmonic Gold Nanoparticles Hyo-Yong Ahn, Hye-Eun Lee and Ki Tae Nam; Material Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

The integration of chirality with plasmonic materials offers a new possibility for nanophotonics including polarization control, enantioselective sensing, and negative refractive index in the visible range. Since the light manipulation of chiral plasmonics relies on delicate nanomaterials, a majority of chiral nanostructure was created by precise lithographic techniques and molecular self-assembled template. Although remarkable chiral structures have been made by these techniques, spontaneous formation of three-dimensional inorganic nanostructure without mirror symmetry is an important challenge and still has not been achieved on a single nanoparticle.

In this study, we developed a peptide-directed strategy for synthesizing chiral plasmonic nanoparticle that allows for the precise control over handedness and chiroptical responses.[1-3] We demonstrated that interactions between peptides and gold surface enable “chirality transfer” to drive the spontaneous development of chirality during the nanoparticle growth. The intrinsic chirality of kink of inorganic high-Miller-index \{h\ k\ l\} planes (h ≠ k ≠ l ≠ 0) served a critical role to provide an enantioselective binding site for peptide on crystalline facets of gold nanoparticles. These unique peptide-gold interactions led to the evolution of asymmetric structure in an individual nanoparticle and consequently created a novel helicoid morphology with a 100-nm size. The highly twisted feature of chiral components in the helicoid gold nanoparticles gave rise to remarkably strong plasmonic optical activity; dissymmetry factor of the randomly dispersed nanoparticle solution reached 0.2 at visible wavelengths and can be further controlled by sequence, handedness, and an enantiomeric ratio of peptides. Theoretical calculation clarified that this optical activity is associated with the formation of strong chiral nearfield at high-order plasmonic mode. Surprisingly, based on the wavelength-dependent polarization rotation ability, a solution of the helicoid gold nanoparticle can modulate the color of transmitted light in a wide range of visible wavelengths. This color transformation operates in real-time by rotating a polarizer and can be observed in naked-eye. In this regard, we expect that our peptide-directed approach will promote the rational design and fabrication of three-dimensional chiral plasmonic metamaterial, as well as improve an understanding of the enantioselective interaction of peptide and inorganic material.

New Earth-Abundant Metallic Nanoparticles for Plasmonics John S. Biggins1, Josee Richard-Daniel4, Sadegh Yazdi1 and Emilie Ringe1, 2, 6, 8
1Department of Chemistry, Rice University, Houston, Texas, United States; 2Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 3Department of Engineering, University of Cambridge, Cambridge, United Kingdom; 4COPL, Université Laval, Quebec, Quebec, Canada; 5Renewable and Sustainable Energy Institute (RASEI), Joint Institute with NREL, University of Colorado Boulder, Boulder, Colorado, United States.

Nanoparticles (NPs) of some metals (commonly Cu, Ag, and Au) sustain oscillations of their electron cloud called localized surface plasmon resonances (LSPRs). These resonances can occur at optical frequencies and be driven by light, generating enhanced electric fields and spectacular photon scattering, opening applications including photocatalysis, photothermal therapy, and enhanced spectroscopies, to name a few. However, current plasmonic metals, in particular Ag and Au, are rare, expensive, and have a limited resonant frequency range. Recently, much attention has been focused on earth-abundant Al, but Al NPs have interband transitions that damp LSPRs in the IR. Here we report earth-abundant Mg NPs that may surmount this limitation. Our colloidal synthesis forms 100-300 nm diameter, 30-50 nm thick hexagonal nanoparticles, reflecting Mg’s simple hexagonal lattice, as shown by SEM and HRSTEM (Figure 1). STEM-EDS and STEM-EELS mapping reveals a self-limiting layer of oxide analogous to that observed in Al NPs, passivating both Cu(100) and Cu(111) surfaces equally. However, the introduction of chloride ions in a narrow range of concentrations disrupts the alkylamine monolayer on Cu(111) but not Cu(100), causing Cu to preferentially deposit onto \{111\} facets on the ends of the nanowires. As in experiments, DFT calculations reveal there is an intermediate Cl coverage window in which HDA chemisorbs to Cu(111) but physisorbs to Cu(111), enabling the selective addition of Cu atoms to the less-protected \{111\} facets on the nanowire ends. This study shows single-crystal electrochemistry, in combination with DFT, can reveal unexpected mechanisms for how anisotropic growth occurs.
The growth of metal nanoparticles on a solid substrate with precise control over their positions is one of the main challenges of plasmonics. Here, we introduce a facile approach based on photoinduced deposition of metal nanoparticles from the liquid phase on a solid substrate, driven and controlled by plasmons. The solid substrate consists of nano gaps in a silver stripe covered by a flat polystyrene film. Surface plasmons excited at the nano gaps initiate and control the growth of silver nanoparticles. We demonstrated that by confinement of light in this way highly ordered lines of silver nanoparticles can be grown with a width of 200nm over the whole laser spot area. Moreover, the near-field intensity pattern formed by the incoming laser light and the light scattered at the surface plasmons (SPs) is able to form much smaller (70nm in width) silver nanoparticle lines experimentally observed in our work. This facile approach opens a new path towards photochemical and plasmon-mediated fabrication of different sophisticated nanostructures. It does not require the usage of an expensive light source, materials or vacuum condition. Only photosensitive chemicals and a suitable light confining structure are needed.
new insights for the understanding of plasmon-mediated spin dynamics.

4:30 PM NM02.05.08
Near-IR Photothermal Ag Nanoparticles-Polymer Nanocomposite Layers with Controlled Plasmonic Coupling for Biofilm Eradication Shuzhi Zhou, Padyrk Merkl and Georgios A. Sotiriou; Karolinska Institute, Solna, Sweden.

With the ever-growing threat of catheter-associated infections, the development of highly effective treatments against bacterial biofilms is crucial while at the same time challenging. For this reason, physical ways to eradicate biofilms are sought, with a popular one the local temperature increase by plasmonic metals and near-IR laser light that is typically induced by expensive gold (nanoshells, nanorods) and complex silver (nanotriangles) nanostructures. Here, a stimuli-responsive polymer nanocomposite simulating the surface of polymer catheters incorporating plasmonic photothermal nanoparticles was designed aiming to destroy biofilms by heat and/or heat-triggered antibiotic drug release. The agglomeration degree during flame nanoparticle synthesis and, thus, controlled plasmonic coupling of inexpensive spherical silver (Ag) plasmonic nanoparticles supported on inert amorphous SiO2 was optimized by adjusting the deposition time on substrates and SiO2 content in the particle films. This enhanced the localized surface plasmon resonance and light absorption in the near-IR region and facilitated efficient heat conversion upon irradiation with an 808 nm laser. Heat generated from the PDMS-Ag nanoparticle-layer-PDMS nanocomposite under near-IR irradiation inhibited the viability of clinically-relevant biofilms. Additionally, laser-induced heat was able to trigger drug release from poly(2-hydroxyethyl methacrylate) hydrogels that were coated on the polymer nanocomposites surface, enabling these nanocomposites to achieve on-demand, heat-triggered antibiotic release against biofilms. The facile, scalable and inexpensive fabrication method of the developed anti-biofilm polymer surfaces based on plasmonic photothermal layers liberates the field from the use of expensive materials and processes facilitating their broad employment and clinical translation.

4:45 PM NM02.05.09
Solution-Derived Plasmonic Metal Surfaces for Optical and Thermal Applications Jyotirmoy Mandal and Yuan Yang; Columbia University, New York, New York, United States.

Solution-based processes, such as galvanic displacement reactions, are a simple method for creating plasmonic metal nano- and micro-structures. However, despite their simplicity, their potential to fabricate metasurfaces tailored for thermal and optical applications remains to be explored in detail. In this talk, we present galvanic displacement reactions as a facile pathway to make plasmonically active metasurfaces tailored to function as, among other examples, selective solar absorbers, super-broadband absorbers/emitters, and stray light absorbers for astronomical and imaging applications. For instance, galvanic displacement reactions are known to yield solar absorbers with solar absorbance > 0.95 and hemispherical thermal emittance <0.1 [1]. Similar reactions can yield super-broadband absorbers with excellent, wide-angle absorbance (e.g. ~0.95 at incidence angles > 60°) from the visible to infrared wavelengths of light. Additional functionalities arising from the optical selectivity of the surfaces and combination with other materials will also be discussed.

With regard to synthesis, galvanic displacement reactions are attractive, as they can be conveniently tuned to yield specifically tailored plasmonic surfaces for different optical and thermal applications. Furthermore, they are simpler, less expensive and greener than currently used fabrication techniques (e.g. vacuum deposition). Lastly, they are compatible with unexotic metals or alloys such as steel, which broadens their applicability. Considering the above uses, these aspects make galvanic displacement-based reaction pathways viable and highly attractive for making plasmonic metasurfaces.

media. The silver-cobalt oxide core-shell nanocrystals (Ag@Co3O4) were synthesized using bi-polar pulsed plasma discharge in water for catalytic oxygen reduction in alkaline solutions. Microstructural and compositional analysis using HRTEM equipped with high resolution EDX elemental mapping verified that the reactive oxygen species generated from plasma-assisted decomposition of water molecules played important role in controlling the phase structure of the nanoparticles. In the presence of abundant oxygenated species, the Ag@Co3O4 core-shell was formed by the preferential oxidation of Co at the surface. The electrochemical measurements for oxygen reduction reaction revealed that the electrocatalytic activity of the Ag@Co3O4 core-shell nanocrystals were higher than that of pure Ag and Co3O4 nanoparticles. This enhanced catalytic activity could be attributed to the electronic effects induced by an upshift in the d-band center via charge transfer between Ag and Co. For the Ag@Co3O4 core-shell architecture, the active Ag interacted more extensively with the Co3O4 monolayer shell at the surface. Owing to this favorable structure, the ORR activity was higher on the core-shell surface than for the subcluster-segregated nanoalloys. This was unlike uniform contacts, and it led to weakened electronic effects. Thus, it was concluded that Ag@Co3O4 core-shell electrocatalysts will be promising candidates for potential applications in catalysis.

Mechanical and Electrical Properties of Nanowire-Based Flexible Galvanic Skin Response Sensor Sun Hwa Park, Ji Hye Park and Jae Yong Song; KRISS, Daejeon, Korea (the Republic of).

Monitoring systems to read human bio-signal have been developed with increasing healthcare applications. Among them, galvanic skin response (GSR) sensor has been used to measure skin conductance, defined as electrical conductance between two regions of skin. GSR sensor can help to evaluate a stress and a lie detection because skin conductance is changed by the sweat gland activity indicating a psychological or physiological arousal. Recently, GSR sensors have been fabricated in the forms of fingerband, armband, hairband and patch. However, these sensors have some limitation due to low sensitivity and difficulty for wearable devices.

In this study, we introduce a low-cost and facile fabrication of highly flexible GSR nanosensor (less than 5 mm in size and 6 um in thickness) which is composed of vertically aligned Ag/Au core-shell nanowires (200 to 300 nm in diameter) embedded in a polyeimide matrix. Vertical configuration of the nanowires within GSR nanosensor enables the sensor to measure skin conductance through thickness direction while the nanosensor is insulating in the in-plane direction. The nanowire based GSR sensor is flexible enough to be easily adapted to the curved skin. Experimental results show that the nanowire based GSR sensors have more excellent sensitivity than commercial GSR sensor. The bending and cycling tests showed that the sensitivities of the GSR sensors are reliably maintained for three months.

NM02.06.04
Regulation of EGFR Signal Transduction by Dynamic Receptor Clustering Qianyun Zhang; Chemistry, Boston University, Boston, Massachusetts, United States.

Epidermal growth factor receptor (EGFR) is a transmembrane receptor tyrosine kinase, whose dysregulation and abnormality have been associated with oncogenesis. Current EGFR targeted therapeutic approaches have failed to meet expectations due to the mutation of EGFR or the resistances of tumor to the treatment. So the development of an efficient receptor targeted drug would be successful only if the molecular mechanism underlying the EGFR signaling pathway are fully understood. It has been known that clustering of receptors play important roles in cell signaling. Thus, we will study the distribution of the epidermal growth factor receptors on the cellular membrane as well as in early endosome in the response to the ligand binding.

Noble gold nanoparticles (NPs) has been used as tool in biosensing and tracking due to their unique optical properties. The most useful property of NPs is that they can induce plasmon coupling, then leads to a spectral shift in the scattering spectrum of the coupled NPs labels. This shift can be conveniently detected by conventional far-field light microscopy, so called Plasmon Coupling Microscopy (PCM). Heterogeneous EGFR distribution will be optically indicated by EGF conjugated gold NPs clusters with different size and colors. Thus, we will develop a gold palisom ruler that can characterize the compartmentalization of growth factor in cancerous cell lines. The first aim is to investigate the regulation of surface receptor clustering to signaling strength. To do that, it is necessary to correlate the spatial organization of EGFR clustering, as measured by PCM, with the receptor activation. The triggered EGFR signaling can be quantified by detecting its phosphorylation levels by specific antibodies.

The next question is how receptor tyrosine kinases determine different cell-fate decisions despite sharing the same signaling cascades. One hypothesis is the tight control of the endosomal distribution of EGF could serve to regulate signal transmission. The cell respond to higher EGF concentration by increasing the number of endosomes, and the average number of phosphorylated EGF receptors in each endosome remains almost constant. If we expose cell to gold NPs with different EGF ligand density, the endosome contained NPs cluster would be different. Thus, we could test hypothesis by quantitatively analyzing the endosomal distribution of EGFR and downstream signaling outcome.

The correlation of EGFR clustering and signaling activation will explicit explain how growth factor activation of this process depend on receptor clustering. Furthermore, we will address the question that whether intercellular EGFR clustering facilitates the decisions of signaling outcome. Therefore, the study of the mechanism of tyrosine kinase receptor in signaling pathway could help to augments efficacy of EGFR targeted therapeutic treatments in the future.

NM02.06.05
Seed-Mediated Co-Reduction Synthesis of Intermetallic Au-Cu Nanocrystals—Insight into the Size-Dependent Disorder-Order Transformation Hannah M. Ashberry, Jocelyn T. Gamler and Sara E. Skrabalak; Indiana University, Bloomington, Indiana, United States.

Intermetallic nanoparticles often show increased catalytic efficiencies and durability towards electrocatalytic processes, such as the oxygen reduction reaction and reduction of carbon dioxide. Typical syntheses of intermetallic materials include thermal annealing of the alloyed counterpart and colloidal chemical syntheses. While both methods can produce intermetallic nanoparticles, little is known about the transformation from the random alloy to intermetallic phase. Previously demonstrated in the Skrabalak group was a size-dependent disorder-to-order transformation from random alloy to intermetallic Au-Cu nanoparticles. Such a size dependent transformation has also been observed in semiconductor systems. Here, this size-dependent transformation is explored with Au-Cu nanoparticles. Specifically, monodisperse Au50Cu50 and Au60Cu40 intermetallic nanoparticles were synthesized by seed-mediated co-reduction using Au-Cu random alloys as seeds. The study of the growth mechanism by analyzing reaction aliquots by TEM and XRD supports that such a disorder-to-order transformation is a general feature that can be exploited with seed-mediated co-reduction to achieve high quality intermetallic samples. This demonstration advances understanding of intermetallic nanoparticle formation in colloidal synthesis, which can expedite the development of electrocatalysts.
Selective Heterogeneous Growth of Polyhedral Cu Nanoshell for Plasmonic Light Scattering Enhancement and Quantitative Naked-Eye Bio-Detection
Jae-Ho M. Kim, Jeong-Fun Park, Mouhong Lin, Sungi Kim, Gyeong-Hwan Kim and Jwa-Min Nam; Chemistry, Seoul National University, Seoul, Korea (the Republic of).

Nanoparticles (NPs) such as AuNPs have wide applications in molecular detection, labelling, and imaging due to their compatible size, large surface area, availability of various conjugation methods, richness in core-shell chemistry, as well as geometry-dominant optical properties such as localized surface plasmon resonance and plasmonic coupling properties. The magnitude of the intrinsic optical properties of individual NP probes are, however, insufficient to detect targets at trace levels. Further, the simplicity, assay speed, and portability are critical elements, especially in developing fast but reliable naked-eye-based bioassays. To address these issues, Ag-based enhancement, known as silver staining, has been extensively studied so far to amplify Rayleigh scattering, surface-enhanced Raman scattering, colorimetric signals and electrical signals. However, the lack of specificity on detection label and low controllability of Ag shell formation limited its practical applications.

Here, we introduce a selective heterogeneous growth of polyhedral Cu nanoshell on Au nanoparticle. This is based on highly controllable polyethyleneimine(PEI)-mediated Cu polyhedral nanoshell (CuP) formation chemistry, specifically formed on AuNP probes, and used this CuP formation method for straightforward, intensive and quantifiable optical signal enhancement. The optical signals from one-to-one overgrown metallic polyhedral nanoshells are amplified about two orders of magnitude, and readily detectable with naked-eyes or an ordinary smartphone camera. In the case of DNA assay (anthrax sequence), we detected 8 fM DNA on an archetypal DNA microarray chip with a dynamic range from 8 fM to 800 pM in this manner. Also for virus detection (norovirus target in this case), clinical stool samples were used, and as low as 2,700 virus copies were detected with >2-orders of dynamic range. The high sensitivity and quantification capability of this CuP enhancement were superior to any other previously reported bio-detection methods detectable with naked eyes. The Cu nanoshell formation chemistry provides a new paradigm in controlling optical properties from selectively overgrown Cu shell nanostructures and their use in bio-detections.

Enhanced Radiation Shielding with Conformal Light-Weight Nanoparticle-Polymer Composite
Qingxuan Li, Qilin Wei and Ming Su; Northeastern University, Boston, Massachusetts, United States.

This abstract reports a new property enabled by nanoparticles, where bismuth nanoparticles added in a polymer matrix can block X-ray radiation several times more efficient than microparticles at the same mass ratio. Bismuth nanoparticles are made with cellulose nanofibers and dispersed evenly into a polymer. A four time reduction in the mass of bismuth material is identified at 2% mass ratio when nanoparticles (3 nm diameter) are used in composite to shield a given flux and energy of radiation, in relative to those of microparticles (5 µm diameter). The enhancement in radiation shielding is primarily attributed to close packing of nanoparticles along projection direction of incoming X-ray, which is enabled by strong affinity of nanoparticles to interstitial space of cellulose nanofibers and even distribution of nanoparticles in polymer. Given its low cost, light weight and structure conformability, bismuth nanoparticle-polymer composite will find its use in a wide range of fields related to personal radiation protection.

A Quantitative Electron Microscopy Study of the Bending of Seed-Mediated Grown Gold Nanorods
Xin Wen1, 2, Torben N. Pingel2, Kasper Moth-Poulsen1 and Eva Olsson2; 1Department of Chemistry and Chemical Engineering, Chalmers University of Technology, Gothenburg, Sweden; 2Department of Physics, Chalmers University of Technology, Gothenburg, Sweden.

Gold nanorods are promising candidates for applications in medicine, optics, electronics and chemistry since they have attractive optical and physical properties, especially strong absorption of localized surface plasmon resonance. In order to manipulate absorption of light in unprecedented ways, researchers have studied how to bend gold nanorods using lasers. However, we have observed gold nanorods synthesized by a binary-surfactant seed-mediated growth method exhibiting high resolution transmission electron microscopy (TEM) and found that they were bending a few degrees spontaneously. The study on formation of bending structure and the deformation in the rods also benefits understanding the dynamic process of gold nanorods' growth. Further researches on TEM have shown that the gold crystal lattice is tilting a small angle (less than 10 degree) around [010] zone axis continuously, which is also transversal axis of the rod. Besides, there is no lattice defects observed on the bending gold nanorod in high resolution images. In order to understand bending mechanism, the distribution of silver element added in growth solution was studied by Energy-dispersive X-ray spectra. We found very little amount of silver concentrated on the outer layer of a gold nanorod, which is the possible reason that causes the bending structure.

Selective Heterogeneous Growth of Polyhedral Cu Nanoshell for Plasmonic Light Scattering Enhancement and Quantitative Naked-Eye Bio-Detection
Qingxuan Li, Qilin Wei and Ming Su; Northeastern University, Boston, Massachusetts, United States.

Mitsuhiro Iwasaki1, Yukatsu Shichibu1, 2 and Katsuaki Konishi1, 2; 1Graduate School of Environmental Science, Hokkaido University, Sapporo, Japan; 2Faculty of Environmental Earth Science, Hokkaido University, Sapporo, Japan.

Recent progress in the crystal structure determination of ligand-stabilized gold clusters has revealed that not only nuclearity but also geometrical structures of inorganic units affect their electronic structures and optical properties. The perturbation effect of the ligand environment is an important feature for developing designer clusters with specific functions, but the role of the organic units is still elusive. In this work, we placed focus on the effect of proximal π-system of organic unit on the optical properties of the gold cluster. A series of core + exo type Au5 clusters decorated by diphenylethene (dppp = Ph2P(=CH2)PPh3) and aryloleolate ligands were synthesized, and their optical properties were studied to obtain insights into the perturbation effect of the organic ligands. Various thiolate and acetylide ligand were induced on the Au5 framework via the reaction of divalent Au5 cluster ([Au5(dppp)3]2+) with the corresponding alkyne and thiol. The produced clusters were characterized by electrospray ionization mass spectrometry and elemental analysis. Pyridinium-substituted Au5 clusters ([Au5(dppp)(SPy)]2+) exhibited absorption and photoluminescence responses to protonation events of pyridyl moieties. Upon protonation, 2- and 4-pyridinemethylate clusters showed larger red shifts of absorption and photoluminescence bands than 3-pyridinemethylate, suggesting that the observed band shifts are associated with the resonance structure of the pyridiniumylates. On the other hand, emission intensities of all regioisomers increased largely. X-ray crystallographic and NMR analyses revealed the electron-deficient pyridinium rings form π-stacks with proximal phenyl groups of dppp in the protonated form. Thus, it was suggested that the rigidity of the ligand environment induced by π-π interactions leads to the enhancement of emission efficiency. These results indicate that optical properties of small gold clusters can be modulated through the electronic and steric perturbations by surrounding organic units.
Simulations that closely mimic the experimental conditions, including the degree of particle roundness, the softening of the particle contacts with the substrate/indenter, and the testing temperature.

We demonstrate that faceted single-crystalline Nickel and Ni-Fe alloy nanoparticles exhibit an ultrahigh compressive strength unprecedented for crystalline metals. Most of the particles yielded with a large strain burst, and their strength exhibited a strong dependence of on the particle size. The strength of colloidal gold nanoparticles with different shapes (rod, star, and sphere) can be quickly assembled by resonance matching with light. One assembly with a diameter of tens of micrometers can be completed within a minute, and patterned arrays of this assembly can also be prepared rapidly. We believe that our proposed method will have a huge impact on the future development of optical and electronic systems, as well as the building-up of plasmonic nanomaterials.

Small scale testing of single crystalline metallic particles offers a unique opportunity to understand the nucleation-mediated plasticity mechanisms. Single crystalline Nickel-Iron (Ni-Fe) particles with different iron content were prepared by solid state dewetting of Ni-Fe bilayers on sapphire substrate. The capillary interaction with pre-patterned solid substrate has been utilized. However, the direct assembly of colloidal nanoparticles without chemical linkers and pre-patterned substrates remains challenging. Here, we propose a novel approaches for rapid and direct positioning of colloidal plasmonic nanoparticles onto diverse solid substrates via photothermal convection lithography. It is based on the photothermal conversion effect of plasmonic nanoparticles by resonant light focusing, which induces convective flow. The convective flow further forces the colloidal nanoparticles to assemble at the illumination point of light. The size of the assembly is increased by either increasing the light intensity or illumination time. Also, we accelerate the assembly by modulating of experimentally controllable variables such as light intensity and solvent viscosity. We show that three types of colloidal gold nanoparticles with different shapes (rod, star, and sphere) can be quickly assembled by resonance matching with light. One assembly with a diameter of tens of micrometers can be completed within a minute, and patterned arrays of this assembly can also be prepared rapidly. We believe that our proposed method will have a huge impact on the future development of optical and electronic systems, as well as the building-up of plasmonic nanomaterials.

Rapid and Direct Assembly of Colloidal Plasmonic Nanoparticles via Photothermal Convection Lithography

Size and Composition Effects in Compression of Ni-Fe Particle Prepared by Solid State Dewetting of Bilayers

Self-Organized Formation of Multilayer Structure in a High Nitrogen Stainless Steel During Solution Treatment

Compared with traditional stainless steels, high nitrogen stainless (HNS) steels have been widely used due to their high strength, toughness along with excellent corrosion resistance and low cost, by partial replacement of Ni (austenite-forming element) by N element. The evolution of the microstructure of a Cr13Mn9Mo4N0.4 stainless steel is investigated by solution treatments at 1010, 1060, 1200 and 1250 degree Celsius for 30min, respectively. A complex multilayer structure has been found. A ferritic layer with nano-scaled particles precipitated along ferrite boundaries, at the surface, is formed. The precipitation of nano-scaled particles in the ferritic surface layer indicates possible diffusion barriers for nitrogen from subsurface to surface. This self-organized formation of multilayer structure can broaden the application of HNS steel to magnetic functional areas.

Surfactant-Free Synthesis of Cu₂O Yolk-Shell Cubes Decorated with Pt Nanoparticles for Enhanced H₂O₂ Detection Jian Lyu1,2, Chuncai Kong1, Sen Yang1 and Zhimao Yang1; 1Department of Materials Physics, Xi’an Jiaotong University, Xi’an, China; 2Department of Nanoeengineering, University of California, San Diego, San Diego, California, United States.

Cu₂O yolk-shell cubes decorated with Pt nanoparticles were synthesised by a liquid-phase, surfactant-free and multi-step route (Figure 1a). ZnCl₂ ions and O₂ dissolved in solution lead to the formation of the yolk-shell Cu₂O cubes. The as-prepared yolk-shell Cu₂O cubes were used as the substrate to hold the growth of Pt nanoparticles though a commonly used photo-reduction reaction without damages of the yolk-shell structures. Then, the as-prepared Pt-Cu₂O composites were used as the active materials for the fabrication of the nonenzymatic sensor for H₂O₂. Decorating Pt nanoparticles hugely increased the electrochemical sensing performance of Cu₂O, compared with the bare yolk-shell Cu₂O cubes. Meanwhile, the Pt-Cu₂O based H₂O₂ sensors show good electrochemical selectivity to the reduction of the H₂O₂, indicating its great promise to serve as the electrocatalytic materials for the sensing of the H₂O₂.

NM02.06.15 Retention of Anti-Cancer Activity of Curcumin after Conjugation with Gold Quantum Clusters—An In Vitro and In Vivo Xenograft Study Puneet Khandelwal1, Aftab Alam1, ArpanKumar Choksi1, Samit Chattopadhyay2 and Pankaj Poddar2; 1Indian Institute of Technology Kanpur, Kanpur, India; 2CSR-National Chemical Laboratory, Pune, India; 3NCCS, Pune, India; 4ICICB, Kolkata, India.

Cancer is a leading cause of death worldwide. However, a significant progress has happened in the cancer theranostics, a huge scope of the development is still exist. Chemotherapy is the most commonly used modality for cancer treatment. Curcumin is one of the very important therapeutically important drug molecules which has applications in wide range of diseases but could not be used clinically much because of its poor water solubility. The nanoparticles based platforms are used to enhance the solubility of curcumin. Since last two decades, metal nanoclusters are becoming increasingly popular for biomedical applications because of their very small size around 1-2 nm, biological inertness, a wide range of luminescence from UV to NIR. Therefore, in the present work, gold quantum clusters (Au QCs) are used to increase the curcumin water solubility by using it as both reducing and capping agent for the synthesis of Au QCs. These curcumin conjugated Au QCs (C-Au QCs) were studied for their cytotoxicity to normal (NIH3T3) as well as cancer cells (MCF7). The curcumin conjugated gold nanoparticles (C-Au NPs) and GSH conjugated Au QCs were also synthesized to evaluate the effect of size and capping agent on the anticancer property. The cytotoxicity mechanism of Au QCs was studied in detail using FACS and western blot analysis. Further, the antitumor activity of C-Au QCs was studied in xenograft mice model and found that C-Au QCs were able to effectively inhibit the tumor growth. The major organ section analysis showed that the C-Au QCs did not exhibit cytotoxicity to the organs. Based on the results, the C-Au QCs are believed to be a promising candidate to treat cancer effectively in near future.

NM02.06.17 Visible Migration of Gold Based on Localized Plasmon Effect on a Paper Substrate Nobuko Fukuda1, Sakae Manaka1 and Toshiharu Enomae1; 1National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan; 2University of Tsukuba, Tsukuba, Japan.

We visually observed color changes of a paper substrate on which gold particles were deposited during a period since deposition. The isolated gold particles are formed on the coated paper by thermal vapor deposition with 0.01 nm/s of the deposition rate for 500 s. The size of each gold particle is about a few 10s nm just after deposition, according to the surface image of the paper collected with a scanning electron microscope (SEM) and an atomic force microscope (AFM). The reflection spectrum for the surface measured with an integrating sphere spectrophotometer shows a high reflection from 400 to 510 nm and the surface color is bluish. The color is derived from localized surface plasmon resonance of the gold particles. After it was placed in air at room temperature for 6 months, the color changed from bluish to reddish. The spectrum shows a high reflection at more than 600 nm. The size of the gold particles after 6 months widely varies from a few 10s nm to 100s nm. Some particles seem to coalesce and the space between grains obviously has widen according to SEM observation. These results suggest that migration of the gold particles on the coated paper occurs at room temperature. In the case that the thermal vapor deposition with 0.01 nm/s was carried out for 1000 s, an incomplete gold sheet with gaps is formed on the paper substrate. The sheet thickness is about 10 nm. The reflection spectrum shows a high reflection at more than 500 nm and the surface color is yellowish and slightly metallic. After it was placed in air at room temperature for 6 months, the color changed from yellowish to reddish. The SEM and AFM images of the surface after 6 months showed isolated gold particles with more than 100 nm in diameter and more than 100 nm in height. It seems that dewetting, isolating, and coalescence of the gold have sequentially occurred on the coated paper. In addition, we expect that the rate of the color changes based on the migration of gold depends on the surface conditions such as roughness, surface free energy, adhesive force, and so on.

NM02.06.18 Preparation and Characterization of NiMnOx Particles Toward Supercapacitor Application Hikaru Ishitsuka and Yoshikazu Suzuki; Graduate School of Pure and Applied Science, University of Tsukuba, Tsukuba, Japan.

Recently, with the increase in worldwide energy demand, rechargeable energy devices and materials are actively studied. Especially, supercapacitor is a promising application in energy storage devices due to its high power density, good reversibility and cycle characteristics. Manganese oxide-based transition metal compounds are candidates for supercapacitor materials. NiMnO₂ has excellent conductivity, stability and electrostatic capacity and does not contain noble metal. NiOCl₂·2Ni(OH)₂·4H₂O (1 mmol), MnO₂ (3 mmol) and urea (15 mmol) were dissolved in 30 mL distilled water to obtain homogeneous solutions. The solutions were hydrothermally treated at 120-160 °C for 6 h, and Ni-Mn precursors were obtained. The as-prepared precursors were calcined at 350 °C for 3 h. The obtained powder samples were characterized by XRD, and the microstructure was investigated by SEM and TEM. The specific surface area was evaluated by N2 adsorption method.

NM02.06.19 Nano-Phase Separation Sintering in Titanium-Magnesium Alloys Kathrin Graetz1, Jonathan Paras1 and Christopher A. Schuh1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Mubea Performance Wheels, Gurten, Austria.

While mechanical milling reliably produces nano-sized grains in metal alloy powders, consolidating as-milled powders into bulk parts—while still retaining the desirable nanocrystalline structure—remains a challenge. This work seeks to use alloying to lower the free energy of grain boundaries and decrease the driving force for coarsening in nanocrystalline Ti alloys, permitting solid-state sintering to high density. Mg is identified as a nano-grain stabilizer for Ti, and the effects of Mg composition on powder consolidation by pressureless sintering are explored. The mechanical milling of Ti-Mg alloys produces grain sizes on the order of 20 nm along with a supersaturation of Mg solute in Ti. Accelerated sintering occurs upon heating, triggered by nano-phase separation of Mg out of solution, in some cases leading to relative densities >95% at low processing temperatures, while maintaining ultrafine grain sizes. The thermal stability of the grain structure is also characterized over a range of temperatures and a kinetic relationship for the coarsening behavior of Ti-Mg alloys is determined.
Surface Versus Incorporated Pd on SnO$_2$—Influence on Gas Sensing

Sebastian Keller, Nicolay J. Pineau, Andreas T. G"{u}ntner and Sotiris E. Pratsinis; ETH Zurich, Zurich, Switzerland.

Size, shape and location of catalytic active Pd on SnO$_2$ has a strong impact on gas sensing properties. In specific, it greatly enhances the sensitivity of gas sensors and reduces response and recovery times and is therefore often applied. However, the exact role of Pd size, location and amount is rarely investigated and remains a trial and error approach. Here, the location (i.e. surface or incorporated) and size of Pd on SnO$_2$, and its role on gas sensing are systematically investigated and optimized at the nanoscale. In a first step, SnO$_2$ nanoparticles with different amounts and locations of Pd were prepared by flame aerosol and wet chemical synthesis. The amount of incorporated and surface Pd was investigated by X-ray diffraction, tunnelling electron microscopy and Pd-leaching. Sensing films of these particles were obtained by doctor blading them onto substrates with interdigitated electrodes. The optimized gas sensors exhibit superior sensitivity to trace analytes even at relevant low ppb levels and could therefore readily be used to detect environmental pollutants, monitoring food quality, detect entrapped humans after a calamity, as well as in medical breath analysis.

Design of Localized Surface Plasmon Absorption in Square-Shaped Silver Nanoparticles

Abhikesh Ramachandran, Anmol Walia and Madhusudan Singh; Indian Institute of Technology Delhi, New Delhi, India.

Shaped nanoparticles are known to enhance absorption in a tailored manner due to the enhancement of electric field modes in incident light. Various fabrication techniques have made it possible to produce nanoparticles with accurate sizes and in a variety of external media resulting in a controlled red shift in the absorption spectrum. This control is valuable in the design of absorbers for potential detector and photovoltaic applications, besides optical coatings. In this work, the dependence of the absorption spectrum on various parameters such as square nanoparticle edge length, height, aspect ratio, wavelength and polarization of incident light, external medium as well as the effect of a proximal conductive substrate was investigated using finite difference time domain numerical techniques, and enhancement factors derived. Absorption peaks were found to redshift from ~625 nm to ~890 nm upon an increase of the edge length from 150 nm to 250 nm (height constant), but blue shift upon increasing height of the nanoparticles (edge length constant). The peak location is found to be strongly dependent on the aspect ratio, but not the volume of the nanoparticles. Higher refractive indices resulted in redshift of the absorption (fixed distance to the conductive substrate). Resonant energy transfer is seen to happen through enhanced absorption for in-plane polarization of light. These results are expected to provide a better path to the rational design of optical absorption through localized surface plasmon resonance of square nanoparticles produced through techniques such as chemical synthesis and e-beam lithography.

Correlating Interfacial Solvent Structures with Catalytic Behavior by Total Scattering

Mirco Eckardt and Miriam Zobel; University of Bayreuth, Bayreuth, Germany.

Noble metal nanoparticles (NP) play a major role in modern heterogeneous catalysis. Reaction conditions like temperature and pressure impact the catalytic activity and selectivity. [1] Although a solvent effect is commonly accepted as a decisive parameter in liquid-phase catalysis, its fundamental understanding on a molecular level is still missing. Pair distribution functions (PDF) analysis based on high-energy X-ray scattering experiments can access the size of and the molecular ordering within solution shells around colloidal NPs. [2] To correlate solvent-dependent catalytic activity with the interfacial solvent structure, we performed the selective hydrogenation of styrene to ethylbenzene under atmospheric hydrogen pressure in various organic solvents like tetrahydrofuran (THF) and toluene. Dodecanethiol stabilized palladium (Pd) NPs with an average diameter of 3 nm acted as catalyst. The difference-PDF signal of the THF dispersions reveals four restructured layers of THF molecules stretching 2 nm away from the NP surface. Corresponding catalytic studies (gas chromatography) allow a structure-activity correlation. Finally, GC-MS can be coupled to in-operando PDF measurements (1 min time resolution) to track structural changes of both NP and interfacial solvent layers in liquid-phase catalysis.

Control of Nanoporous Pd-Al Film Structure by Dealloying Reaction of Al-Pd Alloy Film Using Organic Acids as Chelating Agents

Takashi Ishiguro, Akizumi Kawamoto and Takaji Ube; TUS, Tokyo, Japan.

Nanoporous materials are applied to sensors, catalysts, etc. because of their large specific surface area. For example, since palladium (Pd) selectively reacts with hydrogen gas, application as a sensor is expected. One of the most usual methods to form the nanoporous materials is dealloying, which is chemical or electrochemical dissolution process of the base metal from the precursor alloy with target material. In this case, strong acids such as hydrochloric acid and sulfuric acid or strong alkali are usually used. In contrast to this, we have proposed a dealloying process using environmentally friendly chemicals. Ultrasensitive nanoporous Pd-Al film had been successfully formed by citric acid-assisted hot-water-treatment of Al-Pd alloy film. (T. Harumoto, Y. Tamura, et al., AIP Advances 5, 017146 (2015)). Here the citric acid played a role as a chelating agent for forming the complex with Al$_3^+$ ions. On the other hand, there was a disadvantage that the reaction rate was slow, e.g. it took 30 minutes for dealloying reaction of 70-nm-thick Al-Pd alloy films to be saturated. Therefore, in this study, in order to accelerate the dealloying reaction rate, pH value of the reaction solution was controlled from 4 to the alkaline side. In addition to the citric acid, as the reaction solution, ethylenediaminetetraacetic acid (EDTA) having high chelating ability was also examined. 70-nm-thick Al-Pd (82at%Al) alloy films were prepared by rf sputtering method using Al target with Pd sectors. pH value was controlled by adding NaHCO$_3$ to citric acid solution or Na$_2$CO$_3$ to EDTA solution. Time variation of the visible light transmittance (VLT) during dealloying processing at 370 K was measured by using a digital high-vision video camera. Structure of the film on elastic carbon film were observed by using scanning transmission electron microscope.

