In an effort to create a paintable/printable thermoelectric material, comprised exclusively of organic components, polyaniline (PANI), graphene, and double-walled carbon nanotubes (DWNT) were alternately deposited from aqueous solutions using the layer-by-layer assembly technique. Graphene and DWNT are stabilized with an intrinsically conductive polymer, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS). A 1 μm thick film, composed of 80 PANi/graphene-PEDOT:PSS/PANI/DWNT-PEDOT:PSS quads (QL) exhibits electrical conductivity (σ) of 1.88 X 10^5 S/m and a Seebeck coefficient (S) of 120 μV/K, producing a thermoelectric power factor (σS^2) of 2710 μW/(mK^2). This is the highest value ever reported for a completely organic material measured at room temperature. Furthermore, this performance matches or exceeds that of commercial bismuth telluride. These outstanding properties are attributed to the highly ordered structure in the multilayer assembly. The thermoelectric power output increased with the number of cycles deposited, yielding 8.5 mW at 80 QL for ΔT = 5.6 K. A simple thermoelectric generator was prepared with selectively-patterned, fabric-based system. The electric voltage generated by each TE device increased in a linear relationship with both ΔT and the number of TE legs, producing ~ 5 mV with just five legs and a ΔT of 9.5 K. This unique TE coating system is water-based and uses only organic components. For the first time, there is a real opportunity to harness waste heat from unconventional sources, such as body heat to power devices in an environmentally-benign way.

Large Volume Change in a Conjugated Polymer with Polar Side Chains During Electrochemical Doping 

Eleni Stavrinidou1, Johannes Gladisch1,2, Alexander Giovanitti3,4, Daniel Simon1, Iain McCulloch4,5 and Magnus Berggren1; 1Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, Norrköping, Sweden; 2Printed and Organic Electronics, RISE ICT/Acreo, Research Institutes of Sweden, Norrköping, Sweden; 3Department of Physics, Imperial College London, London, United Kingdom; 4Department of Chemistry, Imperial College London, London, United Kingdom; 5Physical Sciences and Engineering Division, KAUST Solar Center (KSC), King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia.

Conjugated polymers can be doped or de-doped electrochemically by exchange of ions with an electrolyte under the influence of an electric field. Their ability to conduct both electronic and ionic carriers in a tightly coupled fashion makes them attractive materials for bioelectronic and energy applications. During electrochemical doping dimensional changes occur in the polymer film due to ion and solvent movement but also changes in the polymer chain
Thermoelectrics for Harvesting Body Heat in Wearable Devices—Optimizing the System-Level Problem

Kedar Hippalgaonkar1, 2, 3
1Institute of Materials Research and Engineering, Singapore, Singapore; 2Materials Science and Engineering, Nanyang Technological University, Singapore, Singapore. 3Institute of Molecular and Materials Engineering, Nanyang Technological University, Singapore, Singapore.

Thermoelectric (TE) materials are able to transform heat into electrical power. Design and manufacturing of new materials for energy harvesting of low-grade waste heat have different design principles than traditional high temperature, high power applications. For example, low power wearable and Internet-of-Things (IoT) devices such as wireless sensors can benefit greatly from ambient power harvesters, where TE can play a key role. Especially interesting is the opportunity to provide a non-intermittent source of power, which only depends on the existence of a temperature gradient. In this talk, I will describe the state-of-the-art innovation in such low-power applications and demonstrate an energy-harvesting system that is integrated with energy storage. Further, such devices in the low temperature application space will have to rely on next-generation inorganic-organic materials and I will describe progress in understanding and designing such materials for high performance thermoelectrics. Finally, I will end by describing a new approach using Machine Learning (ML) algorithms coupled with novel experimental techniques that can provide a diagnostics tool for TE materials to determine not only Seebeck, electrical conductivity and thermal conductivity, but the underlying performance-limiting bulk and interface properties.
volume fraction (10%) of polymer as a binder for Bi$_2$Te$_3$-based n- and p-type micrograins. The thermoelectric performance of these threads was quantified using a home-built in-situ conductivity/Seebeck vise for calibrated temperature gradient and voltage drop with a pressure-control function to study the effect of lateral pressure on thread operation. The resulting threads showed electrical conductivity only 1 order of magnitude lower than the annealed sintered micrograin samples. A particle boundary model was introduced to explain the resulting energy barrier for charge transport as a consequence of charge depletion at the boundary. The threads showed a thermopower very close to that of the annealed sintered samples. To demonstrate the potential applications of the thermoelectric threads, woven thermoelectric fabric is designed to vertically harvest heat flux. Both n-type and p-type thermoelectric threads have been successfully fabricated in air ambient from 3D-inks made from thermoelectric semiconductor powders (Bi$_2$Te$_3$) embedded in a polymer matrix and extruded. A new double-sided insulating/conducting ribbon will be developed to interconnect a weave of such threads to create the thermoelectric fabric. Textile fabrication is inherently scalable, and weaving fabrics from looms of such thermoelectric threads will drive down manufacturing costs for large-scale production.

High Power Density Mico-Thermoelectric Generators for Powering Wireless Sensor Nodes Jian Zhang, Wenhua Zhang and Dongyan Xu; The Chinese University of Hong Kong, Shatin, Hong Kong.

Thermoelectric generators (TEGs) are promising for harvesting waste heat from the environment to power wireless sensor nodes in smart buildings. In this talk, I will share our recent research effort on developing non-flexible micro-TEGs by integrating pulsed electroplating with microfabrication processes. We systematically studied the effects of the pulsed electroplating conditions on the composition, microstructure, and thermoelectric properties of the electroplated Bi$_2$Te$_3$ thin films. Our results show that the thermoelectric figure of merit of the electroplated Bi$_2$Te$_3$ films can be enhanced by increasing the pulse off-to-on ratio, which is mainly due to the reduced thermal conductivity and the increased Seebeck coefficient. A maximum $ZT$ of 0.16 is obtained at the pulse off-to-on ratio of 50 at room temperature. Based on the fundamental materials research, we further developed cross-plane micro-TEGs on a SiO$_2$/Si substrate. The device consists of a total of 127 pairs of n-type Bi$_2$Te$_3$ and p-type Sb$_2$Te$_3$ thermoelectric pillars embedded in a SU-8 matrix. Both thermoelectric pillars and interconnectors are formed by electroplating, which is advantageous because of low parasitic electrical resistances. The micro-TEG we developed demonstrates a maximum power of 3 mW at a temperature difference of 52.5°C, corresponding to a power density as high as 9.2 mW cm$^{-2}$. The power density of our TEG is more than two times the highest value reported for the electroplated TEGs in the literature, which can be attributed to the low internal resistance and high packing density of thermoelectric pillars.

Compliant and Stretchable Thermoelectric Coils for Energy Harvesting in Miniature Flexible Devices Kewang Nan$^1$, Stephen D. Kang$^{2, 3}$, Kan Li$^4$, Yonggang Huang$^2$, Jeffrey G. Snyder$^2$ and John A. Rogers$^{6, 8}$; 1Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Applied Physics and Materials Science, California Institute of Technology, Pasadena, California, United States; 3Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 4Mechanical Engineering, Northwestern University, Evanston, Illinois, United States; 5Civil and Environmental Engineering, and Mechanical Engineering, Northwestern University, Evanston, Illinois, United States; 6Materials Science and Engineering, Biomedical Engineering, Neurological Surgery, Chemistry, Mechanical Engineering, Electrical Engineering and Computer Science, Northwestern University, Evanston, Illinois, United States; 7Simpson Querrey Institute and Feinberg Medical School, Northwestern University, Chicago, Illinois, United States; 8Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

With expediting trends in electronic device miniaturization, thermoelectric energy harvesting becomes increasingly valuable, especially in wearable technologies and sensors for the internet-of-things. However, it has been impossible to match the device thermal impedance with the natural heat gradient using the thin-film thermoelectric materials much needed for device miniaturization. This limitation has prevented thermoelectrics from competing as a harvester at small scale. Here, we propose and demonstrate an architectural solution to this dilemma, where thin-film thermoelectric materials are mechanically assembled into three-dimensional (3D) coil architectures. This approach not only allows thermal impedance matching but also multiplies the heat flow through the harvester, thus increasing the efficiency for energy conversion. We design and fabricate thermoelectric coils with silicon as the active material that achieve flexibility, scalability, and durability. An array of such coils produces a power of 2 nW, with calculated projections showing the orders-of-magnitude improvement up to a few µW by replacing silicon with state-of-the-art thermoelectric materials. Demonstrations of the idea open up long-waited paths to utilize thermoelectric thin films and provides strategies to interface hard thermoelectric materials with soft harvesting environments, such as those of the human body.

4:15 PM BM08.09.06/TP03.09.06
Flexible Photo-Thermoelectric Nanogenerators Based on MoS$_2$/Nanocomposites for Energy Harvesting Yannan Xie$^1, 2$; 1Institute of Advanced Materials, Nanjing University of Posts and Telecommunications, Nanjing, China; 2College of Energy, Xiamen University, Xiamen, China.

With the rapid growth of economy, the fossil fuel consumption has been sharply increasing to satisfy the energy demand, which results in global warming and environmental pollution. It is crucial to develop clean and renewable energy technology for the sustainable development of human society. Targeting at scavenging thermal energy, thermoelectric effect has been utilized to develop thermal energy harvesting technology. Compared to the pyroelectric energy harvester which has little energy output, thermoelectric devices have been widely recognized as more effective and efficient technologies which has been utilized in practical applications. However, how to harvest thermal energy by using thermoelectrics when the environmental temperature is spatially uniform without any gradients is still a crucial issue and needs to be conquered. The key challenge is to create a significant temperature difference ($\Delta$T) across the device which can act as driving force of thermoelectric generators.

In our living environment, in addition to the direct heat source, light source (such as the infrared light) can also provide thermal energy through the photothermal effect. Based on the photothermal effect and Seebeck effect, photo-thermoelectric generator has been rapidly developed for converting photo energy into electricity without a spatial temperature gradient in the environment. To generate a necessary $\Delta$T, the conventional approach is utilizing various bulky components such as a vacuum enclosure, condenser lens, and heat sink. Nevertheless, these extra modules will not only increase the weight and size of thermoelectric generators but also are unfavorable for the flexibility of the whole devices which is of great importance for wearable electronics. Therefore, developing novel photothermal materials and device structure is essential for the photo-thermoelectric nanogenerator (PTENG).

In this work, we report on a flexible photo-thermoelectric nanogenerator (PTENG) by hybridizing MoS$_2$/PU photothermal layer with tellurium (Te) nanowire based thermoelectric device. The MoS$_2$/PU film which is flexible and transferable exhibits excellent photothermal characteristics due to exceptional surface-area-to-mass ratio of MoS$_2$ nanoclusters. Te nanowire is chosen for the thermoelectric nanogenerator because of its reported outstanding thermoelectric properties, such as low thermal conductivity and a wide temperature range. By integrating the photothermal layer with thermoelectric device, the PTENG can absorb infrared light to form a temperature difference across the device. With this, a potential difference between
two electrodes can be established and used for electrical energy generation. Therefore, the PTENG can generate electricity without a spatial temperature gradient. Furthermore, the PTENG which is flexible and shape-adaptive can demonstrate great practical application of photo-thermoelectric energy harvesting for wearable electronics and implantable electronics.

4:30 PM BM08.09.07/TP03.09.07
Low-Cost Flexible Energy Harvesters Based on Transverse Thermoelectric Effects Radhika Prabhakar and Je-Hyeong Bahk; Electrical Engineering and Computer Science, University of Cincinnati, Cincinnati, Ohio, United States.

Considerable thermal energy is available for energy harvesting from diverse sources in our environment like industrial machines, heat engines and human bodies. This heat, otherwise wasted, can be converted to electrical energy by a thermoelectric energy generator and used to meet daily energy needs like battery charging, powering smart wearable devices or even enabling the Internet of Things. State of the art thermoelectric generators (TEGs) make use of the Bi$_2$Te$_3$ (bismuth telluride) thermoelectric alloys, which are inorganic, brittle, non-flexible, and require expensive processing. The TEGs are typically based on a longitudinal p-n structure, which is complex, both in terms of electrical connections and manufacturing. Moreover, such TEGs often feature a bulky heat sink to maintain high temperature differences between the hot and cold sides. These reasons limit their large scale use in ambient energy harvesting.

In this work we report a low cost, flexible TEG based on transverse thermoelectric effects. A transverse TEG consists of tilted multi-layers made of alternating metal and semiconductor materials. In such a device, a thermoelectric voltage can be generated in the direction perpendicular to the vertical temperature gradients, which makes the transverse structure suitable for planar devices. For our transverse TEG we use aluminum or nickel as the metal layers and carbon-nanotube (CNT)-polydimethylsiloxane (PDMS) composites as the semiconductor layers. Both materials are inexpensive with the TE composites being solution processable. For device fabrication the polymer composite solution is cast in between 3D-printed metal layers followed by air drying to obtain the transverse device. By filling the metal layer gaps partially with the polymer composite solution the upper portions of the metal layers are directly exposed to air at the cold side, thus acting as a fin type heat exchanger for lowering the cold side temperature by air convection. The use of flexible composites as the semiconductor material imparts flexibility to the TEG in one direction. It can therefore make good thermal contact with curved surfaces like hot water pipes, solar reflectors and even human skin, thus enabling TE energy harvesting from such surfaces. Transverse TEG architecture provides a number of degrees of freedom like the layer thickness, tilt angle, fin length, which can be varied to study the power generated. We present detailed thermoelectric properties of the CNT-PDMS polymer composites as well as its performance under bending tests. We also present a full range of experimental results of the fabricated transverse TEGs augmented with finite element simulations to optimize the device design for maximum power output.

4:45 PM BM08.09.08/TP03.09.08
Development of N-Type Single-Walled Carbon Nanotube Sheet with Excellent Air Stability Tsuyoshi Fujigaya1, 2; 1Kyushu University, Fukuoka, Japan; 2JST, Saitama, Japan.