Saturation time of VLT in the pure citric acid solution at pH=4.0 was 30 min. By adding NaHCO$_3$ to this citric acid solution, pH value changed to 9.0 and then saturation time of VLT was shortened to 9 min. Furthermore, when reacting with EDTA at pH=10.0, the saturation time was reduced to 90 sec. By changing chelating agent from the citric acid to EDTA, the film morphology also changed from high-density nanopore (diameter of about 10 nm) structure to nanopore network structure. In addition, the film composition after the dealloying treatment increased up to 92at%Pd in the case of EDTA (pH=10.0) from 85 at%Pd in the case of citric acid (pH=4.0).

It was considered that dissociation of citric acid and EDTA was promoted under the pH conditions on the alkaline side and the chelating ability was activated. As a result, it was found that by controlling the pH value according to the type of chelate, the dealloying reaction rate was accelerated to 20
Fullerene Nanopottery—Design, Shaping and Interconnecting Hollow Nanostructures Fei Han and Hongyu Chen; Nanyang Technological University, Singapore, Singapore.

Hollow nanostructures have been widely applied in nanoscience, but their fabrication remains at a primitive level. Most hollow nanostructures are enclosed spheres. Even creating a bottle in nanoscale is extremely difficult, not to mention creating more complex shapes and assembling interconnected systems. Interconnected hollow system is one of the most fundamental structures both in living system and in human industry, e.g., blood vessel system and nerve system in livings, various tube systems in city, and modern buildings consisted by corridors and rooms. However, the concept of interconnecting hollow spaces still remains blank in nanoscale, which is critical to the synthesis of such structures.

We bring pottery, the oldest and simplest method to create and assemble hollow structures, into nanoscale, to realize the systematical design, synthesis, assembly, and interconnection of hollow nanostructures. Individual fullerene hollow structures of tailored shapes, such as bowls, bottles, and cucurbits, are synthesized through a bottom-up process within one-step. Most importantly, the method allows modularized interconnection of hollow units into interconnected hollow systems. The synthesized structures have a hydrophobic interior and a hydrophilic outer surface. As a proof-of-concept, we create multi-compartment nano-containers, with different hydrophobic nanoparticles isolated in the separate pockets. Hopefully, these findings could expand the synthetic freedom for hollow nanostructures, building a bridge from isolated hollow units to interconnected hollow systems, and hence, have the potential to broaden their applications in a wide range of fields.

In Situ Analysis of Conductive Films Formation Using Cu Nanocrystals Arnau Oliva Puigdomenech 1, Filip Geenen 2, Christophe Detavernier 2 and Zeger Hens 1; 1Chemistry, Ghent University, Ghent, Belgium; 2Solid State, Ghent University, Ghent, Belgium.

Introduction
The constantly growing market of printed electronics requires the development of new materials that can be turned into conductive inks and allow for economic device fabrication. Hereof, due to its top-of-the-line conductivity and affordable cost, conductive inks based on copper nanocrystals have been extensively studied in the recent years. A particular focus of this work has been the prevention of copper oxidation, which can compromise the conductivity of the eventually printed copper. Typically, oxidation has been suppressed by the incorporation of antioxidants or the formation of a shell around the Cu nanocrystals. While effectively slowing down oxidation, such approaches come at the expense of costlier synthesis reagents and conditions. Instead of preventing oxidation at all costs, we propose a flexible and economical synthesis route of Cu nanocrystals, demonstrate by in-situ x-ray diffraction that surface oxidation can be reversed upon sintering, and how the sintering conditions vary depending on the copper nanocrystal size and surface termination.

Results and Discussion
Copper nanocrystals were synthesized by thermal decomposition of copper formate in oleylamine. SEM and TEM imaging presented quasi-spherical nanoparticles resistant as 20 µΩ●cm, which confirms the potential of nanocrystals for printed electronics.

Conclusions
We propose a flexible and efficient synthesis method that yields Cu nanocrystals. We use them as models to study the reduction of copper oxide in Cu nanocrystal films. We find that the unavoidable oxidation of the surfaces can be reversed via sintering. We prove that the temperature at which conversion to copper occurs markedly depends on the size and the surface termination of the nanocrystals. We demonstrate that sintered films attain a resistivity as low as 20 µΩ●cm, which confirms the potential of nanocrystals for printed electronics.

Synthesis and Characterization of Biogenic Selenium Nanoparticles with Antimicrobial Properties Made by Staphylococcus aureus, Methicillin-Resistant Staphylococcus aureus(MRSA), Escherichia coli and Pseudomonas aeruginosa David Medina, Gujie Mi and Thomas Webster; Northeastern University, Boston, Massachusetts, United States.

Antimicrobial resistance is a global concern that affects more than 2 million of people each year. Therefore, new approaches to kill bacteria are needed. Nanotechnology is one of the most promising approaches. While metallic nanoparticle synthesis methods are well studied, they are often accompanied by significant drawbacks such as cost, extreme processing conditions, and toxic waste production. In this work, we explored the environmentally safe synthesis selenium nanoparticles, which have shown promise in killing bacteria

Using Escherichia coli, Pseudomonas aeruginosa, Staphylococcus aureus subsp. aureus Rosenbach and Methicillin-resistant Staphylococcus aureus(MRSA) were used to synthesize biogenic selenium nanoparticles, 90-150 nm selenium nanoparticles were synthesized under standard conditions using an environmentally-safe approach. Bacterial cultures, prepared in Luria-Bertani (LB) media, were inoculated with 2 mM sodium selenite (Na2SeO3) solution to activate the detoxification process that leads to the synthesis of nanoparticles. The nanostructures were characterized using Transmission Electron Microscopy, Energy Dispersive X-Ray (EDX) to determine the chemical compositions and Inductively coupled plasma mass spectrometry (ICP-MS) to validate the chemistry within the samples. Nanoparticles were also characterized and tested for their ability to inhibit the bacterial growth through optical density measurements in a SpectraMax M3 spectrophotometer, and colony forming unit assays. Besides, biocompatibility tests of the nanoparticles with human tissue were accomplished, growing human dermal fibroblast (HDF) cells in media in the presence of biogenic selenium nanoparticles. After an incubation time of 24 hours, the cell growth was analyzed using MTS assay.
It is demonstrated that the bacterial strains used can generate biogenic selenium nanoparticles. The antimicrobial activity of these biogenic selenium nanoparticles was tested against Escherichia coli and Staphylococcus aureus to discover their antibacterial ability. Nanoparticles can produce a decay in the standard bacterial growth. Besides, the growth of Staphylococcus aureus was significantly inhibited for those nanoparticles synthesized by Staphylococcus aureus. In vitro cytotoxicity assays were performed with human dermal fibroblasts (HDF) cells. The experiments showed that all nanoparticle concentrations tested did not inhibit the growth of cells while also confirming a high percentage of cell viability.

As a conclusion, selenium nanoparticles with small and uniformly shape were synthesized with a relatively homogeneous size distribution. Decay in the bacterial growth was achieved against both Gram-positive and Gram-negative bacteria, showing no significant cytotoxicity effect when they were cultured with human dermal fibroblasts (HDF) cells.

Nanoshaping of Metallic Liquid by Stretching—Evading Lithography Zhonglue Hu and Golden Kumar, Texas Tech University, Lubbock, Texas, United States.

Metal nanostructures are integral parts of nanoscale devices and fundamental studies on characterization of size-effects. However, these technological and scientific advancements are hampered by the complex and expensive lithography-based fabrication techniques. Here, we present a novel lithography-free nanomanufacturing by elongation and rupture of glass forming metallic liquid. This approach allows facile fabrication of various structures such as nano-tips, nano-wires, and dog-bone-shaped nano-structures without lithography or expensive templates. The flow behavior of metallic liquids is tuned through temperature and strain-rate to control the shape of resulting structures upon elongation and rupture. Quantitative studies on individual structures are performed to understand the correlation between the initial size/shape, temperature (viscosity), elongation speed (strain-rate), and final shape/size.

NM02.06.29

The study of metal chalcogenide molecular clusters as functional units in macromolecular systems has rapidly expanded in recent years. Their tunable properties allow them to be used in a variety of applications, including energy storage, lighting, magnets and catalysis. While the self-assembly of metal chalcogenide clusters in the solid-state is well studied, their incorporation into polymer systems has been limited. We report a new block copolymer containing a site-differentiated Co6Se8 molecular cluster capable of multi-electron redox processes. The block copolymer system self-assembles in solution to form vesicle structures at the mesoscale whose walls can be further crosslinked after assembly. Moreover, the vesicles can be loaded with molecular cargo such as with a methylene blue dye. This talk will describe the synthesis, self-assembly and characterization of the novel cluster-containing diblock copolymer. The integration of a transition metal-containing molecular cluster into well-defined block copolymers offers exciting possibilities to develop multifunctional assemblies for further applications in catalysis, electrochemistry, and biomedicine. This cluster-containing polymer could also be used to direct hierarchical assembly of novel metal chalcogenide mesostructures.

Investigation of the Effect of Gold Nanoparticle on Alkaline Phosphatase Enzyme Activity for Using Influenza A Diagnosis Studies Yasemin Badam Kılıç, Günsen O. Eren and Rabia Caikır Koc, Bioengineering Department, Yildiz Technical University, Istanbul, Turkey.

In our present study it is focused on examining of effect of colloidal gold nanoparticles which have 40 nm in diameter to ALP-IgY conjugate in order to use in Influenza A diagnosis applications. Influenza A affects all age groups worldwide, and causes significant loss of workdays, human suffering, and mortality every year. Matrix protein 2 (M2) is a structural protein of influenza A viruses and plays an important role in the virus life cycle. M2e is the high sequence conservation of extracellular domain among all known human influenza A viruses. Therefore, M2e peptide specific IgY antibodies were chosen in this study for development of ELISA methods based on gold nanoparticles conjugation.

Transmission Electron Microscopy (TEM-EDX) demonstrated that particles have 40 nm in diameter it is confirmed that IgY-ALP conjugate was successfully bound to gold nanoparticle. Nano-ELISA results demonstrated that after one hour incubation at 37°C absorbance values of IgY-ALP conjugate was higher than IgY-ALP-Au conjugate in every concentrations. In addition kinetic rate was measured by UV-vis analysis and these results indicated that reaction rate of IgY-ALP-AuNPs was slower than IgY-ALP while absorbance values are higher when gold nanoparticle was bound to IgY-ALP conjugate. Fourier Transmission Infrared Spectroscopy (FTIR) results indicated that gold nanoparticle has effect on ALP enzyme structure. The transmittance peaks of amide I and amide II bonds of IgY-ALP-Au conjugate changed due to presence of gold nanoparticle when compared to IgY-ALP conjugate alone.

In result it can be said that gold nanoparticles have a negative effect on ALP enzyme kinetic rate when it used for enzyme-linked immunosorbent assays. Au-NPs increases the activation energy of ALP-substrate interaction due to conformational change and therefore absorbance values of IgY-ALP-Au complex are much lower than IgY-ALP conjugate in ELISA procedure.

Funding and Acknowledgement
This study was supported by the Scientific and Technological Research Council of Turkey with the project titled “The development of a rapid diagnostic kit using the immunochromatographic method of depending on an M2e peptide-specific IgY antibody for the diagnosis of influenza A infection” (Project No: 115S132).

Authors would like to thank the Scientific and Technological Research Council of Turkey.

NM02.06.31
The Core-Shell Engineering on Energy Product of Magnetic Nanometals Shonqiang Ren and Jingming Zhang; University at Buffalo, The State University of New York, Buffalo, New York, United States.

The exchange coupling between magnetically hard and soft materials possesses many desirable magnetic characteristics and thus is extensively explored for high energy product magnets. Here we demonstrate a solution-based growth of magnetically hard and soft FePt-FeCo (Core-shell) nanoparticles with the controllable shell thickness. The transition from spin canting to exchange coupling of FePt-FeCo core-shell nanostructures leads to a 28% increase in the coercivity (12.8 K0e) and a greater than two-fold enhancement in the energy product (9.11 MGOe), as compared to the FePt nanoparticles. Besides the traditional solution method, a eutectic molten salts method has been developed to synthesis L1s hard magnetic phase in one step. The benefit of this method is the ease of removal chemical residual after reaction, and reduce the total preparation time of the L1s phase of FePt. The as-synthesized FePt powder has a coercivity of 15 K0e while no further treatment was needed. The results shown here imply that the eutectic method and core-shell engineering have the potential to enhance the energy product of next-generation nano-magnets.

The Role of Aminosilane Loading Density on the Formation of Gold-Coated Superparamagnetic Core/Shells with Enhanced Dual Surface Heating to Combat Tumor

Manal Almasmari,1,2,3 Roa Fardous,2,3 Edreese H. Alsharab,3,4 Abdalaziz Almalik,3,4 and Ali H. Alhasan1,3,4
1 College of Science and General Studies, Alfaisal University, Riyadh, Saudi Arabia; 2 KACST-BWH/Harvard Centre of Excellence for Biomedicine, Joint Centers of Excellence Program, King Abdulaziz City for Science and Technology, Riyadh, Saudi Arabia; 3National Center for Pharmaceutical Technology, Life Science and Environmental Research Institute, King Abdulaziz City for Science and Technology (KACST), Riyadh, Saudi Arabia.

Despite significant development in the therapeutic strategies for breast cancer, some challenges remain. Conventional treatments such as chemotherapy and surgery cause serious side effects. Among the various approaches to enhance the efficacy of breast cancer therapies, is the use of gold-coated magnetic nanoparticles, which have dual functionality acting as both magneto- and photo-thermal agents. Such nanoparticles may prove valuable in enhancing the therapeutic efficacy if synthesized as quantum-sized nanoparticle, which is still challenging. In this study, we tackle the synthesis of quantum-sized superparamagnetic (Fe3O4) nanoparticles (~10 nm as an inner core) coated with a thin shell of gold (~14 nm) and explore their efficiency to generate heat as a result of their superparamagnetic properties and strong NIR absorption. Our findings show that gold shell formation around a core of quantum-sized nanoparticles is troublesome unless the loading density of 3-aminopropyltriethoxysilane (APTES) onto Fe3O4 nanoparticles is maximized in order to increase the number of gold nanoparticles per Fe3O4 nanoparticle. Exposing Fe3O4/Au core/shell nanoparticles to an external magnetic field and NIR irradiation (~808 nm) results in complete apoptosis–mediated breast cancer death at 45°C, significantly reducing tumor growth in comparison to single mode treatments (magnetic or laser hyperthermia). Apparently, our quantum-sized core-shell nanoparticles afford greater heat efficiency when successfully applied as a dual magneto- photo-thermal therapy for breast cancer.

PH-Controlled Dealloying Route to Hierarchical Bulk Nanoporous Zn Derived from Metastable Alloy for Hydrogen Generation by Hydrolysis of Zn in Neutral Water

Jintao Fu,4 Ziling Deng,1 Timothy Lee,6 John S. Corsi, Zeyu Wang,3 Dongyang Zhang,1 and Eric Detsi;6 University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Dealloyed nanoporous metals made of very reactive elements have rarely been reported. Instead, reactive materials are used as sacrificial components in dealloying. The high chemical reactivity of non-precious nanostructured metals makes them suitable for a broad range of applications such as splitting water into H2 gas and metal hydroxide. On the other hand, the same high chemical reactivity hinders the synthesis of nanostructured metals. In this talk, I will present a nanofabrication route to hierarchical bulk nanoporous Zn and demonstrate its potential to produce hydrogen from neutral water. Typically, we used a pH-controlled dealloying strategy to fabricate bulk nanoporous Zn with bulk dimensions in the centimeter range via the selective removal of Al from metastable face-centered cubic bulk ZnAl at 96% parent alloys. The corresponding bulk nanoporous Zn exhibits a hierarchical ligament/pore architecture characterized by primary ligaments and pores with average feature size in the sub-micrometer range. These hierarchical structures are made of ultrafine secondary ligaments and pores with characteristic feature size in the range of 10-20 nm.

I will show that the bulk nanoporous Zn can spontaneously split water into H2 and Zn(OH)2 at ambient temperature and pressure, and continuously produce H2 at a constant rate of 0.08 mL/min per gram of Zn over several hours. It is anticipated that in this hierarchical bulk architecture, the macropores facilitate the flow of water in the bulk of the material, while the mesopores and ultrafine ligaments provide a high surface area for the reaction of water with Zn. The bulk nanoporous Zn/water system can be used for on-board or on-demand H2 applications during which H2 is produced when needed, without prior storage of this gas compressed in cylinders as it is currently the case. [1]

Synthesizing Cooperative Metal-Support Interfaces for Catalysis

Sheng Dai1,2; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2 Department of Chemistry, The University of Tennessee, Knoxville, Knoxvillle, Tennessee, United States.

Understanding the cooperative interactions of metals with active supports is essential to tailoring their catalytic activities and/or control of reaction pathways. These interfacial interactions can be achieved through two mechanisms: interfacial charge redistribution (electronic interaction) and interfacial atom transport (chemical interaction). In the last two years, a number of new advances have been made by our BES team toward tuning the metal-support interactions. The success of our approach capitalizes on nanoconfined spaces (e.g., confined interface restructuring), complex oxide supports (e.g., perovskite oxides), and 2D material edge sites (e.g., boron nitride), demonstrating that uniquely strong interfacial interactions and cooperativities between nanoparticles and supports can emerge through judicious structural choices of metals and supports. This presentation will be focused on the following three synergistically linked research activities: (1) sacrificial strong metal-support interactions, (2) “intelligent” metal-support interactions, and (3) charge-flow metal-support interactions. The interconnections among the above three metal-support interactions will be also discussed.

Understanding and Controlling Nanoparticle Entrenchment in Oxide Supports

Abha A. Gosavi, Justin Notestein and Chad A. Mirkin; Northwestern University, Evanston, Illinois, United States.

On rapid heating to high temperatures and under inert conditions, metal nanoparticles exhibit entrenchment in the SiO2 layer on a silicon wafer to create nanoparticles. This phenomenon occurs above a critical temperature of around 1000°C, at ramp-rates above 3.3°C/sec, resulting in nanoparticles as deep as 250 nm or more, depending on the thickness of the SiO2 layer. We have studied and characterized this entrenching behavior and subsequent nanopore formation for a wide variety of metal nanoparticles, including Au, Ag, Pt, Pd and Cu. Using Pd on SiO2 as our model system for studying the behavior of nanoparticle entrenchment, we have established the critical conditions (temperature, times and ramp-rates of heating) required to observe entrenchment. The subsequent trends in this behavior with changing particle size and spacing have also been identified. We have thus tried to establish a mechanism by which nanoparticle entrenchment occurs and competes with other surface phenomenon (sintering, evaporation and diffusion) that occur for silicon dioxide supported metal nanoparticles at high temperatures.
The behavior of metal nanoparticles under entrenchment conditions was also studied for various different oxide supports (TiO$_2$, HfO$_2$, and Al$_2$O$_3$) and compared to the nanopore formation on SiO$_2$. We observed that while nanoparticles supported on TiO$_2$ and HfO$_2$ undergo surface coarsening under high temperature treatment, Al$_2$O$_3$ acts a barrier to nanoparticle entrenchment and subsequent pore formation. This behavior inspired a novel tri-layer approach for immobilizing Au nanoparticles in SiO$_2$ supports. By creating a tri-layer architecture consisting of SiO$_2$ on Al$_2$O$_3$ on silicon wafers, we could control the depth to which nanoparticles entrenched between 3-5 nm. This small range enabled us to sufficiently entrench particles for the purpose of immobilization but still maintain access to the nanoparticle surface for catalytic activity studies. The two advances of moving into the sub-15 nm nanoparticle size regime and of controlled particle immobilization through entrenchment have important implications in studying site-isolated and stabilized metal nanoparticles for applications in sensing, separations, and catalysis. As proof-of-concept, we evaluated the reduction of 4-nitrophenol by NaBH$_4$ catalyzed by Au nanoparticles buried 3 nm into the trilayer substrate.

While the nanoparticles immobilized in the tri-layer supports can be used for catalysis, the nanopores formed in the course of the entrenchment could have a wide range of applications on their own. These linear, high-aspect ratio nanopores have diameters comparable to those of the starting nanoparticles (~15 nm) and can be hundreds of nanometers long. The size and surface density of the nanopores can be tuned by changing the particle sizes and distribution of the nanoparticles being heated. The resulting porous, planar materials could have applications in sensing and separation of large molecules.

Size-Controlled Synthesis of CuNi Nano-Octahedra and Their Catalytic Performance Towards 4-Nitrophenol Reduction Reaction
Can Li$^1$, Yiliang Luan$^1$, Bo Zhao$^2$, Amar Kumbhar$^3$ and Jiye Fang$^4$; $^1$SUNY Binghamton, Binghamton, New York, United States; $^2$Texas Tech University, Lubbock, Texas, United States; $^3$University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Compared with noble metal catalysts, non-noble metallic nanocrystals (NCs) as a new class of catalysts have attracted increasing attention due to their low cost, abundant content in the Earth’s crust, and outstanding catalytic performance in some reaction such as oxidation, hydrogenation, and electrocatalysis. It is well-known that some specific crystal facets on the catalysts can promote the catalytic activity. However, most reported NCs with some exclusive facets are noble metal or metal oxide based catalysts. There are limited studies on the synthesis of facet- (or shape-) controlled non-noble metallic NCs. As standard reduction potentials of the non-noble metals are much lower than those of the noble metals, the relatively high sensitivity and instability of the non-noble metal NCs, especially when they expose to air or aqueous solution, make it hard to harvest non-noble metal NCs in controlled shape and size.

Herein, we demonstrate a size-controlled synthesis of CuNi nano-octahedra using a hot colloidal solution approach. Boron morphology was used as a reducing agent to promote a rapid nuclei formation. The as-synthesized CuNi NCs could be stably dispersed into an organic solvent such as hexane with capping ligands anchored on their surface. Two different sizes of CuNi nano-octahedra were chosen and investigated in this report. A number of synthetic factors such as the ratio of oleic acid and oleylamine were identified and optimized in order to efficiently control the size and shape. It was further determined that the concentration remarkably played a key role in the size-control of the CuNi nano-octahedra. In terms of the catalytic evaluation, the size effect of CuNi nanocatalysts on 4-nitrophenol reduction activity was carried out. Our study indicates that the obtained CuNi nano-octahedra exhibited higher catalytic activity compared with those CuNi NCs reported previously, and their performance was strongly size- and shape- dependent due to the surface area and the specific atomic arrangement of the {111} surfaces.

Room Temperature Electrodeposition of Palladium Based Intermetallic Electrocatalyst
Yunfei Wang, Du Sun, Justine Wagner, Tomojit Chowdhury, Thomas J. Kempa and Shoji Hall; The Johns Hopkins University, Baltimore, Maryland, United States.

Recently, ordered intermetallic compounds have become emerging materials for catalysis. The synthesis of ordered intermetallic compounds usually requires annealing at temperatures > 700 C. Here we present a method of preparing ordered intermetallic Pd31Bi12 at room temperature via electrochemical deposition. According to the phase diagram, this system is thermodynamically stable at temperatures between 550 C to 605 C, indicating that the deposited material is metastable. The Pd31Bi12 morphology consists of a compact nanoparticulate film, the particles sizes range from 30nm to 100nm. We assessed the catalytic activity of this material for the oxygen reduction reaction, Pd31Bi12 exhibits 60 times higher specific activity than Pd and Pt at 0.85V. The half wave potential of Pd31Bi12 is 0.93V, 43mV higher than Pd and 69mV higher than Pt. Pd31Bi12 also displays high stability under accelerated durability cycling, after 10K cycles a 4 mV shift of its half wave potential, and 40% decay in specific activity is observed. Ultraviolet photoelectron spectroscopy is applied to compare the valence band of Pd31Bi12. The results show that alloying Bi with Pd drastically lower the center of valence band compared with Pd, thus reduce adsorption energy of intermediate in oxygen reduction reaction. In conclusion, we have demonstrated that electrodeposition can be used to prepare thin films of ordered intermetallic Pd31Bi12 on glassy carbon electrodes. Pd31Bi12 is a highly active and stable material for performing the reduction of O2 to H2O.

A General Route to Synthesize Core@Shell ORR Nanocatalysts
Joceelyn T. Gamler, Hannah M. Ashberry and Sara E. Skrabalak; Indiana University, Bloomington, Indiana, United States.

The need for sustainable energy platforms drives catalyst design and synthesis. In the case of organic liquid fuel cells, improvements in terms of activity, durability, and cost are needed for oxygen reduction reaction (ORR) catalysts, which are largely Pt-based. Typical routes to overcome the high cost and unfavorable surface-adsorbate interactions are to incorporate a secondary transition metal, either through a core@shell architecture or alloy formation; this addition decreases expensive metal loadings and tunes the surface-adsorbate interaction in accordance with the Sabatier principle. The present work demonstrates the versatility of seed-mediated co-reduction (SMCR) to deposit PtM (M = Ni, Co, Cu, Fe) random alloyed shells on PdCu B2 intermetallic seeds, integrating the concepts of a core@shell architecture and alloyed surfaces into one nanostructure. Control of both shell thickness and Pt:M ratio are also demonstrated. The catalytic activity as a function of shell thickness for a model system, B2@PdNi, was evaluated for the ORR. The series of B2@PtM catalysts are also evaluated for the ORR to determine the role surface composition plays in activity and durability. Collectively, this work aims to develop synthetic techniques to achieve complex nanocatalyst compositions.

10:00 AM BREAK
removed from the products. The strong oxidizing power of the traditional oxidants easily leads to overoxidation of alcohols to ketones, lowering the selectivity and yield of aldehydes. In contrast, using ambient oxygen as oxidant is proposed to develop an environmentally friendly synthesis strategy that does not require additional separation. However, ambient oxygen is lack of the power to oxidize alcohols at mild temperatures. Therefore, precisely controlling the oxidizing power of the oxidants becomes crucial to promote the selective oxidation of alcohols to aldehydes. We focus on the use of appropriate metal catalysts (i.e., quantum-sized metal nanoparticles) to improve the selective oxidation with ambient oxygen by converting the molecular oxygen adsorbed on the catalyst to more active species. The change of adsorption states of oxygen relies on the efficient generation of hot electrons in the quantum-sized metal nanoparticle catalysts that are under illumination of visible light. Selective aerobic oxidation of benzyl alcohol to benzaldehyde represents an example to demonstrate the feasibility of enhancing reaction kinetics on quantum-sized platinum group metal (PGM) nanoparticle catalysts with the assistance of simulated solar irradiation.

Synthesis of New Nanoparticle Catalysts for Application in Direct Methanol Fuel Cells Jil Rüter, Hauke Heller and Horst Weller; University Hamburg, Hamburg, Germany.

Direct methanol fuel cells (DMFCs) show great potential for applications in portable power sources or hybrid vehicles.[1] One key challenge for the commercialization is to reduce the high costs of fuel cells due to expensive catalyst materials. The electrocatalysts, mostly based on platinum, are dispersed on a high surface area supporting material. Therefore, a reduced and effective use of the costly platinum is essential. In this context, multimetallic nanoparticles with controllable size and composition are interesting materials to reduce the amount of utilized catalyst material and simultaneously enrich the accessible catalytic metals on the surface. The size, composition and structure of the nanoparticles have a high influence on the efficiency. An increase of the catalytic activity has been proved by combining platinum with various transition metals (e.g. nickel, cobalt, ruthenium)[2] as alloy or core-shell structure, while reducing the cost at the same time. The combination of specific transition metals with platinum increases the activity of oxygen reduction reaction (ORR) due to ligand and strain effects.[3] Moreover, it is advantageous to use core-shell-nanoparticle (CSN) systems, as the platinum amount can be further reduced by using it only on the outer shell. The investigated Ni@Au@NiP[4] and NiPd@NiPt[5] CSNs exhibit a great potential for application as DMFC catalysts due to their high catalytic activity, low platinum amount, high surface area and stability. Here, we demonstrate nanoparticles with an average diameter of 5 nm and a narrow standard deviation. The gold interlayer enhances the durability of platinum due to the prevention of oxidation and dissolution of platinum during the cycling process. Besides platinum, palladium is an attractive material as it has a positive effect on the stability and activation and a lot of different combinations of platinum and palladium or a substitution of platinum may be possible as well. Furthermore, the carbon source for supporting the catalyst material is of great interest. Carbon nanotubes (CNTs) may be an alternative to conventional carbon materials due to their high surface area as well as remarkable mechanical and electric properties.[5] CNTs consist of (multiple) graphene layers in cylindrical form with a closed fullerene end cap. We show that nanoparticles and CSNs were successfully supported on hierarchically ordered CNTs, which are synthesized by chemical vapor deposition and grown on steel meshes. Combining the multimetallic CSNs with CNTs could induce an enhanced catalytic activity. In future, further combinations of palladium and platinum will be investigated.

Development of New Solid-Solution Alloy Nanoparticles for Catalytic Applications on the Basis of Density-of-States Engineering Kohei Kusada1, Dongshuang Wu1, Tomokazu Yamamoto2, Syo Matsumura2, Wei Xie2, Michihsia Koyama2, Katsutoshi Sato2, Katsutoshi NagaoKA3 and Hiroshi Kitagawa3; 1Kyoto University, Kyoto, Japan; 2Kyushu University, Fukuoka, Japan; 3National Institute for Materials Science, Tsukuba, Japan; 4Oita University, Oita, Japan.

The properties of elements are correlated directly with their electronic states. If we can realize a concept of “density-of-states (DOS) engineering”[1] for the design of materials having the most suitable electronic structure for the targeted properties, we will be able to make full use of available elements and relieve the resource problems. To freely control an electronic state of a material, the solid-solution alloy is advantageous because its electronic state can be continuously controlled by tuning the compositions and/or combinations of the constituent elements. However, the majority of bulk alloy systems are the phase-separated type under ambient conditions. Recently, we demonstrated that the nanosize effect offers a chance to find a way out of this metallurgical difficulty; that is, we can obtain metal nanoparticles (NPs) having new phases that do not exist in bulk states.[2] In general, a nanoparticle with the same crystal structure as the corresponding bulk material can be obtained. However, if we find appropriate synthetic conditions, it allows us to develop novel NPs adopting new phases including solid-solution alloy NPs consisting of immiscible combinations.

In this work, we discuss the structural and chemical properties of PdRu2 and AuIr2 alloy NPs as the examples of DOS engineering. Both of binary alloy systems are immiscible and solid-solution alloys of these systems have not been obtained so far. We first succeeded in synthesizing the solid-solution alloy NPs and characterized the alloy structures by synchrotron X-ray powder diffraction technique and scanning transmission electron microscopy coupled with energy dispersive X-ray spectroscopy. It is noted that obtained PdRu and AuIr solid-solution alloy NPs showed very enhanced catalytic properties for three-way catalysis and oxygen reduction reactions, which are comparable to Rh and Pt, respectively.[3] The calculation results indicated that the formation of solid-solution alloy realized new electronic states and provided enhanced properties.

11:30 AM NM02.07.09
Investigating Subnanometer Transition Metal Catalysts for Methane Activation from First Principles Victor Fung1, Zili Wu2 and De-en Jiang1; 1University of California, Riverside, Riverside, California, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Subnanometer transition metal clusters have received significant attention as promising materials for catalysis, particularly over their bulk counterparts. The electronic structure of the exposed metal sites can vary significantly with atomic size and geometry, which presents the opportunity to design metal clusters of a specific atomic size and composition for the desired catalytic application. One such application is towards methane conversion, which requires
suitable catalysts to promote the activation of its strong C-H bond. Using density functional theory, we investigate a selection of promising transition metal clusters and identify promising candidates based on strong methane adsorption and low C-H activation barriers. Our results conclude that facile C-H activation is closely related to the ability of the metal sites to complex with the methane molecule. We further show that these methane activation properties are extremely size, geometry and composition dependent, with significant implications for eventual experimental applications. These studies provide the first step in designing realistic metal cluster catalysts for methane conversion.

Accurate determination of the structure of noble metallic nanomaterials is a key step towards understanding and controlling their properties. This is especially challenging for small particles, below 10 nm, where x-ray diffraction data is often broad and diffuse and not amenable to quantitative crystallographic analysis. In these cases a better approach is the use of atomic pair distribution function (PDF) analysis of synchrotron x-ray total scattering data. Even in this case, extracting detailed models of nanoparticle cores is notoriously difficult.

Nanoparticle models based on close packed crystallographic cores, often simple but at times elaborate, lead to characteristically poor or unreliable fits. We data. Even in this case, extracting detailed models of nanoparticle cores is notoriously difficult.

In these cases a better approach is the use of atomic pair distribution function (PDF) analysis of synchrotron x-ray total scattering data. Even in this case, extracting detailed models of nanoparticle cores is notoriously difficult.

Multinary transition metal nanoparticles (NPs) are of interest for energy applications, e.g. as catalysts in fuel cells. As an immense composition space exists for multinary NPs, efficient experimental strategies are necessary to identify which particular compositions have new or highly-optimized properties. Here, combinatorial co-sputtering (1) from up to five elemental targets (e.g. Cr-Mn-Fe-Co-Ni) was used to synthesize multinary NP libraries into ionic liquids.

Multinary transition metal nanoparticles (NPs) are of interest for energy applications, e.g. as catalysts in fuel cells. As an immense composition space exists for multinary NPs, efficient experimental strategies are necessary to identify which particular compositions have new or highly-optimized properties. Here, combinatorial co-sputtering (1) from up to five elemental targets (e.g. Cr-Mn-Fe-Co-Ni) was used to synthesize multinary NP libraries into ionic liquids.
Due to their low vapor pressure, ionic liquids can be used as substrates that are able to stabilize NP dispersions. The suitability of different ionic liquids for different metal combinations can be tested with high-throughput by using arrays of ionic liquids which are sputtered with one material system (2). The multinary NPs were characterized using atomic-scale characterization methods such as Cs-corrected high-resolution transmission electron microscopy, (scanning) transmission electron microscopy and energy dispersive X-ray spectroscopy. With these techniques the chemical composition as well as size, shape, crystallinity and defects of the NPs are obtained. Effects on the resulting crystallinity of the NPs were found by using either direct current or high-power impulse magnetron sputtering. Furthermore, catalytic properties of the NPs were measured by potential-assisted immobilization of the NPs at a microelectrode which allows the evaluation of their intrinsic electrocatalytic activity in alkaline media. The obtained results indicate that the multinary nature of the NPs affects their catalytic activity: e.g. quinary NPs were found to be more active than all of the respective quaternary subsystems. Antimicrobial Peptide-Based Platform with Fluorescent Gold Nanoclusters for Selective Detection of Listeria monocytogenes
Kamaljit Kaur; Chapman University, Irvine, California, United States.

Listeria monocytogenes is a Gram-positive foodborne pathogen that causes infections such as listeriosis and meningitis. The mortality rate from such infections exceeds 20 percent, which designates this microbe as a high threat to humans (1). Highly sensitive and selective detection of pathogenic bacteria from various samples ranging from human specimens to food samples is a major challenge in industry and medical fields (2, 3). Here we have developed a novel peptide-based biosensor platform utilizing fluorescent gold nanoclusters for quick and easy detection of L. monocytogenes species from different samples. Leucocin A, a potent antimicrobial peptide from class IIa bacteriocins, is used to selectively bind specific receptor present on Listeria monocytogenes, namely, mannose phosphotransferase system permease. A self-assembled monolayer (SAM) of peptide on glass surface is exposed to contaminated sample allowing target bacteria to bind to the immobilized peptide on the surface. The peptide-bound bacteria are then labeled with highly fluorescent gold nanoclusters directly on the glass surface allowing quick detection of bacteria with a limit of detection (LOD) of 2000 cfu in each 10 microliter sample (4). The gold nanoclusters are made by mixing and spotting aqueous tetrachloroauric acid and 3-mercaptopropionic acid (MPA) on top of bacteria on the glass slide. The gold nanoclusters thus formed label the bacteria, and absorb in the UV range and emit fluorescence in the visible to near infrared region (~612 nm) where other biomolecules do not fluoresce and interfere. The biosensor assay developed here is unique as it allows detection of L. monocytogenes in <1 hour and does not require trained personnel. Compared to other techniques for the detection of L. monocytogenes, this method is simple, fast, and requires no sample preparation.

Renal Clearable Catalytic Gold Nanoclusters for In Vivo Disease Monitoring
Colleen Loynachan1, Ava Soleimany2, Sangeeta Bhatia2 and Molly Stevens1; 1Imperial College London, London, United Kingdom; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Recent advances in the synthesis and characterization of ultra-small gold nanoclusters (AuNCs) have enabled their use as sensitive probes for fluorescence and x-ray contrast bioimaging applications.1 However, their intrinsic catalytic activity has yet to be explored for biosensing in vivo. Employing peroxidase-mimicking catalytic AuNCs as reporter probes in sensing applications may enable rapid and facile disease diagnosis at the point-of-care.2 We propose to address this need by leveraging both the catalytic activity of AuNCs and the precise size filtration of the kidney to develop a nanocatalyst amplification platform that produces a direct colorimetric urinary readout of disease state. Here we have engineered AuNC-functionalized protease nanosensors that are disassembled in response to dysregulated protease activity at the disease site. Liberated AuNCs are then efficiently filtered into the urine, where a colorimetric urinary assay enables rapid disease detection in mouse models of cancer and pulmonary embolism.

Renal clearable AuNCs were synthesized via a versatile bio-templated process which introduces protease cleavable peptide sequences on the particle surface with orthogonal functional handles for further site selective modification. The resulting ca. 1.5 nm noble metal nanoclusters exhibited both luminescence and robust catalytic activity. Renal clearance studies in vivo showed that ca. 60% of the injected dose of functionalized AuNCs leave the body via this route and retain their catalytic activity in urine. Peptide functionalized AuNCs were tethered to a protein carrier to form nanosensor complexes, and specific proteolytic cleavage of AuNC complexes was demonstrated in vivo by gel filtration chromatography. Finally, disease detection was demonstrated in vivo in a mouse model of colorectal cancer by monitoring catalytic activity of cleared AuNCs in collected urine. After injection with tumor-specific AuNC nanosensors, urine from tumor-bearing mice showed a 20-fold increase in colorimetric signal compared to healthy mice in our assay.

We developed a library of catalytic AuNC probe complexes which can be efficiently excreted into urine in response to specific enzymatic levels in vivo. This simple and sensitive colorimetric urinary assay can be read by the naked eye in <1 h and has enabled non-invasive disease detection in mouse models of cancer and pulmonary embolism. We envision that this approach will be applicable for rapid detection of a diverse range of disease-associated proteases.

Furthermore, constant potential electrolysis on electrodes modified with these clusters exhibits drastically different product selectivity. That is, whereas CO is predominantly produced on Au25(SR)18 with a selectivity higher than 90%, nearly 75% H2 is produced on PtAu24(SR)18. Density functional theory calculations show that the product selectivity appears to be closely related with the adsorption energies of the reactants, i.e., CO2 and proton on the electrode surface. This understanding is critical for the design of efficient electrocatalysts for CO2 conversion.

Angiogenic tumor vessels are hallmarks of cancer and critical sites for drug delivery, angiogenic therapy, chemotherapy, and immunotherapy. Better characterization of tumor microvasculatures in vivo could lead to better understanding of the tumor microenvironment, improved monitoring of tumor progression and therapeutic responses, and more accurate patient prognosis. Optical coherence tomography angiography (OCTA) provides three-dimensional microvasculature image of the tissue by detecting the dynamic scattering produced by flowing red blood cells (RBC's), and becomes an emerging tool for in vivo microvascular imaging due to its micrometer spatial resolution and millimeter tissue penetration depth. However, due to the abnormal blood flow in the angiogenic tumor vessels and strong light attenuation by the tumor tissue, it is challenging to image the complete tumor microvasculature with traditional OCTA. In this work, we demonstrate that gold nanoprism (GNPRs) can be used as intravascular OCT contrast agents for significantly improved imaging of tumor microvasculatures in the second near infrared window (1100–1400 nm). With the injection of incremental concentrations of PEGylated GNPRs in the mouse blood, higher density of microvasculature can be observed in the tumor tissue of melanoma mice models on the OCT angiograms. After the GNPR concentration reached 2 nM in the bloodstream, OCTA showed an increase of tumor vascular density by 136% compared to the baseline angiogram image. Longitudinal OCTA study shows that the highest vascular density was achieved at 5 min post-injection. Two photon microscopic imaging validated that there is no extravasation of GNPRs within 5 min of injection.

DNA Modified Gold Nanoparticles for Drug Delivery in Cells

DNA modified gold nanoparticles have been extensively studied as a versatile platform for drug delivery due to their ability to recognize and bind to specific messenger RNA signatures and selectively kill model cancerous cells as opposed to healthy cells. New classes of nanoparticle dimers that can accommodate multiplexed synergistic actions of sensing and drug delivery in cells. These multitasking particle assemblies are able to selectively release anticancer drugs in response to specific messenger RNA signatures and selectively kill model cancerous cells as opposed to healthy cells.

References:
Mechanical behaviors of nanomaterials, such as metallic nanowires and nanoparticles, are usually controlled by dislocation nucleation due to the absence of pre-existing glide dislocations in such a small volume. Dislocation theory suggests that a significantly high stress needs to be applied to nucleate a dislocation, leading to an ultrahigh strength of nanomaterials. Thus, nanomaterials has drawn a great attention as the candidate of advanced structural materials. In order to understand the mechanical behavior of nanomaterials, thus, it is critical to understand the dislocation nucleation behavior in detail. Spherical nanoindentsation has been widely used to study the dislocation nucleation phenomena. Upon loading on the flat surface of low dislocation density material, the Hertzian contact of tip can induce the maximum load at the inside of material, leading to the dislocation nucleation. This nano-scale volume plasticity is nearly identical to the plasticity of nanomaterials. So, spherical nanoindentsation is a great method to study the plasticity at small length scales. Tungsten is an excellent model system to investigate dislocation nucleation. Its strong hardness allows the low dislocation density at the underneath of the free surface after the fabrication of flat surface. In this study, therefore, we studied the dislocation nucleation behavior of [0 0 1] tungsten single crystal under spherical nanoindentsation with different indenter tip radii. The surface of tungsten single crystal was chemo-mechanically polished. The spherical nanoindentsation was performed with the tip radii, 0.2, 2, 4, and 20 micrometers, and the critical stress of dislocation nucleation were measured using the Hertzian contact mechanics. Our results show that the critical stress of dislocation nucleation is a strong function of the tip radius. The dislocation theory suggests that the critical stress of dislocation nucleation must be constant regardless of loading condition, but this is inconsistent with our results. We found that stress gradient on the potential site of dislocation nucleation could be different according to the tip curvature, leading to the different critical stress of dislocation nucleation. Therefore, the combined stress gradient theory with the Herzan contact mechanics and confirmed that our model explains the dependence of the tip radius on the critical stress of dislocation nucleation very well. Our new model can be applied in any general cases when the inhomogeneous stress field is available in the nanoscale volume of metals such as the bending of nanowires or the compression/tension on nanoparticles. We confirmed that the same phenomenon is observed in uni-axial compression of dislocation-free gold nanoparticles, and the size effect of its yield strength can be understood by our stress gradient model. In sum, our spherical indentation study can shed a light into a fundamental understanding on the plasticity of nanomaterials.

Effect of Synthetic Parameter on the Cytotoxicity of CdTe/CdSe Nanoparticles Against Osteosarcoma Cell Line 

Vuyelwa Ncapayi1, 2, 3, Sandile P. Songca4 and Samuel O. Oluwafemi1, 2; 1Applied Chemistry, University of Johannesburg, Johannesburg, South Africa; 2Centre for Nanomaterials Science and Technology, University of Johannesburg, Johannesburg, South Africa; 3Centre for Nanomaterials Science and Technology, University of Johannesburg, Johannesburg, South Africa; 4Chemistry, Walter Sisulu University, East-London, South Africa.

LM-8 is a murine osteosarcoma cell line associated with bone tumor and is commonly found in young adult and children. The LM-8 cell line has Nuclear factor (NF)-κB which make them high resistance to irradiation thus limiting their treatment only to chemotherapy and surgery and this has become a source of concern for cancer therapy. In addressing this problem, quantum dots (QDs), which has high potential application in cancer treatment not only as imaging tool but also as a drug transport agent have been proposed as a possible agent to address this problem. Thus, in this study, we herein report the synthesis of CdTe/CdSe QDs core/shell NPs via a simple, economical and green method in the absence of inert atmosphere. The temporal evolution of the CdTe/CdSe QDs cytotoxicity against osteosarcoma cell line was investigated by varying the pH and reaction time. The optical properties of the as-synthesised quantum dots were monitored by UV-Vis and photoluminescence spectrophotometer, while electron microscope was used for structural properties. Prolonging the reaction time and increasing the pH resulted in highly monodispersed CdTe/CdSe core-shell NPs with good optical properties in the near infrared region and high cell viability. The high fluorescence intensity and improved cell viability against the osteosarcoma cell line confirm QDs great potential for imaging and drug delivery applications.

NM02.10.04

Synthesis and Processing of Polymer-Nanoparticle Hybrid Materials for H2 Sensing

Alicja Stolak, Ida Holm, Iwan Darmadi, Christoph Langhammer, Christian Muller and Kasper Moth-Poulsen; Chalmers University of Technology, Göteborg, Sweden.

Nanoparticles bearing Surface Plasmon ( SPR) and Localized Surface Plasmon Resonance ( LSPR) phenomena are excellent tools for novel concepts and technologies such as the creation of bio- and chemosensors7–9, plasmonic lasers, optical metamaterials, photovoltaic devices and metal photocatalysts. However, there is a number of challenges related to the use of nanoplasmic systems related to stability, composition and the large-scale incorporation in real devices. To address the above, we have used wet-chemical synthesis of palladium based plasmonic nanoparticles with tunable optical properties, and implemented these into suitable polymer matrixes, in order to invent cheap, easy and robust nanocomposites. Subsequently the nanocomposites will be applied to realize the creation of an optical hydrogen sensor.

In this project Pd NPs for H2 sensing have been synthesized and successfully implemented into a PMMA matrix resulting in a H2 active nanocomposite. The synthesis of nanoparticles is mainly surfactant based which has series of disadvantages that need to be mitigated such as the disruption of inhomogeneous stress field is available in the nanoscale volume of metals such as the bending of nanowires or the compression/tension on nanoparticles. Our new model can be applied in any general cases when the dependence of the tip radius on the critical stress of dislocation nucleation must be constant regardless of loading condition, but this is inconsistent with our results. We found that stress gradient on the potential site of dislocation nucleation could be different according to the tip curvature, leading to the different critical stress of dislocation nucleation. Therefore, the combined stress gradient theory with the Hertzian contact mechanics and confirmed that our model explains the dependence of the tip radius on the critical stress of dislocation nucleation very well. Our new model can be applied in any general cases when the inhomogeneous stress field is available in the nanoscale volume of metals such as the bending of nanowires or the compression/tension on nanoparticles. We confirmed that the same phenomenon is observed in uni-axial compression of dislocation-free gold nanoparticles, and the size effect of its yield strength can be understood by our stress gradient model. In sum, our spherical indentation study can shed a light into a fundamental understanding on the plasticity of nanomaterials.

Magneto-Optically Active Mn-Doped 2D Quantum Structures

Chi Li1, Sheng-Chih Hsu1, Tom Lin2 and Yihsin Liu2; 1National Taiwan Normal University, Taipei City, Taiwan; 2Chemistry, Washington University, St. Louis, Missouri, United States.

Mn-doped 2D quantum structures are potential diluted magnetic semiconductors (DMS) for spintronic applications, showing strong coupling of spin states with electronic states. The 2D CdSe(ethylenediamine)0.5 containing Mn2+ of various concentrations (0.5-7.7%) were successively introduced to explore optical, magnetic and spin interactive properties within single atomic layers. Giant magneto-optical effects and exciton dynamics are revealed by multiple internal transitions (e.g. 4T1 to 4A1) phosphorescence between 580-660 nm and magneto-optic Kerr effect (MOKE). Strong sp-d exchange interaction of nearly isolated Mn2+ in 2D regimes suggests giant Zeeman effect in magnetic circular dichroism (MCD). Additionally, three anisotropic g-values are characterized in orientation-dependent external paramagnetic resonance (EPR) experiments. Magnetic properties (C=2.62x10^5 emu K/G, μFe = 1.32 μB) from superconducting quantum interference devices (SQUID) with the magneto-optical studies above suggest effective chemical doping of magnetic ions and possibilities of spintronic applications for 2D semiconductors.
Through High-Resolution Transmission Electron Microscopy (HRTEM), we acquired the crystals sizes between 10–30 nm and the diverse morphologies of silver nanocluster.

By Powder X-Ray Diffraction (XRD), we acquired the crystal structure. As for the acetone solution via a magnetic stirrer, we obtained a silver nanocluster.

The most unexpected result we obtained, seen via an optical microscopy, was the detection of a circular morphology depending on employed solutions and the two wet nanomaterials techniques (by either a magnetic stirrer or an ultrasound equipment). All the samples were under the same room conditions of temperature (20–24°C) and humidity (40–60%).

Plasmonically Enhanced Virus Inactivation in a Flow Cell Geometry

Mina Nazari1, Min Xi2, Rahm Gummulura1, Mi Hong4, Björn Reinhard1,5 and Emerson R. Camargo1

Magnetic Resonance Imaging (MRI) allows for early detection of diseases that normally present once treatment is futile (e.g. cancer, cardiovascular dysfunction, or neuropathology). With such an important role, any increase to its functionality will have a great impact in medicine. The MRI can be improved – MRI contrast agents (CAs) can increase signal intensity, enhancing the contrast between healthy and abnormal tissues to allow for clearer diagnosis. MRI CAs provide an opportunity to target specific cells, leading to novel detection methods.

The principle underlying MRI is Nuclear Magnetic Resonance (NMR). NMR is observed as an absorption and emission of electromagnetic radiation by spinning nuclei in an external magnetic field. CAs enhance the MRI quality by affecting the amount of time it takes for the nuclei to relax after excitation.

There are two relaxation times, $T_1$ and $T_2$, that affect the quality of the image. Gadolinium (Gd) chelates, a commonly used CA, offer increased $T_1$ relaxation.
metals of group IB as Au, Ag and Cu. In this work a procedure to control the surface morphological of Ga2O3 nanometric films using Au, Ag and Cu. The

nanostructured films. Both types of ions have partially filled d and f shells, respectively, causing unpaired electrons of the TM ions into the ZnO

nanomaterials, the thermal decomposition method and hot injection utilizing oleylamine as capping agent. The prepared copper nanoparticles were

particularities on the film magnetic behavior, as the increase on the Curie temperature or the magnetoresistive behavior. With the aim to analyze the

influence of the TM dopant and the nanostructure issues on the magnetic characteristics, this study was directed to clarify the origin of the

magnetoresistance on TM doped ZnO nanostructured films (ZnO:TM) grown by the non-equilibrium RF-sputtering method at distinct RF-power regimes.

The nanoscale alternative is the gadolinium oxide (Gd2O3) nanoplate (NP) system. Using these NPs will evade the toxic and tumbling faults of the Gd

chatelates while maintaining the T1 CA properties of Gd. Gd in NPs is thermodynamically stable, preventing any metal deposition or adverse renal effects. This allows NP CAs to be used on the 14% of the total population that has preexisting kidney disease. The larger size of the NPs reduces tumbling in the bloodstream. NPs have a larger Gd to volume ratio which concentrates the part of the system that directly affects T1 relaxation. Encapsulation of the oleic acid coated Gd2O3 NPs with an amphiphilic sulfonic acid copolymer allows for successful phase transfer. Functionalized polyethylene glycol (PEG) derivatives added to this system can enhance its biocompatibility and its targeting properties.

Gd2O3 NPs offer a novel method for detecting non-alcoholic fatty liver disease (NAFLD). Kupffer cells in the liver are found at elevated concentrations with NAFLD. These cells uptake NPs at a high rate in the body. Gd2O3 NPs will accumulate in these cells when NAFLD is present, appearing bright white on MRI. Currently, there doesn’t exist a method to detect NAFLD early enough to treat it but the Gd2O3 nanometal system offers a promising approach.

The Synthesis of Copper Nanoparticles from Thermal Decomposition of Amino Carboxylate Copper Complexes

This paper reports the synthesis of copper complexes with four different ligands; glycine (gly) alanine (ala) valine (val) and picolinic acid (pic). The products were characterized by Fourier Transform Infrared (FT-IR) Spectroscopy, Thermogravimetric analysis (TGA) and Elemental Analysis (EA). The potential use of these complexes as precursor to prepare nanoparticles has been investigated. Two different methods have been applied to produce nanomaterials, the thermal decomposition method and hot injection utilizing oleyamine as capping agent. The prepared copper nanoparticles were characterized by XRD and SEM.

Structural and Magnetic Properties of TM Doped ZnO Films Produced by Growing ZnO/MT/ZnO Arrays by RF-Magnetron Sputtering at Different Power

The optical, Structural and morphological properties of the Ga2O3: M arrays were evaluated using transmittance, X-ray diffraction, scanning electron microscopy and Raman spectroscopy. A relationship between the growth procedure and the resultant microstructure and optical properties is proposed. The nanoparticles were characterized by XRD and SEM.

Effect of the Surface in the Amorphous Ga2O3 Thin Films by Metals of Group IB

Gallium oxide (Ga2O3) is a metal oxide material with a, \( \gamma \), \( \delta \), \( \epsilon \) and \( \beta \) polymorphs; among these polymorphs, the compound \( \beta-\text{Ga}_2\text{O}_3 \) with monoclinic structure is the only thermodynamically stable. There are many reports on the effect on the surface modification caused by doping of \( \beta-\text{Ga}_2\text{O}_3 \) doping with metals of group IB as Au, Ag and Cu. In this work a procedure to control the surface morphological of Ga2O3 nanometric films using Au, Ag and Cu. The procedure is based in the growth of nanometric multilayers Ga2O3/metal/Ga2O3 by RF sputtering and DC-sputtering at room temperature conditions. To study of surface morphology and structural characteristics the amorphous-Ga2O3: M arrays were annealed in dry N2 atmosphere at 600 °C by 30, 60 and 120 min. The morphological results can be related to the evolution of the amorphous character of the films towards the nanocrystalline phase driven by the nature of the intermediate Metal. The optical, Structural and morphological properties of the Ga2O3: M arrays were evaluated using transmittance, X-ray diffraction, scanning electron microscopy and Raman spectroscopy. A relationship between the growth procedure and the resultant microstructure and optical properties is proposed.
1064 nm and a receptivity of 20 kHz was used for the ablation. From the results of SEM image and XRD measurements, the average particle diameter of the AlNP was 19 nm. The magnetic properties of the AlNP powder were measured by SQUID. The M-H curve showed superparamagnetism. But Pauli paramagnetic component was not found from M-T curve.

In order to apply this AlNP powder as a solid material, it was mixed with silver paste and solidified by heat treatment. Note that it was confirmed that the AgNP obtained by drying the silver paste was weakly diamagnetic. The magnetic properties of the composite of AlNP and AgNP ((AlNP)/(AgNP)) showed interesting properties. Here, the number ratio of AlNPs and AgNPs in the composite material is expressed as (AlNP)/(AgNP). Basically, the magnetic properties of the composite material were superparamagnetic. Although the magnitude of its saturation magnetization increased with the value of x, it did not increase monotonically but reached a maximum when x = 0.8. In the M-T curves of the composites, there was a paramagnetic component independent of the temperature. The value of this paramagnetic component was also not proportional to the value of x, and it was the maximum when x = 0.4. This result suggests that the paramagnetic component is not due to defects but Pauli paramagnetism. Even more surprisingly, hysteresis was observed in the M-H curve for the samples with x = 0.6 and 0.8, indicating that the samples are ferromagnetic material. Although the origin and mechanisms of the magnetic properties of these composite materials are under investigation, the experimental results show that the unique magnetic moment is induced in the composites and the existence of the magnetic exchange interaction inside the composites.

Bulk Nanoporous Aluminum for On-Board Hydrogen Generation by Metal Hydrolysis John Corsi and Eric Detsi; Department of Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Hydrogen gas technology is a promising replacement for fossil fuels as a next generation mobile energy solution because of its high gravimetric energy density and minimal environmental impact. However, there are still many scientific and engineering challenges that must be addressed before a true “hydrogen economy” can be realized. Although hydrogen gas has a very high gravimetric energy density, it has a low volumetric energy density. One solution that avoids the safety concerns of transporting and storing pressurized flammable gases is the on-demand production of hydrogen from water-reactive nanostructured materials. This has been demonstrated for materials such as silicon nanoparticles. It is difficult to produce reactive nanomaterials that are oxide free, high yield and allow for morphological tuning. One technique for producing metallic nanostructures is dealloying, a process in which the less noble component of an alloy is selectively chemically removed, leaving behind a bicontinuous structure of nanoscale metal ligaments and voids. Two types of dealloying include chemical dealloying, in which an acid is used as an etchant, and electrochemical dealloying, in which an external voltage or current is used to etch the material. In this work, we propose a scalable fabrication method of nanostructured aluminum through electrochemical dealloying and demonstrate the ability to use this material for hydrogen production through water splitting [1,2].

Metallic AsSb Nanoinsclusions Strongly Enriched by Sb in AlGaAsSb Metamaterials Vladimir V. Chaldyshev1, Nikolay Bert1, Vladimir Nevedomski1, Vitalii Ushanov1, Maria Yagovkina1, Nikolay Cherkashin2, Valeri Preobrazhenski2, Mikhail Putyato3 and Boris Semyagin3; 1Ioffe Institute, Saint Petersburg, Russian Federation; 2CEMES-CNRS, Toulouse, France; 3Institute of Semiconductor Physics, Novosibirsk, Russian Federation.

Motivated by the recent experimental discovery of plasmon resonance in the infrared optical spectra of AlGaAsSb metamaterials, we have studied the microstructure of AsSb nanoinsclusions embedded in the AlGaAsSb matrix by low-temperature molecular-beam epitaxy followed by high-temperature annealing. Measurements of the interplanar spacings in the nanoinsclusion lattice by transmission electron microscopy in both diffraction and high-resolution (HRTEM) modes as well as high-resolution x-ray diffraction showed that the AsSb nanoinclusions possess the rhombohedral A7 structure characteristic of bulk As and Sb. The nanoinsclusions appeared to be strongly enriched by antimony (over atomic 90%) even when the Sb content in the matrix is as small as 2.8 atomic %. Our analysis of the Al-Ga-As-Sb phase diagram showed that the observed strong enrichment should happen just above the AsSb alloy melting point as prescribed by the local thermodynamic equilibrium in the system. The determined composition of the AsSb nanoinsclusion case a substantial lattice mismatch with the AlGaAsSb matrix. By comprehensive structural investigations we determined the orientation relationships between the atomic lattices. The c-axes of the nanoinsclusion lattice, which can be described as hexagonal, is oriented along one of the <111> directions of the matrix, which possesses the zinc-blende structure. The [-2110] direction in the inclusion is parallel to one of the corresponding <110> directions in the matrix. As a result of the lattice mismatch, large AsSb nanoinclusions are accompanied by satellite dislocation loops. In order to determine strain components inside and outside the nanoinclusions we performed geometric phase analysis (GPA) of a HRTEM image with the reference to a known undistorted and quasi-similar lattice. By GPA we also determined the Burgers vector of the dislocation loops, which appeared to be perfect prismatic with b = a[001]. We considered the corresponding problem of elasticity and show that the dislocation loop formation reduces the total elastic energy in the system. The established composition and microstructure of AsSb inclusions in AlGaAsSb laid a solid basis for deeper insight into plasmonic properties of the metal-semiconductor metamaterial.

Monodisperse Dual Plasmonic Au@Cu2-xE (E=S, Se) core@shell Supraparticles—Aqueous Fabrication, Multimodal Imaging and Tumor Therapy at In Vivo Level Yunsheng Xia; Anhui Normal University, Wuhu, China.

We herein report aqueous fabrication of well-defined Au@Cu2-xE (E=S, Se) core@shell dual plasmonic supraparticles (SPs) for multimodal imaging and tumor therapy at the in vivo level. By means of a modified self-limiting self-assembly based strategy, monodisperse core@shell dual plasmonic SPs, including spherical Au@Cu2-xS SPs, Au@Cu2-xSe SPs, and rod-like Au@Cu2-xS SPs, are reliably and eco-friendly fabricated in aqueous solution. Due to plasmonic coupling from the core and shell materials, the as-prepared hybrid products possess an extremely large extinction coefficient (9.32 L g-1 cm-1 for spherical Au@Cu2-xS SPs) at 808 nm, which endows their excellent photothermal effect. Furthermore, the hybrid core@shell SPs possess the properties of good biocompatibility, low nonspecific interactions, and high photothermal stability. So, they show favorable performances for photoacoustic imaging and X-ray computed tomography imaging as well as photothermal therapy of tumors, indicating their application potentials in biological field.

NM02.10.20
High Activity Heterogeneous Catalysts by Plasma-Enhanced Chemical Vapor Deposition of Volatile Palladium Complexes on Biomorphic Carbon Lasse Jürgensen, Michael Frank, Lisa Czypmiel and Sanjay Mathur; Inorganic Chemistry, University of Cologne, Cologne, Germany.

New palladium complexes based on alky and alkenolate ligands were synthesized and structurally characterized. Combination of delocalized allylic sp2-
hybridized carbon centers and a strongly binding N=O chelating unit (e.g. 3,3,3-trifluoro(pyridin-2-yl)propen-2-ol) offered a promising combination of high volatility and thermal lability not commonly observed in noble metal precursors. Application of the new Pd compounds in thermal metal organic and plasma-enhanced chemical vapor deposition demonstrated their clean and efficient decomposition pathways, which in conjunction with their intriguing air stability made them efficient precursors for Pd films and clusters. Plasma-enhanced chemical vapor deposition of the palladium compounds on biomorphic carbon used as a porous substrate with high surface area and interconnected channels delivered recyclable carbon-supported Pd catalysts (Pd@BioC), which showed excellent selectivity, stability, and recyclability in C–C coupling reactions.

Directed and Self-Assembly of Elemental and Bimetallic Thin Films in the Au-Ag-Ni System via Pulsed Laser Dewetting

David A. Garfinkel1, Philip D. Rack1,2, Ryan Allaire1, Jason Fowlkes1,2, Lou kondic1, Miguel Fuentes-Cabreram and Rezee Emery1; 1University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 2CNMS, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3New Jersey Institute of Technology, Newark, New Jersey, United States.

Both directed and self-assembly of metallic thin films via pulsed laser induced dewetting have been demonstrated as viable techniques for generating ordered arrays of metallic nanoparticles. The liquid phase dewetting of single component materials has been the subject of much study, and thus the relevant instabilities in 2D films and 1D filaments, and competing fluid forces of surface energy, viscosity, and inertia, are relatively well understood. The addition of a second component, however, creates intriguing and complementary chemical instabilities and free energy landscapes that can facilitate or compete with the hydrodynamics. For instance, phase instabilities at high temperatures can compete with the dewetting dynamics, and provide an avenue to create unique particle morphologies. Here we will examine both patterned and continuous thin film dewetting of elemental and bimetallic films in the Au-Ag-Ni system. Beyond promising bifunctional magneto-plasmonic properties and applications, the chosen material system also features three unique bimetallic phase behaviors: near complete immiscibility in the solid and liquid phase (Ag-Ni), complete miscibility (Au-Ag), and liquid miscibility with a miscibility gap in the solid phase (Au-Ni). The primary focus is devoted to Au-Ni and Ag-Ni due to the presence of immiscibility in both systems. In this presentation we will briefly overview some of the previous work on single component pulsed laser dewetting, and in particular on the 1D breakup of lithographically patterned thin film strips. We will then compare the Rayleigh Plateau instability and hydrodynamic transport in Ag-Ni and Au-Ni, and illustrate how phase separation affects the dewetting dynamics. We will show complementary molecular dynamics simulations as well as continuum simulations, which will demonstrate how the relevant timescales of the hydrodynamic/chemical instabilities and transport affect the resultant nanoparticle morphology.

NM02.10.22

Nanoporous Metallic Aluminum-Covered Polyimide Nanopaper as Carbon-Free Cathode for Lithium-Air Batteries

Jiwon Jung1, Su-Ho Jung2, Tae Gwan Yoon3, Ki Ro Yoon1, Changhun Kim1, Jun-Young Cheong1, Su-Ho Cho1, Hye Moon Lee4 and Il Doo Kim1; 1KAIST, Yuseong-gu, Korea (the Republic of); 2Korea Institute of Materials Science, Chunchon, Korea (the Republic of).

Although conductive and cheap aluminum (Al), common cathode current collector in Li-ion batteries, is well known to be stable at high voltage, its active use in Li-air batteries has been limited because of a lack of synthetic method for porous, metallic Al layer with high surface area. Herein, we first developed nanoporous metallic aluminum (Al)-coated polyimide nanopaper (PI@nAl Np) as carbon-free air cathode for flexible Li-air batteries: First, self-standing PI Np was synthesized via electrosprinning of PAA solution (pyromellitic dianhydride (PMDA) and 4,4’-oxydianiline (ODA) in N,N-dimethylformamide (DMF)) followed by imidization. Then, using our own Al ink developed by our group (patented in USA), the nAl overlayers were conformally coated on entire surfaces of the PI Np; thickness of Al coating layer was precisely optimized in terms of electronic conductivity (<1 ohms/square), flexibility and pore blockage in controllable manner. The finely designed PI@nAl Np showed greatly important features as porous cathode: (1) Mechanically durable PI Np without reactive carbon in electrolyte provides flexible, porous and light-weight matrix for diffusing O2 and accommodating Li2O2 in large void reservoirs. (2) nanoporous metallic Al coating layers serve as sufficient reaction sites and facile pathway for electron transport. The PI@nAl Np exhibits a highly stable capacity at a fixed capacity of 1000 mAh g−1 for over 300 cycles at a current density of 400 mA g−1. We conducted close-investigation of reaction products in light of morphology, parasitic side reactions in carbon-free air cathode. Flexible pouch- and cable-type Li-air battery cells with the PI@nAl Np were successfully fabricated and applied as power sources for flexible electronics (5.0 V LED and 6.0 V ‘Otto Bot’ operating). Our synthetic strategy will open new opportunities to invent nanostructured Al materials for diverse applications.

NM02.10.23

Silver Core/Silicon Nanocrystal Shell Hybrid Nanoparticle as Antimicrobial Agent

Asuka Inoue1, Hiroshi Sugimoto1, Byungji Kim2, Michael J. Sailor3 and Minoru Fujii1; 1Department of Electrical and Electronic Engineering, Kobe University, Kobe, Japan; 2Materials Science and Engineering Program, University of California, San Diego, San Diego, California, United States; 3Department of Chemistry and Biochemistry, University of California, San Diego, San Diego, California, United States.

Silver nanoparticles (AgNPs) are often used for antimicrobial applications, especially against Gram-negative bacteria, such as E. coli. Upon dissolution, AgNPs release Ag ions that bind to nucleic acids and thiol-containing compounds (i.e. amino acids in enzymes and proteins) to inhibit bacterial growth. However, AgNPs suffer from agglomeration and oxidation, which both degrade antimicrobial activity. To overcome this challenge, AgNPs are often coated with polymers. Recently, we developed a hybrid nanoparticle that is composed of an Ag core and a monolayer shell made of silicon (Si) nanocrystals. [1] With a hydrophobic shell formed by Si nanocrystals, the hybrid nanoparticle is able to disperse in water without agglomeration. Moreover, the size of AgNPs and the thickness of their shells can be tuned by adjusting concentration of Ag ions and Si nanocrystals. A major advantage of the hybrid nanoparticle is that it can be formed into a smooth and flexible film of antimicrobial nanoparticles by simply drop-casting the solution onto a substrate. Herein, we present the potential of the hybrid nanoparticle as an antimicrobial agent against E. coli, as a model Gram negative bacterium. The antimicrobial action of the hybrid nanoparticle is similar to bare AgNPs, in that Ag ions are released from the hybrid nanoparticle core through the Si nanocrystal shell to inhibit bacterial growth. Furthermore, use of the drop-cast films as antimicrobial coatings were studied as a function of structural parameters (i.e., diameter of the Ag core, diameter of Si nanocrystals forming the shell), and antimicrobial efficacy was tested in an agar diffusion assay. The results demonstrate a strong antimicrobial activity by the hybrid nanoparticle film, compared to the bare AgNp film. Moreover, the extent of bacterial growth inhibition depended strongly on the structure of the hybrid nanoparticle. Quantitative analyses reveal that hybrid nanoparticles diffuse on agar by releasing Ag ions, and that the area of the growth inhibition is determined by the diffusion rate which is in turn determined by the structural parameters of the hybrid nanoparticle. The hybrid nanoparticle remains effective when stored in aqueous solution or in air.

NM02.10.24

2D Single-Crystalline Copper Nanoplates as a Conductive Filler for Electronic Applications

Tae-Wook Kim; Korea Institute of Science and Technology, Wanju, Korea (the Republic of).

Metal nanoparticles have received much attention due to their versatile use in catalysis, optoelectronics, magnetics, biotechnology and microelectronics
applications. Because the nanoparticle size is known to be an important factor to enhance the activity or functionality for practical applications, various synthetic methods have been introduced, and a potential growth mechanism has been proposed to explain the relationship between the crystal structure and the optical, physical and electrical functionalities. In this study, we synthesize copper nanowires (Cu NWs) and copper nanoparticles (Cu NPLs) using a hydrothermal process. The combination of a mild reductant, stabilizer, and shape modifier allow the dimensional control of the Cu nanocrystals from one-dimensional (1D) nanowires to two-dimensional (2D) nanoparticles. HR-TEM reveals that the prepared Cu NPLs had a single-crystalline structure. From the XPS analysis, we found that iodine plays an important role in the modification of the copper nanocrystals through the formation of an adlayer on the basal plane of the nanoplates. We successfully synthesized Cu NPLs with an average edge length of 10 μm, and these Cu NPLs are the largest copper 2D crystals synthesized by a solution-based process so far. The application of the metallic 2D crystals as a semi-transparent electrode proves their feasibility as a conductive filler, exhibiting very low sheet resistance (0.4 Ω/sq). The efficient charge transport is due to the increased contact area between each Cu NPL, i.e., so-called plane contact (2D electrical contact).

NM02.10.25

Synthesis and Size Analysis of DNA Conjugated Bio-Hybrid Nanostructures Soubantika Palchoudhury¹, Abdullah Arabshahi², Yasmin Foster¹, Uday Ghar‡¹ and Armel Boutchuen²; ¹Civil and Chemical Engineering, University of Tennessee at Chattanooga, Chattanooga, Tennessee, United States; ²SimCenter, The University of Tennessee at Chattanooga, Chattanooga, Tennessee, United States.

The remarkable advances in synthesis techniques has led to a wide variety of complex nanostructures in recent years. The hybrid nanostructures essentially integrate multiple nanoparticles into one unit to facilitate tailored material properties. Synthesis of bio-hybrid nanostructures integrating biological moieties with inorganic nanoparticles has been of particular interest due to their novel material properties and applications in bio-imaging and drug delivery, but these structures are synthetically challenging to achieve. These hybrid nanostructures are also increasingly complex in terms of metrology. We report the synthesis of a novel hybrid nanostructure containing shape-controlled iron oxide nanoparticles conjugated to metal nanoparticles (e.g., Au) via DNA linkers. The synthesized bio-hybrid nanoparticles are stable in the aqueous phase and are characterized via a transmission electron microscope. The size and surface charge of a nanoparticle is an important metric for several biomedical applications such as targeted drug delivery as it affects the nanoparticle's circulation in vivo. However, it is challenging to establish a metric to accurately assess the size of these bio-hybrid nanoparticles due to their complex structure and morphology. In this study, size and zeta potential of the different bio-hybrid nanostructures synthesized have been investigated in detail on a Litesizer particle analyzer to develop a reliable material characterization method to assess the size of complex nanostructures. The study will be highly useful for biomedical applications like imaging and drug delivery.

NM02.10.26

Facile Signal Amplification of Colorimetric DNA Detection Using “Nano-to-Ion” Processes for High Sensitivity Hye In Cho and Jae-Seung Lee; Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

A number of signal amplification methods have been investigated to achieve high sensitivity of DNA detection schemes. In general, the signal amplification of DNA detection can be classified largely into two categories, depending on the type of the amplification target: DNA targets themselves, and artificially designed surrogate targets. These approaches have been widely taken advantage of in industry and academia owing to the high selectivity and sensitivity of the detection results. However, the amplification of target DNA, such as the polymerase chain reaction (PCR) and the rolling circle amplification (RCA), are limited with their cumbersome, time-consuming enzymatic reactions. To overcome such obstacles, the surrogate target amplification has been developed and employed in various DNA detection schemes, such as bio-barcode assays, with advantages including short detection time, no need for enzymatic reactions, and high sensitivity. Unfortunately, however, the design and incorporation of surrogate targets are accompanied with undesired expenses and labor.

In this work, we developed a DNA detection assay based on the conventional sandwich schemes using magnetic microparticles (MMPs) and silver nanoprobes, each functionalized with probe DNA strands, but with highly reliable and facile amplification technology. Importantly, we took advantage of the presence of nanoparticle probes without amplifying any targets or surrogate targets. Instead, a single nanoparticle probe can be transformed into numerous ions via a “nano-to-ion” process. This numeric enhancement can be directly correlated with the signal enhancement and eventually the improved limit of detection (LOD). To obtain the colorimetric signals, the tremendous number of silver ions is quantitatively analyzed using the C–Ag–C coordination chemistry in assistance with DNA-modified gold nanoparticles. Furthermore, for the better sensitivity of DNA detection, we obtained the photoluminescence of semiconductor quantum dots, which was another quantitative correlation parameter as a function of the silver ion concentration.

NM02.10.27

Investigation of (WO₃), Cluster and Tungsten Oxide Nanoparticle Formation Using Time-of-Flight Mass Spectrometry Stefan Kunis¹, Christof Schulz¹, ² and Hartmut Wiggers¹, ²; ¹IVG, Institute for Combustion and Gas Dynamics, University of Duisburg-Essen, Duisburg, Germany; ²CENIDE, Center for Nanointegration Duisburg-Essen, Duisburg, Germany.

Tungsten oxide (WO₃) is an important gas sensing material due to its sensitivity to, e.g., acetone, toluene, and hydrogen sulfide. The detectability of these gases and the insensitivity to high humidity makes WO₃ interesting for non-invasive breath diagnostics [1]. The acetone concentration in the breath is an indication of diabetes, the concentration of toluene can indicate lung cancer. All these applications require high surface area and thus small particles. Time-of-flight mass spectrometry (TOF-MS) in combination with molecular-beam sampling enables the inline investigation of nanoparticle formation in the gas phase. Molecular-beam sampling instantaneously interrupts all reactive gas-phase processes and thus allows a spatially resolved measurement of gas-phase and particle-phase. TOF-MS can be used to identify the composition as well as intermediate species (clusters) at various locations in a reactor. To gain insight in the tungsten oxide nanoparticle formation process, respective measurements were performed in low-pressure flat-flame.

WO₃ nanoparticles are synthesized by the decomposition of tungsten hexafluoride (WF₆) in a premixed hydrogen/oxygen flame. Due to low pressure (20–30 mbar), an almost one-dimensional, spatially extended flat flame is formed enabling spatially-resolved measurements. A small sample of the aerosol is expanded through a nozzle and a skimmer into high vacuum to form a particle-laden molecular beam. The progress from the initial decomposition of the gaseous precursor to the formation and growth of (WO₃) clusters and nanoparticles can be studied by varying the distance between the burner head and the nozzle position. The distance between the sampling nozzle and the burner (height above burner, HAB), represents the residence time within the reactor. As previous investigations indicate fragmentation of tungsten oxide clusters [2] during TOF-MS measurements, electron ionization was substituted with soft ionization with a vacuum UV (VUV) lamp avoiding fragmentation.