Thermoelectric (TE) conversion is one of the most promising methods for the generation of cost-effective electricity. TE devices have applications in many fields especially microelectronics devices due to their simple device structures. TE generation using Seebeck effect requires both n-type and p-type TE materials for the efficient conversion; however, deterioration of n-type nature due to air oxidation has been the critical issue. Recently, we reported single-walled carbon nanotubes (SWCNT) sheet doped by 2-(2-methoxyphenyl)-1,3-dimethyl-2,3-dihydro-1H-benzimidazole (o-MeO-DBMI) showed n-type property and remarkable air-stability[1] We chose o-MeO-DBMI because of the following reasons; i) o-MeO-DBMI is stable under atmospheric conditions, ii) the cationic form of o-MeO-DBMI is also stable and, iii) n-doping of the other carbon materials such as fullerene and graphene has already been reported.[2,3] Here, we study the mechanism of the air stability of o-MeO-DBMI-doped SWCNT films by changing the doping level.

eDIPS (Meijo Nano Carbon, EC1.5) was used as SWCNT. SWCNT films were dipped in the 0.01, 0.1, 1.0, 10 and 50 mM ethanol solution of o-MeO-DBMI for 10 min and dried in vacuum at room temperature for 12 h. The time course of Seebeck coefficient of the SWCNT films doped with various concentration of o-MeO-DBMI solution was studied. It is noted that the films were kept under air condition at room temperature to evaluate the air stability of the o-MeO-DBMI-doped SWCNT films. Positive value of Seebeck coefficient for 0.01 and 0.1 mM doped films indicated n-type, and negative value for 1.0, 10 and 50 mM doped films showed n-type nature of the films. Interestingly, we found that Seebeck coefficient of 1.0 mM doped film changed to positive, while 10 mM doped film showed stable negative value. From above results, we conclude that the mechanism of the air-stabilization of n-doping is the passivation effect by the formation of o-MeO-DBMI layer onto the surface of SWCNT films.

storage at room temperature. This all-polymer “smart multisensor” fully printed on paper advances on the next generation low cost, disposable, noninvasive, multianalyte sensing wearable biomedical devices.

BM08.10.02 Porous Polymer Microneedles for the Sensing of Subcutaneous Interstitial Fluid Hiyuki Kai, Kumata Hiroki and Matsuhiro Nishizawa; Tohoku University, Sendai, Japan.

The microneedle array, a two-dimensional array of needles of a few hundred micrometers, penetrates skin in a minimally invasive manner, and they have been applied to transdermal drug delivery and sampling and analysis of subcutaneous interstitial fluid. Microneedles with different materials have been developed such as hollow silicon microneedles, hydrogel microneedles, and dissolvable microneedles. We have previously developed a porous polymer microneedle array using a polymer monolith of poly(glycidyl methacrylate). It combines continuous internal micropores to absorb water quickly and sufficient mechanical strength and tip sharpness to penetrate skin.

In this work, we fabricated proof-of-concept microneedle sensors using the porous polymer microneedles. We adopted two different strategies to integrate sensors into the micropores of the microneedles. (1) Electroless gold plating was applied to the surface of the micropores to obtain a porous microneedle electrode, and redox enzymes were immobilized on the electrode surface to conduct amperometric sensing. (2) Hydrogel that contains a boronic acid-based fluorescent glucose sensor was filled into the micropores to optically quantify glucose concentration of an analyte. These designs enable the sensors to quickly interact with analytes absorbed into the micropores. In addition, they do not require an extra step of measurement following the removal from skin, which potentially makes the continuous readout from the outside of the skin feasible.

BM08.10.03 High-Performance Triboelectric Nanogenerators Using Visco-Poroelastic Ion Pump Joo Sung Kim1, Heejae Hwang2, Han Wool Park3, Eunsong Jee1, Dukhyun Cho2 and Do Wun Kim1, Hanyang Univ., Seoul, Korea (the Republic of); Kyung Hee University, Yongin, Korea (the Republic of).

Recently, many attempts have been made to implement stretchable triboelectric nanogenerators (TENGs) that can be energy harvesting systems and self-powered electronic devices. There are several kinds of soft materials to enhance the power efficiency and power density of TENGs. Especially, ionic materials such as ionic hydrogels, which are capable of achieving electrical double layer (EDL) phenomena and polarization of ions, are regarded as a new platform to achieve high-performance and stretchable TENGs. A similar concept has been reported by using ionic materials as conductor and electrification layer. However, since free ions contained in the ion materials are able to carry electric charges, unlike conventional tribo-materials having dielectric characteristics, it is required to consider electrical characteristics and electrochemical properties of ionic materials.

In this talk, we describe a highly deformable and visco-poroelastic ion pump as a potential triboelectric channel with high power density and its impact on mechanical characteristics, it is required to consider electrical characteristics and electrochemical properties of ionic materials.

The family of two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides known as MXenes have received considerable attention for energy storage applications due to their favorable and tunable electronic and physical properties. MXenes have high specific capacitances1 due to their redox-active transition metal surfaces and when MXenes are fabricated into binder free, free-standing films they have high electric conductivity (>8000 S/cm).2 In addition to the intrinsic electrochemical properties of MXenes, their hydrophilicity allows formulation of functional inks that can readily be printed, spray-coated, or spin cast in any desired pattern, enabling the creation of MXene thin-film coatings that are ideal for applications that require microscale energy storage devices.

However, the traditional methods used to create electrodes from 2D materials for energy storage applications, namely vacuum assisted filtration, result in densely restacked films. This electrode architecture impedes electrolyte infiltration and transport in thick films (>10 μm), which has put a limit on the practical implementation of not only MXene electrodes, but other 2D materials like graphene and transition-metal dichalcogenides. For this reason, developing new methods for fabricating thick films using 2D materials is desirable, and in a recent study we have developed a technique for vertically aligning the 2D flakes of MXenes to create rapid, directional ion transport.3 By mechanically shearing a discotic lamellar liquid crystal phase of titanium carbide MXene (Ti3C2), we can produce electrode films that are hundreds of microns in thickness that show thickness-independent specific capacitance. Our approach for aligning 2D materials is not limited to MXenes and energy storage applications, this method can be modified to suit any 2D material and can be extended to any application where directional transport is desirable, e.g. catalysis and filtration systems.

BM08.10.05 A Finite Element Design of a Kirigami-Based Wearable Device for Human Joints Antonio Avila; Mechanical Engineering, Univ Federal-Minas Gerais, Belo Horizonte, Brazil.

Human skin of elbows, ankles and knees undergo considerable deformations during the body motion. Therefore, wearable devices (WD) for such regions shall be capable of sustaining these deformations while remaining into the elastic regime. Silicone rubber, e.g. polydimethylsiloxane (PDMS), is a natural candidate to be used as a substitute for such wearable devices. Unfortunately, most of PDMS have a limitation regarding the total elastic strain, which is in the
200-300% range. Moreover, due to these body part’s morphologies, these wearable devices not only have to undergo extreme large strains but they are also inhomogeneous. To be able to design a stretchable wearable devices for human joints, the ancient Japanese art of paper cutting, often known as Kirigami is applied to PDMS thin films doped with carbon nanotubes. The multi-walled carbon nanotubes were placed into the PDMS surface’s to create a conductive network. The Kirigami configuration is analyzed by a finite element method, where the hyper-elastic second order Ogden model is employed. The wearable device design two main constraints must be fulfilled, i.e. the large stretchability and the MWNT network continuity. Based on these conditions a finite element analysis was performed, where boundary conditions, such as number of cuts, its length and spatial distributions were varied. The main objective was to obtain a near optimum design. The numerical simulations indicate that elastic strains up to 900% can be achieved with effective elastic stress around 75% of the ultimate stress. From the Fracture Mechanics perspective, the Kirigami configuration introduces a increase on local stress field near the cut/crack tip. The MWNT surface distribution not only induces a local inhomogeneity but it also changes the stress intensity factors around the cut/crack tips. Experimental data and the ones obtained from the numerical simulations are in good agreement.

BMO8.10.06  Flexible Ferroelectric Electronic Skins with Ultrahigh Pressure Sensitivity and Linear Response over Exceptionally Broad Pressure Range Youngho Lee, Jonghwa Park, Soowon Cho, Young-Eun Shin, Changgi Baig and Hyunhyub Ko; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Flexible pressure sensors with a high sensitivity and linear response over a broad pressure range can simplify the wearable sensing systems without additional signal processing for the linear output, enabling device miniaturization and low power consumption. Here, we demonstrate a flexible ferroelectric sensor with ultrahigh pressure sensitivity and linear response over an exceptionally broad pressure range based on the material and structural design of ferroelectric composites with a multilayer interlocked microdome geometry. Due to the stress concentration between interlocked microdome arrays and increased contact area in multilayer design, the flexible ferroelectric sensors could perceive static/dynamic pressure with high sensitivity (47.7 kPa⁻¹, 1.3 Pa minimum detection). In addition, efficient stress distribution between stacked multilayers enables linear sensing over exceptionally broad pressure range (0.0013 – 353 kPa) with fast response time (20 ms) and high reliability over 5,000 repetitive cycles even at extremely high pressure of 272 kPa. Our sensor can be used to monitor diverse stimuli from low to high pressure range including weak gas flow, acoustic sound, wrist pulse pressure, respiration, and foot pressure with a single device.

BMO8.10.07  Triboelectric Energy Generator for Powering Implantable Electronics Hong Joon Yoon and Sang-Woo Kim; Sungkyunkwan Univ, Suwon, Korea (the Republic of).

A great challenge in research for powering or being self-powered implantable electronics, scavenging very limited biomechanical energy such as pulse by heart, respiration, circulation, is to generate extremely low electrical energy. Without technological breakthrough, energy harvester would not supply sufficient power to operate not only in vivo medical gadget, but charging rechargeable battery. Here, we demonstrate the use of external mechanical energy as non-invasive kinetic energy to transmit through human skin and trigger oscillation. We first show external mechanical energy driven very tiny oscillation inside the body is enough to induce micrometer scaled displacement of a biocompatible membrane and to generate electrical energy by contact electrification. Generated voltage and current values are 10 V and 500 μA which is almost 100 times higher than previously reported triboelectric generators. In addition, we use this approach to charge commercial Li-ion battery, resulting in charging rate of about 50 μC/s. Our results establish external kinetic triggers as powerful energy harvesting method in biomedical electronics research.

BMO8.10.08  Calculation of Polarization and Bound Charge Density Inside a Dielectric Material in Triboelectric Nanogenerators—Analytical and Numerical Study SeongMin Kim¹, Yohan Jeong² and Sang-Woo Kim¹; Sungkyunkwan University, Suwon, Korea (the Republic of).

We analytically calculated polarization and bound charge density inside the dielectric material in metal-to-dielectric–mode triboelectric nanogenerators (TENG) where the transferred charges are collected on the bottom metal via electrostatic induction from the triboelectric charges that are generated by frictional contact. This bound charge density is associated with the surface density of states (DOS), N(E). Two cases are considered here: i) for N(E) >> 1, it is calculated that the bound charge density is proportional to the dielectric constant and the work function difference between the two materials, but inversely proportional to the thickness of the dielectric material, the bound charge density is mostly proportional to the work function difference between the materials, and inversely proportional to the thickness of the dielectric material.

BMO8.10.09  Highly Sensitive Transparent and Flexible Pressure Sensors Based on ZnO Nanocrystals by All Solution-Process Hong Joon Yoon and Sang-Woo Kim¹; Sungkyunkwan University, Suwon, Korea (the Republic of).

Applications of pressure sensors have increased in popularity as they are used to measure human motion and monitor the industry. However, complicated and expensive processes and/or low sensitivity remained challenging issues. Herein, a simple and inexpensive process using Silver Nanowire (NW) and ZnO Nanocrystals (NCs) without lithography is developed to fabricate a transparent pressure sensor. ZnO NCs guarantee the transparency of the device and improve the sensitivity of the device while it is rugged on the surface. Device performance analysis with structural, chemical, and electronic characterization and conductive atomic force microscopy study reveal that hybrid nanostructure-based pressure sensor shows a sensitivity of higher than 90 kPa⁻¹, reliability and stability. Finally, we demonstrate that all sensors can be easily applicable to many fields such as wearable or attachable sensors by sensing a wide range of pressures.

BMO8.10.10  Flexible, Fiber-Shaped Supercapacitors with Roll-Type Assembly Seongil Yu and Heejoon Ahn; Hanyang University, Seoul, Korea (the Republic of).

A fiber-shaped supercapacitor with a unique roll-type configuration is developed by simply rolling polyaniline-coated carbon fiber bundle electrodes and using an H₃SO₄/polyvinyl alcohol gel electrolyte. The electrochemical performances of this device are characterized and compared with those of a twist-type fiber-shaped supercapacitor. The roll-type polyaniline-coated carbon fiber supercapacitor exhibits four times higher capacitance retention than the twist-type fiber-shaped supercapacitor at a high scan rate of 100 mV s⁻¹ and shows a gravimetric energy density of 2.97 Wh kg⁻¹ at a power density of 4 kW kg⁻¹, which is almost three orders of magnitude higher than that of the twist-type fiber-shaped supercapacitor (0.004 Wh kg⁻¹). The enhanced performance of the roll-type fiber-shaped supercapacitor is attributable to its unique roll-type configuration, which creates a short and consistent distance between the electrodes. The capacitance and voltage are tripled by simply connecting three roll-type fiber-shaped supercapacitors in parallel or series, respectively. In addition, the roll-type fiber-shaped supercapacitor shows excellent mechanical stability. The excellent performance of the roll-type fiber-shaped supercapacitor suggests its potential as a flexible energy storage device in portable and wearable electronics.
Textile-Permeable Conductive Inks for Electrophysiological Sensors on Garments

Textile-Permeable Conductive Inks for Electrophysiological Sensors on Garments

It is important to make soft and stretchable circuits for wearable biometric sensors, since human body has a curvilinear surface which dynamically moves and deforms. Textile is one of the ultimate wearable platform because of their mechanical flexibility, thermal properties and breathability originated from their porous structure. A seamless integration of electronics into the textile has been researched and it became a field of technology, so-called E-textile. Recently, researchers have achieved highly conductive and stretchable wiring on the textile by using metal plating and weaving, although those methods have challenges in patterning which are crucial for electronic circuits. Printing is an alternative method for fabricating conductive wirings on textile. However, it is difficult to achieve high stretchability more than 30% strain since the textile is porous and significant contours on the surface which make printed film susceptible to the cracking. In this work, we propose textile-permeable stretchable conductor which resulted in significant improvement of stretchability and cyclic durability of printed wiring. Specifically, a new type of ink that easily permeates textile substrate was developed, initial sheet resistance of printed wiring on textile was 0.06 ohm/sq, and increased only 70 times after stretching 450%. And resistance change after 100 cycles at 30% strain was less than 10 times while the resistance of printed trace on elastomer film increases 10^5 times. The ink is comprised of silver flakes, fluoroelastomer, and slow evaporating solvent (2-butoxyethoxy ethyl acetate). The key idea to realize stretchable wirings in textile is building conductive pathways inside of the fiber bundles by permeating ink deeply, instead of forming a thick film on the surface of the textile. We systematically investigated penetration of ink by changing evaporation speed and viscosity of ink, also optimized the composition of the ink. Finally, we demonstrate 8-channel EMG monitoring garment which can monitor muscle activity of upper body during the pitching motion of baseball pitcher and transmit the data wirelessly.