The results show a sequential cluster formation and particle nucleation. The number concentrations of differently sized clusters strongly vary indicating “magic” cluster sizes during the nucleation process. The fuel-to-oxygen ratio affects cluster growth and phase composition and low oxygen concentrations cause the formation of sub-stoichiometric clusters. Substituting a small part of hydrogen with methane changes the flame chemistry due to additional charges resulting in a significant decrease of smaller cluster sizes and a shift to larger cluster sizes.

NM02.10.28

Universal Template-Synthesis Method for Three-Component Nanostructures Han-Jung Ryu, Jang Ho Joo and Jae-Seung Lee; Materials Science and
Trimetallic nanoparticles have attracted growing interest recently because of their superior chemical and physical properties. They show excellent catalytic properties which belongs to their synergistic effects based on electronic charge transfers between multiple metal atoms. Despite of these unique properties, however, trimetallic nanoparticles have to suffer from high reaction temperatures, harsh reductants and multistep procedures during their synthesis. To overcome these obstacles, nanosized templates can be used as one of promising solutions. Template methods are widely used for nanomaterial synthesis, because they can provide nucleation sites to facilitate the reduction process of metal precursors. After the removal of the templates, the resultant hollow nanoparticles can obtain high surface area, which is one of the most important virtues for catalyst. In this work, we demonstrate a universal template-assisted room-temperature synthetic method for trimetallic noble metal nanoparticles which were replications of silver halide nanotemplates. As a proof of concept, we demonstrate two types of trimetallic nanoparticles, each composed of Pd-Au-Ag and Pt-Au-Ag, which were synthesized using the universal synthetic method. Importantly, the shape of the trimetallic nanoparticles was able to be controlled by adjusting the shape of the templates. The structural properties and composition of the trimetallic nanoparticles were thoroughly analyzed by transmission electron microscopy (TEM), energy-dispersive X-ray spectroscopy (EDX), elemental mapping, and X-ray diffraction (XRD). Finally, the outstanding catalytic performance of the trimetallic nanoparticles for reduction of harmful toxic Cr (VI) ions were monitored by UV-vis spectrophotometry. They exhibited great catalytic performances for the reduction process because of their synergistic effects owing to multiple types of metals and high surface area derived from hollow structures.

NM02.10.29
Fabrication of Transparent Nanostructural Iridium/Iridium Oxide Film for Biomedical and Electrochemical Applications Ming-Ting Hsieh and Pochun Chen; National Taipei University of Technology, Taipei, Taiwan.

Ir and iridium oxide are attractive materials for biomedical and electrochemical applications due to their desirable stability, electrochemical performance, and biocompatibility. Nanostructured iridium/iridium oxide possesses several advantageous properties including large surface-to-volume ratio, light weight, optical transmittance, and desirable electrical and electrochemical capability. However, controlling film morphology and inter-connectivity of nanostructural iridium/iridium oxide is very difficult. Nanoporous iridium/iridium oxide has excellent properties, and it can also provide extremely high surface area in applications for catalysis, sensors, and bioelectrodes. In addition, the transparency of the nanoporous iridium/iridium oxide can provide a great benefit for biomedical devices such as electronic skin and implantable optogenetic probes.

In this study, we employed a facile process to fabricate a transparent and uniform iridium/iridium oxide film by chemical bath deposition with proper heat and electrochemical treatments. Besides, the formation mechanism of the nanoporous iridium/iridium oxide film was illustrated by a detailed thermodynamic calculation. In addition, we carried out a transfer printing process to attach the nanostructural iridium/iridium oxide film on transparent substrates including ITO and polyimide. We characterized and evaluated the deposited films. The surface morphology, roughness, hydrophilicity, crystallinity, oxidation state, and electrochemical performances of the iridium/iridium oxide film were analyzed.

NM02.10.30
Metal-Curcumin Nanoparticles—Synthesis, Characterization and Therapeutic Potential Apoorva Singh1, Pooya Ghosh2, Suranjana Mukherjee2, Sunita Sharma3, Swagata Dasgupta2, Gayatri Mukherjee2 and Koel Chaudhury1; 1School of Medical Science and Technology, Indian Institute of Technology Kharagpur, Kharagpur, India; 2Department of Chemistry, Indian Institute of Technology Kharagpur, Kharagpur, India; 3Institute of Reproductive Medicine, Kolkata, India.

In recent years, highly promising and innovative approaches involving complex formation of the curcumin molecule with transition metals has proven effective in overcoming the limitations associated with clinical translation of curcumin, i.e. low systemic bioavailability and hydrolytic instability. Owing to the significant role played by transition metals in pathological processes, these metal-curcumin complexes can act as a double-edged sword due to increased specificity and cytotoxicity. Though the complexes exhibit enhanced therapeutic potential, the low aqueous solubility still remains a challenge in achieving targeted drug delivery. Herein, we propose that nanof ormulation of metal-curcumin complexes may pave a new way towards drug delivery and therapeutics due to high stability, bioavailability that may result in longer circulation time.

The objective of the present study is to synthesize metal-curcumin nanoparticles (NPs) with high stability, solubility and long-term sustained drug delivery. For this purpose, the biocompatible and degradable FDA approved poly (lactic-co-glycolic) acid polymer was used as the vehicle along with poloxamer-407 to increase the stability of NPs. Two transition metals, Copper (Cu), and Zinc (Zn) were respectively complexed with curcumin in the ratio 1:1 and characterized using spectroscopic techniques. A nanoprecipitation technique was used to prepare NPs and the formulations evaluated in terms of particle size, zeta potential, surface morphology, X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FTIR), entrapment efficiency (EE) and in vitro release kinetics. In addition to chemical characterization, the therapeutic potential of the NPs was investigated in different cancer cell lines and primary endometrial stromal cells isolated from endometriotic lesions.

It was found that the prepared NPs were in the size range of 180-220 nm with EE of 77±2.43 to 82±4.43%. The low polydispersity index and high negative zeta potential indicated monodispersiv and stable nature of NPs. FTIR and XRD confirmed the entrapment of respective compounds within NPs without any major structural alterations, while release kinetics indicated a sustained release pattern exhibited by Cu- and Zn-Cur NPs as compared to Cur NPs over a period of time. The enhanced anti-proliferative activity of metal-Curcumin NPs was evident in all the cancer cells lines and primary endometriotic cells as compared to Cur NPs. In conclusion, for the first time metal-Cur NPs with high aqueous solubility, bioavailability and diverse potential benefits were successfully prepared and characterized.

NM02.10.31
Masking Strategies for DNA Detection—What can Mask Catalytic Nanoparticle Surfaces for DNA Targets? Won Kyu Lee, Yoon Hyuck Kim and Jae-Seung Lee; Materials Science and Engineering, Korea University, Seoul, Korea (the Republic of).

DNA-functionalized gold nanoparticles (DNA-AuNPs) have been widely used for sensitive and selective colorimetric detection of nucleic acids, because they exhibit excellent chemical and physical properties such as sharp melting profiles, cooperative binding properties, reversible assembly properties, and intense optical properties based upon the surface plasmon resonance (SPR). In particular, the conventional nanoparticle-based “luminescent” test schemes proved the DNA-AuNPs to be powerful and efficient diagnostic tools in various diagnostic applications for DNA targets. The color changes were determined by the [target] and the presence of mismatches, which were correlated with the interparticle distance of the DNA-AuNPs. While simple and rapid, however, this detection scheme had to suffer from low sensitivity, and often low signal intensity, especially at lower [DNA-AuNPs]. As a result, this assembly-based colorimetric detection scheme is practically of little interest in the community. Considering its fundamental reliability and simplicity, however, it would be a significant advance if a modification could improve its sensitivity and signal intensity.

We previously demonstrated a conceptually advanced detection scheme, where the protein target binding leads to the masking of catalytic nanoparticle surfaces. Eventually, the catalytic activity of the particles can be systemically controlled, which can be quantitatively correlated with the color signals. In case of DNA targets, however, they are not sufficiently large enough to “mask” the nanoparticle surfaces. Instead, the DNA targets can “assemble” the DNA-AuNP probes as described in the conventional assembly-based schemes, which ultimately results in masking DNA-AuNP surfaces using other DNA-AuNPs. Taking advantage of this masking strategy, where the concentration of the target DNA controls the exposed surface area of AuNPs, the detection
scheme in this work could be highly sensitive and selective for the colorimetric detection of DNA targets. In order to characterize and elucidate the processes controlling the exposed surface area of DNA-AuNPs, we analyzed the laboratory samples using an ICP-OES spectrometer (Inductively Coupled Plasma Optical Emission Spectroscopy), scanning electron microscopy (SEM) and dynamic light scattering (DLS). Melting transitions were also obtained as a function of temperature by monitoring the extinction change at 525 nm using UV-visible spectroscopy. Furthermore, we investigated the catalytic properties of the assembled DNA-AuNPs for the oxidation of α-phenylenediamine (OPD) and the reduction of 4-nitrophenol (4-NP). Our masking strategy studies of the DNA-AuNP assembly process will play a significant role in demonstrating colorimetric detection of the target DNA based on the self-assembly of gold nanoparticles.

NM02.10.32  
Effect of Hydrogen on the Mechanical Properties of Nanocrystalline α-iron Using Atomistic Simulations  
Mohamed A. Hendy1, Tarek Hatem1 and Jaafar A. El-Awady2; 1The British University in Egypt, Cairo, Egypt; 2Department of Mechanical Engineering, Johns Hopkins University, Baltimore, Maryland, United States.

Hydrogen embrittlement is a persistent problem causing premature failure for steels. Nanocrystalline metals have unique mechanical properties compared to coarse grain counterpart which makes them suitable for future structural applications. In order to assess the effect of hydrogen on nanocrystalline α-iron, 3D Molecular dynamics (MD) simulations have been performed for bulk random-oriented nanocrystalline α-iron. The simulation cells are of size 76nm × 76nm × 76nm composed of 40 grains of different size with periodic boundary conditions. The simulation cells are deformed by applying strain along the x-axis with strain rate of. The effect of hydrogen on the deformation mechanism and fracture have been investigated through simulating a hydrogen-free nanocrystalline iron cell and hydrogen charged one with hydrogen concentration of 100 appm. In both cases, intergranular failure has occurred, however, the results showed a significant reduction in fracture strain for hydrogen-charged simulation cell compared to the hydrogen-free one. Moreover, hydrogen accelerated intergranular crack propagation. The hydrogen charged simulation cell experienced different deformation activities compared to hydrogen free one. For both cases, many deformation modes interact and co-exist (twinning, partial dislocation emission and grain boundary sliding).

Flame Inspired Nanostructuring—Flexible Ceramic Hybrids for Advanced 3D Nanotechnologies  
Yogendra K. Mishra; University of Kiel, Kiel, Germany.

Recently introduced flame based approach offers unique opportunities for advanced metal oxide nanostructuring, ranging from quasi 1D nanowires to microscopic 3D porous interconnected tetrapodal networks.[1] The present strategy offers direct integration of ZnO nano- and microstructures and their networks on the desired substrates for various applications, e.g., whispering gallery modes, photocatalysis or nanosensing (UV/gases) applications.[1,2] The flame grown ZnO tetrapods ZnO nano- and microstructures exhibit very low cytotoxicity and they have shown strong potentials against antiviral applications.[3] The unique 3D shape of the ZnO tetrapods facilitates them to be used as efficient fillers for fabricating advanced composites, e.g., self-reporting composites[4] and many others. The 3D porous, flexible and conducting network from ceramic materials are now-a-days very important because of their technological relevance and the developed flame method offers desired synthesis of various ZnO and SnO2 nanomaterials.[1] These 3D porous networks can be decorated with other nanostructures for designing hybrid multifunctional materials[7] and can also be used as sacrificial templates to grow new nanomaterials.[8,9] Additionally, polymers can also infiltrated within the network to make different polymer based composites and template can be removed later on, if needed, to develop porous polymers.[10] An overview about the possible nanostructuring opportunities by the flame method will be presented and few application examples will be discussed.

Reversible Magnetic Agglomeration—A Mechanism for Thermodynamic Control Over Nanoparticle Size  
Dale L. Huber1, Grant Bleier1, John Watt1, Simocko K. Chester2 and Judith Lavin1; 1Sandia National Laboratories, Albuquerque, New Mexico, United States; 2San Jose State University, San Jose, California, United States.

We present a method for the synthesis and precise size control of magnetic nanoparticles in a reversible magnetic agglomeration mechanism. In this approach, nanoparticles nucleate and grow until a critical susceptibility is reached, in which magnetic attraction overcomes dispersive forces, leading to agglomeration and precipitation. This phase change in the system arrests nanoparticle growth and gives true thermodynamic control over the size of nanoparticles. We then show that increasing the alkyl chain length of the surfactant, and hence increasing steric stabilization, allows nanoparticles to grow to larger sizes before agglomeration occurs. Therefore, simply by choosing the correct surfactant, the size and magnetic properties of iron nanoparticles can be tailored for a particular application. With the continuous addition of the precursor solution, we can repeat the steps of nucleation, growth, and magnetic agglomeration indefinitely, making the approach suitable for large scale syntheses.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science. Engineering Nanoscale Selenium Surface Functionalization for Clinical Antibacterial Applications  
James W. Maxley, Paria Ghannadian and Thomas Webster; Northeastern University, Boston, Massachusetts, United States.

Antibiotic resistance (ABR) is rapidly gaining attention within the scientific community as an escalating threat to the global health care infrastructure. The increasing frequency of occurrence of resistant bacterial strains, specifically multidrug resistant (MDR), extensively drug resistant (XDR), and totally drug resistant (TDR) phenotypes, would seemingly necessitate demand for a new generation of small-molecule drugs for clinical implementation. Fortunately;
the compounded effects of administrative barriers, technical complications, and selective economic pressures has significantly reduced the rate of discovery for new antibiotic species. Novel approaches for the management of bacterial growth in clinical settings are clearly desirable. One such approach is the development of nanoscale selenium surface functionalization for medical materials and instrumentation.

Selenium nanoparticle functionalization was achieved by heterogeneous nucleation along a range of solid supports provided by academic and federal collaborators. These materials were coated in small-batch processes, in which the supports (2 mm x 2 mm x 0.5 mm) were immersed in a reaction solution (100 μM glutathione, 25 μM sodium selenite, and 80 μM sodium hydroxide) for 60 seconds, followed by several washing stages with deionized water. Nanoparticle coatings were characterized with atomic force microscopy (AFM), scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDS), X-ray photoelectron spectroscopy (XPS), and contact angle measurement. Functionalized surfaces were assessed for antibacterial properties by means of colony forming unit (CFU) assay with gram-positive (Staphylococcus aureus, ATCC 25923) and gram-negative (Escherichia coli, ATCC 25922) bacterial strains.

Physical characterization demonstrated that treatment yielded homogeneous surface coverage, with average particle interspacing smaller than the dimensions of both S. aureus and E. coli. Chemical characterization verified that observed nanoparticles were composed of elemental selenium. CFU assay demonstrated a statistically significant reduction in S. aureus bacteria over a 12 hour interval for the two current test materials, carbon-microfiber sheets and basalt-epoxy blocks. For carbon-microfiber sheets, treatment resulted in a 32% and 63% reduction in CFU at the targeted operational temperatures of 50 °C and 40 °C, respectively. For basalt-epoxy blocks, treatment resulted in a 77% and 82% reduction in CFU at the targeted operational temperatures of 60 °C and 50 °C, respectively. A trend of reduced bacterial colonization has also been observed for E. coli in preliminary studies.

Nanoscale selenium surface functionalization has demonstrated antibacterial efficacy along clinical surfaces in vitro. Future studies will focus on elucidating the mechanism of antibacterial activity, assessing mammalian cell biocompatibility, and determining antibacterial efficacy under biofouling conditions.

NM02.10.36
Colloidal ReO₃ Nanocrystals—Extra Rhenium d-electron Instigating a Metallic Optical Behavior Sandeep Ghosh; The University of Texas at Austin, Austin, Texas, United States.

Plasmonics exhibited by nanocrystalline metals has been an active area of research, mostly due to interest in exploring their unique optical response. Although elemental metals like gold and silver have been the major focus in these studies, other materials have also been shown to exhibit a metallic optical response. In this presentation, we will describe a solution based synthesis of nanocrystals (NCs) of rhenium (VI) oxide (ReO₃) which exhibit localized surface plasmon resonance (LSPR) specific to the metal's unique electronic band structure. The presence of an extra d-electron in the outer electron shell of the rhenium (VI) ion leads to partial filling of the conduction band and manifests in its characteristic metallic conductivity and optical properties. The colloidal synthesis of these NCs follow a simple wet-chemistry method, based on the reduction of Re(VII) precursor to the Re(VI) oxidation state. This is different from the usual chemical mechanism that a majority of the metal oxide NCs of interest, coupled with unavailability of suitable Re(VI) precursors. In this presentation, these synthesis challenges and strategies employed to overcome them and design a successful chemical route will be described. The as-obtained NCs exhibit an LSPR optical response in the visible-near-infrared region, and are stabilized in solution by L-type ligand coordination. The advantage of such ligand coordination is demonstrated by the ease of switching between solvents of choice without having to go through the cumbersome ligand exchange procedure, most prevalent otherwise in case of X-type ligation in colloidal NCs. These NC solutions were then spin-coated on appropriate substrates and further characterized by means of electrical transport and spectroelectrochemical measurements.

NM02.10.37
Polyelemental Nanopatterns via Low-Energy Plasma Bombardment for High Performance Gas Sensor Woo-Bin Jung and Hee-Tae Jung; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Three-dimensional nanopatterns that consist of polyelemental components are promising platform for potential applications, whereas there are no effective strategies for fabrication of polyelemental nanopatterns, in which three-dimensional architectures can be explored in a systematic and site-specific manner. Generation of high resolution (<30 nm) nanoscale pattern with multi-components regardless types of elements is one of the biggest challenge in nanotechnology because of difficulties of nanoscale mixing and 3D nanopatterning at the same time. Recently, a few study based on precursor such as diphenylphosphine and block copolymer template have been reported, but previous approaches are limited to shape and combination depending on compatibility of elements.

In this study, we accomplished significant progress toward developing general method for fabricating complex nanostructures with a mixture of two or more types of elements. By simply using low-energy plasma bombardment process, followed by secondary sputtering on the sidewall surfaces of the pre-pattern, the polyelemental components with diverse shapes and high resolution were generated. Unlike previous approaches, this discovery is significant in terms of the fabrication of a wide range of polyelemental complex nanostructures. Firstly, this method is not restricted to the selection of elements and their combination, and a wide range of combination of metals and semiconductors can be generated by the simple deposition of metals or semiconductors on a substrate. Secondly, nanostructures with several components of greater than three can be fabricated by simply plasma bombardment process on multi-layered films. Thirdly, the complex shapes and array of multi-component nanostructures with high resolution (~10 nm) and tunable inner structures can be achieved. Finally, this approach can be applied to hydrogen gas sensing, with the highest sensing speed observed using Pd–Au bimetallic nanopatterns. Notably, only one Pd-based bimetallic line-shaped nanostructure was examined in this study; this may not even be the best one, but its performance exceeds that of conventional materials. This study is expected to open the door for a large family of multi-component metals for use in a wide range of applications.

NM02.10.38
Intermetallic L1₀-MP (M=Fe, Co) Nanoparticles Advance Pt Catalysis in Fuel Cells Junru Li and Shouheng Sun; Brown Univ, Providence, Rhode Island, United States.

Stabilizing transition metals (M) in Pt alloy under acidic conditions is challenging, yet crucial to boost Pt catalysis towards oxygen reduction reaction (ORR) in fuel cells. ~9 nm tetragonal core/shell L₁₀-MP/Co nanoparticles with 2-3 atomic layers of strained Pt shell were synthesized for ORR. At 60°C in acid, the tetragonal L₁₀-MP better stabilizes M than its cubic A1-MP counterpart. L₁₀-FePt/Co showed superior activity to commercial Pt/C catalyst in the membrane electrode assembly (MEA) and almost no activity drop after 30,000 voltage cycles at 80°C. L₁₀-CoPt achieved mass
activities (MA) of 0.56 A/mgPt before durability test and 0.45 A/mgPt after 30,000 voltage cycles in the MEA at 80°C, exceeding the DOE 2020 targets on Pt activity and durability (0.44 A/mgPt in MA and ~40% loss in MA after 30,000 cycling). Density functional theory study suggests that the ligand effect of Co and the more compressive strain brought by Co compared to Fe better tunes the binding of oxygenated species to the 2–3 Pt shell, thus leading to enhanced ORR performance in fuel cells.

NM02.10.39
Hot Carrier Generation via Surface Plasmons Polaritons for Enhanced Glycerol Electro-Oxidation Reaction

Kyoungwha Chung1,2; Yu Jin Jang1,2; Akira Baba3; Jianfang Wang4; and Dong Ha Kim1; 1Ewha Womans University, Seoul, Korea (the Republic of); 2Department of Energy Science, Sungkyunkwan University, Suwon, Korea (the Republic of); 3Chinese University of Hong Kong, Hong Kong, Hong Kong; 4University of Niigata, Niigata, Japan.

Surface plasmon polaritons (SPPs), which can be observed from the metal films or the metal gratings, dissipate only through non-radiative decay, whereas localized surface plasmons (LSPs) in metal nanocages decays either via radiative or non-radiative relaxation processes. The non-radiative decay of plasmonic energy can generate hot electrons, which possess higher energy than Fermi level. Plasmonic hot carriers are promising for applications in optoelectronics, plasmonics and energy conversion. However, plasmonic hot carrier generation was mostly carried out in metal nanostructures supporting LSPR modes, while very few works were reported with SPPs. In this work, surface plasmon resonance (SPR)-enhanced hot-carrier generation was demonstrated for a model electrocatalytic reaction in Kretschmann configuration. SPR coupling was employed to overcome the low efficiency of thin film-based photon-to-carrier conversion. Arrays of Au nanobipyramids decorated with Pt nanoparticles (AuNBPs@AgPt) were introduced on Au film surfaces to form the nanoparticle-on-mirror (NPoM) geometry and the performance for the glycerol electro-oxidation reaction exhibited ~2.5 times improved photocurrent evolution under illumination of p-polarized light compared with the activity based on the neat Au film with the photon-to-hot carrier conversion efficiency of 2.4 × 10−4. The results obtained in this study may pave a way to provide new opportunities for the SPP-driven energy conversion applications for electro-/photocatalysis and redox species-mediated optical sensing.

NM02.10.41
Dehydration Sensing of a Polymer Film via Plasmonic Nanoparticles
Miliana Lisinova1,2; Ralph E. Martin Department of Chemical Engineering, UARK, Fayetteville, Arkansas, United States; 2School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia, United States.

It is well known that plasmonic nanoparticle's possess a high sensitivity to the refractive index sensitivity of the surrounding medium. Such capabilities already widely explored in bio-plasmonic detectors to sense adsorption events. The high refractive index sensitivity allows to utilize plasmonic nanoparticles to distinguish hazardous solvents vapor from the water vapor.

However, the dehydration/dehydration sensing by plasmonic nanoparticle's which detect water molecules absorption/desorption by soft matter has not been introduced yet. The dehydration sensing of the soft matter is of a particular interest due to the difficulties of the utilization standard techniques in characterization dehydration process of the ultra-thin films or their complexity and extremely high cost. Therefore the development novel approach to control water molecules desorption seems a great challenge. Moreover, the non-traditional method of the water molecules absorption/desorption studies in soft matter to simulate tissue are required. Among prospective candidates for the refractive index sensitivity by plasmonic nanoparticle's are relatively new type materials such as plasmonic nanocages (NCs) which possess the ultra-high refractive index sensitivity of ~1000 nm/RIU. Such high refractive index sensitivity by NCs allows to distinguish a minor changes in refractive index of about 0.01 RIU to 0.001 RIU.

The aim of the research is on the elucidation of the applicability of the refractive index sensitivity of the plasmonic NCs in evaluation dehydration of the ultrathin transparent polymer films, such as poly(vinyl alcohol) (PVA). The PVA has been chosen because of the wide applicability in biomedical field due to the non-toxicity and biocompatibility, better film and fiber forming, excellent chemical resistance and water solubility.

The study is the first to examine the dehydration kinetic of the free standing films based on PVA via refractive index sensitivity of the NCs. Unlike well-studied plasmonic substrates which allows to research adsorption molecules on the surface, the incorporation plasmonic nanoparticles between the polymer layers, polymer/NCs/polymer, allows to research water molecules absorption which involves whole volume of the film. The utilizing nanoparticles allows to estimate rate of polymer film hydration/dehydration. For instance, the NCs introduced to polymer with 2 μm thickness of each layer possess the dehydration time of about 180 (s), dehydration rate ~0.22 (vol% per s) and dehydration rate constant ~ 50X10−4 (s−1).

The work was supported by the University of Arkansas Foundation. I thank Jingyi Chen and Samir V. Jenkins for synthesis of the plasmonic bimetallic nanocages and Nano Bio Photonics group (npbphotons.uark.edu). The initial research was performed under supervision of Prof. Mostafa El'Sayed and Dr. Mahmoud Mahmoud at GATECH supported by U.S. Department of Energy, Office of Basic Energy Sciences under award # DE-FG02-09ER46604.

NM02.10.42
DNA-Coated Gold Nanoparticles for the Detection of mRNA In Vivo Within Hydra Vulgaris Animals

Maria Elena Kyriazis1; Maria Moros4; Araf El-Sagheer2; Tom Brown1; Claudia Tortiglione1 and Antonios Kanaras1; 1University of Southampton, Southampton, United Kingdom; 2Istituto di Cibernetica “E Caiamiello”, Pozzuoli, Italy; 3University of Oxford, Oxford, United Kingdom; 4University of Zaragoza, Zaragoza, Spain.

The ability to detect and monitor biomolecules such as mRNA in live cells has been shown to be of great importance. For example, changes in mRNA expression levels in individual cells have been associated with the development of diseases such as cancer. Common detection strategies are often based on real-time polymerase chain reaction, microarray analysis or in situ hybridisation. However, promising developments have been made by associating nucleic acids with gold nanoparticles (AuNPs) creating a so-called spherical nucleic acid (SNA). These systems have been shown to successfully penetrate the cell membrane without the aid of transfection agents and resist nuclease degradation. When hybridised to fluorophore complements, DNA-coated AuNPs have shown great promise at visualising mRNA in living cells as they exhibit high signalling and have low background fluorescence. Nevertheless, there is less work associated with the use of such systems in a more complex in vivo environment.

In this study we demonstrate the targeted detection of mRNA using DNA-coated AuNPs in the freshwater polyp Hydra vulgaris. Hydra, an invertebrate model that has been thoroughly used in nanomedicine is found at the base of metazoan evolution and presents an intermediate complexity between cell cultures and vertebrates. We show the biocompatibility of DNA-coated AuNPs upon incubation with live animals and specifically focus on selectively imaging Hymyc1 mRNA, whose downregulation is found to be associated with the progression of common cancers. We demonstrate how a precise and recognisable fluorescent pattern can be observed, which mirrors the expected Hymyc1 expression pattern thus indicating high levels of specificity. However, target specificity is also demonstrated via the use of DNA-coated AuNPs for the detection of mRNA that is not expressed within Hydra where a fluorescent signal is significantly absent. Ultimately this research aims to expand our knowledge on the behaviour of the aforementioned systems within live animals in order to further optimise and develop it into a system that could successfully combine efficient mRNA sensing and targeted drug delivery within an in vivo environment.
NM02.10.43
Revisiting Design of Upconverting Nanoparticles for Efficiency and Lasing
Bruce E. Cohen; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Multiphoton imaging techniques that convert low energy excitation to higher energy emission are widely used to improve signal over background, reduce scatter in subsurface imaging, and limit sample photodamage. Multiphoton imaging relies on luminescent probes able to efficiently sum the energies of 2 or more incident photons, as well as lasers powerful enough for multiphoton excitation. Lanthanide-doped upconverting nanoparticles have proven to be among the most efficient multiphoton probes, but even UCNPs with optimized lanthanide dopant levels require laser intensities that may be problematic for living systems. Here, we develop protein-sized, alloyed UCNPs (aUCNPs) that can be imaged at the single particle level at laser intensities below 300 W/cm², over 300-fold lower than needed for comparably-sized doped UCNPs. Using single UCNP characterization and kinetic models of lanthanide energy transfer, we find that addition of inert epilayer shells radically changes optimal lanthanide content from Yb³⁺, Er³⁺-doped NaYF₄ nanocrystals to fully alloyed compositions. At high levels of the emitter Er³⁺, these ions can adopt a second role to enhance the effective aUCNP absorption cross-section by desaturating sensitizer Yb³⁺ or by absorbing photons directly. Core/shell aUCNPs are brighter than comparably sized doped UCNPs at all laser intensities tested, over 4 orders of magnitude. Core/shell aUCNPs 12 nm in total diameter can be imaged with strong contrast (signal:background >25) through several millimeters of tissue in live mice using a laser intensity of just 0.1 W/cm². aUCNPs open up the possibility of using both low irradiance and low-energy excitation wavelengths for non-destructive bioimaging experiments. Additional recent work about dye-sensitized UCNP emission and UCNP-based micron-sized lasers will also be discussed.

Highly Porous Black Metals Formed by High-Pressure Thermal Evaporation
Jun Gi Min and Sangwoo Ryu; Kyunggi University, Suwon, Korea (the Republic of).

Vacuum thermal evaporation is one of the well-known deposition processes to form dense films of metals. In conventional thermal evaporation process, heterogeneous nucleation and growth of the evaporated metal species on the substrates are key mechanisms of the dense films. The evaporation method introduced in this presentation utilizes high pressure inside the vacuum chamber during the evaporation so that it causes repeated collisions of evaporated metal atoms with each other, which is led to homogeneous nucleation and growth before arriving at the substrates. This process results in the formation of nanoporous structures composed of nanoparticle aggregates of the parent metals. The porosity and the color of the porous metals varies depending on the working pressure of the background inert gas. The porosity estimated by the dimensions determined by the electron microscopy exceeds 95% and the obtained nanoporous structures absorb almost all visible light showing black color. Herein, we present the details of this high-pressure thermal evaporation, examples of Au, Cu, Sn, and applications to chemical sensors or Li-ion batteries.

Fabrication of Hollow Metal Nanoshapes by Solid State Dewetting and Oxidation of Al on Sapphire Substrate
Nimrod Gazit¹, Gunther Richter², Amit Sharma¹, Leonid Klinger¹ and Eugene Rabkin¹; ¹Technion-Israel Institute of Technology, Haifa, Israel; ²Max Planck Institute for Intelligent Systems, Stuttgart, Germany.

The Al-Al couple is a classic example of a system in which the Kirkendall effect and Kirkendall porosity represent a major reason for failure in microelectronic devices. In this work we demonstrated that the Kirkendall effect during controlled oxidation of Al in the Al-Au core-shell nanoparticles can be utilized for the synthesis of hollow particles of the intermetallic phase.

We produced metallic nanoshapes by performing a solid state dewetting treatment of Al thin film deposited on sapphire substrate, followed by the deposition of thin Au layer on the top of dewetted sample. Annealing of the core-shell nanoparticles in air resulted in outdiffusion of Al from the particles, formation of pores, and growth of the Au₈Al₇ intermetallic phase in the particles. We demonstrated that the driving force for hollowing is the oxidation reaction of the Al atoms at the Au-sapphire interface, leading to the homoepitaxial growth of newly formed alumina at the interface. We developed a kinetic model of hollowing controlled by diffusion of oxygen through the Au thin film, and estimated the solubility of oxygen in solid Au.

NM02.11.02
Nanoparticle Megalibraries—Expanding the Materials Genome Through Size
Edward J. Kluender¹, James L. Hedrick¹, Rahul Rao², Benji Maruyama² and Chad A. Mirkin²; ¹Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; ²Air Force Research Laboratory, WPAFB, Ohio, United States; ³Chemical Engineering, Northwestern University, Evanston, Illinois, United States; ⁴Chemistry, Northwestern University, Evanston, Illinois, United States.

The nanomaterial landscape is so vast that a combinatorial approach, with complex parameter inputs, is required to fully understand the underlying structure-function relationships. To address this challenge, a new approach for the synthesis and screening of megalibraries of unique nanoscale features (>10 million features) with tailorable size, shape, and composition has been developed. Polymer pen lithography, a massively parallel scanning probe lithographic technique, is combined with a novel method for spray-coating the pen array with gradients of inks such that each pen in the array has a different, but deliberately chosen, quantity and composition of ink. With this technique, gradients of Au-Cu bimetallic nanoparticles have been synthesized on SiO₂ micropillars, and then screened for activity by in situ Raman spectroscopy with respect to single-walled carbon nanotube growth (SWNT) via chemical vapor deposition. Through this methodology, Au-Cu, a structure not previously known to catalyze SWNT growth, has been identified as the most...
active composition.

High Density Ag Nanoparticle Clusters for High Sensitive SERS Substrate Han Lu and Mingliang Jin; South China Academy of Advanced Optoelectronics, South China Normal University, GuangZhou, China.

Surface-enhanced Raman scattering (SERS) is a powerful analytical tool for sensitive detection of chemical[1] and biological molecules[2] even allowing the single-molecule detection[3]. The nanoparticle clusters (paired, trimers, tetramers and linear chains) has emerged as one of the most efficient and widely used configurations in studies involving surface-enhanced phenomena, producing intense electromagnetic fields in the interstices of a reasonably simple structure. Numerous methods have been developed to fabricate nanoparticle clusters in the past few decades, including evaporative self-assembly[4], surface modification[5], template-guided assembly[6] and light-directed assembly[7]. However, these methods are time-consuming and expensive. Thus, it is a challenge to fabricate a simple and cheap nanoparticle clusters for a surface enhance Raman spectroscopy (SERS) substrate with high sensitivity to detect single-molecules and excellent reproducibility and stability of signal. In this work, we introduce a simple method that generates Ag nanoparticle clusters for SERS substrate with high sensitivity and excellent reproducibility based on galvanic reaction in one step without any additional assembly steps. We systematically investigated the effect of the concentration of cetyltrimethylammonium bromide (CTAB), reaction time and temperature on the morphologies of Ag nanostucture. Fig.1a shows the SEM images of Ag nanoparticle clusters. Fig.1b-c shows the SERS spectra of 1 × 10^13 M R6G aqueous solution and 1 × 10^10 M L-Phenylalanine solution respectively, in which the main vibrational features of R6G molecules and L-Phenylalanine molecules are clearly observed, which reveals excellent Raman sensitivity in the Ag nanoclusters SERS substrate. The Ag nanocluster clusters may serve as high sensitivity SERS substrate for wide-ranging applications in single-molecule detection and molecule diagnostics.

9:15 AM NM02.11.04
Holistic Structural Hierarchy in Metal Nanoparticle Composite Superlattices Robert J. Macfarlane; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Structural hierarchy is a powerful design concept where specific geometric motifs are used to influence material structure across multiple size regimes. These complex levels of organization are typically achieved in the laboratory by conceptually breaking a material down into the smallest components that can be manipulated (e.g. individual molecules, macromolecules, or nanoparticles), and using the geometric information in those components to control how they build up into larger length scale patterns. Conversely, complex assemblies in natural systems are commonly achieved through a more holistic approach where assembly behaviors at the molecular, nano, and macroscopic scales are interlinked. This means that not only does structural information contained in molecular building blocks filter upwards to dictate material form at the nano to macroscopic levels, but also that the environment created by the larger length scale features can affect the behavior of individual components. Despite the potential of such a method of materials design, our ability to mimic these natural processes and holistically program structural hierarchy in artificial materials is still severely underdeveloped. Here, we demonstrate a metal nanoparticle-based building block that enables nanoscale geometry to function as a design handle to directly modulate the assembly behavior of a collection of supramolecular binding groups. The ability to use nanoscale geometry to modify molecular behavior allows a single set of nanoparticles to access different nanoscale bonding valencies, resulting in different mesoscale particle arrangements and different supramolecular bond strengths. The formation of distinct hierarchical structures at the nano and mesoscale is therefore both a consequence of and a direct influence on the molecular binding events that drive assembly. The use of nanoscale geometry to dictate supramolecular binding provides a major step forward in understanding how the assembly of hierarchically ordered artificial materials can be done in a holistic manner across multiple size regimes.

Nanostructured Hybrid Metal-Polymer Nanoparticle Systems and Continuous Flow Chemistry Synthesis Riggberto C. Advincula; Case Western Reserve University, Cleveland, Ohio, United States.

The synthesis of various hybrid metal-polymer nanomaterials pre-supposes the ability to utilize various synthetic approaches based on topologically exact dendrimers (and star polymers) and their ability to surround the metal as stabilizing ligands. For the polymer component, the use of macromonomers is known to synthesize the various block copolymer and miktoarm systems that can surround the metal nanoparticles core. In dendrimers, this can be based on convergent and divergent approaches of carefully designed AB2 monomers to dendrons that can be linked. In this work, we outline and demonstrate the use of various dendrimer and polymer synths to form hybrid nanoparticle systems. We also describe the use of continuous flow chemistry fabrication methods at the benchtop level to make metal nanoparticles and atomic clusters resulting in higher throughput synthesis and better distribution. We describe control of the metal nanoparticle synthesis parameters based on pressure, temperature, flow rate and mixing ratios. The grafting on surfaces and electropolymerization methods enable us to apply these nanomaterials hybrid into electron and charge transfer properties. These materials have the potential for use in catalysis. Also, a key to the analysis of such materials is the use of surface sensitive analytical methods as well as microscopy imaging methods.

Fabricating Ultra-Low-Density Nanoporous Metals by Freeze-Casting Nanowire Suspensions Alyssa L. Trokes, Tyler M. Fears, Fang Qian, Tom Braun, Anna Ringuette, Joshua A. Hammons, Michael Nielsen, Jean-Baptiste Forien, Theodore Baumann, T. Yong Han, Sergei Kucheyev and Michael Bagge-Hansen; Lawrence Livermore National Laboratory, Livermore, California, United States.

Ultra-low-density (1-30 mg/cm³) nanowire aerogels are a new class of monolithic nanoporous materials with potential applications in energy storage, generation, and utilization. These materials can be fabricated by freezing suspensions of metal nanowires and gently removing the solidified matrix, e.g., via freeze-drying, to prevent collapse of the porous nanowire network. As such, the macroscopic properties of the final aerogels are intrinsically linked to the composition of the feedstock suspensions, namely solvent composition, nanowire dimensions, and surface ligands. Herein will be discussed recent developments at Lawrence Livermore National Laboratory to produce high-quality ultra-low-density metal (Cu, Ag, Au) aerogels with ligaments of controlled diameter between 5 and 30 nm via a facile freeze-casting approach. We will demonstrate how the modification of suspension characteristics can be used to tune the final mechanical, electrical, and chemical properties of the aerogels. This work was performed under the auspices of the U.S. DOE by LLNL under Contract DE-AC52-07NA27344.

Bias-Dependent Chemical Enhancement and Non-Classical Stark Effect in Tip-Enhanced Raman Spectromicroscopy of CO-Terminated Ag Tips Rebecca Gieseking1,2, Joonhee Lee3, Vartkess Apkarian4 and George Schatz2; 1Department of Chemistry, Brandeis University, Waltham, Massachusetts, United States; 2Department of Chemistry, Northwestern University, Evanston, Illinois, United States; 3University of California, Irvine,
Tip-enhanced Raman spectromicroscopy (TERS) with CO-terminated plasmonic tips can probe Ångstrom-scale features of molecules on surfaces. The development of this technique requires understanding of how chemical environments affect the CO vibrational frequency and TERS intensity. At the scanning tunneling microscope junction of a CO-terminated Ag tip, we show that rather than the classical vibrational Stark effect, the large bias dependence of the CO frequency shift is due to ground-state charge transfer from the Ag tip into the CO π* orbital softening the C-O bond at more positive biases. The associated increase in Raman intensity is attributed to a bias-dependent chemical enhancement effect, where a positive bias tunes a charge-transfer excited state close to resonance with the Ag plasmon. This change in Raman intensity is contrary to what would be expected based on changes in the tilt angle of the CO molecule with bias, demonstrating that the Raman intensity is dominated by electronic rather than geometric effects.

Metal Enhanced Fluorescence (MEF) has promising applications in the field of optical displays, bio-sensing and photodynamic therapy. In this work, we exploit the plasmons of embedded silver nanoparticles (Ag-NPs) fabricated by ion implantation to enhance the fluorescence of Coumarin 515 dye (C515) via MEF. Ion implantation of 70 keV Ag ions in quartz matrix at different fluences was carried out to synthesize Ag-NPs inside quartz matrix. The formation of Ag-NPs is characterized by the optical absorption measurements. Rutherford Backscattering Spectrometry (RBS) measurement was used to obtain the depth profile and concentration of silver within the substrate. From the RBS results, it was determined that front edge of the layer containing Ag was formed at an average depth of 16 nm below the surface, which closely agreed with Stopping and Range of Ions in Matter (SRIM) calculations. Increase in the size of the Ag-NPs is observed as the fluence of the silver within the substrate is increased. The MEF of drop casted C515 dye was studied using steady-state emission and excitation spectra measurements. Photoluminescence (PL) enhancement factor ranging from 1.2 to 2.1 with a maximum enhancement for the largest fluence was obtained. The observed MEF was ascribed to a combination of plasmon enhancement with larger nanoparticles due to increase in fluence and to increase plasmonic hot spots.

A theory has been established to describe the formation of facets on metal crystals grown from their melt. There exists a temperature for each crystallographic orientation below which it will form a facet, and above which the metal surface will be rounded and atomically rough. Here we have extended this theory to electrodeposition. We used potentiostatic electrochemical impedance spectroscopy to measure the approximate surface energy of Au at different applied potentials to determine the roughening temperature for each potential. From this, we grew different nanostructures with different proportions of facets and tested them as electrocatalysts for CO2 reduction.

With increasing worldwide demands for green energy, catalyst engineering has rapidly developed for several decades. Noble metals such as platinum (Pt) show outstanding catalytic activity and stability in various energy production/conversion techniques. However, high cost of the noble metal catalysts disturbs growth of energy industry. Bimetallic nanoparticles are emerging as low-cost but high-efficiency catalysts. Catalytic reactions only occur on the surface of nanoparticles, therefore, it is essential to understand surface morphology and atomic arrangements of alloy nanoparticles in order to improve their catalytic properties. In this study, we predicted energetically stable atomic arrangements on the surface and shape of different bimetallic nanoparticles such as Au-Pt, Cu-Pt, and Pd-Pt by Monte Carlo (MC) and molecular dynamics simulations. This works provide phase diagrams of the bimetallic nanoparticles in terms of size, shape, atomic composition and temperature of the system. Also, the trends in mixing alloy nanoparticles are discussed with regard to difference of binding energies between two elements.

Droplet-based reactors for nanoparticles are receiving attention due to their ability to maintain thermal and compositional equilibrium within and between droplets, enabling flow operations for inline analyses and the scale-up of nanomaterial syntheses. This presentation will show the versatility of these microreactors by synthesizing different dimension-controlled and shape-controlled nanostructures through manipulation of the relative flow rates of reagent stock solutions. Specifically, different Pd shell thicknesses can be grown on cubic or octahedral Au seeds. In addition, Au-Pd nanocrystal shapes ranging from sharp-branched octopods to core@shell octahedra can be controlled using seed-mediated co-reduction on Au octahedral seeds. This approach allows process conditions to be modified inline, rather than from batch to batch, to achieve particles with different shell thicknesses and shapes, and this procedure should be applicable to other multicomponent systems.

Selective Control of Crystal Structure in Solid-Solution Alloy—fcc and hcp Phases in Au–Ru Nanoparticles Quan Zhang, Kohei Kusada, Dongshuang Wu, Tomokazu Yamamoto, Syo Matsumura, Yoshiki Kubota and Hiroshi Kitagawa; ‘Chemistry, Kyoto University, Kyoto, Japan; 2Kyushu University, Fukuoka, Japan; 3Osaka Prefecture University, Osaka, Japan.
The crystal structure is one of the most dominant factors that strongly affect the properties of an alloy because its electronic and surface structures change drastically with the crystal structure. A solid-solution alloy, in which the constituent atoms are randomly and homogeneously mixed at the atomic scale, generally adopts one of three principal crystal lattice forms: body-centred cubic (bcc), hexagonal close-packed (hcp) and face-centred cubic (fcc) structures. However, once its constituent elements and composition are fixed, the crystal structure of the alloy is uniquely determined. Therefore, it is difficult to change the crystal structure of a solid-solution alloy at a certain composition. Here, we propose a new approach for selective control of the crystal structure in solid-solution alloys by using a chemical reduction method. By precisely tuning the reduction speed of the metal precursors, we demonstrated the first example of selective control by synthesizing fcc- and hcp-AuRu3 alloy nanoparticles (NPs). The alloy adopts an fcc structure when the Au precursor starts to be reduced slightly earlier, while it adopts an hcp structure when the reduction of Ru precursor begins slightly earlier. The structures of the obtained NPs were investigated using synchrotron powder X-ray diffraction analysis and atomic resolution scanning transmission electron microscopy (STEM). The mechanism of crystal structure control is discussed by using the results of UV-Vis spectral and electrochemical analyses. The influence of crystal structure on the catalytic performance for oxygen evolution reaction (OER) was also examined.

*In Situ Nucleation Mechanism of the Nanometer-Sized Precipitates of the AA7050 Aluminium Alloy* Tsai-Fu Chang1, Yang Yo-Lun1, Hsiao-Chien-Nan2, Li Wei-Chih1 and Yang Jer-Ren1; 1National Taiwan University, Taipei, Taiwan; 2Department of Mechanical Engineering, Imperial College London, London, United Kingdom; 4E.A. Fischione Instruments, Inc., Pittsburgh, Pennsylvania, United States.

Cs-corrected high-angle-annular-field scanning-transmission-electron microscopy (Cs-corrected HAADF-STEM) with nanometer-scale energy-dispersive X-ray (EDX) was employed to investigate the transformation mechanisms of the η → η precipitation sequence of AA7050, an Al-Zn-Mg-Cu alloy. Evidence from Cs-corrected HAADF-STEM coupled with EDX showed that in-situ nucleation of a new η2 precipitate (one form of η) took place, wherein it gradually developed from the original η precipitate via a similar hexagonal structure with different compositions. The in-situ transition product was composed of two distinctive regions; one was identified as η', and the other, as η.

*Mono- and Bimetallic Nanoparticles of Noble Metals—The Influence of the Composition and Nanostructure on Biological Effects* Alexander Rustič1, Marina Breitsch1, Kateryna Loza3, Kevin Pappert1, Viktoria Grasnik1, Marc Heggen1, Manfred Köller1, Christina Sengstock2 and Matthias-Epple3; 1Inorganic Chemistry and Center for Nanointegration Duisburg-Essen (CeNIDE), University of Duisburg-Essen, Essen, Germany; 2Bergmannsheil University Hospital/Surgical Research, Ruhr-University Bochum, Bochum, Germany; 3Ernst Ruska-Centre for Microscopy and Spectroscopy with Electrons, Forschungszentrum Jülich GmbH, Jülich, Germany.

Metallic nanoparticles represent a well-established field of nanoscience, medicine, catalysis, and industry. Due to the numerous applications, a contact with biological systems is unavoidable. Depending on the nanoparticles’ characteristics, the biological response can be rather different. Therefore, a detailed investigation of the structure and composition of monometallic, alloyed, and core-shell nanoparticles is a decisive factor for the assessment of biological effects. In addition to colloid-chemical and spectroscopic methods for the characterisation of nanoparticle dispersions, high-resolution (HRTEM) and scanning transmission electron microscopy (STEM) are advantageous to elucidate size, crystal structure (e.g. domains), and internal composition of mono- and bimetallic nanoparticles.

Spherical Rh, Pd, Pt, Ag, Au, and bimetallic (alloy, core-shell) nanoparticles (5-10 nm) were wet-chemically prepared, stabilised with poly(N-vinylpyrrolidone) and characterised by colloid-chemical and spectroscopic methods. Particle diameters as determined by analytical disc centrifugation and dynamic light scattering correspond very well to the results obtained by HRTEM. The overall elemental composition was determined by atomic absorption spectroscopy and X-ray powder diffraction. The nanostructure and elemental distribution was assessed by high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM), and energy-dispersive X-ray spectroscopy (EDX).

The biological studies comprised the analysis of the antimicrobial activity against gram-positive and gram-negative bacteria as well as the biocompatibility towards human mesenchymal stem cells (hMSC). Silver-containing nanoparticles with a high silver content showed a significant concentration- and time-dependent antimicrobial effect against *S. aureus* and *E. coli* as well as a toxicity towards hMSC. The other metals showed neither an antimicrobial effect nor a toxicity against hMSC. Interestingly, Rh, Pt and AgPt (≥50 % Pt) nanoparticles led to a nodule-like convergence of hMSC indicating a cell activation.

2:30 PM NM02.12.05
*Chiromagnetic Nanoparticles and Gels* Jiheon Yeom1, André F. de Moura2 and Nicholas A. Kotov1; 1University of Michigan, Ann Arbor, Michigan, United States; 2Federal University of São Carlos, São Carlos, Brazil; 3Massachusetts Institute of Technology, Boston, Massachusetts, United States.

The manipulation of chiroptical effects using a magnetic field is one of the ubiquitous interplays of chirality and magnetism. Ceramics such as transition metal oxides are intriguing in this regard, since many useful magnetoptical properties involve electric and magnetic transitions to amplify or modulate the chiroptical activities of the system. Here we synthesized chiral magnetic nanoparticles (NPs) using cobalt to investigate the enhancement of the rotatory optical activity and magnetic field modulations. The obtained NPs showed g-factors as high as 0.02 and strong optical rotation in the visible range that is at least 10 times higher than conventional chiral metal or semiconducting NPs. It was also possible to observe an increase of light transparency in the UV region with an external magnetic field. The chiral ceramic NPs prepared herein are versatile and fundamental experimental systems for potential application in chiroptical and magnetoelectrical effects, as well as for the investigation of (up to second-order) magneto-chiral and magneto-dielectric effects.

*Near-Infrared Fluorescent Metal Nanoclusters for the Gene Delivery and Bioimaging* Yuanqing Sun, Yiming Ouyang, Jiaqing Luo and Jian Liu; College of Science, China University of Petroleum, Beijing, Beijing, China.

We synthesized tunable near-infrared fluorescent gold nanoclusters (AuNCs) protected by branched polyethylenimine (PEI) modified by surface segmental attachment of sulphydryl groups (PEI-SH). The cationic polymer PEI-SH with positive charges enables AuNCs to perform gene delivery, and the gene transfection efficiency can reach 22.8%. Moreover, the fluorescence of AuNCs is tunable from visible red light (wavelength 609 nm) to NIR light (wavelength 811 nm) with high quantum yields, which is very suitable for bioimaging. To obtain nanomaterials with longer fluorescent wavelength in
near-infrared region (NIR), we introduced Cu element into system to prepare Au/Cu alloy nanoclusters, which possessed the second near-infrared region (NIR-II) fluorescence emission at 1080 nm. The Au/Cu alloy nanoclusters exhibit high quantum yields (~2%), which are 5 times higher than that of the commercial carbon nanotube. More interesting, Au/Cu alloy nanoclusters show tunable luminescence from NIR-I (811 nm) to NIR-II (1130 nm) corresponding to increasing the content Cu element in the nanoclusters. The Au/Cu alloy nanoclusters with high photoluminescence intensity, good fluorescence stability and low cytotoxicity can be used as an excellent NIR-II fluorescent probe for potential applications in the field of in vivo NIR-II fluorescent imaging.

Thermomechanical Nanomolding of Crystalline Metals—The Smaller the Easier Jan Schroers1 and Ze Liu2; 1Yale University, New Haven, Connecticut, United States; 2Wuhan University of Technology, Wuhan, China.

Molding, associated with a materials flow-ability, becomes increasingly more difficult with decreasing mold size. The flow-ability of crystalline metals is usually much lower than that of thermoplastics, gels, and some glasses. As a consequence, attempts to mold on the nanoscale have been limited to thermoplastics, gels, and glasses, while crystalline metals have not been considered. Here, we report a thermomechanical nanomolding method for crystalline metals which becomes easier, quantified by the ratio of mold depth to mold diameter, with decreasing mold diameter. As the underlying diffusion mechanism is present in all metals and alloys, discovered nanomolding process provides a toolbox to shape essentially any metal and alloy into nanosize features. Technologically, this highly versatile and practical thermomechanical nanomolding technique offers a method to fabricate high-surface area metallic nanostructures which are impactful in diverse fields of applications including catalysts, sensors, photovoltaics, microelectronics, and plasmonics.

3:45 PM NM02.12.08
3D Nano-Printing Technique Based on Ion-Assisted Aerosol Lithography Woook Jung1,2, Yoon-ho Jung1,2, Petr Pikhitsa2 and Mansoo Choi1,2; 1Seoul National University, Seoul, Korea (the Republic of); 2A Global Frontier Center for Multiscale Energy Systems, Seoul, Korea (the Republic of).

On demand of miniaturization of 3D structure manufacturing following up the growth of nanodevice study, developing bottom-up based nanoparticle assembly technique has received attention. Establishing successful capability of 3D structure is closely related to precise positioning of nanoscale elements into 3D structures. We have developed Ion assisted aerosol lithography (IAAL) for charged metal nanoparticles assembly, making it possible to deposit nanoparticles to the desired location. IAAL utilizes the distorted local electric field induced by accumulated ions on a pre-patterned substrate to manipulate the trajectory of charged metal nanoparticles as they get attracted to the substrate by electrostatic attraction. The distorted electric field has brought the nanoparticles to the desired location. IAAL utilizes the distorted local electric field induced by accumulated ions on a pre-patterned substrate to manipulate the trajectory of charged metal nanoparticles as they get attracted to the substrate by electrostatic attraction. The distorted electric field has brought the nanoparticles to the desired location. IAAL utilizes the distorted local electric field induced by accumulated ions on a pre-patterned substrate to manipulate the trajectory of charged metal nanoparticles as they get attracted to the substrate by electrostatic attraction. The distorted electric field has brought the nanoparticles to the desired location.

This direct 3D nano-printing technique, which utilizes the charged metal nanoparticles as building blocks, has an ability to depositing various materials. Manufacturing various shapes of multicomponent 3D metal nanostructures is relative ease for demanding applications.

This work was supported by Global Frontier R&D Program on Center for Multiscale Energy System by National Research Foundation (NRF) under the Ministry of Science, ICT and Future Planning, Korea (Grant no.2012M3A6A7054855).

4:00 PM NM02.12.09
Covalent Surface Functionalization of Ultrasmall Gold Nanoparticles (2 nm) by Click Chemistry for Protein Targeting Selina B. van der Meer1, Kateryna Loza2, Christine Beuck2, Peter Bayer2 and Matthias Epple1; 1Inorganic Chemistry and Center for Nanointegration Duisburg-Essen (CeNIDE), University of Duisburg-Essen, Essen, Germany; 2Department of Structural and Medicinal Biochemistry, University of Duisburg-Essen, Essen, Germany.

Ultrasmall gold nanoparticles of 2 nm diameter are smaller than most proteins and therefore should allow a specific epitope targeting on a protein surface. Thereby, the conformation and the function of a protein can be manipulated.1 A surface functionalization of the gold nanoparticle with azide groups and a subsequent click reaction, i.e. a copper-catalyzed azide-alkyne (CuAAC) cycloaddition, permits an orthogonal covalent conjugation under mild conditions.2 Azide-terminated ultrasmall gold nanoparticles were prepared by reducing tetrachloroauric acid in the presence of an azide-carrying cysteine-containing tripeptide.1 Functional molecules with an alkyn function were covalently attached to the particles by CuAAC click chemistry. The hydrodynamic diameter of the functionalized gold nanoparticles was measured by diffusion ordered NMR spectroscopy (DOSY), also ensuring the absence of dissolved molecular impurities or reaction by-products.4 Disc centrifugal sedimentation (DCS) and transmission electron microscopy (TEM) showed the dispersion state of the nanoparticles and the diameter of the metallic core. Atomic absorption spectroscopy (AAS) gave the gold concentration and allowed us to compute the particle number concentration. 1H-1H-TOCSY NMR spectroscopy showed the binding between the gold surface and the cysteine of the tripeptide. The successful click reaction to the azide-functionalized gold nanoparticles was demonstrated by DOSY with propargylglycine as model compound clicked to the gold nanoparticle surface. This synthetic route offers a wide range for the synthesis of covalently functionalized ultrasmall gold nanoparticles for protein targeting.

Whereas the equilibrium shape of a metallic nanocrystal can be predicted by the Wulff construction, it can hardly be anticipated when this nanocrystal is covered by a shell formed of another metal. Different parameters are well known for their influence on the geometry of core-shell nanocrystals; these are, for instance, the size of the nanocrystals or the core / shell volume ratio. However, the construction of a metal-metal internal interface during the growth process should also play a determining role.

In order to analyze this mechanism, we choose to combine experimental and modeling approaches. Nanoclusters are experimentally grown using a ultra-high vacuum (UHV) physical vapor deposition method, magnetron sputtering, in order to limit interaction with their environment (gas, liquid, ligands…) during the growth process. This process makes it possible to use high temperatures which promote atomic diffusion during deposition or annealing steps. In addition, it is possible to proceed sequentially, by growing the shell on the previously formed core, or to proceed by co-deposition of the core and shell metals. The modeling approach combines DFT calculations with large-scale (MD) or Monte Carlo (MC) molecular dynamics simulations to study systems with size comparable to the experimentally grown nanocrystals (5-15 nm).

After a presentation of the different parameters that should be taken into account during the formation of the crystalline interface, with a particular emphasis on the concept of nanoepitaxy, we will report the results obtained on the Fe-Au system. This system is indeed of particular interest as it is likely to adopt a core-shell geometry fully compatible with applications in the biomedical field.

Through our combined experimental and modeling results, we will then discuss the effects of size and composition on the equilibrium shape of the nanoclusters as well as the evolution of the iron core when coated by the gold shell.

Surface analysis of nanowires is inherently difficult as most surface science techniques have been designed to address “infinite” flat 2D surfaces. However, with some clever sample design and dedicated measurement strategies it is possible to use most surface common analysis methods also on nanowires. As a result, it is possible to measure nanowire surface geometry, chemistry and electronic properties down to the atomic scale. As examples, I will show how scanning probe and photoelectron spectroscopies/microscopies can be used for detailed surface analysis of nanowires, even during device operation. An emphasis will be on explaining the strategies that enable you to use most surface science tools for studies of high aspect ratio nanostructures and devices at the highest possible performance levels.

Semiconductor nanowires (NWs) are promising building blocks for next generation solar energy conversion at low cost. NW ensembles constitute a new class of metamaterial. While the photonic properties of small dielectric structures have been widely studied within the framework of Mie scattering, coupling to poorly confined waveguided modes drives the absorption spectrum in NWs. This tutorial session describes how vertical NWs interact with light. We will show the theoretical and experimental methods to investigate these properties. Based on the special light-matter interactions in NWs, we discuss completely new designs of solar cells that are not possible in the bulk form.

SESSION NM03.01: Nanowire Photonic Devices: Photodectors and Sensors
Session Chairs: Jordi Arbiol and Martin Eickhoff
Monday Morning, November 26, 2018
Sheraton, 2nd Floor, Back Bay D

8:30 AM *NM03.01.01
GaN/AlN Nanowire Photodetectors—From the UV to the IR Akhil Ajay1, Maria Spies2, Jonas Lähnemann1, Martien den Hertog2 and Eva Monroy1; 1INAC-PHELIQS, CEA-Grenoble, Grenoble, France; 2Institut Néel, Grenoble, France.

Nanowire photodetectors attract broad interest due to their low dimensionality, small electrical cross-section, and ultrahigh photocurrent gain. In the ultraviolet region, ZnO and GaN nanowires have been intensively studied as spectrally-selective photodetectors. For this application, III-nitride nanowires present advantages in terms of heterostructuring possibilities and stability against chemical, mechanical or electrical stress. In a single-GaN-nanowire UV photodetector, the efficiency can be enhanced by the insertion of a GaN-AlN heterostructure [1,2], which leads to an increase of the responsivity by about two orders of magnitude, improved linearity, and the possibility to select the detected wavelength, while maintaining a UV/visible contrast larger than six orders of magnitude. Furthermore, devices with a linear photoresponse to the optical power can be implemented by using nanowires with a thickness below a certain threshold [3]. On the other hand, the insertion of quantum dots in nanowires is also interesting for infrared photodetection using intraband transitions. Therefore, intraband transitions in GaN/AlN nanowire heterostructures have been investigated, varying the geometry and doping level of the GaN insertions [4]. Based on this research, we present the first single-nanowire quantum well infrared photodetector (NW-QWIP), operating at the 1.55 μm telecom band [5]. Finally, the study has been extended to cover the mid-infrared spectral range, up to around 6 μm, using intraband transitions in GaN/Al0.4Ga0.6N dots-in-a-wire.

Comparison of such materials showed the dependence of 1-D nanostructured device UV response properties on ZnO morphologies.

With d-spacing approximately 2.6 angstroms, while 1-D nanostructure-grown samples exhibited similar or slightly lower (002) preference, indicated by the reaction of chemisorbed oxygen and photo-generated charge carriers at grain boundaries. The demonstrated ultrathin nanowire arrays, the observed superlinear photoconductivity can be explained by a new type of photoelectrochemical thermionic charge emission mechanism involving the reaction of chemisorbed oxygen and photo-generated charge carriers at grain boundaries. The demonstrated ultrathin nanowire device and synthesis fabrication methods have potentials for fully CMOS-compatible integration of nanowire sensor devices and circuitries. The identified photoelectrochemical grain boundary thermionic emission mechanism provides an improved understanding on the superlinear photoconductivity observed in nanostructured materials.

9:15 AM NM03.01.03
Plasmonic Au/ZnO Nanowires for Room Temperature NO2 Detection
Bo Zhang, Jiyu Sun and Puxian Gao; University of Connecticut, Storrs, Connecticut, United States.

Plasmonic Au-ZnO nanostructures with a size less than the incident light wavelength have been found to exhibit a localized surface plasmon resonance (LSPR) that may lead to strong absorption, scattering, and local field enhancement. These resonances, associated with noble metal nanostructures create sharp spectral absorption and scattering peaks as well as strong electromagnetic near-field enhancements. However, operation of ZnO gas sensors is limited to elevated temperature, which leads to reduced energy consumption and large sensor size. Thus, reducing operating temperature or room temperature gas detection become significant in future sensor development. In this work, by utilizing the wavelength tunable photo-irradiation, selective gas detection has been demonstrated at room temperature based on Au/ZnO nanowire arrays. The Au/ZnO nanowires were synthesized by the microwaves-assisted hydrothermal deposition of ZnO nanowires followed by Au nanoparticle (NP) dip-coating process. Compared to pristine ZnO, the Au-ZnO nanowire sensor performance was enhanced in both UV and visible regions, especially with highly enhanced sensitivity observed at 550 nm. The sensitivity towards 20 ppm NO2 could reach as high as 250%, and the detection limit is determined to be around 1 ppm at 25 °C. The sensitivity enhancement resulted from UV is due to the migration of photo-generated electrons from Au NPs to ZnO. On the hand, the sensing mechanism in the visible region is primarily due to the LSPR effect of Au. The oscillated electrons become more sensitive to the charge density and dielectric environment of Au. Besides, a large selectivity was found for NO2 gas over CO, NH3 and O2 at 330 nm UV irradiation. The ratio of cross sensitivity towards target gas and interfering gases is larger than 300. It is clear that with tunable light irradiation, room temperature NO2 gas detection could be achieved using plasmonic Au/ZnO nanowires with high sensitivity and selectivity.

UV Sensitivities of Catalyst-Free Grown ZnO 1-D Nanostructures on High Crystallinity Atomic Layer Deposition Seeds
Yun-Yi Chu1, Shang You Tsai1, Chun-Chi Chen2 and Fu-Hsiang Ko1; 1Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2Nano Device Laboratories, National Applied Research Laboratories, Hsinchu, Taiwan.

Zinc Oxide is a nontoxic material, with a wide direct band gap (3.4 eV), high exciton binding energy (60 meV) and good thermal stability, making it suitable for UV LEDs, photo catalysts, UV sensors and gas sensors. At the surface of zinc oxide, a layer of positive space charge is usually formed to cancel out the charge of surface oxygen species. Removal and addition of said surface oxygen species may affect the electrical properties at the surface. Utilizing this mechanism, applications such as sensor devices were studied by others. Here, we explored the various factors that may affect the UV absorbing and sensing properties of ZnO 1-D nanostructured devices, including crystallinity, contact junctions, and morphology. Regarding morphology, 1-D nanostructures have high surface area ratios and can exhibit surface properties in larger scales, as the structures can be viewed as wrapping surfaces around lines.

In this study, 1-D nanostructured ZnO UV sensors were developed on silicon dioxide using an atomic layer deposition (ALD) seed and chemical vapor deposition (CVD) nanostructure growth to investigate nanostructure properties. An ALD process was selected to deposit the seed layer due to the capability of uniform thickness growth and excellent crystallinity. The CVD process with vapor-solid (VS) growth provided a clean method to grow zinc oxide nanostructures without introducing unnecessary additives, by using a source of zinc metal powder and high purity oxygen. Compared to wet chemical methods and vapor-liquid-solid (VLS) growth of ZnO nanostructures, the VS processes would not have salts and metal particles, which may affect devices in undesired ways, such as salt interactions with humidity, Ohmic or Schottky contacts by metal particles with ZnO and stability issues of metal catalysts.

Different 1-D nanostructures such as nanowires and free-standing nanorods were deposited through the control of seed layer quality, zinc source temperature and substrate undercooling. Characterization of ZnO structures was done by SEM, X-ray reflection (XRR) and XRD techniques for morphology, thickness and crystallinity; UV-VIS, Photoluminescence spectroscopy and a Keithley 2400 instrument were used for the absorption, emission spectrums and UV irradiated conductivity change. The ALD seed ZnO layer showed highly preferred (002) plane crystal growth by a strong XRD peak with d-spacing approximately 2.6 angstroms, while 1-D nanostructure-grown samples exhibited similar or slightly lower (002) preference, indicated by XRD peaks. Structures with conductivity responses after 5 minutes of 3V UVA LED (345nm to 425nm, < 0.5 mWatts) irradiation from 3% to 22% were observed, with diagonally crossing nanowires showing lower responses, and vertical free-standing nanorods of higher responses. Comparison of such materials showed the dependence of 1-D nanostructured device UV response properties on ZnO morphologies.
Light Emitting Silicon Nanowires—From Photonics to Sensing Applications
Antonio A. Leonardi1,2,3, Maria José Lo Faro4,2, Dario Morganti1,2, Cristiano D'Andreà1, Barbara Fazio1, Paolo Musumeci1, Pietro Antoni1, Cirino S. Vasi2, Gerardo Palazzo1, Luisa Torsi2, Francesco Priolo1,4,6 and Alessia Irrera1;1 Dipartimento di Fisica ed Astronomia, Università degli Studi di Catania, Catania, Italy; 2Istituto per i Processi Chimico Fisici, Consiglio Nazionale delle Ricerche, Messina, Italy; 3Sezione di Catania, Istituto Nazionale di Fisica Nucleare, Catania, Italy; 4Matis-IMM, Consiglio Nazionale delle Ricerche, Catania, Italy; 5Dipartimento di Chimica, Università degli Studi di Bari Aldo Moro, Bari, Italy; 6Scuola Superiore di Catania, Catania, Italy.

The scientific community has devoted an increasing interest to quantum confinement materials. In particular, silicon nanowires (Si NWs) are considered one of the most appealing resource to be employed in nanoscaled devices. Si NWs with an efficient room temperature (RT) light emission would represent a great industrial advancement, opening the route to a wide range of unexpected photonic applications. Nevertheless, to achieve a good control on quantum confined Si NWs fabrication is complex and challenging with the current technology. The most diffuses approaches such as lithography or Vapor-Liquid-Solid techniques suffer of different limits restraining the realization of quantum confined Si NWs. We demonstrated the realization of an ultradense array (10^12 NWs/cm^2) of light emitting Si NWs by using a modified metal assisted chemical etching without any type of mask or lithography. This method is fast, cheap and compatible with the standard Si technology. NWs achieved by this technique exhibited a very bright RT PL and EL tunable with NWs size in agreement with the occurrence of quantum confinement effect. With this method we demonstrated the realization of a 2D random fractal array of aligned Si NWs without any lithographic process or mask and by using a fractal gold layer realized by a Si technology compatible approach. We were able to control and tune the optical properties of the system by changing the fractal morphology of the Si NWs array [1]. In-plane multiple scattering and very strong light trapping with diffuse reflectance below 0.1% related to the fractal structure were observed overall the visible range [1-2]. An innovative generation of Si NW-based optical biosensor is realized, which exploits the PL properties for the ultrasensitive and selective detection of proteins [3] in a wide range of concentrations. The occurrence of non radiative phenomena introduced by the target analyte on the NWs surface determines the quenching of the PL signal. In particular, we realized a sensor for C-reactive protein (CRP), which is crucial for heart-failure pathology. Cardiovascular problems are some of the major cause of death for both men and women. The availability of high sensitivity, low cost and reliable CRP sensors is a priority demand in clinical diagnosis for cardiovascular diseases. Si NWs sensors are fast, highly selective and offer a broad concentration dynamic range. Moreover, these sensors reach a FM sensitivity permitting non-invasive analysis in saliva [3]. Si NWs open the route towards new optical label-free cheap sensors and a full compatible with the standard Si technology for primary health care diagnosis of biomarkers. Moreover, by changing the functionalization the use of Si NW sensors opens the route towards a new class of promising label free optical sensors for different application fields.

10:30 AM NM03.02.01
Probing Fundamental Charge Carrier Dynamics in Metal-Halide Perovskite Microwires
Eva L. Unger1,2 and Aboma Merdasa3; 1Chemical Physics and NanoLund, Lund University, Lund, Sweden; 2Helmholtz-Zentrum Berlin für Materialien und Energie, Berlin, Germany.

Metal halide perovskites exhibit favorable properties for optoelectronic devices. This talk will summarize results on metal halide perovskite wires illuminating fundamental properties of metal-halide perovskites. Intermittency effects in the photoluminescence suggest the existence of photo-induced dynamic state in metal-halide wires that lead to non-radiative recombination.[1] For wires longer than 10 µm, photoluminescence quenching at defined positions along the wire suggest localized states that periodically become activated, leading to efficient charge carrier quenching. The gradient in photoluminescence, the charge carrier diffusion length can be estimated from this one-dimensional model system.

Structural defects also play a role in the observed phase coexistence and hysteresis during the tetragonal to orthorhombic phase transition in methylammonium lead iodide wires.[2] The phase transition temperature appears to be dependent on the local defect concentration with more defective domains more readily transforming from the tetragonal to orthorhombic domain. This leads to charge carriers being funneled to lower energy tetragonal sites during the phase transition shown by photoluminescence microscopy and super-resolution imaging.

11:00 AM NM03.02.02
Orientation-Dependent Hybrid Perovskite Conversion of VLS-Grown Lead Halide Nanowires
Hyewon Shim and Naechul Shin; Chemical Engineering, Inha University, Incheon, Korea (the Republic of).

Organic-inorganic hybrid perovskites, such as methylammonium lead iodide (CH3NH3PbI3) have shown outstanding optoelectronic properties, promising extensive application in solar harvesting. Although most hybrid perovskite materials have been synthesized under solution process, recent demonstrations of the vapor phase synthesis of the hybrid perovskite nanostructures suggest there is an emerging interest in controlling their properties under highly-confined structures. In particular, single-crystalline 1D lead halide nanowires can be prepared via vapor-liquid-solid (VLS) growth mechanism through the self-catalyzed growth mechanism, which then converted to hybrid perovskite. Since the conversion occurs on the preformed nanowire, electronic properties 1D perovskite depend on the original nanowire structure. In this study, we report the VLS growth of lead iodide (PbI2) nanowires on a c-sapphire (0001) substrate followed by conversion to CH3NH3PbI3 using methylammonium iodide, and confirm that the degree of perovskite conversion depends on the growth orientations of PbI2 nanowires. We observe two different growth directions; vertically-oriented [0001] nanowires and kinked nanowires. Photoluminescence (PL) measurements on each growth direction suggest that the oriented nanowires exhibit a higher degree of conversion compared to the [0001] oriented nanowires. In addition, [0001] oriented nanowires exhibit the position-dependent degree of conversion, depending on the presence of the catalyst tip on top of the nanowire. In particular, the conversion is observed both on the catalyst tip and the base of nanowire, suggesting
methylammonium iodide incorporates into the nanowire either by vapor trasport and surface diffusion. Our observation indicates that the vapor phase conversion of PbI2 to CH3NH3PbI3 is a diffusion-limited process. This finding is an important step towards an structure engineering of perovskite nanowires.

11:15 AM NM03.02.03
First-Principles Insights of Electronic Structure in Quasi-One-Dimensional Van der Waals Materials Baiyu Zhang and Xiaofeng Qian; Texas A&M University, College Station, Texas, United States.

Low dimensional materials have been one of the focus areas in materials science for more than three decades. In particular, the low dimensionality and reduced dielectric screening lead to pronounced optoelectronic properties such as excitons and polaritons. Here we demonstrate that quasi-one dimensional (1D) materials exhibit unique electronic structure and optical properties promising for low-cost photovoltaics and novel optoelectronics. First, we will present our first-principles study of a few quasi-1D van der Waals crystals with non-toxic and earth-abundant elements, and will elaborate the role of 1D structure and defects on their highly anisotropic optical and electronic properties. Our results shed light on new thin-film photovoltaic systems with excellent defect tolerance. Second, we will show that quasi-1D van der Waals crystals exhibit exciting nonlinear optical effects, and a microscopic picture is provided based on first-principles theory. We believe the theoretical findings presented here will open up many exciting opportunities in quasi-1D materials and nanostructures.

11:30 AM *NM03.02.04
Growth and Optoelectronic Applications of Single-Crystal Nanowires of Metal Halide Perovskites Song Jin; Madison, University of Wisconsin, Madison, Wisconsin, United States.

The remarkable performance of lead halide perovskites in solar cells can be attributed to the excellent photophysical properties that are also ideal for lasers and light-emitting devices (LEDs). The chemical and structural characteristics of halide perovskites make their crystal growth behaviors very different from conventional inorganic semiconductor materials. Here we first report new insights on the crystal growth of halide perovskites and developed the solution growth of single crystal nanowires, nanorods, and nanoplates of methylammonium (MA), formamidinium (FA) and all-inorganic cesium (Cs) lead halides perovskites (APbX3) via a dissolution-recrystallization pathway. We also developed the vapor phase epitaxial growth of aligned CsPbX3 perovskite nanowires and single-crystal thin films. Moreover, nanostructures of metastable perovskite phases, such as FAPbI3 and CsPbI3, can be stabilized via new chemical strategies by using surface ligands. These single-crystal nanowires are excellent model systems to study the intrinsic properties of perovskite materials, such as carrier transport and ionic interdiffusion. We also demonstrated high performance room temperature lasing with broad tunability of emission color from 420 nm to 824 nm from single-crystal lead halide perovskite nanowires with estimated lasing quantum yields approaching 100%. LEDs can also be fabricated with nanoscale structures of 3D or 2D perovskites. The excellent properties of these single-crystal perovskite nanowires of diverse families of perovskite materials with different cations, anions, and dimensionality make them ideal for fundamental physical studies of carrier transport and decay mechanisms, and for enabling high performance semiconductor lasers, LEDs, and other optoelectronic applications.