Electronic skins (e-skins) with high sensitivity to multidirectional mechanical stimuli are crucial for healthcare monitoring devices, robotics, and wearable sensors. Previously, numerous e-skins have been successfully demonstrated to improve the tactile sensing performance using various microstructure arrays. However, there have been no systematic studies of the effects of the microstructure geometry on force-induced microstructure deformation and the resulting force sensitivity and selectivity in response to multidirectional mechanical stimuli. To investigate the geometrical effects of microstructure arrays on force-sensing capabilities, we here present three kinds of piezoresistive e-skins based on carbon nanotube/elastomer composites with different surface microstructures (i.e., dome, pyramid, and pillar). In addition, we compared the experimental piezoresistive properties and finite-element simulations of changes in the contact area and localized stress distributions in the microstructures. Depending on the microstructure geometry, distinct variations in contact area and localized stress distribution are observed under different mechanical forces (i.e., normal, shear, stretching, and bending), which critically affect the force sensitivity, selectivity, response/relaxation time, and mechanical stability of e-skins. As proof-of-concept demonstration in healthcare monitoring applications, our e-skins are used for detecting various bio-signals including acoustic waves, breathing, and human artery/carotid pulse pressures. Unveiling the relationship between the microstructure geometry of e-skins and their sensing capability provides a platform for the future development of high-performance microstructured e-skins.

Smartphone Based Phage-Colorsensor to Detect Ovarian Cancer

Smartphone Based Phage-Colorsensor to Detect Ovarian Cancer

We developed phage-based colorimetric sensors to diagnose ovarian cancer. Ovarian cancer is known as a “silent killer” because its symptoms are minimal or very rare. The 5-year relative survival rate of ovarian cancer is higher than 90% if detected early, whereas drastically lowered to 40% when detected after stage III. Therefore, early diagnosis is critical for treatment and survival of the ovarian cancer. It has been known that serum and salivary CA125 and HE4 biomarkers were correlated in ovarian cancer patients. Therefore, we developed phage-biosensor to detect the CA125 and HE4 ovarian cancer biomarkers in saliva. We identified highly specific phages to CA125 or HE4 through high-throughput phage display technique. We then genetically engineered the phages to express CA125 and HE4 receptors on the major coat protein. Using the resulting engineered phages, we fabricated self-assembled matrices composed of quasi-ordered fiber bundle structures to exhibit tunable colors by self-templating assembly approach. Upon exposure of different concentrations of biomarkers, the multi-color phage matrices exhibited distinct color changes that can be correlated to colorimetric measurement. Furthermore, we used home-designed smart phone app to detect the biomarkers selectively and sensitively from the human saliva. We believe that our phage-based ovarian cancer biomarker detection approach will be useful for early detection of ovarian cancer and increase of the survival rate.

All Transparent-Stretchable Electrochromic-Supercapacitor Wearable Patch Device

All Transparent-Stretchable Electrochromic-Supercapacitor Wearable Patch Device

Electrochromic devices, that control transmittance of ultraviolet and visible light by electrochromism due to charge transfer, have been applied to low emission mirrors and energy saving systems by suppressing the internal temperature rise of the smart building system. Furthermore, electrochromic device can be used as a wearable healthcare device that detect harmful substances in human body as electric signals. For example, wearable electrochromic-chemical sensor technology have been developed by integrating a chemical sensor that detects resistance change by a target chemical component and an electrochromic device that generates a color change by electron movement. Wearable electrochromic devices have attractive functions and development possibilities that can be applied in everyday life however, the limitations of conventional electrochromic devices based on ITO-glass, which is brittle and required external electrical input did not overcome. All transparent-stretchable electrochromic-supercapacitor wearable patch devices with high electrochemical and electrochromic performance was fabricated to overcome the limitations of conventional electrochromic devices. All transparent-stretchable wearable patch device was consisted of transparent-stretchable low density silver nanowire embedded PDMS substrate, electrospunned WO₃ nanotube-PEDOT.PSS thin layer composite and transparent-stretchable Li ion-poly acrylamide based hydrogel electrolyte. Especially, the contact efficiency of WO₃, nanotube is considerably increased by even employing low density silver nanowire current collector. In addition, PEDOT.PSS thin overlayer was introduced to prevent the delamination of
WO₃ nanotube and offer enhanced coloration efficiency by dual electrochromic coloration. As a result, electrochemical energy capacity, electrochemical cycle reliability and electrochromic coloration efficiency were enhanced 20.6%, 7.0%, 12.0% by using WO₃ nanotube-PEDOT:PSS active materials. The electrochromic-supercapacitor wearable patch device capable of stretching-bending deformation and simultaneously electrochromic coloration-electrochemical energy storage with enhanced electrochemical-electrochromic properties was operated by integrated hydrogel electrolyte with high ionic conductivity, transparency and more than 80% elongation. Therefore, the fabricated all-transparent-stretchable electrochromic-supercapacitor wearable patch device is highly suitable for wearable electronic applications.

BM08.10.15
Polymer-Based Wearable Throat Microphone with High Sensitivity and Flat Frequency Response Singyoung Lee, Hyungsuk Lim, Woong Sung, Sangsik Park and Kilwon Cho; Pohang University of Science and Technology, Pohang, Korea (the Republic of).

Flexible and skin-attachable vibration sensors have been researched for wearable mechanosensors to recognize human voice, the most important bio-signal for communication. However, the reported sensors so far have shown low sensitivity and non-flat response. In this work, we present polymer-based wearable throat microphone that detects the neck skin acceleration, which has high and linear correlation with the voice pressure. Our device exhibits a high sensitivity over 4 V/Pa with flat frequency response over the voice band, which results from the polymer with low stiffness and low damping constant, and the hole-patterned diaphragm structure: Our device has superior skin conformity due to polymer-based ultrathin structure (< 10 μm). We successfully demonstrated voice security authentication and voice-controlled system notwithstanding ambient noise or use of mouth mask. This development enhances the utility of voice recognition application in human machine interface and Internet of Things area. In addition, the device enabled vocal healthcare monitoring conveniently even in noisy work places, by measuring quantitatively phonation time, voice frequency and pressure. This diagnostic application can provide a valuable monitoring approach for more than one-third of the working population, who use their voice as the primary tool.

BM08.10.16
Polymer Functionalized Carbon Nanomaterials for Flexible Tactile Sensors S. Ramaprabhu1, Krishnan Balasubramanian2, Vetrivel S1 and Ashwin Namb1; 1Department of Physics, Indian Institute of Technology Madras, Chennai, India; 2Department of Mechanical Engineering, Indian Institute of Technology Madras, Chennai, India.

In biomedical applications, sensors play a critical role in detecting and monitoring the human activities. In particular, tactile sensors are useful in detecting the external stimulus which is highly required in designing the biofunctional prosthetic system. In real time, prosthetic system may undergo different kinds of motion like bending, twisting and rotating. Functioning of tactile sensor in all these circumstances, demands high flexibility along with robustness. To design such system, fabrication of polymer nanocomposite is one of the ideal solutions. In this regard, researchers have started exploring novel nano materials like carbon nanotubes (CNT), graphene, nanowires and nanoparticles. Due to the exceptional electrical, mechanical and thermal properties, CNT and graphene can be used as nano-fillers in the polymer matrix substrate to enhance the electrical characteristics of the polymer nano-composites. Due to the high surface energy of the nano-fillers, it gets easily agglomerated in the polymer matrix and reduces the electrical conductivity of the film. Hence, it is essential to functionalize the nano-fillers to enhance the dispersion in the matrix and hence the electrical conductivity. In the present work, we analyzed the effect of two selective polymer functionalisation of multiwall CNT and hydrogen exfoliated graphene (HEG) fillers in a suitable polymer matrix and investigated the electrical conductivity of the polymer composites. The polymer functionalisation enhances the dispersion of the nano-fillers without introducing the defects in the structure and enhances the electrical conductivity. When force/strain is applied on the polymer nanocomposite, the established conducting networks is affected which leads to change in resistance, which is used as an electrical readout signal for actuating the prosthetic system. This sensor can be extended to the different applications like wearable electronics, robotics and structural health monitoring.

BM08.10.17
Surface Roughening with Iron Nanoparticles for Promoted Adhesion of Spin Coated Microsupercapacitor Electrodes Aarin Vyas, Fabio Cornaglia, Qi Li, Mazharul Haque, Volodymyr Kuzmenko, Anderson D. Smith, Per Lundgren and Peter Enoksson; Chalmers University of Technology, Gothenburg, Sweden.

In order to be able to use autonomous (wireless) miniaturized sensor nodes as part of the Internet of Things, integrating CMOS compatible sensor manufacturing technology with energy harvesting and energy storage devices would be a significant advantage. Supercapacitors are devices which store energy by charge accumulation (and/or transfer) at an electrode-electrolyte interface. Previous attempts at manufacturing microsupercapacitor electrodes for microsystem integration have required techniques such as laser scribing, doctor blade coating, or reactive chemical growth for their deposition. Replacement of these techniques with a simple CMOS compatible spin coating technique is therefore highly desirable. Although previous investigations establish fabrication of microsupercapacitors through spin coated graphene oxide (GO) layers, the non-uniformity in the spin coating of the electrodes remained a critical issue. Moreover, poor adhesion of the carbon material to the metal contact pads leads to the risk of low electrode retention in subsequent fabrication steps – resulting in low output power and energy performance. In this work, we present a CMOS compatible electrode deposition process for reduced graphene oxide (rGO) using spin coating. Additionally, we report improvements in adhesion and surface uniformity by employing surface roughening through Fe nanoparticle formation. A 4 nm thick Fe layer was evaporated on the bare Si/SiO₂ surface and then annealed at 500°C for 2 min, which magnifies the average mean surface roughness from 0.175 nm to 1.45 nm. After comparison with a sample without the Fe deposition and annealing, we see more than 300% improvement of surface coverage of the electrosynthesized rGO (from 19% to 79% of the surface covered), which was performed by image processing in MATLAB (ver. R2015b). A 1.80 µm thick electrode was deposited on the roughened surface, compared to the 1.01 µm accumulated on the non-roughened sample. A 40 sec sonication test of the spin coated electrodes revealed a 62% GO mass retention on the roughened sample in comparison to only 18% retention on the non-roughened device. We believe that these characteristics will directly translate to better electrochemical performance for the final microsupercapacitor devices which will be demonstrated at the conference.

BM08.10.18
A Solution Processable Conjugated Polymer for Direct Metabolite Sensing and Energy Powering Device Georgios Nikiforidis, David Ohayon and Suhika Inal; KAUST, Thuwal, Saudi Arabia.

Biosensors and biosensing protocols can detect a wide range of compounds, sensitively and selectively, with their application range extending from security and health care for point-of-care analyses of diseases to environmental safety. Since the first implantation of a pacemaker in 1960, tremendous efforts have been made to develop small power-supply medical devices for environmental safety, healthcare monitoring, neural disorders and hearing loss. Amongst them, biofuel cells have attracted significant attention due to their ability to convert the energy of metabolism into electricity. Unlike other conventional fuel cells, biofuel cells find their substrate directly in biofluids, where the metabolite of choice is abundant, cost efficient and offers a clean source of energy.
Herein, we present a novel enzymatic biofuel cell design, based on an n-type semi-conducting polymer where the anode creates current in the presence of metabolites in the solution. Due to the specific design of the polymer structure, enzymes are able to adsorb on the surface of the polymer film, avoiding the tedious processes of enzyme immobilization and leading to a mediator-free system. Moreover, since the power output of the cell is directly dependent on the metabolite concentration, the enzymatic biofuel cell acts itself as a biosensor. The polymer based (i.e biocompatible) membrane-less biofuel is simple and scalable. The power output of this novel n-type polymer-based biofuel cell (626 mW cm⁻²) outperforms other systems reported. Finally, the power delivered from the proposed biofuel cell can be collectively implemented to measure multiple analytes. This design paves the route of self-powered multi-analyte sensors for continuous healthcare monitoring.

BM08.10.19
Aloe Vera-Based Conducting Polymer Electrodes for Transcranial Electrical Stimulation Jeremy Savarir1, Georgios Spyropoulos1, Jennifer Gelinas3, Eleni Stavrinidou2 and Dion Khodagholy1; 1Columbia University, New York, New York, United States; 2Laboratory of Organic Electronics, University of Linköping, Linköping, Sweden.

Transcranial electrical stimulation (TES) is an emerging neurostimulation technique. It is minimally invasive and utilizes electrodes on the surface of the skin or skull, avoiding damage to brain tissue. However, the poor mechanical contact combined with high electrochemical impedance of the metal-body interface mandates high power stimulation protocols for effective interventions. As a result, TES has poor spatial resolution and anatomical specificity. We hypothesize that improving the interface between the stimulating electrode and body would result in lower stimulating power and better localization of electric stimulation. We developed TES electrodes that consist of a standalone composite film based on aloe vera hydrogel and poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS). The aloe vera hydrogel matrix provides unique properties to the film including conformability, softness when in a hydrated state, and strong adhesion with the surface of the skull after dehydration. In parallel, PEDOT:PSS ensures high conductivity and a low skull-electrode interface impedance, enabling efficient ion-to-electron conversion. The hydrogel-based electrodes were implanted on the surface of the rat skull, where SEM images of the skull-electrode interface demonstrated a conformable contact, highlighting its efficient mechanical interface. The effect of film composition and surface area on the electrochemical impedance were characterized and compared to a conventional TES electrode, and a significant reduction in impedance and increase in charge capacity was observed. The hydrogel-based electrodes did not require any additional adhesive to attach to the surface of the rat skull, forming an in vivo TES-based, closed-loop system for detection and stimulation of interictal epileptiform discharges (IED). Efficacy and stimulation thresholds were determined in vivo electrochemical impedance spectroscopy and power titration, and comparison was made to conventional metallic electrodes. Overall, such films demonstrated high stability, biocompatibility, and spatial resolution for transcranial stimulation and hold a great promise in improving the efficacy of TES as a non-invasive intervention for neuropsychiatric disorders.