Epitaxy of Hybrid Bi- and Tri-Crystal Quantum Materials by Molecular Beam Epitaxy Peter Krogstrup1, 2; 1Niels Bohr Institute, Copenhagen, Denmark; 2University of Copenhagen, Microsoft Quantum Materials Lab, Copenhagen, Denmark.

Interfaces are key elements in nanostructured device architectures. The quality of interfaces is particularly important for quantum devices where the device performance depends on the order, uniformity and purity of the interfaces that takes part in the quantum device structure. Hybrid nanowire materials with semiconducting, superconducting and magnetic components properties constitute some of the most promising candidates in the search for materials suitable for topological quantum computing [i]. I will discuss the mechanisms of hybrid epitaxy by Molecular Beam Epitaxy [ii] that lead to well defined interfaces between crystals of different structural and electronic properties. I will present on new characterization schemes of how to extract information from the hybrid epitaxial materials and discuss the challenges and material requirements needed for realizing and eventually manipulating topological protected quantum states.

2:00 PM NM03.03.02
In Situ Patterned Superconductor/Semiconductor Nanowires Damon J. Carrad, Martin Bjergfelt, Martin Aagesen, Thomas N. Kanne, Filip Krizek, Peter Krogstrup, Thomas S. Jespersen and Jesper Nygård; Center for Quantum Devices, Niels Bohr Institute, University of Copenhagen, Copenhagen, Denmark.

We present electrical and structural characterisation of superconductor/semiconductor hybrid nanowires consisting of previously unexplored materials combinations. Each superconductor was deposited in-situ after semiconductor growth, without breaking vacuum. This ensures a clean and transparent interface between the semiconductor and superconductor; a crucial requirement for inducing a ‘hard’ BCS superconducting gap in the nanowires. Additionally, we developed a shadow mask method for patterning the superconductor layer during deposition. This allowed us to fabricate functional devices without need to develop specific etches and/or lithography techniques for each material. The method thus streamlines growth and fabrication while minimizing the risk of materials degradation during post-processing. We have demonstrated several key architectures including tunnel probes, Josephson Junctions and Majorana islands. These devices facilitated characterization of induced superconductivity properties in InAs nanowires, and provided insights into the requirements for obtaining a hard gap. Also of interest were the nanoscale superconducting properties of each material since the critical temperatures and critical magnetic fields differ strongly from bulk values. In particular, the materials we studied show dramatically increased out-of-plane critical field compared to aluminium, which is highly desirable for many proposed applications in topological superconductivity. The ability to fabricate
devices based on a wide variety of interfaces broadens the scope for future applications of superconductor/semiconductor hybrid devices.

2:15 PM NM03.03.03
Spin-Orbital Kondo Effect in InAs Nanowire Crystal Phase Double Quantum Dots
Heidi Potts1, Malin Nilsson1, Sebastian Lehmann1, Adam Burke1, Kimberly A. Dick1,2 and Claes Thelander1; 1 Division of Solid State Physics and NanoLund, Lund University, Lund, Sweden; 2 Centre for Analysis and Synthesis, Lund University, Lund, Sweden.

Semiconducting nanowires offer a unique platform to study fundamental physical effects. Recent advances in crystal phase engineering enable switching between zinc-blende and wurtzite crystal phases in InAs nanowire growth. Using this knowledge, a quantum dot (QD) can be created consisting of a thin zinc-blende section between two wurtzite tunnel barriers [1]. Furthermore, the QD can be split into two parallel coupled QDs using two local sidegates and a global backgate [2]. This system can be considered an artificial molecule, for which the electron population on the two dots can be changed separately, and the tunnel coupling between the two dots can be tuned. This offers a great flexibility to study for example the interaction between electrons and spins located on the two dots [3].

In this work, we use the crystal phase InAs QD system to investigate Kondo transport. The Kondo effect is an extensively studied many-body phenomenon which can be observed in QDs with two degenerate levels containing only one particle. Experimentally, the spin-degeneracy is often used to study the Kondo-effect. Recently the degeneracy of two orbitals in parallel coupled QDs has also been used to explore the so-called orbital-Kondo effect [4-6]. Special interest has arisen in the condition where both the spin- and the orbital-Kondo effects are present, resulting in a SU(4) symmetry. The challenge in experimental studies is to distinguish between the spin- and orbital-Kondo effects.

The InAs parallel QD system allows us to study the crossing of two spin-degenerate orbitals, one from each QD. The large single QD orbital spacing results in even-odd level spacing, making it evident whether the electron population on the dot is even or odd. At zero magnetic field, we observe enhanced conductance at zero bias due to spin-Kondo transport when one (or both) of the QDs contains an odd number of electrons. We further observe a Kondo peak when two orbitals from the QDs are aligned and contain only one electron. The zero-bias peak due to the spin degeneracy splits in magnetic field (Zeeman effect). Similarly, we demonstrate that the zero-bias peak due to the orbital degeneracy splits when detuning the orbital energies. The large g-factor of InAs allows us to study the orbital-Kondo effect independently of the spin-Kondo effect, and to demonstrate that the zero-bias peak at the orbital degeneracy persists, even though the spin-degeneracy is lifted by applying a magnetic field.

In conclusion we demonstrate both spin- and orbital-Kondo effects in InAs nanowire QDs formed by crystal phase engineering, and clearly show how the system can be tuned to have either one or both effects present at zero bias.

2:30 PM *NM03.03.04
Selective Area Epitaxy of a Materials Platform for Scalable Quantum Computing
Philippe Caroff; Station Q Delft, Microsoft Quantum, Delft, Netherlands.

Nanofabricated III-V semiconductor superconductor heterostructures have demonstrated potential to advanced quantum transport physics, in particular to host the elusive Majorana quasiparticles. Virtually all progress on the materials side in the last 6 years has relied on high quality vapor liquid solid growth of III-V free-standing nanowires functionalized at a later stage by ex-situ deposited Al. Despite these early successes a more robust, scalable materials platform is still missing to enable the future topological quantum computer.

Here I will report on our progress in using molecular beam epitaxy (MBE) to grow both III-V semiconductor nanowire networks and a high quality epitaxial s-wave metal superconductor, using selective area epitaxy. I will first introduce the current state of the art, advantages and challenges of the selective area approach and MBE with respect to other growth techniques and geometries. Then a new method to successfully map the selective area epitaxy window in the ultra-high purity MBE environment will be detailed. Fundamental knowledge gained by growth studies will be applied to obtain reproducible, high yield advanced high spin-orbit III-V nanowire/superconductor networks. The materials properties and quality are assessed by a combination of morphological, compositional and structural analyses.

High-Quality Narrow-Band Gap III-V Semiconductor Nanostructures Grown by Molecular-Beam Epitaxy
Jianhua Zhao; Institute of Semiconductors, Chinese Academy of Sciences, Beijing, China.

Among the III-V group semiconductors, InAs and InSb nanosheets have attracted much attention since they exhibit narrow-band gaps, high electron mobilities, strong spin-orbit couplings and giant g factors. These unique properties make them ideal materials for applications in high-speed and low-power electronics, infrared optoelectronics and especially topological quantum computing. All these applications need not only a high crystal quality but also a high degree control of the material morphology. In my talk, I will firstly give a brief introduction about our work on the successful growth of free-standing single-crystalline InSb nanosheets/nanowires on one-dimensional InAs nanowires stems on Si (111) substrates by molecular-beam epitaxy (MBE) [1,2]. Then I will present the growth of the wafer-scale free-standing high-quality two-dimensional InAs nanosheets also by MBE. These InAs nanosheets show the outstanding electrical and optical properties. Finally, I will forward to our recent progress on the heterostructures composed with the narrow-band gap
Semiconductor nanowires are often grown from metal nanoparticle seeds via the solution-liquid-solid (SLS) or the vapor-liquid-solid (VLS) mechanism. Germanium nanowires and nanorods have a broad spectrum of potential applications including electronic devices, lithium ion batteries, sensors etc. We present in this contribution the growth of highly crystalline Ge nanowires and nanorods at temperatures as low as 170 °C. [1] These structures grow either via the solution-liquid-solid (SLS) or the vapor-liquid-solid (VLS) mechanism depending on the growth conditions employed. The decomposition of the Ge precursor is catalyzed by the presence of Ga seeds as suggested by the growth temperatures below the onset of the thermal composition of the pure precursor. The compositional and structural characterization of the anisotropic Ge nanostructures has been carried out by different analytical methods including TEM, EDX as well as XRD. The analyses demonstrated the incorporation of unusually high Ga contents of up to 3-4 at% in the Ge. Unusually high metal incorporation in group IV nanowires has been observed for other semiconductor/metal combinations, but the effect on the electronic properties typically not very significant. [2] The electrical characterization at different temperatures of individual Ge nanowires demonstrates a very low resistivity and a quasi-metal like behavior. [3] Temperature treatment at slightly higher temperatures can be used to induce phase separation of this material with metastable composition leading to Ga segregation. We will also demonstrate how to switch between thermodynamically controlled Ge NW growth and the kinetically controlled formation of Ga-hyperdoped Ge.

Selective Patterning of Si/Ge Surfaces and Nanowire Heterostructures via Surface Initiated Polymerization Amar Mohabir, Trent Weiss, Gozde Tutucucoglu, Eric M. Vogel and Michael A. Filler; Georgia Institute of Technology, Atlanta, Georgia, United States.

Functional devices (e.g., transistors) contain one or more features with nanoscale dimensions. When such devices are to be produced at very large manufacturing rates (e.g., for large-area integrated circuitry), an alternative to top-down patterning is necessary to define key features. In this study, we show how Si and Ge surfaces can be selectively masked using the surface-initiated growth of polymer films. Our approach is particularly useful for patterning axially-encoded Si/Ge nanowire heterostructures. Surface masking of Si, but not Ge, is accomplished in a two-step procedure. Atom transfer radical polymerization (ATRP) of polymethylmethacrylate (PMMA) first occurs from a surface-tethered initiator. The selectivity of initiator attachment leads to thick and thin PMMA layers on Si and Ge surfaces, respectively. Unwanted PMMA on the Ge surface is subsequently removed by a clean-up etch. We use this fashion opens up the possibility of nanoscale patterning in a truly scalable manner.

4:45 PM NM03.04.05

Seeded Nanowire Growth from Lithium Alloys Sang Yun Han, Matthew G. Boebinger, Neha Kondekar, Trevor Worthy and Matthew McDowell; Georgia Institute of Technology, Atlanta, Georgia, United States.

Semiconductor nanowires are often grown from metal nanoparticle seeds via the solution-liquid-solid (SLS) or the vapor-liquid-solid (VLS) mechanisms.
Although SLS or VLS growth of semiconductor nanowires is common, related wire growth in all metal systems is rare. Here, we report a new synthesis method that results in the spontaneous growth of nano- and microwires from Li-rich bulk alloys containing Au, Ag, or In at relatively low temperatures (\(-300^\circ C\)). Wire growth was induced by heating metal foil bilayers in an argon environment to cause alloying, followed by cooling. Optical microscopy of samples during this heating and cooling procedure showed that wires grew only during cooling. Scanning electron microscopy (SEM), cryo-transmission electron microscopy (TEM), and x-ray photoelectron spectroscopy (XPS) showed that the wires consisted of Au-, Ag-, or In-rich metal tips and polycrystalline LiOH shafts. Based on these results and systematic experiments to determine growth parameters by varying heating temperature, metal molar ratio, and cooling time, we conclude that the wires grow from alloy seed particles as lithium metal and are converted to LiOH during and/or after growth due to exposure to H\(_2\)O and O\(_2\). The growth mechanism involves the traverse of the two-phase region containing Li metal and liquid alloy on the phase diagram, which causes Li growth from the Li-rich alloy particles. The Li needed for growth is supplied to the seed particles via surface diffusion of Li from the Li-rich alloy reservoir below. It is also thought that the growth of passivating LiOH plays a key role in determining the 1-D morphology. While there are a few important differences, such as the source of the growth species, this mechanism is similar to VLS or SLS growth of semiconductor nanowires. These experiments revealing wire growth from Li-rich alloys demonstrate a new, simple, low-temperature method for nanostructure synthesis, and the results indicate that nanowire growth in other all-metal systems is also possible.

On the Visible-Light Photoelectrochemical Activity of Double-Walled TiO\(_2\) Nanotubes Obtained by Anodization in Ionic Liquids

Herberto Wendel\(^1\), Renato V. Gonçalves\(^1\), Adriano F. Feit\(^1\), Pedro Migowski\(^2\), Jairton Dupont\(^2\) and Sérgio R. Teixeira\(^3\)

\(^1\)Institute of Physics, Federal University of Rio Grande do Sul, Porto Alegre, Brazil; \(^2\)Centro Interdisciplinar de Nanociência e Micro-Nanotecnologia, Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, Brazil; \(^3\)Institute of Physics, Federal University of Rio Grande do Sul, Porto Alegre, Brazil.

In recent decades, a rapid development has been achieved in the development of semiconductors oxide photocatalysts for solar-to-hydrogen energy conversion through water splitting. Anodic TiO\(_2\) double-walled nanotubes (DWNTs) have been explored due to its stability and superior activity compared to single-wall nanotubes (SWNTs). In this work, DWNTs transformation of self-organized TiO\(_2\) SWNTs was studied and their photoelectrochemical properties investigated in detail. The as-formed TiO\(_2\) SWNTs morphological properties were considerably affected by the amount of 1-n-butyl-3-methyl-imidazolium tetrafluoroborate ionic liquid (IL) and NH\(_4\)F in the mixed or pure electrolytes. Besides several discussions in the literature, we show that the double-walls were formed after annealing at 400 °C because of decomposition of IL entrapped in the nanotubes, as evidenced by XPS and FESEM analysis. The TiO\(_2\) DWNTs exhibited a photocurrent density of 1.36 mA\(\text{cm}^{-2}\) at 1.23 V\(_\text{OHE}\), 1.8 times higher than TiO\(_2\) SWNTs (0.77 mA\(\text{cm}^{-2}\)) under one sun illumination. Similar behaviour was obtained when the samples were illuminated only with UV light (\(\lambda < 400\) nm). However, under visible light irradiation (\(\lambda > 400\) nm), TiO\(_2\) DWNTs presented 15.9 times more photocurrent compared with TiO\(_2\) SWNTs. IPCE experiments confirmed the superior activity of TiO\(_2\) DWNTs which extends to the visible range up to 480 nm.

Tuning Composition of PdPt NPs over TiO\(_2\) Nanowires for Optimized Catalytic Activities Towards the Oxygen Reduction Reaction

Anderson Gabriel Marques d. Silva and Susana I. Córdoba de Torres; Universidade de São Paulo, São Paulo, Brazil.

The synthesis of bimetallic nanoparticles at metal oxides surfaces represents an emerging strategy to maximize catalytic performances and increase stability of heterogenous catalysts. However, the controllable synthesis of these nanohybrids as well as the systematic role played by the addition of a second metal in their composition over catalytic performances remains unclear. Here, we present an approach based on the optimization of both the support material and active phase to achieve superior catalytic performance in the oxygen reduction reaction, consisting in small PdPt NPs deposited onto TiO\(_2\) nanowires. The composition could be systematically tuned by varying the molar ratios between Pd and Pt metal precursors. They displayed an uniform 1D morphology, monodisperse PdPt NPs sizes, no agglomeration, strong metal-support interactions, and high concentration of oxygen vacancies at their surface. These features led to improved activities and stabilities for the Pd\(_{25}\)Pt\(_{75}\)-TiO\(_2\) sample towards the oxygen reduction reaction (ORR) relative to the commercial Pd/C and Pt/C catalysts as well as other reported materials. Moreover, a volcano-type relationship between the activity and the PdPt loading was detected. We suggest that the optimized catalytic activities observed for the Pd\(_{25}\)Pt\(_{75}\)-TiO\(_2\) catalyst are a result of the higher concentrations of oxygen vacancies and Pd(0)/Pt(0) species investigated by XPS analysis. We believe that the catalytic activities and stabilities described herein for the ORR because of the optimization of both the support and active phase may inspire the development of novel catalytic systems towards a wealth of sustainable transformations.

**NM03.05.03**

Centimeter Long Nanowires Based on a Polymer Fiber Scaffold for Improved GHz Frequency Telecommunication Devices

Aykut Aydin\(^1\), Lu Sun\(^2\), Xian Gong\(^2\) and Roy G. Gordon\(^1, 2\)

\(^1\)Department of Chemistry and Chemical Biology, Harvard University, Cambridge, Massachusetts, United States; \(^2\)School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

Bundles of twisted conductive wires are used as effective inductors in communication devices that operate in the lower MHz frequencies. To make such a bundle be useful in the GHz frequency range, the constituent wires need to be around a micron or less in diameter. They also need to be sufficiently long and strong for the twisting process, and each individual wire needs to be coated with an insulator. Nanowires prepared with most conventional methods do not meet these requirements.

We present a new method for the preparation of flexible and centimeter long nanowires using a polymer fiber scaffold. Poly(m-phenylene isophthalamide) fibers are electrospun onto a rotating collector such that single strands of centimeter long fibers with diameters in the range of 300 – 600 nm can be collected. These fibers are sufficiently strong when suspended on frame-shaped holders that they can be coated with various deposition methods. With physical vapor deposition methods, since the deposition follows line-of-sight coverage, the frames can be coated from two opposite sides to maximize the conformity of the layer. Highly conformal layers can be deposited onto the fibers with chemical vapor or atomic layer deposition, and the polymer fibers are thermally stable enough (\(\sim 350^\circ C\)) to survive most such methods.
NM03.05.04
Growth and Characterizations of Coherent Si$_{1-x}$Ge$_x$/Si$_{1-x}$Ge$_x$ Graded Multishell Nanowire Heterostructures 
Jinkyoung Yoo and Nan Li; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

High-mobility carrier transport channel at nanoscale is an important platform for electronic devices and quantum transport studies. Recent interest on implementation of topological quantum computation with semiconductor nanomaterials requires fabrication of high-mobility conduction channel in nanowires. Group-IV semiconductors (Si and Ge) have been considered candidates for nanowire-based topological quantum computers due to spin-orbit interaction, especially for Ge. However, Si/Ge-based heterostructures were not suitable materials for high-mobility conduction channel, such as III-V-based heterostructures. Recent advances in group-IV materials growth show that strained Ge quantum well embedded in graded Si$_{1-x}$Ge$_x$ heterostructures in thick film architecture can have high-mobility enough to observe quantum Hall effect. Here, we present the growth and transport characterization of Si$_{1-x}$Ge$_x$/Si$_{1-x}$Ge$_x$ (0<x<1) graded multishell nanowire heterostructures. The nanowire heterostructures show structural coherency. Moreover, the nanowire heterostructures can have several carrier transport paths: core Si wire, sandwiched strained shell, outmost shell by changes of experimental conditions. The coherent graded nanowire heterostructures were prepared by low-pressure chemical vapor deposition. The core Si$_{1-x}$Ge$_x$ nanowires were grown by Au-catalyzed vapor-liquid-solid process with silane and germane. Subsequently, Si and SiGe multishell layers were epitaxially grown by chemical vapor deposition. By controlling the ratio of silane and germane the composition of SiGe was controlled. The electrical conductivity type and doping concentration of core SiGe NWs and outmost SiGe shells were controlled by introducing diborane and phosphine. Top-gated single nanowire heterostructure devices with multi-terminals were fabricated by e-beam lithography and metallization processes. Transmission electron microscopy was employed to characterize the structural properties of the interfaces between adjacent layers. Fully single crystalline coherent graded multishell nanowire heterostructures were successfully prepared. The transport characteristics at various temperatures will be discussed in detail.

NM03.05.05
Influence of Growth Sequence on Single Axial Junction InP Nanowire Solar Cells 
Jungkil Kim et al. Photon-triggered nanowire transistors. We believe that our photon-triggered NW transistors using a more reliable and simple fabrication procedure. We employed the 100-nm-diameter bottom-up Si NWs that possess the n-type high doping level and extremely smooth surface. First, the Si NWs were dispersed on a Si$_3$N$_4$ substrate and PMMA was uniformly coated on the NWs. The PMMA with a length of 360 nm was opened on a NW by electron-beam lithography. Then, the exposed NW region became porous by metal-assisted chemical etching method in which Ag nanoparticles are used as catalyst. Next, the electrical contacts on both ends of the NWs were fabricated by first mechanical transfer to a thermally oxidized Si substrate followed by EBL patterning to define electrodes and wet etching to remove the surface native oxide. Finally, Ti/Au electrodes on nanowires were formed by electron beam evaporation and lift-off.

A series of nano-scale characterization techniques such as photoluminescence, cathodoluminescence, photocurrent mapping and electron beam induced current on the solar cells were employed to characterize the p-n junction configuration and understand the device behavior. It is found that due to the suppression of Zn-diffusion, an improved efficiency up to 7.73% has been achieved in nanowire solar cells with the n-p growth sequence compared with the efficiency up to 6.5% achieved in the axial p-n nanowire solar cells.

NM03.05.06
Photon-Triggered Transistor in Bottom-up Silicon Nanowire Ha-Reem Kim, Jungkil Kim, Hoo-Cheol Lee, Jae Hyuck Choi and Hong-Gyu Park; Korea University, Seoul, Korea (the Republic of).

Exposing a porous Si segment to light can trigger a current in a Si nanowire (NW) with a high on/off ratio. Using this unique property, photon-triggered NW transistors, photon-triggered NW logic gates, and a single NW photodetection system have been recently demonstrated. In this work, we develop photon-triggered NW transistors using a more reliable and simple fabrication procedure. We employed the 100-nm-diameter bottom-up Si NWs that possess the n-type high doping level and extremely smooth surface. First, the Si NWs were dispersed on a Si$_3$N$_4$ substrate and PMMA was uniformly coated on the NWs. The PMMA with a length of 360 nm was opened on a NW by electron-beam lithography. Then, the exposed NW region became porous by metal-assisted chemical etching method in which Ag nanoparticles are used as catalyst. Next, the electrical contacts on both ends of the NWs were fabricated by another electron-beam lithography and thermal evaporation. To characterize the device properties, the electrical current was measured while the laser was focused on the porous Si segment. The current level was controlled by the power of incident laser as well. The measured on/off ratio was ~10$^5$ at a forward bias of 5 V. In addition, we investigated the porous-segment-length-dependent responsivity of the NW device with the porous Si segment. When the porous segment length is shorter than 360 nm, the responsivity decreased because of the high dark current level. Furthermore, we demonstrated the NW transistor device with ten porous Si segments in a single Si NW, using our new fabrication procedure. We believe that our photon-triggered NW transistors offer a new venue towards programmable logic elements and ultrasensitive photodetectors.

NM03.05.09
AACVD Synthesis of p-n Metal Oxide Nanowires for Gas Sensing—From NP-Decorated to Core-Shell Prototypes 
Eric Navarrete$^1$, Carla Bittencourt$^2$, Polona Umek$^3$, Frank Guell$^4$ and Eduard Llobet$^1$; 1Universitat Rovira i Virgili, Tarragona, Spain; 2Research Institute for Materials Science and Engineering, Université de Mons, Mons, Belgium; 3Jozef Stefan Institute, Ljubljana, Slovenia; 4Electronics, Universitat de Barcelona, Barcelona, Spain.

We have demonstrated coated fibers with a conductive metal layer and an outer insulating layer to produce wires that can be twisted into a bundle to serve in telecommunication devices. We have also demonstrated adding multiple alternating layers of metal and insulator to make core-multishell structures that could have applications in photonics and related fields. Being compatible with a large range of deposition methods, this polymer fiber scaffold offers a new way making centimeter long nanowires with high materials generality.
Motivation:
Single crystalline, metal oxide semiconductor nanowires (NWs) loaded with metal oxide nanoparticles (NPs) are very promising for developing a new
generation of inexpensive, yet highly sensitive and more stable gas sensors.1 By supporting p-type metal oxide NPs on n-type metal oxide NWs, both
chemical and electronic sensitization effects can be obtained, which can dramatically tune the response to target gases of the resulting hybrid
nanomaterials, thus enabling the engineering of selectivity. Here we show that the aerosol-assisted chemical vapor deposition (AACVD) is a technique that
enables growing a wide range of nanostructures. In particular, the synthesis of single crystalline metal oxide NWs supporting homogeneously distributed,
mono-modal metal oxide NPs in a wide range of loading levels is studied (from few sparse NPs to a complete coverage leading to core-shell
nanostuctures). SEM, TEM, XRD, XPS, Raman and PL are used to analyze results. Gas sensing properties (response, selectivity and stability) are obtained
and sensing mechanisms are discussed in detail.

Results:
AACVD is run at moderate temperatures and atmospheric pressure, which enables the direct and fast (matter of minutes, rather than hours in high-vacuum)
growth of nanomaterials in a wide range of application substrates including MEMS, ceramic or flexible polymeric transducers for achieving
chemoresistors. We demonstrate the growth of single crystalline WO3 n-type NWs, loaded with metal oxide NPs of p-type late transition metals (Pt, Pd, Ni,
Co or Ir). Single-step or two-step AACVD methods are implemented to achieve a wide range of metal oxide loadings onto WO3 NWs (from under 1% at.
to higher than 15% at.), as confirmed by XPS. NWs are up to 20 microns in length and about 50 nm in diameter and NPs are 2 to 5 nm in diameter. While
in a single-step AACVD the precursors for NWs and NPs are mixed together, in the two-step AACVD two independent processes are conducted
(WO3 NWs are grown at first and then loaded with metal oxide NPs). A two-step process is needed for correctly achieving high loading levels and core-
shell nanowires. The selection of late transition metals and the loading levels has enabled us to design highly selective materials for H2, NO2 or H2S with
moderate humidity interference and low operating temperatures (from 250°C down to room temperature). The reasons for this superior performance are due
to chemical (catalytic) and electronic (modulation of potential barriers at the p-n heterojunction interfaces) sensitization effects that will be discussed in
detail.

AACVD is revealed as an excellent approach for growing high-quality 1-D nanomaterials in a flexible and scalable way. The technique allows for fine
tuning the gas-sensing properties of nanomaterials, particularly selectivity, paving the way for realizing inexpensive, highly performing devices.

NM03.05.10
Ag-Decorated ZnSe Nanowires—Charge Transfer and Luminescence Modifications
Aswathi Kanjamurapath Sirivan, Lorenzo Di Mario, Silvia Rubini and Faustino Martelli; Istituto Officina dei Materiali, CNR, Trieste, Italy; Istituto di Struttura della Materia, CNR, Rome, Italy; Istituto per la Microelettronica e i Microsistemi, CNR, Rome, Italy.

Because of their complementary optical properties, plasmonic nanoparticles (NPs) and semiconductor nanostructures when combined may enhance their
opto-electronic properties making them important heterostructures with high potentialities in photocatalytic and photovoltaic applications.1 When the two
materials are in close vicinity, indeed, many interactions between the electronic states of the semiconductor and the surface electrons within the metal NPs
occur, with interaction enhancement when the electronic states of the two materials are close in energy. Examples of materials with this property are silver
NPs and ZnSe, with the localized surface plasmon resonance (LSPR) of silver resonant with the ZnSe band-gap (2.7 eV at RT).2 In this work we investigate
how Ag NPs affect the optical properties of ZnSe nanowires (NWs) and give rise to charge carrier transfer from the NPs to the NWs, ZnSe NWs were
grown by molecular beam epitaxy at low temperatures (300-350°C) in order to assure a good optical quality.3 A thin Ag film (5 nm) is evaporated on the
NW sidewalls and the Ag NPs are obtained by thermal dewetting. Photoluminescence (PL) and fast transient absorption spectroscopy (FTAS) in pump-
probe mode with a temporal resolution of 50 fs were carried out on as-grown and Ag-decorated samples. The presence of Ag NPs drastically modifies the
temperature PL spectra of ZnSe NWs. The Near-Band-Edge (NBE) recombination is enhanced and the impurity-related recombination show a
shrinking of the relative emission with well-defined band of equally spaced peaks corresponding to the LO-phonon replica of ZnSe. The transient
absorption spectra showed an increase of the rise time and a decrease of the decay time of the ZnSe band-gap bleaching signal in the presence of the Ag
NPs indicating carrier transfer between the Ag plasmons and the ZnSe NWs, and increased phonon-carrier scattering, respectively. Finally, both the low
temperature PL and FTAS show a decrease in the relative intensities of the defect band, typical of ZnSe, in the presence of Ag NPs. The physical origin of these
effects will be discussed at the conference.4

Synthesis of Perylene Diimide, Carbon and Boron Nitride Nanofiber Aerogels from a Single Precursor
Sally DeMaio-Turner, Hu Long, Marcus A. Worsley and Alex Zettl; University of California, Berkeley, California, United States; Lawrence Livermore National Laboratory, Livermore, California, United States.

Aerogels are a fascinating class of materials that possess high surface areas and large porosities, while maintaining low densities. They have the ability to
incorporate macroscopic amounts of material into a single multifunctional structure without sacrificing the intriguing properties of the building block. For
these reasons, aerogels based on nanomaterials have been the subject of extensive research. One dimensional nanomaterials in particular have received
interest due to their large exposed surface areas and low densities, making them candidates for supercapacitor and battery electrodes, hydrogen storage,
water treatment, and chemical sensing, among others.

In this talk, I will show that using a single polycyclic aromatic hydrocarbon precursor, aerogels based on 1D semiconductor nanofibers, conductive
nanofibers, and insulating nanofibers can be synthesized. This route is both inexpensive and scalable. Perylene diimide hydroxide (PTCDI) is used as a
precursor and converted to the diimide form, which in situ self-assembles into nanofibers. At high concentrations of PTCDI, the nanofibers entangle to
form a self-supporting hydrogel and a strong forward solvent nanofibers. Through carefully selected carbonization temperatures and a subsequent ammonia/boric acid treatment, carbon nanofiber (CNF) and boron nitride nanofiber aerogels are synthesized, respectively. We present several
parameters which can be altered to produce a dynamic range of properties such as pore structure, density, as well as crystallinity of nanofibers. Extensive
characterization of the material with Raman and infrared spectroscopies, X-ray diffraction, as well as scanning and transmission electron microscopies is
completed to confirm the chemical composition, crystallinity, and morphology of the materials. These nanofiber aerogels are expected to be promising for
many prospective applications including electron transport layers and battery electrodes for organic semiconductor aerogels, supercapacitors and
electrolytes for conductive CNF aerogels, and as additives in the formation of nanocomposites for BN nanofiber aerogels.
Impurity Effects on GaP Nanowire Optical Properties

Bruno C. da Silva, Odilon D. Couto Jr., Fernando Ikawa and Monica A. Cotta; University of Campinas, Campinas, Brazil.

III-V semiconductor nanowires have been highlighted as promising structures for high efficiency optoelectronic devices and as an alternative to integration with Silicon technology. However, some challenges remain, as the limitation of gold as catalyst due to the deep levels in Silicon and, more specifically, questions about the optical properties of wurtzite (WZ) GaP nanowires, such as the exact band gap energy and the origin of deep level emissions. Here we present the optical analysis of hexagonal GaP nanowires grown by chemical beam epitaxy using gold catalysts; we have grown very large WZ GaP nanowires to enhance the very weak signals of the fundamental optical transitions of the hexagonal material. Thus we were able to carry out excitation photoluminescence spectroscopy (PLE), as well as Raman and photoluminescence spectroscopy. We speculate that the broad emission bands are associated to defects, such as gallium vacancies and complex involving phosphor vacancies. This is supported by the results of the optical emission spectra of doped samples, undoped and different growth conditions. We also noted an enhancement of the Donor-Acceptor Pair recombination, compared with other emission bands, with impurity doping which is consistent with the presence of the gallium vacancy attributed to the latter bands. In order to avoid impurity effects on the growth dynamics, we have explored aluminum catalyst particles. Since Aluminum does not originate deep levels in silicon, it also may pose as an alternative for III-V semiconductor nanowires integration into current silicon technology.

Self-Catalyzed Growth of GaAs$_{x}$Sb$_{1-x}$ Axial Nanowires on Mono-Layer Graphene by Molecular Beam Epitaxy

Surya Nalamati$^{1}$, Prithviraj Deshmukh$^{2}$, David Snyder$^{3}$, Jeffrey Kronz$^{1}$, Michael Zuger$^{3}$, Lewis Reynolds$^{3}$, Yang Liu$^{4}$ and Shanthi Iyer$^{1,2}$; $^{1}$Electrical and Computer Engineering, North Carolina A&T State University, Greensboro, North Carolina, United States; $^{2}$Nanoengineering, North Carolina A&T State University, Greensboro, North Carolina, United States; $^{3}$Penn State Applied Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania, United States; $^{4}$Materials and Science Engineering, North Carolina State University, Raleigh, North Carolina, United States.

GaAs$_{x}$Sb$_{1-x}$ semiconductor nanowire (NW) arrays are of great interest for the next generation infrared (IR) photodetectors due to the ability to tune the bandgap in this material system from 0.73 eV to 1.42 eV, encompassing the important communication wavelength range. Graphene as a substrate is very attractive due to its favorable material characteristics, namely, high electrical conductivity, optical transparency, mechanical flexibility along with it being cheaper for large area synthesis, making it a potential alternative to conventional III-V substrates. Hence, GaAs$_{x}$Sb$_{1-x}$ NWs on graphene provides a pathway for fabricating next-generation flexible and cheaper SWIR photodetectors. Presence of only weak van der Waals bonds between the layers and absence of dangling bonds in graphene pose a challenge to achieve NWs in an axial configuration. In this work, epitaxial growth of GaAs$_{x}$Sb$_{1-x}$ (x<0.1) NWs by using Ga-assisted molecular beam epitaxy on monolayer graphene/SiO$_2$/Si has been demonstrated. Growth optimization that leads to minimal 2D growth, vertical NWs with good spatial distribution across the sample will be presented. A systematic and detailed study on growth parameters, namely temperature, V/Ill flux ratio and initial Ga shutter opening time dependencies was carried out. Micro-photoluminescence (µ-PL) measurements on the NWs thus grown under optimized conditions exhibited an emission peak at 1.35 eV with full-width half maxima (FWHM) of 69 meV. Further, NWs grown on monolayer graphene substrate manifest higher intensity and lower FWHM compared to nanowires grown on Si/SiO$_2$ substrate with similar growth recipe, suggesting the superior optical quality of the nanowires. Raman Spectra of graphene exhibits the symmetric shape of GaAs$_{x}$Sb$_{1-x}$ LO and TO phonon modes at 260.7 cm$^{-1}$ and 282.2 cm$^{-1}$, respectively. These are redshifted with respect to the corresponding reference GaAs$_{x}$Sb$_{1-x}$ (x=0.075) NWs peaks grown on (111) Si substrate suggesting increased Sb incorporation in the NWs. Raman Spectra of graphene exhibits D, G and 2D peaks at 1350 cm$^{-1}$, 1581 cm$^{-1}$ and 2674 cm$^{-1}$, respectively in which a weak D mode is observed, attesting to minimal defects after growth of NWs.

Band Structure and Carrier Dynamics in Single InGaAs and InGaAs/InP Nanowires

Samuel M. Linser$^{1}$, Araj A. Shojaei$^{1}$, Giriraj Jnawali$^{1}$, Howard E. Jackson$^{1}$, Leigh M. Smith$^{1}$, Amira Ameruddin$^{2}$, Philippe Caroff$^{3}$, Hark Hoe Tan$^{2}$ and Chennupati Jagadish$^{2}$; $^{1}$Department of Physics, University of Cincinnati, Cincinnati, Ohio, United States; $^{2}$Dept of Electronic and Materials Engineering, The Australian National University, Canberra, Australian Capital Territory, Australia.

We employ transient Rayleigh scattering (TRS) and photoluminescence (PL) to dynamically and statically characterize the band structure of single semiconducting nanowires. Our samples include Wurtzite InGaAs nanowires and InGaAs-InP core-shell nanowires. Employing ultrafast pump and probe pulses, our TRS measurements show a substantial increase in the carrier lifetime because of passivation of the InGaAs shell. Optical transitions in both the bare InGaAs core and the core-shell structure exhibit band-to-band transitions which are substantially above the expected Zincblende band edge. We anticipate development of PL measurements in these wires to help identify the fundamental band edge. Thermalization dynamics extracted from our TRS spectra suggest that the core-only wires cool rapidly via optical phonon emission, whereas the core-shell wires cool by a slower process with early optical and later acoustic phonon emission.

Exploring Alternative Catalysts for the Bottom-up Synthesis of Silicon Nanowires

Ashkan D. Dashtestani, Arezo Behroudj, Ardeeshir Moeinian, Waheed Ahmad and Steffen Strehle; ULM University, Ulm, Germany.

Silicon nanowires can be readily grown in a bottom-up manner by utilizing the well established metal-catalyzed vapor-liquid-solid (VLS) synthesis. Within the last decade, various silicon nanowire devices, such as label-free transducers, were demonstrated. However, the use of metal catalysts, such as gold, must be critically reviewed considering for instance device yields, nanowire conformity, metal incorporation as well as cross-contamination within the device fabrication process. In this regard, we widely explored alternative strategies in comparison to gold to facilitate reliable and controlled silicon nanowire synthesis and device fabrication. In particular, we studied various catalyst materials like silver, gold alloys, platinum silicides and even metal-free techniques. Here, we were able in all cases to growth silicon nanowires partly with significantly increased epitaxial growth yield. Also p- and n-type doping were realized. The implementation of ultra-thin platinum silicides allowed us for instance to grow silicon nanowires that lack the typical metal catalyst tip presumably based on so-called silicide mediated crystallization rather than VLS growth. In principle, all these alternative methods facilitate nanowire device assembly or growth-in-place strategies. Nevertheless, metal-induced electronic trap formation and surface degradation remain as critical challenges.
issues. Therefore, we studied further also metal-free synthesis protocols allowing already at the present stage to locally grow nanowires in high density presumably in a self-catalytic manner. Besides growth and morphological aspects, we discuss the nanowire purity, the surface Fermi-level pinning as well as the surface charge carrier concentration. For the nanowire synthesis itself, a home-built low-pressure chemical gas phase reaction system was utilized in the temperature range of 475°C to about 800°C using the precursors SiH4/H2 as well as B2H6 and PH3 for p- and n-type doping, respectively.