BM08.10.20
Patternable Nano-Cracked Strain Sensor Based on One-Step Laser Heat Encapsulation Chan Park, Hyunsuk Jung, Hyunwoo Lee, Hong Sung Uk, Hyonguk Kim, Seong Kyung Hong and Seong Jin Cho; Department of Mechanical Engineering, Chungnam National University, Chungnam, Korea (the Republic of).

Skin mountable or wearable electronic devices have recently grown in popularity due to their numerous advantages in the context of human–machine interactions. Despite the improved performance of recently developed flexible and stretchable strain sensors, performance degradation caused by a change in external environmental conditions such as humidity and dust is a critical barrier to practical use. Here, we report a benefits of highly stable crack-based strain sensor using a novel laser heating encapsulation method optimized for thin film structure. first, unlike other encapsulation methods such as liquid polymer, multi-layer, resin, bar sealing, and laser sealing, it is possible to fabricate the patternable, cutting, and bonding of sensors without complicating one-step. Second, the novel encapsulation process is an economical process because it does not require any additional materials such as PDMsPoly(dimethylsiloxane), resin, film. Third, it does not adhere directly to the metal thin film, so the performance does not deteriorate. Since the part to be bonded is the edge to which the laser is irradiated, there is no influence on the metal. Finally, we evaluated the performance of the sensor after inserting sensor in water, and confirmed the possibility of encapsulation by comparing the performance of the sensor encapsulated in dust state and detergent state and the bare sensor. We believe that our sensor and encapsulation process will be useful in environments that need to be controlled by shape, and in environments such as underwater conditions motion monitoring where there are many foreign substances.

BM08.10.21
MXene Enables Wearable Energy Storage Shayan Sevedin1, 2; Si (Alex) Qin1, Jizhen Zhang1, Zhiyu Wang1, Raquel Ovalle-Robles1, Ray H. Baughman1, Yury Gogotsi2 and Joselito Razal1; 1Institute for Frontier Materials, Deakin University, Geelong, Victoria, Australia; 2A.J. Drexel Nanomaterials Institute, Drexel University, Philadelphia, Pennsylvania, United States; 3Nan-Science & Technology Center, Lintec of America, Richardson, Texas, United States; 4Alan G. MacDiarmid NanoTech Institute, The University of Texas at Dallas, Richardson, Texas, United States.

A recently discovered family of 2-D early transition metal carbides or carbonitrides called “MXene” has presented a distinct combination of metallic conductivity, outstanding electrochemical properties, and hydrophilic behavior. MXenes have been used to prepare films, papers, and composites with electrical conductivity of up to ~10,000 S cm⁻¹ and volumetric capacitance of up to ~1,500 F cm⁻³, rivaling existing materials for energy storage applications. To date, however, approaches for preparing MXene-based fibers or yarns for wearable applications have been relatively unexplored. Small sheet size (<2 µm), weak inter-sheet interactions, and lack of efficient processing have made it challenging to fabricate MXene-based fibers or yarns. Here, we present strategies to achieve fibers or yarns from the most prominent member of MXene family (Ti₃C₂). We first demonstrate MXene’s potential in fabricating high-performance yarn supercapacitors by coating MXene on conductive carbon fiber bundles. The MXene-coated yarn supercapacitor device (at mass loading of 2 mg cm⁻²) showed a high length capacitance of ~123 mF cm⁻² which is higher than the literature reports (typically lower than 100 mF cm⁻²). We then produce MXene-based fibers using a wet-spinning technique by taking advantage of the templating role of liquid crystalline (LC) graphene oxide (GO). We show that the favorable interactions of GO and MXene flakes result in the preservation of the LC property of the GO dispersion at an extremely high MXene content of ~88 wt. %, a key to its fiber processing. The MXene-based fiber demonstrates excellent flexibility and a high volumetric capacitance of ~341 F cm⁻³. By employing a bisscaling technique that traps MXene nanosheets within carbon nanotube yarn scrolls, we achieve yarns that are predominantly composed of MXene (containing up to ~98 wt. % MXene). This MXene-based yarn provides an areal capacitance of as high as ~3,188 mF cm⁻² (volumetric capacitance ~1,083 mF cm⁻³), which exceeds the previously recorded performance for any fiber or yarn supercapacitor electrode. When fabricated into a yarn supercapacitor device, the asymmetric electrode configuration reach a maximum energy and power densities of ~61.6 mWh cm⁻³ and ~5,428 mW cm⁻³ respectively. We show that the MXene-based fibers and yarns are useful for powering small electronic devices when knitted or woven into a textile. The MXene fibers and yarns developed in this work, introduce new classes of fibers and yarns from an emerging family of 2-D nanomaterials, and are excellent candidates for integration with textile-based electronics to meet the energy demands of future wearable devices.

BM08.10.22
Chemically/Biochemically Enhanced Nanoelectronic Gas Sensor for Airmen Performance and Protection Yen Ngo1, 2, Taneka Littlejohn1, Michael
Air Force interest in wearable sensors for continuous force protection and human performance monitoring require airborne chemical/biochemical sensors with high sensitivity, selectivity and specificity. Additionally, these sensors must be both portable and energy-efficient for continuous deployment. Sensors with all of these attributes are currently unavailable in commercial off-the-shelf sensors. Of these challenges, specificity is particularly challenging, especially in the presence of the large number of non-specific analytes found in human/environmental field samples. Increasing the affinity and/or specificity of the Chemical Recognition Elements (CREs) will benefit the sensor response to the target, leading to a corresponding enhancement of not only the signal to noise ratio, but also a significant reduction in sensor response time and non-specific interferences. Based on nature’s olfactory receptor-like concept, we demonstrated how a bio-inspired CRE acts as the “sensing material” which can selectively bind to the target chemical. The CRE’s influence on enhancing the sensitivity and selectivity of a nanoelectronic/electrochemical sensor is discussed in this talk. In addition, we will discuss other, future detection strategies we are pursuing for an airborne simulant chemical warfare agent.

BM08.10.23

Highly Sensitive Pressure Sensor Based on Baking-Like Foaming Process for Wearable Human Activity Monitoring Device

In this study, we present highly sensitive pressure sensor fabricated by simple and fast baking-like foaming process. The mixture of PDMS and Ecoflex is used to form an elastomeric insulator of pressure sensor. In order to introduce microporous structure in the insulator, NaHCO₃ and CH₃COOH are blended as pore precursors in PDMS/Ecoflex. Since NaHCO₃ and CH₃COOH are used even for food, they are biocompatible and easy to use. While curing the elastomeric mixture, NaHCO₃ and CH₃COOH chemically react and produce CO₂ gas. All the process to fabricate the insulator are completed within 1 hour. Flexible electrodes are made of PDMS coated with AgNW, and two electrodes are separated by the insulator. The pressure sensors will be electrically characterized by a capacitance versus pressure measurement system.

BM08.10.24

Integrating Optically Actuated Liquid Crystal Elastomer Fibers into Textiles

Flexible physical sensors that can replace human skin or interface human to robots have been attracting many interests over last several decades, as revealed by the outstanding developments in various applications, such as artificial electronic textile/skin, motion monitoring, and personal healthcare. Such physical sensors are classified mainly by the signal to be measured, such as pressure, strain, temperature and humidity. Among the various physical sensors, the pressure sensor can detect the pressure generated by human-body activity, which is distributed in low-pressure regimes (<10 kPa) and medium-pressure regimes (10-100 kPa). The pressure can be detected typically by three types of transduction mechanisms, such as piezoresistivity, piezocapacitance and piezoelectricity, converting pressure stimuli into electrical signals. The piezocapacitive pressure sensors are normally composed of an elastomeric insulating polymer, such as polyurethane, polydimethylsiloxane (PDMS) and Ecoflex, sandwiched between the two conducting plates, and preferred to detect wide pressure range up to about 100 kPa. When the pressure is applied to the surface of sensors, the thickness of insulator is reduced, causing the increase in capacitance. Therefore, it is necessary for the elastomeric insulator to be deformed sensitively according to the external pressure. For that intention, microstructured, porous, or air-gap embedded form have been typically suggested for high sensitivity at the low-pressure regime. However, although those sensorsshave excellent sensitivity, they have a relatively narrow pressure sensing range. Porous structures were conventionally fabricated by hard-template/etching and phase separation, which are highly time-consuming processes. In this study, we present highly sensitive pressure sensor fabricated by simple and fast baking-like foaming process. The mixture of PDMS and Ecoflex is used to form an elastomeric insulator of pressure sensor. In order to introduce microporous structure in the insulator, NaHCO₃ and CH₃COOH are blended as pore precursors in PDMS/Ecoflex. Since NaHCO₃ and CH₃COOH are used even for food, they are biocompatible and easy to use. While curing the elastomeric mixture, NaHCO₃ and CH₃COOH chemically react and produce CO₂ gas. All the process to fabricate the insulator are completed within 1 hour. Flexible electrodes are made of PDMS coated with AgNW, and two electrodes are separated by the insulator. The pressure sensors will be electrically characterized by a capacitance versus pressure measurement system.

BM08.10.25

Inkjet Printing E-Textiles for Flexible Electronics and Wearable Devices

The use of printed electronics on textile platforms have led new advancements in wearable technology, becoming one of the most appealing routes for e-textile fabrication. However, limitations are remained in high processing cost, low resolution in pattern designs, and undesirably significant change in surface characteristics of the textile materials. Albeit inkjet printing is an alternative technique to solve the aforementioned challenges in fabricating e-textiles, nozzle clogging is one of the most significant challenges in terms of printing nano- and micro-particle based inks due to small nozzle diameters.
<100 μm in the inkjet system. In this study, we introduce a novel technique of inkjet printing e-textiles for wearable technology applications utilizing particle-free, reactive silver inks. The reactive silver inks minimized nozzle clogging in the inkjet system with low viscosity around 17 cps, requiring subsequent annealing process to reduce silver ions and form thin layers around 100 nm on fiber substrates. Multiple layers of ink deposition passes and in situ annealing process provides a unique method for tailoring the electrical conductivity, from >10KΩ/sq to 0.1 Ω/sq for up to 15 print passes on polyethylene terephthalate (PET) single-jersey knit textiles. Wash fastness of the inkjet printed e-textiles was tested based on AATCC TM61, and the result showed electrical conductivity maintained until 25 wash cycles without further encapsulation, implying enhanced performance compared to previous studies on e-textiles. In addition, unique structural characteristics of textiles were utilized to understand the use of this process toward wearable strain sensors. For example, conductive patterns printed as course direction showed higher electrical conductivity than wale direction, derived from the different geometrical structures of the knit loops. The electrical resistance of the sensors decreased with increase in strain and recovery of electrical resistance was measured with release from elongation. This study demonstrates novel materials and processing technologies in inkjet printing e-textiles for wearable technology applications.

BM08.10.26

**Nanoparticle Sensitized Direct Conversion Organic-Inorganic Hybrid X-Ray Sensors**

Imalka Jayawardena1, Hashimi Thirimanne1, Andrew Nisbet1,2, Indrachapa Bandara R M1, Chris Mills1 and Ravi Silva1; 1University of Surrey, Guildford, United Kingdom; 2Department of Medical Physics, Royal Surrey County Hospital NHS Foundation Trust, Guildford, United Kingdom.

X-rays are a critical tool which finds applications in a number of different sectors including medical diagnostics and treatment, homeland security and non-destructive evaluation among many others. The modern genre of detectors or imagers used in this regard are based on a flat panel architecture whose geometric restrictions necessitates either complicated arrays of X-ray sources or a significant level of post-computational activities. For example, cadmium telluride or even single crystal perovskites often requires high quality single crystals that are several millimetres thick.

Organic semiconductors have emerged as a route towards enabling system that have the potential to address factors such as cost and geometric restrictions placed by conventional semiconductor systems. However for X-ray detecting applications, the X-ray attenuation or stopping power enabled by organics is significantly low for satisfactory X-ray detection.

Herein, we introduce a direct conversion X-ray sensing architecture[1] based on the incorporation of high Z bismuth oxide nanoparticles within a ~20–30 μm thick organic bulk heterojunction system consisting of hole transporting polymer [mainly, poly(3-hexylthiophene) or P3HT] and electron transporting small molecule [mainly, [6,6]-Phenyl-C71-butyric acid methyl ester or PC70BM]. These hybrid detectors demonstrate high sensitivities of ~1.7 mC mGy⁻¹ cm⁻² when irradiated under a 50 kV X-ray source which are ~1-2 orders of magnitude higher in terms of sensitivity obtained using other emerging and enabling X-ray sensing materials such as perovskites. We also expand the application of these hybrid X-ray sensors to the Hard X-ray energy range by carrying our measurements under a medical Linear Accelerator (LINAC). Noticeably, this hybrid detector architecture enables a sensitivity of ~ 60 μC mGy⁻¹ cm⁻² which exceeds previous reports on direct and scintillator based X-ray detectors [2,3]. Notably, such high sensitivities are enabled at low bias voltages of ~10V which indicates the potential of this new detector architecture for real time radiation monitoring in a real world environment.

**Applying the Double Network Principle on the Macroscale to Toughen Soft Materials**

Takashi Nakajima1, 2, Takayuki Nonoyama1, 2, Takayuki Kurokawa1, 2, and Jian Ping Gong1, 2; 1Graduate School of Life Science, Hokkaido University, Sapporo, Japan; 2Faculty of Advanced Life Science, Hokkaido University, Sapporo, Japan; 3Soft Matter GI-CoRE, Hokkaido University, Sapporo, Japan.