1D Nanowires of 2D Silicon-Based Chalcogenide Si2Te3 Keyue Wu1, Jiyanghang Cui1, Xiaoshou Chen1 and Jingbiao Cui1; 1Physics and Materials Science, University of Memphis, Memphis, Tennessee, United States; 2College of Electrical and Photoelectronic Engineering, West Anhui University, Lu’An, China.

Si2Te3 is a 2D material with a unique crystal structure where Si atoms form dumb-bells sandwiched between the Te layers, i.e. Si-Si dimers in the sites between the hexagonally close-packed Te atoms1. Covalent bonds are formed between the Te and Si within each layer while weak van der Waals bonding exists between the layers to form a layered crystal structure. A theoretical study showed that rotation of the Si dimer with four possible orientations within the Si2Te3 layer gives rise to a unique structural variability that could have potential new applications in electronic and optoelectronic devices2. Recently single-crystal Si2Te3 nanowires are synthesized by chemical vapor deposition (CVD) and thin layers of Si2Te3 were mechanically obtained by using scotch tape to peel the layers off from the CVD microplates3.

In this study, we have for the first time successfully synthesized 1D nanowires of 2D Si2Te3. It was found that the nanowires grow along c-axes, i.e., along the [0001] direction, and is the stack of layered nanosheets with van der Waals force to form the unique one-dimensional structures. Two-dimensional materials preferably grow into thin layers and the stack of the layers by van der Waals force to form a few layers or bulk materials. Though not common, it is possible for the 2D materials such as SnTe to form nanowires4. The one-dimensional nanowires of 2D materials offer a new horizon for fundamental study as well as new opportunities for applications. Future more, the 1D NWs of Si2Te3 material exhibit a unique resistance switching behavior under an applied potential, which is of great interest for both fundamental understanding and practical applications in ReRAM and memristors.

Large Scale Uniformity in Electroluminescence Emission of Well-Oriented Nanofin LEDs Robin P. Hansen and Babak Nikoobakht; National Institute of Standards and Technology (NIST), Gaithersburg, Maryland, United States.

One-dimensional (1D) nanostructures have been examined for their use in the semiconducting industry as well as numerous fields such as on-chip light sources, nanophotonics and optoelectronics. The ability to produce arrays of such devices on a large scale setting would advance their development and use bringing them to a mass manufacturing scale.

Presented here is a bottom up synthesis technique for the production of semiconducting nanofins on p-GaN (0001) substrate providing an ideal II-VI, II-V, heterojunctions for UV-visible LEDs. The initial growth is a vapor-liquid-solid (VLS) growth process which results in lateral ZnO nanofins that grow epitaxially across a GaN surface. Methods will be discussed on how to energize select nanodevices at the user’s discretion. We show a remarkable uniformity in electroluminescence of nanoscale light sources owed to the control we have created in organizing 1D-nanostructures in their place and direction such that electrical connections can be made to individual nanostructures. In this regard I present steps for the removal of defective nanostructures and the preparation of them for electrical connections. I also present evidence of high quality heterojunctions and their uniformity across a large area based on the sharp electroluminescence UV peaks observed among the fabricated nanoscale light sources. The developed process remains compatible with current semiconducting processes and can be extended for complex device schemes such as computer chips as well as large scale production of miniaturized light sources.

NM03.05.20
Electrospun Metal Nanofibers for Application in Flexible Transparent Electrodes Robert Frohnhoven, Tim Ludwig and Sanjay Mathur; University of Cologne, Cologne, Germany.

In the last decade, in order to replace the market-leading high-cost and brittle indium tin oxide (ITO) as a material for transparent conductive electrodes, all-solution-processed 1D metal nanofibers are very promising tools for biological applications5. Their small dimensions, which are on the same length scale as many cell
components, make them an ideal tool to probe and stimulate cells with minimal perturbation. However, it has been shown that accessing the cytosol with nanowires is challenging and either a centrifugation step, or the application of an electric field, is necessary in order to reach intracellular access.\(^2\)\(^3\) Here, we use alumina hollow tubes made from GaP nanowires to inject biomolecules into cells. We will present our progress towards accessing the cell interior, transfecting cells, as well as probing the cellular cell state.

Lattice Mismatch Strain and Confinement in Nanoscale Si/SiO₂ Structures Fabricated Using Thermal Oxidation Erin Vaughan, Danhong Huang, Clay Mayberry and Ashwani Sharma; Space Vehicles Directorate, Air Force Research Laboratory, Albuquerque, New Mexico, United States.

The transport behavior of semiconductor materials is influenced by lattice-mismatch-induced interfacial (Si/SiO₂) strain coupled with confinement in the nanoscale regime in such a way that the carrier transport properties are beneficially affected. These properties in semiconductors are thought to change gradually from bulk to nanoscale. In the transition region the governing physics changes from classical to quasi-quantum to quantum, and the electrons begin to exhibit more wave-like behavior than particles, and thus react to narrow-paths and interface effects. Additionally, the single discrete charge becomes a significant fraction of the total current. Further, the established macroscopic nature of resistance, capacitance, and inductance changes to a more exotic microscopic one in this regime. Although others have described anomalous effects in scaled versions of Si device structures on their electronic and optical properties as compared to bulk devices, a detailed experimental study describing the incremental transitioning effects of scaling that led to these anomalous effects has not yet been conducted. In this work, we report on the fabrication and characterization of nanoscale planar, wall-like, and wire-like Si/SiO₂ nanoscale structures. As the Si nanostructure dimensions were scaled down to the quantum regime by thermal oxidation of the Si, changes to the band structure and carrier effective mass were observed by both optical and electrical techniques. Thermal oxidation of the Si region is a method that is both highly controllable and effective for fabricating high-quality nanostructures. The oxidation process improves surface roughness at the interface, while also drawing impurities and contaminants away from the core and interface. Photoluminescence measurements showed changes in the peak energies, which illustrates changes in the band structure, as the Si/SiO₂ dimensions are scaled. Metal-semiconductor-metal devices containing these nanostructures were fabricated to further characterize the material properties as a function of scaling. Room temperature dark current measurements showed that conductivity increased as the Si dimensions were reduced. This result is indicative of decreased resistivity and increased mobility and carrier velocity. A decrease in photocconductivity response was observed in samples with Si regions smaller than about 30 nm, which can be attributed to confinement effects on the hole mobility. Transient-time response measurements were also performed to examine the carrier generation and recombination behavior as a function of scaling. Signal rise times decreased for both carrier types by an order of magnitude as Si dimensions were reduced from 200 to 20 nm, meaning that the carrier velocity is indeed increasing with smaller scale structures. This result is indicative of decreased Si band gap energy and carrier effect mass.

Engineering the Wetting Behaviour of Gallium Nanodroplets and Correlation with GaAs Nanowire Orientation Leo Ghisalberti, Rajrupa Paul, Akshay Balgarkashi, Lucas Gunia, Woonjong Kim, Martin Friedl, Craig Carter and Anna Fontcuberta i Morral; 1École Polytechnique Federale de Lausanne, Lausanne, Switzerland; 2Massachusetts Institute of Technology, Boston, Massachusetts, United States.

III-V nanowires (NWs) represent promising building blocks for new generation devices in fields such as electronics, optoelectronics, photovoltaics and quantum computation.\(^1\)\(^2\) Among the possible growth techniques available, the vapor-liquid-solid (VLS) approach provides the possibility to modify the crystal phase and growth directions by engineering the catalytic droplet.\(^4\)\(^5\)

So far most studies have focused on Au-catalyzed NWs growth. Here we focus on self-catalyzed Ga-assisted growth. We modify the contact angle of Ga by modifying the surface energy of the substrate. In a combined theoretical and experimental approach, we identify the range of possible shapes and contact angle of the droplets that can be obtained by modification of the underlying substrate. Among the surface coatings considered are SiO₂, TiO₂, TiO, MoO₃, SiN and graphene. We demonstrate what materials combinations reduce the wetting of the Ga nanodroplets. Finally we correlate the contact angle with the orientation and growth direction of the NWs. This work opens new avenues for a full control of the growth direction and orientation of nanowires and thus for an integration with a large variety of substrates.

NM03.05.24

GaAs-In(Al)GaAs Core-Shell Nanowire Lasers on Silicon Thomas Stuttner, Tobias Kostenbader, Andreas Thurn, Daniel Ruhstorfer, Jochen Bissinger, Hubert Riedel, Michael Kaniber, Gregor Koblmueller and Jonathan Finley; Walter Schottky Institut, Garching, Germany.

Semiconductor nanowire (NW) lasers are nanoscale coherent light sources that exhibit a small footprint, low-threshold lasing characteristics, and properties suitable for monolithic integration onto Si photonic circuits. An important milestone on the way towards novel on-chip photonic functionalities is the integration of individual, deterministically addressable NW lasers on Si waveguides with efficient coupling and mode propagation in the underlying photonic circuit. In this presentation, we demonstrate the monolithic integration of single GaAs-based NW lasers directly onto lithographically defined Si ridge waveguides (WG). When subjected to optical excitation, the observed lasing behavior shows clear “s-shape”-characteristics, linewidth narrowing and threshold values down to 19.8±1 µJ/cm², which is the lowest value reported to date for this kind of integrated lasing structure.\(^1\) The lasing mode of individual NW lasers is shown to couple efficiently into propagating modes of the underlying orthogonal Si WG, preserving the spectral characteristics during mode propagation in the WG in sound agreement with Finite-Difference Time-Domain (FDTD) simulations. Using a WG structure with a series of mask openings along the central mode propagation axis, we further illustrate the out-coupling properties of both spontaneous and stimulated emission and demonstrate propagation of the lasing mode over distances > 60 µm, despite absorption in the silicon dominating the propagation losses.\(^1\)

By replacing the bulk GaAs active gain medium in the NW-laser structure by multiple InₓGa₁₋ₓAs quantum wells (MQW), the emission wavelength can be shifted towards telecommunication bands in order to reduce the absorption losses in silicon. In total, seven 8 nm thick QWs are embedded in 10 nm thick (Al)GaAs barriers. Starting from an In-molar fraction of nominally 15%, lasing emission shows a distinct red shift (>80 meV) compared to NW-laser structures which host pure GaAs MQWs as gain medium.\(^2\) By successively increasing the nominal In-molar fraction up to ~40%, while controlling the incorporation of In by growth temperature, we demonstrate that lasing can be achieved close to 1.2 eV (~1050 nm).\(^3\) We further show that controlling
emission wavelength and lasing characteristics depends sensitively on a number of structural properties, which are evaluated by correlated scanning transmission electron microscopy (STEM) and atom probe tomography (APT) analysis of the coaxial NW-MQW laser structure.

NM03.05.25
Vapor-Solid Selective Area Molecular Beam Epitaxy and Doping of Catalyst-Free GaAs Nanowires on Silicon
Daniel Ruhstorfer, Simon Mejia, Hubert Riedl, Jonathan Finley and Gregor Koblmüller; Walter Schottky Institut, Technische Universität München, Garching, Germany.

III-V semiconductor nanowires (NWs) have gained significant interest due to their potential of monolithic integration on silicon to create various different nanoscale devices on-chip. For all the prospective devices utilizing NWs, control of the doping profiles is key and directly affects performance when designing the necessary pn-junctions. In common vapor-liquid-solid (VLS) grown NWs, doping has proven to be difficult due to non-uniform incorporation of dopants during growth [1] and the reservoir effect that is caused by the droplet catalyst. Particularly in GaAs, where in planar samples the growth of n-type material directly from the vapor phase using the amphoteric dopant silicon is well established, so far only p-type material could be realized for VLS-grown NWs. Literature from liquid phase epitaxy points out that the preferential incorporation of Si dopants on Ga lattice sites only occurs for temperatures beyond 860°C [2], which are inaccessible in VLS molecular beam epitaxy.

In this contribution, we present our recent advances in establishing the selective area molecular beam epitaxy of completely catalyst-free Si-doped GaAs NWs on silicon. We achieve this by applying a high temperature surface treatment to our SiO2-masks to mask the surface of non-masked segments before growth, which transforms the usual 7x7 surface of (111)-silicon to a 1x1-As terminated surface reconstruction. The GaAs NWs are then grown in a high arsenic pressure regime, in which we find the NW aspect ratio to increase with increasing V/III flux ratio and with decreasing mask opening diameters, achieving peak aspect ratios greater than 20. By varying the growth temperature, we manage to exceed a total NW length of 1µm for 1h of growth time. While the yield of undoped NWs decreases for smaller mask openings, adding a high doping flux of silicon increases the yield to over 95% and decreases fluctuations in length and diameter drastically [3].

In TEM, our NWs show a high density of twinned segments, indicating a twinning induced growth mechanism where the twin induced rotation of the crystal structure exchanges fast and slowly growing facets, leading to enhanced axial growth rates. We discuss how the influence of doping affects this mechanism so that the experimentally observed increase in yield and uniformity can be explained.

In addition, we investigate the Raman spectra of the Si-doped GaAs NWs with various doping levels for signatures of the site distribution of the amphoteric silicon dopants while material quality and carrier density is probed by photoluminescence spectroscopy and electrical properties are characterized by NW-FET measurements.

NM03.05.26
Ab Initio Studies of the Electronic and Optical Properties of Eu Doped GaN Nanowires
Assa Aravindh Sasikala Devi, Naresh Alaal and Iman S. Roqan; King Abdullah University of Science and Technology, Jeddah, Saudi Arabia.

Nanostructures comprising of rare earth (RE) doped wide band gap nitrides are of interest for optoelectronic applications, such as in visible lasers [1]. One material of particular interest in this context is GaN doped with RE elements due to its exceptional electronic and optical properties. Here, we present the properties of Eu-doped GaN nanowires (NWs) grown along the wurzite [0001] orientation, calculated using density functional theory (DFT) based on the generalized gradient approximation (GGA), including the Hubbard (U) parameter. We used the plane wave code VASP to carry out the computations [2].

Energy formation calculations show that Eu atoms are the more stable on the NW surface, than native point defects. However, as the number of Eu atoms increases, an outward lattice relaxation occurs, to accommodate the increase in number of atoms, and reduces the formation energy of point defects. The Density of States (DOS) indicate that the Eu f-states are located in the band gap of GaN. DOS also show that valence band maximum (VBM) shifts towards/away from the Fermi level in presence of N and Ga vacancies (VN and VGa), which may give rise to intra-band f/f transitions that are related to optical centers. Optical calculations reveal that the prominent absorption peaks appear between 0 and 3 eV. Moreover, our analyses show that there is no significant change in the peak positions in the optical absorption spectra of Eu-doped NWs as Eu concentration increases. Thus, our theoretical predictions suggest that Eu-doped GaN NW is a favorable candidate for optoelectronic applications.

Detection of Cellular Traction Forces Using GaP-GaInP Nanowires
Zhen Li, Christelle Prinz, Karl Adolfsson and Magnus Borgstrom; Solid State Physics, Lund University, Lund, Sweden.

Cellular traction forces play a crucial role in many cellular processes, including deformation, division and differentiation. We have previously demonstrated that vertical nanowire arrays can be used for assessing cellular traction forces. Compared to other measurement methods, nanowires have an ultra-small (< 100 nm) diameter and can therefore improve the spatial resolution of force measurements. In our first attempt, we used GaP nanowires, functionalized with organic fluorescent dyes for measuring cellular forces during neuronal growth (1). However, the fast bleaching of the dyes limited the acquisition time of our experiments.

Here we use nanowires with a GaP base and a photoluminescent GaInP tip with negligible bleaching (2) to measure the traction forces of MCF-7 and
MCF-10A cells (i.e. cancer and normal-like epithelial breast cells). A high spatial resolution force map is created using automated image analysis based on the localization of the photoluminescent tips of the nanowires. We show that the force distribution and magnitude differ between MCF7 breast cancer cells and MCF10A normal-like breast epithelial cells, and that monitoring traction forces can be used to investigate the effects of anticancer drugs (3).

NM03.05.28
A Facile Route to Structural Design of Zinc Stannate (Zn2SnO4) Nanofibers and Functionalization with Co-Catalysts for High Performance Acetone Sensor เฮ็้ม จี จุ๊ง; ศาสตราจารย์จิน จี จุ๊ง; ฮี ซู จวอ; ฮี ดุ จี ควน; 1KAIST, จุน, ประเทศเกาหลี; 2Massachusetts Institute of Technology, บอสตัน, แมสซาชูเซตส์, สหรัฐอเมริกา.

The metal oxide based chemiresistive sensors are getting attention as emerging exhaled breath sensors due to their flexibility in production, low cost, and easily interpreted results. To enhance the sensing properties, nanostructures with large surface area and high porosity are highly desired since the gas reactions, which are transformed into an electrical signal such as resistance, occur on the surface of the metal oxide.

Zinc stannate (Zn2SnO4) possesses high electrical conductivity, high thermal stability, and high chemical sensitivity. Furthermore, Zn2SnO4 nanofibers can be easily synthesized using electrospinning method. During electrospinning, the morphology of the nanofibers can vary depending on which polymer is used.

In this work, the Zn2SnO4 nanofibers with high porosity were synthesized via in situ phase-separation between poly(vinyl acetate) polymer and inorganic metal precursors (zinc acetate and tin acetate), elongation of poly(vinyl acetate) polymer during the electrospinning step, and subsequent calcination. As a result, longitudinal pores were formed within Zn2SnO4 nanofibers, which offered large surface area and pore volume. In addition, Zn2SnO4 nanofibers were co-functionalized with graphene oxide and palladium to further increase the sensitivity and selectivity toward acetone molecules. The graphene oxide and palladium co-functionalized Zn2SnO4 nanofibers showed a dramatically enhanced response toward acetone (Racetone/Rair = 125 at 5 ppm), which was 3.78-fold higher than that of pristine porous Zn2SnO4 nanofibers (Racetone/Rair = 33.07 at 5 ppm). Furthermore, the graphene oxide and palladium co-functionalized Zn2SnO4 nanofibers exhibited superior selectivity toward acetone compared to interfering gases, namely, toluene, pentane, carbon monoxide, and hydrogen sulfide in a highly humid atmosphere (95% RH) (Racetone/Rair < 6.5). This work paves the way for a facile route to structural design of metal oxide nanofibers and co-functionalization with catalysts for high gas sensing performance, and also demonstrated the extremely sensitive acetone detection capability in highly humid condition such as exhaled breath.

NM03.05.29
Direct Synthesis of α-CsPbI3 Nanowires with a 1.73 eV Bandgap by Two-Injection Method จุว จูน, หลง จูน, จินฟง จัง แอนด์ เหา จ่วน; ฮูฮาวจิ้น จิวเวิ่น นาวิส แอนด์ เทคโนโลจี, หวูฮาน, จีน.

One-dimensional all-inorganic halide perovskites have emerged as one of the most prominent materials in the application of photoelectric devices due to remarkable properties such as low defects, morphological anisotropy, mechanical flexibility as well as fast charge transfer capability. Particularly, the one-dimensional cubic (α) phase CsPbI3 has the narrowest band gap of 1.73 eV among all-inorganic lead halide perovskites, suggesting the greatest potential in the solar cells application. However, the direct synthesis of α-CsPbI3 nanowires (NWs) is challenging and remains unfulfilled because the reaction usually involves a phase change process, resulting in an orthorhombic (δ) phase with the wider bandgap of 2.82 eV. Herein, we report a simply synthetic approach to directly grow α-CsPbI3 nanowires at low temperature using a two-injection method. The as-synthesized CsPbI3 nanowires can be up to 20 μm in length and have an average length of 14 μm. The XRD results verify that these cubic phase nanowires can be steady at room temperature for 90 days. The CsPbI3 nanowires show a photoluminescence (PL) peak located around at 685 nm and the UV-vis absorption spectrum further reveals that the band gap is about 1.73 eV. The excellent optical properties of the CsPbI3 nanowires offer great potential in the field of optoelectronic devices.

NM03.05.30
Chitosan-Templated Bimetal Catalysts Loading on Porous Metal Oxide Nanofibers—Exceptionally Improved Gas Sensing Performance พิยง จิน จ็อง แอนด์ ได จี ควน; มหาวิทยาลัยอินดัสทรีไอแอนซ์ แอนด์ เทคโนโลจี, จุน, ประเทศเกาหลี.

Metallic particles prepared from chitosan-metal complexes (CS-M) possess very small size (< 5 nm) and high dispersibility because they are encapsulated by chitosan molecules. Due to these advantageous properties, CS-M have been frequently applied in catalysis, e.g. for hydrogenation, air cathode, and removal of dyes. Similarly, semiconducting metal oxides (SMOs) based gas sensor also requires highly dispersed small-sized catalysts to significantly enhance sensing performance. Thus, CS-M can be regarded as highly useful templates for functionalization of catalysts on SMOs based gas-sensing materials. Moreover, since chitosan decomposes at high temperature, it can generate numerous mesopores on supporting SMOs, which facilitate surface gas reactions. In this work, for the first time, we demonstrate chitosan-templated catalysts on one-dimensional metal oxide scaffolds as superior chemiresistors, e.g. for human breath analyzer and indoor air monitoring system. First, as a breath analyzer, we synthesized chitosan-templated Pt nanocatalyst loaded mesoporous SnO2 nanofibers by combining chitosan-Pt complex with electrospinning route. Due to the well dispersed ultrasmall (~2.6 nm) Pt catalysts and enhanced mesoporosity by decomposition of chitosan template, Cs-Pt loaded SnO2 NFs showed outstanding response (Rgas/Rair = 141.92 at 5 ppm), excellent selectivity, long-term stability, and fast response (12 s/recovery (44 s) speed toward 1 ppm of acetone at 350 °C and human breath humidity condition (90% RH). Second, we extended catalysts from single metal (Pt) to heterogeneous metal oxides (NiO-Fe2O3) by using chitosan-Ni/Fe dual complexes. Moreover, by controlling ratio of Sn precursor to polymer in electrospinning solution, we developed SnO2 fiber-in-tube (FIT) structure, thus resulting in formation of NiO-Fe2O3 sensitized mesoporous SnO2 FITs. NiO-Fe2O3 loaded SnO2 FITs exhibited unparalleled response (Rgas/Rair = 7.44), superior cross-selectivity, and extremely fast response speed (12 s) toward 0.2 ppm of formaldehyde gas at 350 °C and indoor air humidity condition (30% RH). The strategy employed in this work can pave the way for highly reliable and simple sensitization of catalytic particles on sensing layers.

NM03.05.31
Effect of Annealing on the Microstructure and Properties of GaSb Nanofibers Induced by Ions Irradiation พิยง จิ้น, จุน จิ้น, จุน จิ้น, จุน จิ้น; มหาวิทยาลัยอินดัสทรีไอแอนซ์ แอนด์ เทคโนโลจี, จุน, ประเทศเกาหลี.

The binary compound semiconductor GaSb is one of candidate materials for manufacturing high-frequency, low-power electronic devices. At room temperature, Fe+ ion beam irradiation of GaSb bulk single-crystal wafer. The nanofibers possess special optoelectronic properties after recovering lattice damage by furnace annealing. It makes GaSb semiconductors gain highly potential applications in the field of optoelectronic device fabrication. At room temperature, Fe+ ion beam irradiation of GaSb at 400 keV with the fluences of 1×1016 Fe+/cm2. Amorphous GaSb nanofibers were induced by ion irradiation of bulk GaSb single-crystal wafer. The nanofibers possess special optoelectronic properties after recovering lattice damage by furnace annealing. It makes GaSb semiconductors gain highly potential applications in the field of optoelectronic device fabrication.
of the GaSb LO phonon absorption peaks decreased after ion beam irradiation. And two new modes are observed at ~150 cm⁻¹ and ~114 cm⁻¹, respectively.

NM03.05.32
Silver Nanowire Based Flexible Transparent Electrodes with Different Drying Conditions Seobum Chu, Dongwook Ko, Hyojin Song and Jongbok Kim; Kumoh National Institute of Technology, Gumi, Korea (the Republic of).

ITO (Indium Tin Oxide), which is the most typical transparent electrode, has excellent electrical conductivity and transmittance and is applied to various optoelectronic devices. However, it is inappropriate as next generation transparent electrode because it is not flexible. Ag nanowire (AgNW) based transparent electrode with excellent optical and electrical properties, great flexibility is a strong candidate to replace ITO. To construct AgNW based transparent electrode, people generally spin-coat AgNW solution on the substrate and then dry it at hotplate to evaporate the solvent. However, some substrates are weak to heat and requires different drying methods. Here, we investigate how drying methods affect surface structures and physical properties including the electrical and optical properties in AgNW based transparent and flexible electrodes. Specifically, we spin coated polymethyl methacrylate (PMMA) on the cleaned glass substrate to make easy separation of the AgNW from the glass. Then, the AgNW was spin-coated on the substrate at 1000 rpm for 1 minute. As drying methods for AgNW film, we adopted three different approaches: i) drying it on hotplate, ii) natural drying it in air and iii) drying it under vacuum. When drying it on hotplate, drying time was fixed at 1 min and temperature was from 50°C to 120°C. In case of natural drying and drying under vacuum, drying time was from 5 min to 30 min at room temperature, respectively. Then, NOA 63, a photocurable polymer, was spin-coated on it, followed by UV curing and peeling it to complete flexible electrode fabrication. The surface of AgNW based electrodes was observed by AFM and SEM, and their transmittance was analyzed using a UV-Visible-NIR spectrometer. In surface roughness, we found that room temperature-dried and vacuum-dried transparent electrodes are more rough than that of the heat-dried transparent electrode. In the transmission, the heat-dried and room temperature-dried and vacuum-dried transparent electrode has almost the same transmittance regardless of drying time. We also measured the conductivity of various AgNW based electrode using 4-point sheet resistance meter. The conductivity of the heat-dried transparent electrode tends to increase with increasing drying temperature. However, the conductivity of the transparent electrodes which were dried at room temperature and vacuum tended not to increase. Then, we measured contact angle on the electrodes. The contact angle of the transparent electrode dried at 120°C was considerably decreased compared to the other conditions. As a result, we prepared AgNW based electrodes under different drying condition and characterized their electrical, optical, surface properties and contact angle characteristics. Then we found that drying at room temperature can generate AgNW based electrodes with comparable conductivity and transmittance to vacuum drying and heat-drying.

Investigation of Magnetic Properties of Cobalt Ferrite Nanorods Formulated Through a Facile Templated Electrodeposition Method Brent Williams, Robert Croson and Carlos Castano; Mechanical and Nuclear Engineering, Virginia Commonwealth University, Richmond, Virginia, United States.

Rare-earth based materials have been dominating the magnetic industry for centuries. Due to their nonquenched spins in the f block, materials such as NdFeB and Terfenol have the best magnetic properties for magnetostriiction which can be used for magnetic lensing and permanent magnets for electric motors and generators. However, due to the cost of rare-earth materials formulating magnetic materials from the 3d block elements have been investigated. Cobalt ferrite which contains both magnetostriactive and a high demagnetization field needed for a permanent magnet has been thoroughly studied. For many of these applications high thermal stability and magnetic anisotropy is needed to withstand thermal decomposition and loss of magnetization. Ferrites are known for their high thermal stability and cobalt ferrite in particular is known to have a high magnetocrystalline anisotropy in comparison to other magnetic oxides and a high ferro-paramagnetic transition temperature around 800 K. However, decreasing particle size to single domain structures also leads to a decrease in thermal stability as well as Curie temperature. In order to compensate for the size effects, routes for formulation of nanorods or nanowires are being established. Elongated particles form an easy axis for free electron spins which may enhance coercivity, thermal stability and Curie temperature through a phenomena called shape anisotropy. While routes for synthesizing cobalt ferrite are well established, many of the facile routes lead to agglomeration or wide size distribution, while control of particle size and shape normally depends on high boiling point solvents which accumulate waste and reproducibility in bulk is an issue. Within this work cobalt ferrite nanorods with control over rod diameter have been established through electrodeposition into an anodized alumina template. Unlike previous routes which, need nonenvironment friendly solvents, this method is done mainly at room temperature in an aqueous solution. The magnetic properties of the system were studied to observe the improved magnetic properties including coercivity and Curie temperature which is attributed to shape anisotropy. With this research facile routes for formulating magnetic materials with better control over particle dimensions were established for applications in magnetic sensing and permanent magnets.

NM03.05.34
Large-Scale Synthesis of Byproduct-Free Zn₃P₂ Nanowires Using Highly Porous Zn Pellets Yixi Chen¹, Rakesh Polinnaya¹ and Sreeram Vaddaraju¹, ²; ¹Chemical Engineering, Texas A&M University, College Station, Texas, United States; ²Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

Nanowires have been shown to be promising materials as building blocks for the next-generation electronic and optical devices. Translating these successes in the laboratory to commercial applications, however, requires the capabilities of mass production of high-quality nanowires, which not only afford control over the dimensions of the obtained nanowires, but also ensure that the obtained nanowires are byproduct-free. Herein, a novel approach to synthesis of Zn₃P₂ nanowires in a gram scale is described, in which highly porous Zn pellets were directly converted to that composed of Zn₃P₂ nanowires by chemical vapor deposition (CVD). No unreacted reactants remain mixed with the nanowire product. This method is an improvement over previous works demonstrating the mass production of nanowires using phosphorus reaction with heated zinc foils, and it can be extended to synthesize other nanowires in a large quantity.

NM03.05.35
Fabrication of Epoxy-Based Shape Memory Polymer Composites Embedded with Highly Elastic Nanowires Yixi Chen¹, Nazanin A. Kazerooni², Arun Srinivasan¹ and Sreeram Vaddaraju¹, ²; ¹Chemical Engineering, Texas A&M University, College Station, Texas, United States; ²Mechanical Engineering, Texas A&M University, College Station, Texas, United States; ³Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

Shape memory polymers (SMPs) have been shown to be promising materials for biomedical and aerospace applications. However, relative to shape memory alloys, they exhibit lower recovery stresses, lower recovery speeds, and lower cycle lives. With the intent of improving these properties,
Role of Wire-to-Wire Junction Resistance in Percolation Resistivity of Transparent, Conductive Metal Nanowire Networks

Junying Li, Jeremy Hicks, Tsung-Ying Tsai, Shreshtha Mishra and Ant Urail; Electrical and Computer Engineering, University of Florida, Gainesville, Florida, United States.

There has been significant research interest recently in random networks of one-dimensional (1D) elements, such as carbon nanotubes, graphene nanoribbons, and metal nanowires, for next-generation transparent conductors. In particular, silver and copper nanowire networks exhibit high transmittance, low sheet resistance, mechanical flexibility, and fast deposition. These unique properties make metal nanowire networks promising candidates to replace indium tin oxide (ITO), which suffers from brittleness, scarcity, high cost, and slow deposition.

Monte Carlo simulations are employed to calculate the resistivity of metal nanowire networks, which is governed by percolation transport. In most simulations, it is assumed that the resistance of the wire-to-wire junction is much larger than that of the nanowire itself, resulting in a junction resistance-dominated network. Although this is the case for carbon nanotube networks, recent experiments have shown that, for metal nanowire networks such as silver, the junction resistance can be significantly lowered by post-deposition treatments such as thermal annealing, plasmonic welding, joule heating, and mechanical pressing. In such cases, the nanowire resistance becomes comparable to the junction resistance and can no longer be ignored. When the junction resistance approaches zero, the network becomes nanowire resistance-dominated, which is the lowest resistance limit for a given set of nanowire and device parameters. Furthermore, by controlling the junction resistance, the resistivity of the network can be tuned, opening up further applications such as resistive switching.

In this work, we perform systematic Monte Carlo simulations to study the effect of the wire-to-wire junction resistance on the resistivity and percolation critical exponents of metal nanowire networks. In particular, we compute the network resistivity as a function of the wire-to-wire junction resistance over a span of six orders of magnitude, ranging all the way from a junction resistance-dominated to a nanowire resistance-dominated network. We study this effect when other nanowire/device parameters are also varied, namely nanowire density and length, device length and width, nanowire alignment, and nanowire curviness. We find, for example, that the effect of curviness on resistivity decreases for nanowire resistance-dominated networks. We also investigate the effect of the wire-to-wire junction resistance on the percolation critical exponents over a wide range of nanowire and device parameters. We find that the junction resistance plays a critical role in determining both the resistivity and the critical exponents of metal nanowire networks.

These studies illustrate how the junction resistance affects the macroscopic resistivity of the network. They also show that Monte Carlo simulations are an essential tool for providing insights into the percolation resistivity of transparent, conductive metal nanowire networks.
trifluoroethylenchlorofluoroethylene) [PVDF-TrFE-CFE] to form multilayer heterostructure nanocomposites. In addition to the interfaces between the polymer and nanowires, additional interfaces introduced between nanowires and nanowires give rise to the permittivity and displacement of the nanocomposites, which contributes to enhanced discharged energy density. Also, the effect of nanowires on the relaxation process of nanocomposites was studied by dielectric spectroscopy. The addition of nanowires could decrease the apparent activation energy for space charge relaxation and the constant in VFT equation related to activation energy for α relaxation, resulting from the existence of nanowires will shorten the distance for charge motion as well as segregate polymer chains and diminish the inter molecular cooperativity. What’s more, the introduce of nanowires with a large aspect ratio could influence much area of the polymer matrix and improve the local homogeneity, which results in a more concentrated relaxation time for α relaxation.

Using Ultrathin Parylene Films as an Organic Gate Insulator in Nanowire Field-Effect Transistors

Jan Gluschke¹, Jakob Seidl¹, Roman Lyttleton¹, Damon J. Carrad¹-², Jack Cochrane¹, Sebastian Lehmann¹, Lars Samuelson¹ and Adam P. Micolich¹; ¹UNSW Australia, Sydney, New South Wales, Australia; ²Center for Quantum Devices, University of Copenhagen, Copenhagen, Denmark; ³Solid State Physics/NanoLand, Lund University, Lund, Sweden.

We demonstrate the use of the organic polymer parylene (poly p-xylencylene) as an ultra-thin (~20 nm), lithographically-patterned gate insulator for use in nanoscale transistors. Parylene is well known for its biocompatibility and is FDA approved for human implantable devices, which sees it widely used for medical implant encapsulation. It is also common as an environmental protection coating for printed circuit boards and other industrial electronics. In these applications the parylene films are much thicker, typically 0.5 to 50 microns. Even where parylene has been used as a transistor gate insulator, for example in organic semiconductor transistors [1], the film thickness is ~200 nm to avoid pinholes adversely affecting the device. Indeed, ultra-thin parylene is often thought unsuitable due to pinhole issues, we show this issue can be surmounted for the tiny interfacial areas in nanoscale devices.

We used a custom-built parylene deposition system to put a ~20 nm thick conformal coating onto a 50 nm diameter InAs nanowire field-effect transistor [2]. This device relies on two key properties of parylene: the ability to deposit directly from the gas-phase and its high solvent resistance. The former enables conformal deposition like commonly used oxides, e.g., SiO₂, Al₂O₃ and HfO₂, deposited by atomic layer deposition. Notably, parylene deposition can be performed onto chemically-treated semiconductor surfaces without destroying the surface chemistry in contrast to ALD. The solvent resistance means parylene is amenable to resist-based lithographic patterning, enabling the fabrication of devices as simple as top-gate transistors and as complex as the gate-all-around (GAA) transistors. An added advantage is that parylene is readily etched by oxygen plasma, removing the need for the toxic hydrofluoric acid etches used with oxides. Our gate-all-around transistors give sub-threshold slopes as low as 140 mV/decade and on-off ratios exceeding 1000 at room temperature with low gate leakage (~20 pA) and high yield.

The material and fabrication processes should be transferable to a variety of other semiconductor materials, including graphene, transition metal dichalcogenides and topological insulator systems, as well as a variety of other nanoscale device designs. The ability to deposit ultra-thin parylene films and pattern them at the nanoscale with standard lithographic techniques opens the way to their more widespread use in nanoscale electronics. The intrinsic biocompatibility of parylene means this work is particularly relevant to bioelectronics applications from neural sensing to medical implants.

p-GaAs Nanowire Transistors with Near-Thermal Limit Gating

Rifat Ullah¹, Frank Meyer¹, Jan Gluschke¹, Shagufta Naureen², Philippe Caroff²-⁴, Peter Kroegsturp³, Jesper Ngyár³ and Adam P. Micolich¹; ¹UNSW Australia, Sydney, New South Wales, Australia; ²RSPE, The Australian National University, Canberra, Australian Capital Territory, Australia; ³Center for Quantum Devices, University of Copenhagen, Copenhagen, Denmark; ⁴Microsoft Station Q, Delft University of Technology, Delft, Netherlands.

Modern integrated circuits are heavily reliant on complementary architectures featuring both n- and p-type transistors to minimise power consumption. Continued miniaturisation spurred the development of nanowire CMOS, most recently focussing on III-V nanowire field-effect transistors (NWFETs) integrated on Si to obtain high performance at low cost. Progress has been better for n-type than for p-type. Near-thermal limit gating performance has been obtained for n-type NWFETs. Integration on Si and GHz operation have also been demonstrated. Challenges with growth, doping and fabrication of high-quality gates and ohmic contacts have impeded progress for p-type NWFETs.

Candidates for p-type III-V NWFETs include GaSb, GaAs, In(Ga)As, InP and InSb. In-based materials are hard to deploy because surface state effects make them naturally n-type. Thus the prevailing p-type material is GaSb. It can be challenging to grow, it is also natively p-type due to antisite defects, meaning it cannot also be used for n-type applications. GaAs is natively intrinsic and can be doped to make n- and p-type devices. However, reliable low resistance contacts have been a roadblock for p-GaAs NWFETs [1].

We have developed p-GaAs NWFETs with near-thermal limit gating, low contact resistance and competitive frequency response with strong potential for nanowire CMOS applications. The key to low resistance ohmic contact was adding a heavily Be-doped GaAs shell to the nanowire. We obtain contact resistance as low as 30 kΩ for a shell acceptor density NA = 1.5 x 10¹⁹ cm⁻³ using unannealed AuBe contacts [1]. This shell doping is so high that nanowire CMOS applications. The key to low resistance ohmic contact was adding a heavily Be-doped GaAs shell to the nanowire. We obtain contact resistance as low as 30 kΩ for a shell acceptor density NA = 1.5 x 10¹⁹ cm⁻³ using unannealed AuBe contacts [1]. This shell doping is so high that nanowire CMOS applications. The key to low resistance ohmic contact was adding a heavily Be-doped GaAs shell to the nanowire. We obtain contact resistance as low as 30 kΩ for a shell acceptor density NA = 1.5 x 10¹⁹ cm⁻³ using unannealed AuBe contacts [1]. This shell doping is so high that nanowire CMOS applications. We obtain contact resistance as low as 30 kΩ for a shell acceptor density NA = 1.5 x 10¹⁹ cm⁻³ using unannealed AuBe contacts [1].