Double Network (DN) gels possess high toughness and strength, in significant contrast to traditional gels which are brittle and weak. DN gels have a structure that consists of two interpenetrating networks, where the “1st network” is hard and brittle, while the “2nd network” is soft and ductile. When force is applied to the DN gel, the 1st network fractures, prior to global fracture of the composite structure. The 1st network structure therefore contributes sacrificial bonds, which break efficiently to dissipate energy and avoid stress concentrations. This results in the dramatic increase in toughness seen in DN gels. This toughening mechanism can be generally referred to as the DN principle, and the DN principle is known to hold without depending on chemical species. The goal of this research is to understand the breadth of the DN principle, and attempt to make macroscale composites which match the design principles of DN gels. We aim to reproduce the sacrificial bonds of the 1st network by changing the material and the scale, and we have designed various structures that greatly influence the energy dissipation of the composites. Samples were fabricated by first 3D printing a rigid grid that acts as the 1st network, and embedding it in silicone rubber (matrix) which is used as the 2nd network. The mechanical properties and internal fracture behavior of the obtained composites were evaluated by uniaxial tensile tests. Despite different materials and scale, we can see influence of the DN effect on the mechanical properties. Specifically, we see increased stiffness and energy dissipation. When the composite is stretched, the 1st network is loaded imparting high stiffness, but quickly fractures at low strain. The stress then transfers to the 2nd network, which builds force with increased stretching, until the 1st network again fractures. This cycle is repeated until all sacrificial bonds are consumed. This indicates that the sacrificial bonds can be reproduced on the macroscale. From this work, we find that the internal fracture behavior of composite changes as the fracture force relationship between the grid and the matrix varies. Our results show that when the fracture force of the matrix exceeds that of reinforcing grid, multistep internal fracture occurs, dissipating significant energy. When the fracture force of the reinforcing grid exceeds that of the matrix, brittle fracture occurs, resulting in minimal energy dissipation, even less than the neat matrix without reinforcement. Understanding these design parameters will help develop new composite materials useful for future applications in biomaterials and soft robotics.

SESSION BM08.11: Flexible/Wearable Energy Storage I
Session Chair: Renkun Chen
Thursday Morning, November 29, 2018
Sheraton, 2nd Floor, Grand Ballroom
Reduced Graphene Oxide—Aramid Nanofiber Capacitors for Structural Energy and Power. Jodie Lutkenhaus1, James Boyd1, Dimitris Lagoudas1, Micah Green2 and Haleh Ardebili2; 1Texas A&M University, College Station, Texas, United States; 2University of Houston, Houston, Texas, United States.

Structural energy and power systems offer both mechanical and electrochemical performance in a single multifunctional platform. These are of growing interest because they potentially offer reduction in mass and/or volume for aircraft, satellites, and ground transportation. The long-term vision is to combine the mechanical properties of structural composites with the energy storage properties of batteries or capacitors. However, there is a natural tradeoff between mechanical and energy storage properties, such that it remains difficult to synergistically optimize both. To this end, flexible graphene-based supercapacitors have attracted much attention due to their extraordinary mechanical and electrical properties, yet they suffer from poor strength. This problem may be exacerbated with the inclusion of functional guest materials, often yielding strengths of less than 15 MPa. Here, we show that reduced graphene oxide paper supercapacitor electrodes containing aramid nanofibers as guest materials exhibit extraordinarily high tensile strength (100.6 MPa) and excellent electrochemical stability (Kwon, S. et al. ACS Nano 11 (7), 6682-6690 (2017)). This is achieved by extensive hydrogen-bonding and π-π interactions between the reduced graphene oxide sheets and aramid nanofibers. Aramid nanofibers are the nanoscale version of Kevlar, which is known for its exceptional mechanical properties and use in bullet-proof vests. The tradeoff between capacitance and mechanical properties is evaluated as a function of aramid nanofiber loading, where it is shown that these electrodes exhibit multifunctionality superior to that of other reduced graphene oxide-based supercapacitors. We anticipate these composite electrodes to be a starting point for structural energy and power systems that harness the mechanical properties of aramid nanofibers. Our future work, which includes an informatics-driven assessment of the system as well as functionalization effects of the reduced graphene oxide sheets will also be discussed.

Flexible All Organic Batteries Based on Conducting Redox Polymers. Christian Strietzel, Rikard Emanuelsson, Maria Stromme and Martin Sjödin; Nanotechnology and Functional Materials, Department of Engineering Sciences The Ångström Laboratory, Uppsala University, Uppsala, Sweden.

Batteries consisting of naturally occurring organic materials can be envisioned as sustainable alternatives to conventional metal-based batteries, thus avoiding the negative environmental impact associated with the production and recycling of the latter. In this way the negative environmental impact of the constantly increasing demand for secondary batteries can be decreased. Apart from being fully organic, such batteries also open up for flexible battery designs as they can be produced in a roll-to-roll process and are anticipated to be viable in a broad range of applications as energy supplies in innovative flexible electronics designs. In the current work, fully organic batteries are realized utilizing conducting redox polymers (CRPs) as electrode materials. CRPs combine the high charge storage capacity of a redox active pendant group (PG) with the conduction properties of a conducting polymer (CP) backbone, both to reduce the need for addition of conductive carbon black and increasing the stability of the PG redox conversion in a battery setup. The first results from a fully organic, aqueous battery based on CRP electrode material are presented. Challenges and possibilities of this type of battery in flexible battery designs are discussed.

Reduced Graphene Oxide—Aramid Nanofiber Capacitors for Structural Energy and Power. Jodie Lutkenhaus1, James Boyd1, Dimitris Lagoudas1, Micah Green2 and Haleh Ardebili2; 1Texas A&M University, College Station, Texas, United States; 2University of Houston, Houston, Texas, United States.

It is critically important to develop miniature energy storage and conversion devices in modern electronics, e.g., for portable and wearable electronic facilities. Here a novel family of energy storage and conversion devices as well as their integrated devices in 1D configuration are carefully discussed with unique and promising advantages such as lightweight and weaveable compared with the conventional planar architecture. For the energy conversion devices in 1D configuration, fiber-shaped dye-sensitized solar cells, polymer solar cells and perovskite solar cells are covered. For the energy storage devices, fiber-shaped electrochemical capacitors, lithium ion batteries, lithium sulfur batteries, lithium air batteries and zinc air batteries are carefully investigated. The main efforts will be made to highlight the recent advancement in the electrode material, device structure and property extension.

Thermally Chargeable Supercapacitors with Charging and Discharging Cycles for Wearable and IoT Electronics. Angela Mohammed Abdul Mageeth, Myunghwan Jeong and Choongho Yu; Texas A&M University, College Station, Texas, United States.

Thermally chargeable planar supercapacitors are good candidates for energy harvesting and storage in wearable and internet-of-things (IoT) electronic devices. We report a graphene oxide based supercapacitor which can be thermally chargeable and has good areal capacitance and charge storage capability in conjunction with a shape memory polymer (SMP) to create a device operating in a cyclic manner having thermal charging and discharging cycles. The supercapacitor has reduced sulfate graphene oxide electrodes fabricated by laser irradiation on a film of graphene oxide over PET substrate using a 3D printer with laser diode assembly. Graphene oxide with H2SO4 acts as separator/electrolyte for the super capacitor. The fabricated supercapacitor employs the Soret effect as the transport mechanism, which results in high thermoelectric voltage. The shape memory polymer was prepared from EPON 826 resin with neopentyl glycol diglycidyl ether (NGDE) added at 1:1 molar ratio to have a glass transition temperature just above room temperature. The SMP after fabrication was casted onto a rubber mold of desired shape made by 3D printing and cured to impart the final shape. An array of supercapacitor specimen modules were placed over the SMP film connected in series or parallel depending on the voltage and current requirements of the device application. Temperature gradients applied across the two ends of the SMP film were used for thermal charging, and a shape change was utilized for discharging when the applied temperature gradient raised the temperature of the SMP. The mechanism developed here can be easily integrated into various devices operating intermittently with low power consumption.

Design of A Flexible and Stretchable Full-Cell Lithium-Ion-Battery Based on Hydrogel Electrolyte and Polymer Composite Current Collector. Xi Chen, Long Pan, Huijian Huang and Markus Niederberger; Laboratory for Multifunctional Materials, Department of Materials, ETH Zurich, Zurich, Switzerland.

We designed a flexible and stretchable thin film battery with potential application in wearable devices and flexible electronics. A polymer electrolyte is prepared by utilizing the swelling behavior of a cross-linked hydrogel, which allows the water contained in the network structure of the polymer chains to be replaced by the concentrated aqueous solution of the lithium salt. A high ionic conductivity of 10^{-1} S/cm is achieved at room temperature, which is comparable to the typical liquid electrolyte and about 100-1000 times higher than the conventional polymer gel electrolytes. The outstanding flexibility and stretchability of the hydrogel are also preserved after the salt incorporation. The ultra-high lithium salt concentration successfully broadens the stability voltage window of the hydrogel electrolyte to about 3.0 V, ensuring a good energy density of the battery. Being limited by this window, a rational material screening process is performed and LiMn2O4-Fe2O3 is selected as a proper electrode pair which can reach the optimized performance. Instead of using copper or aluminum foil, a flexible and stretchable current collector is fabricated with adequate conductivity to ensure the realization of the overall targeted
MXene-Coated Cellulose Based Yarns for Wearable Supercapacitor Applications

Ti$_3$C$_2$ MXene, the most widely studied MXene in the family to date, has been incorporated into yarn fibers to provide the pathway for the electrons, and carbon black (CB) particles that lie around the joint location of the CNT can benefit the preservation of the electronically connected status of the CNT network while stretching. A phase-inversion membrane forming process is conducted to prepare the composite film with a porous structure, which can further enhance the conductivity upon strain. In-situ tensile and resistance tests show that the composite possesses a high Young's modulus as well as a low sheet resistance of about 80 Ω/sq at the strain-free status, which increases to only 200 Ω/sq at 100% strain. The active materials are directly deposited onto the porous surface of the current collector membrane to achieve a strong adhesion without any powder peeling off during stretching. To fabricate the full cell, the hydrogel electrolyte and the current collector deposited with anode and cathode powders are sandwiched and treated with a moderate heating process that results in a good contacting. The laminated thin film is then sealed inside a PDMS packaging. The charge/discharge cycling and impedance of the full cell are tested in bent, rolled, folded, twisted and stretched (up to 200% elongation) states, respectively.

SESSION BM08.12: Functional Materials and Devices with Energy Harvesting and Storage I

10:15 AM BM08.12.01
MXene Fibers for Wearable Energy Storage, Harvesting and Sensing
Simge Uzun1, Ariana S. Levitt1, Mohamed Alhabeb1, Genevieve Dion2 and Yury Gogotsi3; 1Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Design, Drexel University, Philadelphia, Pennsylvania, United States.

Two-dimensional (2D) metal carbides, known as MXenes, have recently attracted much attention due to their unique combination of properties, including high metallic conductivity (up to 10,000 Scm$^{-1}$ as a free-standing film), excellent mechanical properties, electrochemical activity, and chemical stability. As such, MXenes are promising for a diverse range of wearable applications, including energy storage, harvesting, sensing, and electromagnetic interference (EMI) shielding. These applications require the development of highly conductive fibers that are well-suited for dynamic environments, meaning that the fibers are light-weight, flexible, and durable.

Ti$_3$C$_2$ MXene, the most widely studied MXene in the family to date, has been incorporated into yarns via a variety of methods, including dip-coating, drop-casting, and electrospinning. Using these fiber-processing methods, MXene fibers can be produced with tunable properties, such as fiber diameter, which can range from the nano-scale via electrospinning to the micro-scale, via wet-spinning. Not only have MXenes demonstrated unique properties on their own, but they have also been incorporated into a variety of polymer matrices and mixed with other nanomaterials, such as carbon nanotubes (CNTs) and graphene oxide (GO) and processed into composite fibers. These MXene composite fibers have shown enhanced mechanical, thermal, and electrochemical properties. This talk, an overview of the methods developed to process MXenes into fibers will be presented, in addition to their electrochemical, electronic, and mechanical properties. The potential applications of these fibers in wearable applications, such as energy storage, will be discussed.

10:45 AM BM08.12.02
Colloidally Synthesized Nanomaterials as Building Blocks for Functional Fibers
Vida Jamali1, Farnaz Niroui1, Matteo Pasquali2 and A. P. Alivisatos2; 1University of California, Berkeley, Berkeley, California, United States; 2Rice University, Houston, Texas, United States.

Smart fabrics that combine traditional clothing with functional devices are a topic of a growing field of research with a broad range of applications in areas including healthcare, sports and internet of things development. Two common approaches for producing smart fabrics are 1) to adhere fabricated devices on top of a pre-woven fabric, and 2) to develop devices in form of fibers that can be then integrated into large area textile. The latter approach allows us to combine fibers with different functionalities into a large area fabric showing a collective complex functionality. Functionality of the fibers can be tuned using a large library of nanomaterials as building blocks. Here, we propose a layer by layer assembly process to fabricate functional fibers using colloidally synthesized nanomaterials. As an example, we will discuss fabrication of solution-processable, flexible, and wearable light emitting fibers with a potential to be incorporated into light-emitting fabrics.

11:00 AM BM08.12.03
MXene-Coated Cellulose Based Yarns for Wearable Supercapacitor Applications
Simge Uzun1, Ariana S. Levitt1, Mohamed Alhabeb1, Genevieve Dion2 and Yury Gogotsi3; 1Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Design, Drexel University, Philadelphia, Pennsylvania, United States.

In this work, we demonstrate a scalable dip-coating approach for fabricating high-performing supercapacitor yarns using low-cost, commercial cellulose-based yarns. Since MXenes are processible in various solvents [3], it can be incorporated into conventional yarns using a simple dipping and drying procedure. Concentration and flake size distribution of MXene solutions were tailored to ensure effective penetration of MXene flakes into the individual fibers and under the yarn surface without sacrificing adhesion to the fiber substrate. The high porosity of cellulose-based yarns offers a large surface area for MXene uptake and electrolyte exposure to facilitate charge transport. Finally, the knittability of the electrode yarns into full fabrics on industrially used machines will be discussed. This study provides insight into the processing requirements for coating cellulose-based yarns. Furthermore, the effect of MXene flake size on coating uniformity, yarn conductivity, and supercapacitor performance was investigated. Our findings suggest the potential use of MXene for achieving large-scale and cost-effective production of high-performance supercapacitors as energy storage devices for powering wearable electronics.

11:15 AM BM08.12.04
Waterproof, Skin-Like, Electronics-Enabled Microfluidic Systems for Sweat Collection, Biomarker Analysis and Digital Thermography in Aquatic Environments Jonathan Reeder1, Jungil Choi1, Yeguang Xue1, Justin Hanson1, Philipp Gutruf2, Mark Liu1, Tyler R. Ray1, Amany Bandodkar2, Rauldel Avila1, Wei Xie3, Siddharth Krishnan4, Shuai Xu4, Roozbeh Ghaffari4, Yonggang Huang1 and John A. Rogers1; 1Northwestern University, Evanston, Illinois, United States; 2University of Illinois at Urbana-Champaign, Champaign, Illinois, United States.

Non-invasive, in situ biochemical and biophysical monitoring of sedentary, ambulatory, and exercising people could enable new forms of healthcare diagnostics and personalized hydration strategies. Present sweat collection and sensing strategies are not applicable to aquatic or arid environments due to unique challenges in eliminating interference/contamination from surrounding water, maintaining robust adhesion in the presence of viscous drag forces and/or vigorous motion and preventing evaporation of collected sweat. This talk introduces materials and device architectures for waterproof, skin-like, microfluidic and electronic systems that adhere to the skin to enable capture, storage and analysis of sweat, even while fully underwater. A method of forming ultrathin, low modulus epidermal microfluidic systems and a scheme for using physically patterned, skin-safe adhesives enable reliable operation during swimming for two hours, or more, with minimal influence of the surrounding water or of biological effects such as compensatory sweating. The combination of an elastomeric polymer with excellent barrier properties and computationally guided design of microfluidic channel geometries prevents contamination from environmental water and minimizes evaporative loss of collected sweat during dryland studies. Field trials demonstrate the functionality of these devices during cycling and swimming in controlled, indoor conditions and in open water swimming in the ocean. Wireless, digital measurements of skin temperature via integration of systems that operate via near field communication protocols not only elucidates differences in the thermal response of the skin during exercise in aquatic and dry environments but also, more generally, illustrates the ability to co-integrate electronics into these platforms. A demonstrator device leveraging all of the key materials and design strategies introduced here enables quantitative in situ measurements of chloride concentration, total sweat loss (and sweat rate), and skin temperature during vigorous physical activity in aquatic environments.

SESSION BM08.13: Functional Materials and Devices with Energy Harvesting and Storage II
Session Chair: Jodie Lutkenhaus
Thursday Afternoon, November 29, 2018
Sheraton, 2nd Floor, Grand Ballroom

1:30 PM *BM08.13.01
Energy Harvesting, Energy Storing and Comfort Adjusting Yarns and Textiles Ray H. Baughman; The University of Texas at Dallas, Richardson, Texas, United States.

The design, fabrication, and performance of multifunctional yarns and fibers for energy harvesting, energy storage, and actuation in textiles, as well as for other applications, will be discussed. Our bisscrolling technology can be used to trap up to 95 wt % of a functional guest in the helical corridors of nanofiber yarns that are weavable, braidable, sewable, and knot-able without sacrificing guest functionality. One application area is in comfort adjusting clothing that automatically opens and closes porosity depending upon the temperature or the presence of perspiration. When used as large-stroke artificial muscles, these yarns are twisted until they fully coil, and in this coiled state they can deliver tensile strokes exceeding 40% and generate contractile stresses, gravimetric work densities, and gravimetric power densities that are 230, 65, and 95 times that of natural muscle, respectively. Depending upon the relative chirality of yarn and coil, homochiral and heterochiral muscles are obtained, which respectively contract and expand when yarn volume increases. Related electrochemical twistron mechanical energy harvesters will also be described, which are electrochemical muscles operated in reverse. Without requiring an external power source to provide a bias voltage, these twistrons can generate 250 watts per kilogram of peak electrical power when cycled up to 30 hertz, as well as over 41 joules per kilogram of electrical energy per mechanical cycle, when normalized to harvester yarn weight. All solid-state twistrons will be described that are woven into textiles to generate electricity from body movement.

2:00 PM BM08.13.02
Ultraflexible Organic Photovoltaic Diodes Combined with Organic Light-Emitting Diodes for Self-Powered Wearable Indicators Hiroaki Jinn1,2, Kenjiro Fukuda1, Xiaomin Xu2, Sungjun Park2, Tomoyuki Yokota2, Itaru Osaka3 and Takao Someya1,2; 1The University of Tokyo, Tokyo, Japan; 2Riken, Wako, Japan; 3Hiroshima University, Higashi-Hiroshima, Japan.

For continuous operation of wearable sensors for the Internet of Things (IoT), ultraflexible organic photovoltaics (OPV) are the most promising among all existing energy harvesting power sources because of their exceptional flexibility, environmental stability, and high efficiency [Ref 1, 2]. Since sufficiently high output power (typically ranging from 1-10 mW) is necessary to operate external circuitry, sensors, and displays, making OPVs as module devices with series and/or parallel connection to achieve high current and/or voltage output is necessary for practical applications [Ref 3]. Moreover, to our knowledge, there are no examples of ultraflexible self-powered devices integrated with ultraflexible light-emitting diodes (LEDs). Here, we show ultraflexible and efficient OPV modules with various series and/or parallel connections to achieve high current and/or voltage output. The OPV modules are based on an inverted structure with an active layer of a D–A polymer with quaterthiophene and naphtho[1,2-c:5,6-c’]bis[1,2,5]thiadiazole (NTz) (PNTz4T) and [6,6]-phenyl C71-butyric acid methyl ester (PC71BM). The module with 10 series connections features high open circuit voltage up to 6.8 V and short circuit current of 0.61 mA on 1-μm-thick foil. At the maximum power point of the OPV module, the module shows an output power of 2.78 mW. We achieved large-area OPV modules with 5 parallel connections, each containing 3 single cells in connected in series. The module exhibited an output voltage of 2.01 V and a short-current of 4.81 mA, resulting in a maximum power of 5.54 mW. Additionally, inverted structure ultraflexible OLEDs with yellow-orange emission were fabricated. The ultraflexible OLED shows an external quantum efficiency of 1.3%, which is sufficiently high enough to be detected by the human eye. Finally, we demonstrated a self-powered indicator for imperceptible wearable devices consisting of an ultraflexible OPV module with 8 series connections connected to an OLED. These results highlighted the potential advantage of ultraflexible OPVs for IoT device applications.
In recent decades, research and development of flexible and wearable electronics has attracted significant interest and attention for applications in flexible displays, smart textiles, electronic skin, etc. To achieve these applications, much work has been focused on the development of electric circuit fabrication on polymer substrates. However, in most cases, either the input is externally applied or the output is externally measured; thereby, forgoing a fully integrated stand-alone device. Here, we have developed an integrated flexible self-powered display, which harvests the energy of human motion to actuate a display. The development of the power source is done in conjunction with reducing the power requirements of flexible displays. Our printable thin film energy harvester generates output voltage up to 10s of V and output current up to μAs. It is used to power both a polymer dispersed liquid crystal (PDLC) display and an electrophoretic display with slight finger motions. This development will enable direct operation of stand-alone low power flexible electronics without external circuitry and holds potential for harvesting large-scale mechanical energy.

Prepared by LLNL under Contract DE-AC52-07NA27344.
devices are rigid, bulky, and heavy, making them not suitable for wearable applications. On the other hand, fibres are materials that have been worn by human beings for more than a thousand years. Fibres are flexible, lightweight, conformal, and highly manufacturable. This talk will introduce how our research group makes use of fibre for wearable electrochemical energy storage devices including supercapacitors and lithium batteries. These fibre-based devices can maintain the flexibility, lightweight, permeability, processibility, and even washing ability like textiles. In addition, we also show that fibrous materials can significantly improve the electrochemical properties of the devices.

4:00 PM BM08.14.02
Ultra-Tough Ion Conducting Elastomers for Stretchable Lithium-Ion Batteries **David Mackanie**¹, **Yi Cui**² and **Zhenan Bao**³; ¹Chemical Engineering, Stanford University, Stanford, California, United States; ²Materials Science and Engineering, Stanford University, Stanford, California, United States.

Batteries for wearable electronics should be safe, flexible, and robust. Solid-state batteries based on either solid or gelled polymer electrolytes have the potential to fulfill these criteria. However, many current electrolyte architectures in solid-state batteries utilize polymers that are either weak or easily deformable. Herein, we employ rational polymer design and synthesis to create a series of extremely tough elastomers with remarkably high lithium-ion conductivity. The catalogue of ion conducting elastomers (ICEs) are created by varying the strength of polymer-polymer interactions within the electrolyte. In their optimal configuration, the gelled ICEs can be stretched elastically to over 30x their original length and have an ionic conductivity of 2E-4 at 25 °C. By tuning the strength of polymer-polymer interactions, we develop insights into the effect of mechanical strength on the chemical, electrochemical, and ion transport properties of a series of ICEs. It is observed that controlling polymer-polymer interactions allows for de-coupling of ion transport from the mechanical robustness of the films. We also demonstrate the application of ICEs in a quasi-solid-state battery configuration. In this setup, ICE is used as both a solid electrolyte and a binder for the electrodes. Intermolecular interactions help adhere the battery layers, leading to an integrated all-stretchable battery stack. The interfacial interactions also minimize interfacial impedance, leading to improved cycling. Successful operation of such a battery is demonstrated at conditions that mimic those of wearable electronics.

4:15 PM BM08.14.03
A Novel Strategy of One Device Achieves Two Functions—Energy Storage and Temperature Sense Multi-Functions Device Based on Graphene Planar-Structure Supercapacitor **Ziyu Yue** and **Chunyang Jia**; University of Electronic Science and Technology of China, Chengdu, China.

Multi-functions devices attract much attention due to their great potential and large demands in wearable electronics. Besides some practical applications of integrated different functional devices as one, there is a novel strategy to fabricate multi-functions devices, that using one device to achieve two or more functions. Herein, we report the energy storage and temperature sense dual function device based on graphene planar-structure supercapacitor. Combining the supercapacitor and electronic components on one flexible printed circuit board, the obtained device could detect environmental temperature by measuring the change of leakage current of supercapacitor. The temperature sense function exhibits a high resolution of 0.0588 °C due to the 0.0407 μA precision of leakage current measurement, and the high accuracy of 1 °C comparing with temperature sensor chip. Meanwhile, as an energy storage device, the supercapacitor presents excellent electrochemical performance with the areal capacitance of 118 μF cm⁻² at scan rate of 0.1 V s⁻¹. This work demonstrates the feasibility of using one supercapacitor to achieve energy storage and temperature sensing dual function simultaneously.

4:30 PM BM08.14.04
2D Auxetic Reentrant Graphene Nanostructures for Stretchable Energy Storage Electrodes **Jeong Gon Son**; Korea Institute of Science and Technology, Seoul, Korea (the Republic of).

Stretchable electronics, which require the flexibility and stretchability necessary to endure complex motions from humans, have recently attracted considerable attention because of the increasing demand for bio-implantable and wearable devices. To accommodate large applied strains without fracturing the materials, structure-assisted stretchability, which provides brittle materials with the stretchability, can be an ideal approach. In this talk, we suggest self-assembly based approaches for structure-assisted stretchable energy storage electrodes. A source of electricity is necessary to operate the stretchable devices, and the power supply for an energy storage unit should be integrated into the stretchable device. Therefore, the energy storage device should also be deformable/stretchable and retain these attributes under various deformations. Herein, we introduce novel 2D reentrant cellular structures of porous graphene/CNT networks for omnidirectionally stretchable supercapacitor electrodes. Reentrant structures, with inwardly protruded frameworks in porous networks, were fabricated by the radial compression of vertically aligned honeycomb-like rGO/CNT networks, which were prepared by the directional crystallization method. Unlike typical porous graphene structures, the reentrant structure provides self-assisted stretchability, such asaccordion and biaxial structures, to otherwise unstretchable materials. The 2D reentrant structures of graphene/CNT networks maintained excellent electrical conductivities under biaxial stretching conditions and showed a slightly negative or near-zero Poisson’s ratio over a wide strain range because of their structural uniqueness. For practical applications, we fabricated all-solid-state supercapacitors based on 2D auxetic structures. Radial compression process up to 1/10th densified the electrode, significantly increasing the areal and volumetric capacitances of the electrodes. Additionally, vertically aligned graphene/CNT networks provided a plentiful of surface area and induced sufficient ion transport pathways of the electrodes. Therefore, these exhibited high gravimetric and areal capacitance values of 152.4 F g⁻¹ and 2.9 F cm⁻², respectively, and had an excellent mechanical resilience while maintaining high room temperature ionic conductivity. A solid-state lithium metal/LiFePO₄ full cell with this resilient electrolyte can operate at room temperature with a high cathode capacity of 152 mAh g⁻¹ for 300 cycles and can maintain operation even after being subjected to intense mechanical impact testing. Our new dual crosslinking design provides robust mechanical properties without decreasing the ionic conductivity and opens a route toward stable, high-performance operation of solid-state batteries even under extreme abuse.

4:45 PM BM08.14.05
Dual-Crosslinking Design for Resilient Lithium-Ion Conductor **Jeffrey F. Lopez**¹, **Yongming Sun**², **Yi Cui**² and **Zhenan Bao**³; ¹Chemical Engineering, Stanford University, Stanford, California, United States; ²Materials Science and Engineering, Stanford University, Stanford, California, United States.