The second involves carefully etching the shell at the gate location to make a p-GaAs nanowire MESFET [3]. The advantage is that the gate is self-insulating due to the GaAs Schottky barrier. Our device gives strong performance compared to single horizontal p-GaSb nanowire MOSFETs [4], with typical sub-threshold swing of 62 mV/dec, within 4% of the thermal limit, on-off ratio ~10⁵, contact resistance ~30 kΩ and high-fidelity ac operation up to 10 kHz, opening the path to all-GaAs nanowire complementary circuits with simplified fabrication and improved performance.

Inorganic Nanowire Enabled Next Generation High Performance Battery Separators

Novarials inorganic nanowire battery separators have superior performance: ultrahigh safety (nail penetration safe), ultralong cycle life (double cycle life), and high power density etc. Novarials has a technical leadership on preparation, processing and characterization of a variety of inorganic nanowires. Using these inorganic nanowires, we have developed several nanowire based technology platforms including bendable ceramic nanowire membranes, flexible ceramic hollow fiber membranes, and inorganic nanowire enabled battery separators. We will share these amazing industry achievements with energy community.

Band Structure of Wurtzite InAs Nanowires Measured by Polarized Photocurrent Spectroscopy

We use polarized photocurrent spectroscopy to measure the optical band gap and valence band structure of wurtzite InAs nanowires. The nanowire device was fabricated from 50nm diameter nanowires dispersed on a Si/SiO2 substrate, and two titanium/aluminum metal pads were deposited at either end of the nanowires using photolithography and liftoff. Using tunable excitation light polarized along the long axis of nanowire and perpendicular to that, the band structure of this hexagonal wurtzite material was revealed. According to theory, the transition from the first valence band to the conduction band in a wurtzite structure is only allowed for the light perpendicularly polarized to the c-axis (long axis) of the nanowire. In contrast, carriers can be optically excited from the second and third valance bands to the conduction band with either polarization. The data shows a 0.43eV fundamental band gap at room temperature, 70 meV greater than the zincblende structure, as expected. In addition, the splittings between the valence bands are measured and appear to be consistent with theory.

Highly Conductive Nanorods Underlayer Effect to the Hematite Nanorods with TiO2 Passivation Layers for Photoelectrochemical Water Splitting

Host-guest nanochannel system has proven to be a successful strategy in overcoming the poor majority (electron) collection of α-Fe2O3 electrode for photoelectrochemical (PEC) water splitting. Here we report a novel Sb-doped SnO2 nanorod underneath the α-Fe2O3 nanorod sheathed with TiO2 for PEC water splitting. The experimental results, corroborated with theoretical analysis demonstrate that the Sb-doped SnO2 nanorod underlayer effect to the α-Fe2O3 nanorod sheathed with TiO2 plays an important role in enhancing the PEC water splitting performance. We report the growth of well-defined Sb-doped SnO2 nanorods as a conductive scaffold to improve α-Fe2O3 PEC water oxidation performance. The α-Fe2O3 grown on Sb-doped SnO2 nanorods exhibits improved performance for PEC water oxidation compared to α-Fe2O3 grown on flat fluorine-doped tin oxide (FTO) glass. Furthermore, a simple and facile TiCl4 chemical treatment further introduces the TiO2 passivation layer forming onto the α-Fe2O3 to reduce recombination and eliminate adverse reactions on the surface.

Microbial-Nanowire Enabled Diffusive Memristor Working at Ultralow Cellular Voltages

A type of diffusive memristors has been constructed using microbial protein nanowire-based thin film. The operating voltage in the device was observed to be <80 mV, falling into the biological cellular voltage regime (e.g., cell membrane potential or action potential). The memristor can also mimic the synaptic Ca2+ dynamics with similar temporal response. The material composition (e.g., protein) and ultralow working voltage (e.g., cellular voltage) in the devices have led to both material and functional proximity/mimicry to biological synapse.
Guided Nanowire Optoelectronics Ernesto Joselevich; Weizmann Institute, Rehovot, Israel.

The large-scale assembly of NWs with controlled orientation on surfaces remains one challenge toward their integration into practical devices. During the last few years we reported the growth of perfectly aligned, millimeter-long, horizontal NWs of GaN [1], ZnO [2], ZnSe [3], ZnTe [4], CdSe [5], CdS [6], CsPbBr3 [7] and other materials, with controlled crystallographic orientations on different planes of sapphire [1-7], SiC [8], quartz [9], and spinel [10]. The growth directions and crystallographic orientation of the NWs are controlled by their epitaxial relationship with the substrate, as well as by a graphoepitaxial effect that guides their growth along surface steps and grooves. As a proof of concept for future applications, we demonstrated the massively parallel “self-integration” of NWs into circuits via guided growth [11]. Here we will show how guided nanowires with complex morphologies and heterostructures can be used for the bottom-up fabrication of nano-optoelectronic devices, including photodetectors, photodiodes and photovoltaic cells [12].

9:00 AM NM03.06.02 Crystallographic Mapping of Guided Nanowires by Second-Harmonic Generation Polarimetry Regev Ben-Zvi1, Lior Neeman1, Dan Oron2 and Ernesto Joselevich1, 3Materials and Interfaces, Weizmann Institute of Science, Rehovot, Israel; 3Complex Systems, Weizmann Institute of Science, Rehovot, Israel.

The growth of horizontal nanowires (NWs) guided by epitaxial and graphoepitaxial relations with the substrate is becoming increasingly attractive owing to the possibility of controlling their position, direction and crystallographic orientation. In guided NWs, as opposed to the extensively characterized vertically grown NWs, there is an increasing need for understanding the relation between structure and properties, specifically the role of the epitaxial relation with the substrate. Furthermore, the uniformity of crystallographic orientation along guided NWs and over the substrate has yet to be checked. Here we perform highly sensitive second-harmonic generation (SHG) polarimetry of polar and nonpolar guided ZnO NWs. We optically map large areas on the substrate in a nondestructive way, and find that the crystallographic orientations of the guided NWs are highly selective and specific for each growth direction with respect to the substrate lattice. In addition, we perform SHG polarimetry along individual NWs and find that the crystallographic orientation is preserved along the NW in both polar and nonpolar NWs. However, while polar NWs show highly uniform SHG along their axis, nonpolar NWs show a significant change in the local nonlinear susceptibility along a few microns, reflected in a reduction of 40% in the ratio of the SHG along different crystal axes. We suggest that these differences may be related to strain accumulation along the nonpolar wires. We find that SHG polarimetry to be a powerful tool to study both selectivity and uniformity of crystallographic orientations of guided NWs with different epitaxial relations.

9:15 AM NM03.06.03 Direct Integration of Multifunctional Nanowire and Nanofiber Networks on a Single Chip for Selective Gas Detection David Graf, Ashish Lepcha, Aida Raauf, Albert Queraltó, Rishabh Garg, Matthias Grosch, Thomas Fischer and Sanjay Mathur; University of Cologne-Inorganic Chemistry, Cologne, Germany.

The high surface-to-volume ratio of nanowires as well as the typically high crystallinity and directional charge carrier transport of metal oxide NWs are beneficial for the use in chemo-resistive gas sensors. Semiconducting n-type SnO2 nanowire networks have been site-selectively deposited on gas sensor platforms by chemical vapor deposition (CVD) approach based on a catalyst-mediated vapor-liquid-solid (VLS) growth mechanism. Compared to classical screen-printed SnO2 sensors, the direct integrated nanowire network demonstrated superior sensing performance in terms of sensitivity and response time. To date, selective detection of target gas molecules in complex gaseous compositions or in presence of high humidity is quite challenging. We improved the lack of selectivity toward gaseous species through surface decoration with metal oxide (VO2, Nb2O5) or noble metal (Rh, Pd) nanoparticles by a second CVD step and investigated the sensing mechanism. For this approach, we developed tailored volatile molecular precursors based on bidentate heteroarylalkenolate and enaminonate ligands. To improve the sensing performance under high humidity, which is very important for clinical breath analyses, we electrospun a nanofiber mesh consists of zeolite microcrystals (Mordenite, ZSM-5 and BEA) embedded in thermal stable polymer on top of the sensor. The hydrophilic porous nanofiber mesh acts as water vapor adsorbing or selective filter material to improve the sensitivity and selectivity. Moreover, we fabricate ternary metal oxide (BiFeO3, LaFeO3, PrNbO4 and Sn2Nd2O7) nanofibers on top of the sensor platform, which exhibit excellent selective sensing characteristics. The selective synthesis of the perovskite and pyrochlore materials were achieved by deploying bimetallic alkoxide precursors. Gas sensing measurements demonstrated the highly sensitivity towards SO2 below 0.5 ppm of ferrite materials and the selective H2 detection of pyrochlore Sn2Nd2O7.

9:30 AM NM03.06.04 Controlling Morphology and Composition of Self-Assembled InAsP and InAlAs Nanowires on Monolayer Graphene Substrates Mohadesheh A. Baboli1, 2, Michael A. Slocum2, 3, Alessandro Giussani2, Hyun Kum2, 4, Thomas S. Wilhelm1, 2, Stephen J. Polly2, Seth Hubbard1, 2 and Parsian Mohseni1, 2; 1Microsystems Engineering, Rochester Institute of Technology, Rochester, New York, United States; 2NanoPower Research Laboratory, Rochester Institute of Technology, Rochester, New York, United States; 3Air Force Research Laboratory, Wright-Patterson Air Force Base, Dayton, Ohio, United States; 4Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Monolithic integration of high crystal quality III-V semiconductors with two-dimensional (2-D) monolayer nanosheets can be achieved via growth of high aspect ratio nanowire (NW) structures using the pseudo-van der Waals epitaxy (vdWE) approach. In this regime, growth of dislocation-free NWs is accommodated by weak vdW forces between a 2-D nanomaterial, with no surface dangling bonds, and the III-V epilayer. However, the monolayer substrate offers limited possibilities for arrangement of the overlaying crystal based on the lattice constant of the III-V compound, the finite number of atomic positions on the 2-D surface, and the limitations imposed by the binding energy of adatoms at available residence sites. Here, we present self-assembly of vertically-aligned, high aspect ratio InAsP1-x, InAlx,As, and core-shell InAsP-InP NW arrays on single layer graphene (SLG) via vdWE.
using metalorganic chemical vapor deposition (MOCVD). By altering growth temperature \( (T_G) \) and molar flow ratio of precursors \( (\rho) \), compositional and morphological tuning of hybrid ternary III-V on-2-D nanomaterials systems is realized. For InAsP \( \rho \) NWs, the hydride precursor molar flow ratio \( (\rho_{H_2}) \) is varied from 0 to 0.98 at growth temperatures of 650 °C and 700 °C. The morphology and number density of NWs, as well as parasitic island coverage, are observed to be independent of \( \rho_{H_2} \). Although growth at \( T_G = 700 ^\circ C \) enables higher solid-phase P-incorporation, increasing temperature also adversely affects NW number density. To overcome this challenge, heterostructured InAsP/InAs NWs are grown in a two-temperature growth regime with InAs bases formed at \( T_{G,base} = 650 ^\circ C \), followed by InAsP segments formed at elevated \( T_{G,shell} \geq 700 ^\circ C \). This approach permits growth of high number density NWs with InAsP \( \rho \) segments having composition \( y \approx 0.80 \). Higher P-content segments are grown as shell layers on existing InAsP core segments. Next, the dependences of InAl\(_x\)As NW morphology, verticality, and number density on growth temperature and composition are investigated. At constant \( T_G = 600 ^\circ C \), composition dependences are studied by varying the metalorganic precursor molar flow ratio \( (\rho_{H_2}) \) between 0 and 0.75. Similarly, at constant \( \rho_{H_2} = 0.50 ^\circ C \), temperature dependences are studied in the 600 °C ≤ \( T_G \) ≤ 700 °C range. Optimal conditions are presented for uniform-diameter and vertical InAlAs NWs at \( T_G = 650 ^\circ C \) and \( \rho_{H_2} = 0.50 \). A growth mechanism for vdWE of ternary InAsP and InAlAs NWs is proposed to relate the observed trends for NW number density and morphology to lattice coordination and binding energy of growth species on SLG. We anticipate the use of such hybrid III-V-on-2-D nanomaterials in low-cost and flexible optoelectronic device applications.

Surface-Guided Halide-Perovskite Nanowires—New Building Blocks with Unusual Properties for Optoelectronics

Ronit Popovitz-Biro, Lothar Houben and Ernesto Joselevich; Weizmann Institute of Science, Rehovot, Israel.

Metal-halide perovskites (MHPs) are remarkable optoelectronic materials due to a rare combination of low-cost fabrication and exceptional properties. Recently, nanowires of MHPs have emerged as promising building blocks for various optoelectronic application and as an intriguing one-dimensional system for investigating and modeling fundamental MHPs properties. Both for research and applications, controlled and well-defined nanowire systems are highly advantageous, and at times a real necessity. Here we employ a surface-guided approach to grow horizontally aligned arrays of single-crystal CsPbBr\(_3\) nanowires. The nanowires grow with well-defined facets and a uniform crystallographic orientation to form aligned arrays with 6-fold and 2-fold symmetries. We highlight the advantages of such arrays for fundamental research, as we investigate their optical properties, and present a unique perspective on photon-transport processes and anomalous diameter-dependent emission shift. In addition, we demonstrate the potential of planar MHPs nanowires as building blocks for functional devices by fabricating photodetectors that exhibit faster response times than any CsPbBr\(_3\)-based photodetectors reported so far. Arrays of horizontally aligned MHPs nanowires are a promising platform for investigating the intriguing properties and potential applications of these unique materials.

10:30 AM *NM03.07.01
GaN Nanowire Devices Grown with Selective Area Epitaxy

Kris A. Bertness; National Institute of Standards and Technology, Boulder, Colorado, United States.

We have developed a highly flexible process for selective-area growth of GaN nanowires on silicon substrates with polarity-controlled buffer layers. With this process, fully selective nanowire growth can be obtained by molecular beam epitaxy in both dense arrays or for isolated nanowires, enabling a wide range of device architectures. Self-shadowing of growth fluxes can be eliminated in isolated nanowires, allowing for synthesis of junctions and heterostructures with radial geometries. In this talk, we examine first the optical and electrical characteristics of nanowire LEDs grown by this technique, which have an n-type core and a conformal p-type shell layer. Electrical contact is made to the core through the GaN nucleation layer and to the p-type shell via a top surface metallization layer, allowing for measurement of single nanowires or parallel measurement of multiple nanowires. Under forward bias, these nanowire LEDs produce electroluminescence at 380 nm, corresponding to donor-acceptor-pair recombination from electrons injected in the p-type shell. In this design, however, the shell thickness is comparable to the minority carrier diffusion length so that most electrons pass through the p-type shell to the contact without recombining with holes, and efficiencies are low. We have demonstrated dramatically improved light emission by introducing heterostructures such as replacing GaN with AlGaN in the p-type shell. We will also discuss using selective epitaxy to place these nanowire LEDs on AFM cantilever tips by growing and processing the LEDs on silicon-on-insulator substrates and then etching cantilevers out of the substrate. Finally, we will present data that suggests the array structure produces strong surface phonon-polariton interactions.

11:00 AM NM03.07.02
Selective Area Growth of In\(_{x}\)Ga\(_{1-x}\)As Nanowires on HfO\(_2\) Templates for Highly Scaled nMOS Devices

Paloma Tejedor; Instituto de Ciencia de Materiales de Madrid (ICMM), Consejo Superior de Investigaciones Científicas, Madrid, Spain.

The replacement of the strained Si channel in n-metal-oxide-semiconductor-field-effect-transistors with III-V compound semiconductors, particularly In\(_{x}\)Ga\(_{1-x}\)As, is considered nowadays the best alternative to improve the drive current at low supply voltages in high-performance CMOS applications at sub-10 nm-technology nodes. As the device is scaled down, the reduction of the source/drain contact geometries results in current crowding and a significant increase in access resistance. Mitigating this effect is hence one of the most difficult challenges to fabricate highly scaled III-V devices. In this work, we present the development of a self-aligned process based on selective epitaxial growth of In\(_{x}\)Ga\(_{1-x}\)As \((x \approx 0.1)\) raised source and drain nanowire structures on etched recessed areas adjacent to a nanopatterned high-k dielectric, i.e. HfO\(_2\), using conventional and atomic H-assisted MBE as key process to integrate high mobility III-V materials in 3D device architectures.

In the first part of this work we studied the interaction of atomic H with the surface of HfO\(_2\) prior to the epitaxial process in ultra-high vacuum, by using AFM, ToF-SIMS, ARXPS and HR-TEM. The study showed that in the 350-400 °C temperature range in-situ cleaning with atomic H effectively reduces the concentration of the major impurities on the HfO\(_2\) surface, which occurs through a layer-by-layer etching reaction with activation energy of 23 Kcal/mol\(^1\). The second part of the work was devoted to the investigation of several fundamental aspects of the selective epitaxial growth of In\(_{x}\)Ga\(_{1-x}\)As nanowires on HfO\(_2\)/GaAs templates fabricated by interferometric lithography. Special emphasis has been placed on the impact of atomic H on the process window for III-V selective growth, the nucleation and growth dynamics, the relief of lattice mismatch in the open trenches and the structure and composition of the epi-layers grown on the prepatterned substrates. Selective growth has been observed for all values of \( x \) between 0 and 1. HRTEM images have revealed the
conformality of the growth and the absence of microtrench formation near the HfO2 mask edges. Our results have demonstrated that the use of atomic H lowers the temperature process window for selective growth down to 400 °C, due to the lower energy of nucleation required on the H-terminated III-V surface and the blocking of HfO2 active sites by H, which inhibits the nucleation of the III-V compound on the masked areas. HRXRD measurements have shown that the best crystal quality corresponds to InGaAs samples grown at 500 °C, with little differences between samples grown by H-assisted and conventional MBE. Finally, those InGaAs alloys grown on H-treated HfO2 patterned substrates exhibit a higher uniformity in chemical composition (absence of In segregation) and full strain relaxation for x≤0.5.

Financial support by the Spanish Government under grant MAT2016-78433 and by CSIC under grant 2018E058 is greatly acknowledged.

11:15 AM NM03.07.03
Ordered GaAs p-n Radial Junction Nanowire Arrays on Silicon Wonjong Kim, Léo Balembois, Jelena Vukajlovic-Plestina, Gozde Tutuncuoglu, Dmitry Mikulik, Pablo Romero, Lucas Guniat, Martin Friedel and Anna Fontcuberta i Morral; EPFL, Lausanne, Switzerland.

Semiconducting nanowires (NWs) are expected to play an important role on third-generation photovoltaics. The vertical configuration of the NW is shown to be promising for enhancing absorption cross-section due to resonances and light-concentrating effect1,2. In this work, we present in-depth studies on self-assisted GaAs NW arrays grown on silicon by molecular beam epitaxy. Reproducible high yield (> 85 %) of vertical NW arrays3 enables us systematic doping studies on our GaAs NW arrays. Although there are several groups reporting NW array based photovoltaic devices4,5, to date there have been very few reports on MBE grown ordered GaAs NW array on silicon6. We will present our latest results on our GaAs NW array-based devices and discuss the growth and doping mechanism, comparing our findings to previous results obtained for self-assembled GaAs NWs7,8. We demonstrate experimentally the effect of device performances on inter-wire spacing, doping concentration of the NW core and shell within the array system which can be of fundamental importance for the realization of NW based photovoltaic devices.

11:30 AM NM03.07.04
The Geode Process—A Route to the Large-Scale Manufacturing of Functionally-Encoded Semiconductor Nanowires Martiza Mujica, Gozde Tutuncuoglu, Victor Breedveld, Sven H. Behrens and Michael A. Filler; Georgia Institute of Technology, Atlanta, Georgia, United States.

Future large-area electronic and photonic technologies will require the manufacturing of materials and devices at very high rates without sacrificing nanoscale control of structure and composition. Semiconductor nanowires can be produced with exquisite spatial control of composition and morphology using the vapor-liquid-solid (VLS) mechanism that, unfortunately, remains limited to very small manufacturing rates. Here, we introduce the Geode process to synthesize functionally-encoded semiconductor nanowires at throughput orders of magnitude beyond the state-of-the art. Central to the Geode process are sacrificial, porous-walled, seed particle-lined silica microcapsules, whose interior surface serves as a high-surface area growth substrate. Microcapsules protect the growing nanostructures, are produced with a scalable emulsion templating technique, and are compatible with large-scale chemical reactors. We will show how microparticle structure and drying is influenced by silica nanoparticle type and concentration, emulsification parameters, and nanoparticle cross-linking agent. We will also demonstrate the synthesis of Si nanowires with programmable dopant profiles on the microcapsule interior, which not only shows the versatility of the process, but also allows the impact of precursor gas transport limitations to be characterized.

11:45 AM NM03.07.05
In Situ Reflectometry Measurements and Simulations of Highly Oriented Vertical VLS Growth of Germanium Nanowire Assemblies Michael Braun1, Lucas Guniat1, Anna Fontcuberta i Morral1 and Paul C. McIntyre1; 1Laboratoire des matériaux Semiconducteurs, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2Materials Science and Engineering, Stanford University, Stanford, California, United States.

Aligned arrays of semiconducting nanowires have drawn significant interest, in part because of their relevance for end-of-roadmap electronic and nanoscale optoelectronic devices. In all these applications, the in-situ analysis of nanowire growth is advantageous, both for understanding fundamental aspects of the growth kinetics and for process monitoring. While several methods have been commercialized for thin film growth monitoring, laser reflectometry analysis of nanowire growth is a more novel application. In this study, we report an in-situ method of monitoring the vapor-liquid-solid (VLS) growth of germanium nanowires via a simple laser and detector system, operating at an oblique angle. The monitoring system is mounted on a lamp-heated, cold-wall chemical vapor deposition (CVD) chamber. Previous studies have reported on either vertical reflection from nano-patterned nanowire arrays, or grazing reflection from highly non-vertical random nanowire arrays with a broad range of diameters. In contrast, we have grown highly vertical (≥ 99.9 %) randomly dispersed nanowire arrays with a range of controlled diameters and areal densities, and at a range of growth pressures. These conditions enable us to analyze the nucleation time, growth quality, and growth rate of the same samples for growth times beyond 30 minutes. Analysis was based on fitting the exponential decay of the signal and oscillation period of the successive constructive/destructive interference effects. The experimental measurements are compared to simulation via a novel evolution of numerical finite difference frequency domain (FDFD) simulations as a function of growth time. These simulations are performed in two and three dimensions as well as with supercells of nanowires of non-identical spacing. The supercells attempt to separate artifacts from photonic crystal effects of the periodic simulation compared to the random experimental arrays. Simulation results are compared to a simple thin film effective-index model as a gauge of the impact from resonant modes and enhanced scattering from nanoscale features.

1:30 PM *NM03.08.01
Thermal Phonon Engineering with Nanowires Martin Maldovan; Georgia Institute of Technology, Atlanta, Georgia, United States.

In recent decades, the improved ability to manipulate electrons and photons has made possible remarkable technological developments in electronic, optoelectronic, and energy applications. Contrarily to electrons and photons, a similar degree of control over thermal phonons (i.e., thermal lattice vibrations) has not yet been achieved. Considering the remarkable success on using electronic and photonic materials to manipulate electrons and light, it is certainly valuable to extend this knowledge to lattice thermal vibrations and create new approaches to manipulate heat flow.

In this talk, I discuss semiconductor nanowires (NWs) as a powerful material platform for manipulation of thermal phonons and control of heat flow. I will show how the rational design of structural and material properties of nanowires can be used to tailor the thermal phonon transport properties. Nanowire atomic structure and composition, surface characteristics, porosity, and morphology are among the physical variables that can be exploited to control thermal energy transfer. This “thermal phonon engineering” of nanowires can be leveraged to achieve unprecedented control over nanoscale heat conduction.

2:00 PM NM03.08.02
Thermal Transport in Si Nanowires with Axially Modulated Diameters Gozde Tutuncuoglu1, Abhinav Malhotra2, Sampath Kommandur2, Shannon Yee1, Martin Maldovan1,3 and Michael A. Filler1; 1Chemical and Biomolecular Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2G. W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 3School of Physics, Georgia Institute of Technology, Atlanta, Georgia, United States.

Semiconductor nanowires, because their nanoscale structure can be precisely engineered, offer exciting opportunities to control thermal transport. Despite initial demonstrations that morphology, diameter, and surface roughness can modify the thermal conductivity of Si nanowires, these effects remain poorly understood and difficult to rationally engineer. In this work, we combine state-of-the-art nanowire synthesis, thermal transport characterization, and modeling to understand, predict, and control heat transport in Si nanowires. The synthesis of nanowires with axially-modulated diameters is accomplished by combining the vapor-liquid-solid (VLS) mechanism with the post-growth selective etching of axially-encoded doped segments. A single nanowire, suspended four-bridge thermal transport method eliminates the impact of contact resistance on the measured thermal conductance. Simulations using the complete frequency- and temperature-dependent solution to the phonon-Boltzmann equation permit an accurate description of phonon-surface interactions. We find that thermal conductivity decreases as the modulated diameter decreases and it can be further engineered by the aspect ratio of the diameter-modulated section. We also determine the relative importance of backscattering and wave effects. By connecting local nanowire diameter and morphology to phonon transport and the resulting thermal properties, our work paves the way for the rational design of future thermal materials.

2:15 PM NM03.08.03
Understanding the Kink Effect on Thermal Transport Through Nanowires Yang Zhao, Lin Yang, Qian Zhang and Deyu Li; Vanderbilt University, Nashville, Tennessee, United States.

Transport mechanisms underlying heat transfer in micro/nanoscale structures are of fundamental interest and critical for a broad range of applications, including thermoelectrics, electronic device thermal management, and data storage. In the past two decades, the effects of the characteristic size, surface roughness and acoustic phonon softening on thermal transport through nanostructures have been studied, which provides powerful strategies to alter the thermal transport properties of nanomaterials. Here we show that kinked morphology could be a new degree of freedom to tune thermal conduction in nanowires and further disclose the phonon transport mechanisms in kinked nanowires.

From experimental studies, we found that the thermal conductivity of kinked boron carbide nanowires can be reduced by up to 36% as compared to corresponding straight nanowires of similar diameters and carbon concentrations. Analysis indicates that this level of reduction means that the kink structure poses ~30 times larger thermal resistance than the corresponding straight nanowire segment of an equivalent length. The pronounced kink resistance is attributed to the strong backscattering of highly focused phonons in the kink region, which is supported by the interesting discovery that defects in the kink region, instead of posing resistance, actually assist phonons passing through the kink by increasing phonon scattering rates at the kink.

To further explore the kink effect, we further conducted measurements on kinked silicon nanoribbons with multiple kink structures. Compared to boron carbide nanowires, a single kink in the silicon nanoribbon poses only ~1.2 times thermal resistance because of its significantly lower elastic anisotropy. However, a maximum thermal conductivity reduction of 21% can be achieved by having multiple kinks in the silicon nanoribbons.

To further disclose phonon transport mechanisms in kinked nanowires, we performed non-equilibrium molecular dynamics simulations to model thermal transport through straight and kinked silicon nanowires. Results clearly demonstrate that back scattering of phonons from the free surface of the kinked region is the underlying mechanism for the additional kink resistance. Furthermore, by adding heavy isotope atoms into the kink region, we verify the experimental observation that defects can indeed assist phonon transmission through the kink region via scattering phonons into the other branch of the kink.

2:30 PM NM03.08.04
Significant Effects of Electron-Phonon Interactions on the Lattice Thermal Conductivity of Quasi-1D NbSe2 Nanowires Lin Yang1, Yi Tao2, Jinyu Liu1, Chenhan Liu1, Qian Zhang1, Yang Zhao1, Qijiang Mao1, Yunfei Chen1 and Deyu Li1; 1School of Mechanical Engineering, Southeast University, Nanjing, China; 2Department of Physics and Engineering Physics, Tulane University, New Orleans, Louisiana, United States.

The interaction between electrons and phonons is a fundamental process in solids and plays critical roles in various physical phenomena. While the effects of electron-phonon (e-ph) interactions on electronic properties of condensed matter have been extensively studied, its contribution to lattice thermal conductivity is still in debate and quantitative analyses have been largely lacking. Through systematic studies of the transport properties of niobium triselenide (NbSe2) nanowires, we show the significant influence of e-ph coupling on the lattice thermal conductivity ($\kappa_L$), which provides direct evidence on the importance of e-phonon coupling in $\kappa_L$.

NbSe2 belongs to a class of van der Waals (vdW) materials with quasi-one-dimensional (quasi-1D) crystal structures, where covalently-bonded molecular chains assemble together via vdW forces. Owing to the restricted dimensionality, the density of free electrons in NbSe2 spontaneously develops a wave-like variation due to a lattice distortion when temperature drops below a critical value ($T_{CDW}$), which is called charge density wave (CDW). The variation of charge carrier concentration upon the onset of CDW results in the spontaneous change of e-ph coupling strength, which is reflected as the abnormal peaks in the extracted lattice thermal conductivity.
To confirm that e-ph interactions cause the distinct signatures in $\kappa_e$, we combine first-principles calculations with a phenomenological model to extract the contribution of e-ph scattering. Extensive modeling efforts show that without considering e-ph scattering, $\kappa_e$ follows the typical shape for crystalline materials with a smooth profile in the whole temperature range. However, with the e-ph scattering term introduced, the modeled $\kappa_e$ can fit the experimental data remarkably well. The perfect match of the shape for the two abnormal peaks strongly indicate that it is indeed the e-ph scattering that leads to the distinct signature in $\kappa_e$. Moreover, for nanowires with smaller transverse dimensions, the peaks in $\kappa_e$ are less significant due to competing scattering mechanisms, which is also well captured by the theoretical model.

The observed abnormal peaks in $\kappa_e$ provide solid evidence to answer the long-standing, fundamental questions of whether and how e-ph interactions affect phonon transport. Given the ubiquitous nature of e-ph coupling in semiconductors and metals, this discovery will lead to new understanding of transport processes in microelectronic, photovoltaic and optoelectronic devices, which will enable further improved device design and performance.

SESSION NM03.09: Transport and Energy Conversion
Session Chairs: Michael A. Filler and Martin Maldovan

Sheraton, 2nd Floor, Back Bay D

3:00 PM BREAK

3:30 PM *NM03.09.01

It has been predicted [1,2] that thermoelectric energy conversion based on ideal energy filters can, in principle, be performed near thermodynamically ideal efficiency limits, but this prediction has never been experimentally verified. Using a quantum dot (QD) embedded into a semiconductor nanowire, we directly measured the engine’s steady state electric power output. Taking into account also the calculated electronic heat flow, we find that at maximum power conditions the electronic efficiency is in agreement with the Curzon-Ahlborn efficiency, and that the overall maximum electronic efficiency is in excess of 70% of Carnot efficiency. [3] I will describe how these results may be used to enhance energy conversion efficiency also in solar cells, by harvesting non-equilibrium electronic energy based on photothermoelectric principles [4], and will show first results demonstrating a high open-circuit voltage [5].

4:00 PM NM03.09.02
Transport Phenomena and Thermoelectric Properties in Modulation-Doped GaAs/AlGaAs Core-Sphere Nanowires Sergei Past, Jonathan Becker, Damon J. Carrad, Dominik Ibler, Jakob Seidl, Anton Faustmann, Bernhard Lotisch, Gerhard Abstreiter, Jonathan Finley and Gregor Koblmueller; Walter Schottky Institut and Physik Department, Technische Universität München, Garching, Germany.

Generating electricity from waste heat has the potential to have a noticeable impact on our ecological footprint, provided the conversion efficiency is high enough. Semiconductor nanowires (NW) are central to this effort since electrical and thermal effects can theoretically be decoupled in 1D systems, which will enable further improved device design and performance.

A suitable platform for circumventing this problem is presented in this work, employing radial modulation-doped core-shell NWs. Our studies are based on Si-delta doped high-mobility GaAs/AlGaAs core-shell NW heterostructures, which hold the potential for both high-performance steep-slope NW-field...
effect transistors (NW-FETs) [1] and for in-depth investigations of low-temperature quantum transport [2]. Top-gated NW-FETs were used to study the quantum transport characteristics at low temperature (4–7 K) on a set of core-shell NWs with different GaAs core diameter. During pinch-off we observe clear plateau-like signatures, consistent with the depopulation of quasi-1D subbands as confirmed by correlated simulations for the range of core diameters investigated [2]. Subsequent Seebeck effect measurements show distinct spikes in the Seebeck voltage as a function of applied gate voltage and different heater powers which correspond to the 1D-like plateaus in conductivity [3]. Furthermore, thermal conductivity measurements were carried out on suspended NWs using Raman spectroscopy [4], to probe the effect of the surrounding AlGaAs barrier on phonon scattering and reductions in the thermal conductivity of GaAs NWs at room temperature. We found that Si-delta-doped GaAs/AlGaAs core-shell NWs exhibit reduced thermal conductivity with respect to their uncapped pure GaAs NW counterpart, being in the range between 7 and 12 W/(m K)[3]. Ongoing experiments aim to extract systematically the Seebeck coefficient to ultimately provide quantitative results for the figure of merit ZT.

Flexible Nanowire LED—Optimization of White Light Based on Phosphor Down Conversion
Nunoo Amador Méndez1, Nan Guan1, Dai Xing1, Hezhi Zhang1, Akamsha Kapoor2, Catherine Bougerol3, Lorenzo Manconi4, Martin Foldyna2, Subrata Das5, Sudipta Som,6 François Julien,7 Joel Eymery7, Christophe Durand6 and Maria Tchernycheva1; 1Center of Nanoscience and Nanotechnology, Orsay, France; 2Université Grenoble Alpes CEA, Grenoble, France; 3Université Grenoble Alpes CNRS, Grenoble, France; 4LIPCM-CNRS, Palaiseau, France; 5National Institute for Interdisciplinary Science and Technology, Kerala, India; 6National Taiwan University, Taipei, Taiwan.

Flexible light sources and displays are key emerging technologies highlighted in the Photonics 2020 roadmap. Today, this market is dominated by organic semiconductors. Despite their low cost, the organic devices cannot compete with inorganic devices in terms of lifetime and efficiency. Still the mechanical rigidity of the inorganic semiconductor thin films limits their application in the areas where bended surfaces or flexible devices are required. To make them flexible, the emitter size should be reduced.

Semiconductor nanowires attract a strong attention for fabricating LEDs with new functionalities. The high material quality of the nanowires results in advantageous optical and electrical properties. In addition, they have a small footprint and are mechanically flexible. Therefore, semiconductor nanowires are excellent candidates for optoelectronic applications requiring high efficiency and mechanical flexibility.

In this presentation, we report the fabrication and characterization of flexible white nanowire LEDs [1]. The devices rely on the blue electroluminescence from the InGaN/GaN nanowires, which is downconverted by micro-sized phosphors in a PDMS layer. The nanowires are grown by MOVPE technique without catalyst on c-sapphire substrates. Seven core/shell InGaN/GaN quantum wells are radially overgrown around the n-doped GaN stems and covered with a p-doped GaN shell. To process flexible LEDs, semiconductor nanowires are encapsulated into a PDMS, mechanically peeled-off from their growth substrate and the resulting membrane is contacted with a flexible transparent silver nanowire mesh. A PDMS cap doped with micro-phosphors is added on top of the nanowire LED. To optimize the quality of the white light (namely, the chromaticity coordinates, the CCT and CRI), different phosphors were investigated. Namely, orange-emitting Sr1.95Eu0.04Tb0.01Si5N8 (1 wt% Sr3N2) coated by 2.5 wt% Mg(OH)2 and yellow Y2.95Ce0.05Al5O12 (1 wt% BaF2) phosphors were used and different thicknesses of the capping layer were analyzed. The resulting electroluminescence of the flexible devices was recorded under different injection current. The pumping blue nanowire LED wavelengths was also changed from λ=430 to λ=460 nm by adjusting the In content in the quantum wells. The chromaticity coordinates of the white LED previously reported [1] were x=0.3011 and y=0.4688 with a CCT and CRI of 6306 K and 54, respectively. Increasing the mass aspect ratio of micro-phosphors/PDMS of the capping layer we reached a CRI value of 91. An overall improvement of the white light quality is achieved by optimizing the pump wavelength and the type of micro-phosphors. The best-achieved values were located in x=0.3028 and y=0.3577 with a CCT and CRI of 6629 K and 88, respectively.

Surface Passivation Study of Single p-i-n Doped InP Nanowire Solar Cells Using EBIC
Lucas Hrachowina and Magnus Borgstrom; Solid State Physics, Lund University, Lund, Sweden.

Photovoltaics enable the direct conversion of solar energy to electricity and thus play an important role in sustainable energy production. Nanowires have several superior properties compared to their bulk material and with a specific pattern of a nanowire array it is possible to reach similar efficiencies like thin films by using only a fraction of the material. In order to utilise the potential of nanowire solar cells, electron-beam-induced current (EBIC) has been used to characterise as-grown wires. However, it has been shown that due to the high surface-to-volume ratio the surface passivation of InP nanowires plays a crucial role, even though the surface recombination velocity of native InP is quite low.

In this study, as-grown p-i-n doped single InP nanowire solar cells are compared with nanowires passivated by a selection of atomic layer deposited oxides in a nanoprobe system inside a SEM. In this way, key parameters for solar cells can be measured without the need to process samples into functional solar cells. Furthermore, EBIC is used to optimise the junction in the nanowires for immediate feedback on the carrier generation. The gathered information will extend knowledge about InP surface passivation and help to manufacture InP nanowire solar cells with higher efficiencies.