Solid-state electrolyte materials are attractive options for meeting the safety and performance needs of advanced lithium based rechargeable battery technologies because of their improved mechanical and thermal stability compared to liquid electrolytes. However, there is typically a tradeoff between mechanical and electrochemical performance. Here we describe an elastic Li-ion conductor with dual covalent and dynamic hydrogen bonding crosslinks to provide high mechanical resilience while maintaining high room temperature ionic conductivity. A solid-state lithium metal/LiFePO₄ full cell with this resilient electrolyte can operate at room temperature with a high cathode capacity of 152 mAh g⁻¹ for 300 cycles and can maintain operation even after being subjected to intense mechanical impact testing. Our new dual crosslinking design provides robust mechanical properties without decreasing the ionic conductivity and opens a route toward stable, high-performance operation of solid-state batteries even under extreme abuse.
BM08.15.01
Diagnostic Redox Biosensors Based on Immobilized Aptamer Scaffolds
Nancy Nguyen, Jessica Anderson, Amira Gee and Mehnaaz F. Ali; Chemistry, Xavier University of Louisiana, New Orleans, Louisiana, United States.

Applications of detection systems at the nanomedicine regime require highly sensitive, quantitative and selective analysis platforms for the real-time multiplexed monitoring of target analytes. Developing biosensors with an electrochemical output allows for the sensitive detection of analytes with an inherent amplification system that can be easily amenable to bioelectronic devices. Our work focuses on sensing relevant small-molecules and biomarkers through the design of aptamer scaffolds that are bound to a redox trigger. The aptamer scaffolds allow for allosteric binding of both the redox signaling trigger and the clinical target. We use a redox trigger within a double-surface electrochemical approach where target recognition is performed at a different surface from that enabling signal transduction. This strategy allows for independent optimization of the target recognition and electrochemical detection steps. We have demonstrated the use of such systems for clinically relevant molecules such as miRNA’s and small molecules such as ATP. Current studies demonstrate the design of an adaptable aptamer scaffold, which is utilized for the detection of biomarkers for prolonged concussion symptoms. Isothermal titration calorimetry is used to elucidate the affinities of the signaling trigger to a newly designed set of aptamer scaffolds. Specific parameters to optimize binding of the electrochemical trigger to the binding loops within the aptamer are explored. This body of work is important for the use of aptamer based sensing systems within an adaptable electrochemical device. Such diagnostic mechanisms are aimed at enhancing selectivity and sensitivity of the detection of clinically relevant biomarkers.

BM08.15.02
Development of a Micro-Supercapacitor with Tannins Enhanced Capacitance
Julien Lemeux and Clara Santato; Engineering Physics, École Polytechnique Montréal, Montréal, Quebec, Canada.

At a time when the number of both independent power sources and environmental issues are increasing, electrodes based on tannins could enable environmentally friendly storage devices on a flexible substrate. Tannins, a family of polyphenol molecules from secondary metabolites of higher plants, exhibit many redox moieties and metal binding properties via their catechol and galloid units, investigated in order to produce efficient micro-supercapacitors. We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of tannin-based pseudo-supercapacitor (where electrostatic and redox processes both contribute to accumulate charge). Santato’s group has already demonstrated that eumelanin, an organic pigment ubiquitous in flora and fauna, can be used in micro-supercapacitors [1].

Here we report on the energy storage properties of three different molecules of tannins, tannic acid (TA), Pyrogallol (PG) and Catechin (Ctn). PG and Ctn molecules have been selected as they are basic units of all the tannins molecules and TA is a complex of esterified gallo with a glucose already used in a number of technologies. Ctn and galloid moieties are the building blocks of most of the tannins and they proved to be able to form uniform coatings [2]. Mukhopadhyay et al. [3] combined tannins and polypyrrole and Oh et al. [4] used a metal-phenolic network on carbon nanotubes to create supercapacitors.

On the other hand, in this work we used a technique similar to Geissler et al. [5] and Ball et al. [6] for the deposition of tannins on carbon paper to reduce the quantity of heavy metals and keep an easy processing route, both on a glass and on a flexible plastic substrates. Besides cyclic voltmetry and galvanostatic charge-discharge cycles, XRD, AFM, SEM and XPS measurements have been performed in order to understand the physicochemical properties of the tannin coating and extract sound structure-properties relationships.

BM08.15.03
Two-Dimensional Titanium Carbide (MXene) in Accommodating Lens Design
Emma J. Ward1, 2, Susan Sandeman1, Joseph Lacey2 and Yury Gogotsi1; 1School of Pharmacy and Biomolecular Sciences Huxley Building, University of Brighton, Brighton, United Kingdom; 2Rayner Intraocular Lenses Limited, Worthing, United Kingdom; 3A. J. Drexel Nanomaterials Institute, Philadelphia, Pennsylvania, United States.

Intraocular lenses (IOLs) have been under development to treat cataracts since the late 1940s[1]. Whilst significant changes in materials and design have enhanced IOLs, there still remain several deficiencies linked to poor biocompatibility and failure to mimic the refractive properties of the natural lens. One approach is to incorporate transparent, electrically conductive, biocompatible materials. A new class of two-dimensional metal carbides, known as MXenes have increased considerably. With approximately 20 variations of MXenes being synthesised, the most studied being titanium carbide (Ti3C2)[5,6].

We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of supercapacitors. We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of supercapacitors. We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of supercapacitors. We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of supercapacitors. We made the hypothesis that the presence of the redox moieties and the chelation properties of the material allows the development of supercapacitors.

As a result of our research involving MXenes, the biological evaluation of toxicity remains largely understated evaluated[5]. Optoelectronic properties of Ti3C2 were optimised and fully characterised. In vitro cell models were used to measure the suppression of oxidative stress, cell adhesion and inflammatory response of Ti3C2 thin films.

Flexible electronics is a branch of electronic fabrication that allows increasingly ergonomic devices. However, its production still requires multi-step, expensive and time-consuming processes. Laser direct writing (LDW) is a clean and low-cost alternative technique to produce electronics on flexible substrates with high resolution, without the need of masks or direct contact with the device. Laser induced graphene (LIG), a particular type of LDW, is a technique where by the irradiation of polypyrrole (PPy) films with a pulsed CO2 infrared laser a photothermal reaction occurs, which leads to the formation of stacked graphene structures. LIG emerges thus as a rising substitute to produce graphene-based devices. This work consists in the development and optimization of flexible UV sensors with zinc oxide nanostructures as the active layer for the UV detection, PI as the substrate and its respective LIG as electrodes. The nanostructures with higher area-volume ratio, synthesized through a microwave assisted hydrothermal method, were selected and deposited by drop casting onto the electrodes that in turn were optimized to enhance electrical properties by varying the laser parameters. The assembled sensors were able to successfully detect the UV radiation with a responsivity of 92 and 2 mA/W for 1 V bias for the PI substrate. In addition, the PI sensor has shown to be capable of working under strain and to be stable after several hours of constant cyclic operation.

Flexible Electrodes Towards Low Cost Flexible Electronics and Its Applications to Sensors

Flexible electronics combines the materials chemistry with the conventional printing technology resulting in high throughput fabrication of cheap and light-weight electronic devices. The work described here demonstrates printing of PEDOT:PSS onto flexible nonwoven polyester (PET) textile as well as stretchable spandex fabric. Firstly, an optimization study was carried out to determine the relationship between number of printing layers and resistance of printed PEDOT:PSS. PEDOT:PSS based organic wires on PET was shown to have current carrying capacities approaching that of copper. To demonstrate the practical applicability of the printed wires, PEDOT:PSS wires connected to Ag/AgCl electrodes was shown to recording electrocardiogram (ECG) signal. Secondly, PEDOT:PSS wires were then combined with PEDOT:PSS electrodes on PET and ECG signal were recorded at rest in both dry skin conditions and with a moisturizing lotion on skin. Lastly, a prototype shirt was also developed with PEDOT:PSS electrodes for measuring ECG signal under exercise avoiding the need of hydrogel and adhesive around the electrode. The signal was recorded in dry skin conditions which showed an increase in amplitude because of transpiration of water vapor from the skin. The prototype was shown to record signal even after 1 month of fabrication and also after three wash cycles. The above work focuses on designing prototype device for health monitoring from commercially available sources using a conventional screen printing process rendering it industrially scalable. The applications of this prototype could be extended beyond healthcare into military and gaming industry.
BM08.15.09
High-Gain Low-Power Active-Load Monolithic Amplifier Based on Depletion-Mode Organic Field Effect Transistor (OFET) for Health Monitoring Applications Chenxi Xu and Ni Zhao; The Chinese University of Hong Kong, Hong Kong, Hong Kong.

Wearable technologies have been developed rapidly recently, from tracking of personal sweat chemicals during exercise to daily cardiovascular monitoring for prevention of chronic diseases. Wearable electronics are designed to achieve high fidelity and ease of use. However, the poor signal-to-noise ratio of the measurement circuitry often limits the devices from picking up small physiological signal variations at the device-skin interface. In-situ amplification of sensor signals could be an effective way to minimize the wiring-induced noise and greatly reduce the stringent requirement of rear-end amplification circuit, and it calls for a device technology that can be easily integrated with the sensor fabrication.

Organic transistors are a suitable candidate for this application owing to their fabrication versatility, mechanical flexibility and tunable amplification gain via material engineering. In this work, we introduce a novel monolithic active-load amplifier (MALA) based on threshold-voltage-tunable depletion mode OFET, which can achieve a gain up to $34dB@17Hz$ with a battery voltage source. This MALA also holds a great potential to be optimized towards a fully flexible in-situ pre-amplifier utilized in biomedical signal sensing such as ECG/EMG, which will highly enhance the simplification of data acquisition circuit for wearable electronics. In this presentation I will mainly focus on the design principles of the device structure, the achievement of tunable gain via composition tuning of the active material and the implementation of MALA-assisted ECG measurement.

BM08.15.10
Glucose Responsive Nanogel-Immobilized Silk Hydrogel Microneedle and Light-Stimulated Monitoring Hyojung Kim, Ji-Won Seo and Hyunjoon J. Lee; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

A continuous glucose monitoring (CGM) system that tracks glucose concentrations in real-time is important as it provides abundant data to devise effective treatments for diabetic patients. Being developed fluorescent nanogel-based CGM systems which measure glucose concentration intuitively and no any skin irritation or electric interference compared with amperometric-based CGM systems, it still has inadequate problems like immobilization to apply the CGM system in vivo. Here, we propose a new CGM system based on a biocompatible silk fibroin hydrogel which is immobilized with glucose responsive fluorescent nanogels. In addition, glucose responsive silinked silk hydrogel in a microneedle array structure allows easily tracking glucose level through epidermis without painful implantation. We found that functionalized poly(N-isopropylacrylamide) (pNIPAM)-bounded silk fibroin hydrogel microneedle array showing high sensitivity ($<1mM$), fast response ($<100sec$), reversibly and continuously measure change of glucose concentration through epidermis. This preliminary study shows the potential for real-time, chronic glucose monitoring.

BM08.15.11
Low-Voltage Operational, High-Performance Wearable Fibriiform Organic Field-Effect Transistors via Twist Assembly Micro-Fiber Electrodes Soo Jin Kim,1-3, Ho Won Jang1 and Jung Ah Lim1; 1Institute of Science Technology, Seoul, Korea (the Republic of); 2Seoul National University, Seoul, Korea (the Republic of).

As a new platform for wearable device, fiber-shaped devices for electronic textile(E-textile) have been demonstrated with flexibility, light weight, low-cost and comfort to wear. Especially, fibriiform organic field-effect transistors (OFETs) are essential component for realizing circuit integration based on E-textile. In the practical wearable device, fibriiform OFETs require high performance with low-power consumption. In this study, we have demonstrated high-performance fibriiform OFETs with new device configuration which is capable of high output current under low voltage. With this structure, channel length and width could be easily controlled by thickness of semiconductor film and length of fiber. In particular, utilization of ion-gel as a gate dielectric allows low-voltage operation due high capacitance. We found that nanostructure control of organic semiconductor layer plays a critial role to improve the mechanical durability as well as charge carrier mobility. The resulting fibriiform OFET show high performance with good on/off ratio of 10^5 and on-current level of 10mA at 1.5 V which is proper to operate the current-driven LED devices. It was confirmed that these device performance almost remains even after weaving process with the common threads and repeated of bending deformations.

BM08.15.13
Ultra-Sensitive, Highly-Selective, Real-Time Chemical Wearable Sensors Based on Hydrogel Interferometer Xinmin He1, Mo Sun1, Ruobing Bai2 and Zhiqiang Suo2; 1University of California, Los Angeles, Los Angeles, California, United States; 2Harvard University, Cambridge, Massachusetts, United States.

The fast development of wearable sensors has been promoted by the broad needs for real-time monitoring the bodily functions and air quality. Interests in many wearables electronic sensors however have seen a decrease over time, due to the needs of frequent charging of batteries in practical usage. Wearable colorimetric sensors, using optical read-out signals under ambient light without any electronic components, become highly advantageous. Here we report an adaptive colorimetric sensing platform based on a bulk structure of covalently bonded hydrogel thin film-substrate system. External stimuli from the analytes can rapidly change the thickness of the hydrogel film, resulting in an instant color change. The soft and highly stretchable robust synthetic hydrogel materials can form a highly compliant contact to human epidermis and has good self-recovery capability, as an ideal candidate for soft matrices of wearable devices. Also, this colorimetric sensing platform allows for in situ quantitative analysis by naked eye or camera via analysis app, as a wireless wearable sensing component for the next-generation textile. We have shown this customizable adaptive platform can detect a large variety of analytes including cations for hydration and other physiologic metabolic state monitoring. Cu2+ for Wilson's disease prescreening, glucose for diabetes monitoring, and sulfur dioxide and nitrogen dioxide for air quality detecting. This sensing platform showed a high performance on the sensitivity and response time. The limit of detection for Cu2+ could reach as low as 10.0 pM with only 1-2 second. Such high performance is attributed by this unique chemo-mechano-optical signal transduction mechanism, which effectively amplifies the nm-scale hydrogel thickness change to a greater and more detectable optical spectrum change. This will lead to a broad platform of a new class of wearable sensors with superior performance at low cost.

BM08.15.14
Crack-Based Strain Sensor with High Sensitive and Low Hysterisis for Pulse Wave Monitoring Hyeonsuk Jung, Chan Park, Hyunwoo Lee, Hong SungUk, Hyonguk Kim and Seong Jm Cho; Chungnam National University, Daejeon, Korea (the Republic of).

Measuring pulse wave technology has received great attention because it indicates the status of the heart and blood vessels. For measuring precise pulse wave, high sensitivity (gauge factor $>$500) at low deformation ($<$1% strain) and repeatability are necessary. Because pulse of blood causes micro-scale deformation of skin, high sensitivity sensor is required to measure the small deformation. In addition, repeat measurements are required for using as clinical application. However, other studies are low sensitivity under 1% strain and poor hysteresis that makes unreliable repeatability. Here, we have fabricated strain sensors which has high sensitivity (gauge factor $>$6,000) at 1% strain and can measure micro deformation ($<$1% strain) for pulse wave measurement. Our sensors also exhibited excellent hysteresis and repeatability (100,000-cycle test).
For high sensitivity and low hysteresis, we optimized nanocracking structure's shape, thickness and substrate's characteristics. Sensing performance of the sensors depends on morphology of substrates, material property of sensing layer and interfacial property such as adhesiveness. We studied their effects on the sensing performances and resulted optimal conditions for pulse wave measurement. In addition, we developed a novel pre-strain process to improve hysteresis and sensitivity. By applying the optimal pre-strain, the hysteresis was significantly reduced at low strain range (<1%), and the gauge factor (gauge factor=6,000) was be increased up to 100times, compared to the conventional sensors. Through optimization and pre-strain process, we successfully developed a crack-based sensor with a high sensitivity (gauge factor=6,000), low hysteresis and repeatability (100,000-cycle test). Considering the outstanding performances, we believe that our sensor is highly suitable strain sensor for accurate pulse wave monitoring.

BM08.15.15
ZnO Nanostructures Based Flexible FET for Immuno-Sensing Applications Syed K. Pasha, Fahmida Alam, Mubarak Mujawar, Nezih Pala and Shekhar Bhanusali; Florida International University, Miami, Florida, United States.

Zinc oxide (ZnO) nanostructures serve as an ideal substrate for binding bio-recognition molecules viz., antibodies, aptamers, enzymes, microorganisms etc. Biocompatibility, ease of deposition and low cost makes it an ideal material for application to biosensing. The binding of biomolecules to ZnO is facilitated by the difference in the isoelectric points of the bioreceptor molecules (~5) and ZnO (~9). Using this strategy, construction of bio-functionalized field effect transistors (FETs) is proposed here for linker-free and label-free detection of biomarkers. ZnO thin film/nanostructure-based FETs with channel length 2, 1, 0.5 mm and width as 4mm were fabricated on both rigid (Si/glass) and flexible (PET) substrates. The ZnO films were deposited using sputtering and sonochemical method. The thin film thickness varied between 30 - 100nm after deposition, the films were characterized using SEM, XRD and Raman spectroscopy. Electrical properties of the FET devices were measured using semiconductor parameter analyzer. The surface of the ZnO nanostructures was functionalized with cortisol-specific antibodies without any linker molecules for label-free detection of cortisol. Cortisol, the stress hormone is chosen as a model biomarker because of its importance in health-related disorders.

BM08.15.16
Assessment of the Chemical Properties of the Supported Monolayer CVD Grown Graphene Using a Hybrid Substrate Towards Biosensing Applications Ayaz Hassan and Frank N. Crespiolho; USP, Institute of Chemistry of Sao Carlos, Sao Carlos, Brazil.

Graphene, a 2D material exhibits exceptional electronic, thermal and mechanical properties and due to these unique properties, graphene-based materials have gained a widespread attention in various applications, including electronics, optoelectronics, semiconductors, energy storage and many others. However, to properly exploit the use of graphene in these devices, a chemical functionalization is usually required, because this approach allows the proper understanding of the electron transfer properties of these electrodes, exploitation of their physical and chemical properties and finally their use in various applications. The main approach to functionalize monolayer graphene on substrate is the covalent functionalization through diazonium chemistry. Nevertheless, due to single atomic layer, the chemical properties and hence the reactivity of supported graphene depends on various factors, including the number of layers of graphene, shape of graphene and nature of the substrate, the last one of fundamental importance in diazonium chemistry. Though several substrates have been used to evaluate the electronic properties of the graphene, in all the previous studies the graphene is mostly supported on one substrate or other. Here in this work, we proposed a hybrid substrate, based on the modification of the surface of SiO2/Si substrate with some metallic film, such as Au, Pt, Cu etc, which is lithographically decorated on SiO2/Si and then supported with monolayer chemical vapor deposition (CVD) grown graphene. The metallic substrate beneath the graphene is expected to further enhance the electronic properties of the graphene as compared to the graphene supported on SiO2/Si. This was initially observed in the diazonium chemistry, where a surface coverage of 4.3 x 10⁴ mol.cm⁻² was achieved for the graphene, supported partially on the metal and partially on the SiO2/Si, as compared to the surface coverage of 2.3 x 10⁻⁹ mol.cm⁻² obtained for the graphene supported only on SiO2/Si; almost 20 times enhancement was achieved for the attachment of the molecules to the surface,. The chemical functionalization of the graphene was confirmed through micro-FTIR spectroscopy and FTIR chemical imaging, as well as through micro-Raman spectroscopy on both kinds of substrate. The charge transfer properties of the fabricated graphene device were further evaluated through various electrochemical techniques, where a 2-3 fold enhancement in the electron transfer kinetics was achieved for the graphene supported on M-SiO2/Si (M= Au, Pt, Cu) substrate as compared to the substrate without the presence of metal i.e SiO2/Si. Our developed device may thus find potential applications in the ultra-fast and sensitive sensing of biomolecules in the biosensors and biodiodes.

BM08.15.17
Multifunctional Electrospun Multilayered Separator for Flexible Battery Applications Wisawat Keaswejareansuk and Jianyu Liang; Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

Lithium-ion battery (LIB) is highly demanded in rapidly developing smart and connected livings, sensorization, and wearable electronics. While the battery safety is a visible challenge beside the numerous efforts to increase electrochemical performance, the flexibility in shape and size is an important factor for moving toward those applications. A separator is an electrochemically inactive component and essential for providing safety to the battery. It is known as the weakest component because of an anisotropic characteristic of the primary commercial separator, polyolefin. Electrospinning is a simple and efficient process to create the continuous fibers at nanoscale and fabricate the high porous membranes with high surface area to volume ratio. The electrospun, nonwoven mats are lightweight with spaces between the mesh for electrolyte uptake and surface functionalization. The membrane’s characteristics and properties are customized by simultaneously adjusting material parameters. In this work, the electrospun separators with multilayers of different types of polymer are created with good physical affinity. The multilayered separators offer multifunction owing to the material properties of different polymers. In this presentation, we will discuss the material selections, material and process parameters of the electrospinning, the electrospinning routines, and the characteristics of the fabricated electrospun multilayered separator, which has enhanced battery safety, increased ionic conductivity, and provided shape flexibility.

BM08.15.18
Intrinsically Stretchable Organic Electrochemical Transistors Yang Li¹, Shiming Zhang² and Fabio Cicora³; ¹Department of Chemical Engineering, Polytechnique Montreal, Montreal, Quebec, Canada; ²California NanoSystems Institute, University of California, Los Angeles, Los Angeles, California, United States.

Stretchable electronics show great significance for emerging biomedical sensing and wearable healthcare application, since it can allow intimate contact with soft objects. Recently, organic electrochemical transistors (OECTs) become suitable candidates for biological interfacing and logic circuitry applications due to the synthetic tunability, facile fabrication and bio-compatibility. However, intrinsic stretchable OECTs, which enable simple fabrication process and low cost, haven’t achieved intrinsic stretchability, due to the brittleness of conducting polymer and metal electrodes. This talk focuses on intrinsically stretchable OECTs, which can be stretched up to 30% strain while maintaining identical transistor characteristics. The intrinsic stretchability is obtained by synergistically optimizing the processing conditions during device fabrication through which we can control the formation of microcracks in
the device with a pre-set strain. These microcracks maintain the current stable while being stretched. This work paves the way for OECTs applications as conformable biosensors and its integration with wearable electronics.

Low-Cost, Mass-Manufacturable Microfluidic Systems for Wearable Diagnostic Devices

Amber Bouitteau, Matthew Talbot, Bailey Corless, Chris Toothaker and Caitlin Howell; Department of Chemical and Biological Engineering, University of Maine, Orono, Maine, United States.

The use of microfluidics in wearable diagnostics presents multiple opportunities for sophisticated, continuous monitoring. However, many of the most popular microfluidic components used today are typically made of materials that are expensive and difficult to manufacture on a large scale. In this work, we use an existing roll-to-roll release paper manufacturing process to create precisely patterned sheets of flexible acrylated channels on a paper backing. The channels are used to direct capillary or pressurized fluid flow, mix in reagents, and direct the final sample to a detection zone. Proof-of-concept tests and theoretical modeling examining the efficacy of these systems toward applications in “smart” bandages and diapers are presented.

**BM08.15.20**

Transferring Microelectromechanical Devices to Breathable Fabric Carriers with Strain-Engineered Grippers

Canisha Ternival, Mohammad S. Islam, Jasmin Beharic and Cindy K. Harnett; University of Louisville, Louisville, Kentucky, United States.

We demonstrate a path to transfer microelectromechanical systems (MEMS) from silicon wafers to soft, porous, fiber-based materials using strain engineering to wrap micro-fabricated grippers around fibers in a target mesh. Applications include sensor integration into breathable, high conduction flow-through structures like tissue engineering scaffolds, bandages, and air filters.

Grippers were made from thin-film bilayers on a silicon substrate, typically a metal on a thermal oxide, using a self-aligned lift-off and etch process to define bilayer beams with lengths in the 0.2 -1 mm range. The patterned silicon substrate was loosely covered with a fiber mesh by taping it down at the edges. A xenon difluoride (Xactix Inc) dry silicon etcher exposed the substrate to 3 Torr XeF₂ for 20 cycles, undercutting the grippers through holes in the mesh. The compressively-stressed oxide layer caused the MEMS grippers to curl from the surface and interact with the mesh fibers. The grippers’ radius of curvature was set by the thickness and elastic modulus of the layers [1].

We were able to release bilayer structures underneath 100% nylon mesh with 0.5mm to 1mm diameter openings and fiber diameters of ~50 microns. We investigated which planar layouts and curvatures worked well as grippers in this range of fiber diameter and mesh hole spacing. Because the goal is to transfer large-area integrated circuits to porous carriers, we also investigated serpentine structures to connect multiple grippers into a continuous circuit that could survive the transfer process.

Stretchable electronics fabrication generally relies on fine-tuning adhesion forces, putting some restrictions on what the carrier layer can be. In contrast to adhesion, mechanical tangling makes more kinds of carrier materials available. Antibacterial, conductive, heat-responsive and other functions can be brought in by fiber networks as long as they are compatible with the highly selective silicon etch process. The grippers can also bring electronic contacts from one side of a mesh to the other, which is difficult to do on continuous thin films of other soft materials like silicone or polyimide. Our solution produces large arrays of redundant contacts that could potentially be used for connecting soft circuits without alignment [2]. When used with a stretchable mesh, this surface micromachining method provides a route for MEMS and integrated circuits to move from a small-diameter wafer to a larger surface area.

Conductive Silk Material Produced from Silk Fibroin and Waste Biomass

Diego López Barreiro1, Zaira Martin-Moldes2 1, Francisco J. Martin-Martinez1, David Kaplan2 and Markus Buehler1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Tufts University, Medford, Massachusetts, United States.

Silk fibroin (SF), a protein obtained from Bombyx mori cocoons, can be used to manufacture biocompatible and biodegradable materials with outstanding flexibility and mechanical properties. Activated carbons (ACs) derived from biomass are nanostructured porous materials with highly aromatic structures populated with doping elements (mainly nitrogen), and with good electron conductivity. The polar nature of the ACs facilitate their interaction with SF. Thus, combining ACs and SF to manufacture conductive silk-based materials is a promising approach to develop environmentally matched and biocompatible biomaterials where silk provides flexibility and strength, and ACs provide conductivity and mechanical reinforcement. These materials can be of interest for the biomedical field, to develop wearable sensors or conductive coatings, among other biomaterials. In this work, we present the mechanical properties, cytocompatibility and nanostructures of SF-AC biomaterials, such as membranes or hydrogels, using a synergic approach of experimental synthesis and computational modeling.

**BM08.15.22**

Ultrathin, Stretchable, and Flexible Structural Color Filters Based on a Metal-Dielectric-Metal Structure

David D. Ordinario, Hiroaki Jinno, Md Osman Goni Nayeem, Yutaro Tachibana, Tomoyuki Yokota and Takao Someya; University of Tokyo, Tokyo, Japan.

Color filters are a simple yet highly relevant device in today’s increasingly technology-driven world and can be found in a large number of applications such as displays, sensors, and photovoltaics. For flexible electronics, a flexible color filter would be suitable for a wide range of potential uses where an unusual form factor is required, or even integration with wearable devices. One important factor to consider is conformal adhesion to a complex surface while preserving filter effectiveness. Increased adhesion while preserving filter effectiveness would be highly conducive for any future applications. Here, we demonstrate ultrathin, stretchable, and flexible structural color filters based on a simple MDM (metal-dielectric-metal) structure on a 1.3 µm-thick ultrathin substrate. We first fabricate and characterize the basic optical and mechanical characteristics of the flexible color filters. We next investigate how effective they are at both passing the desired wavelengths and blocking the undesired wavelengths both before and after mechanical deformation. We also describe their angular sensitivity and assess its overall impact on filter performance. Remarkably, we find that the performance of the filters is not greatly
impacted by repeated mechanical deformation. Overall, our findings represent a potential strategy for making adhesive color filters with compatible mechanical properties to current flexible and/or wearable technologies without sacrificing functionality.

**Patternable Ionic Gels for Tactile Sensors**

Yoon Ji Seo, Heecheon Lee, Hyemin Lee and Hyunsik Yoon; Seoul National University of Science and Technology, Seoul, Korea (the Republic of).

Wearable electronics and robotics have received attention because of potential applications such as health monitoring and rehabilitation. For the devices, there are many components which should be developed, for example, power sources, actuators, and sensors. Ionic gels have been studied to be harnessed as wearable sensors due to their stretchability, biocompatibility and conductivity. However, when we synthesize the ionic gel in water environment, the modulus is too small to be constructed in microscale. Moreover, it is almost impossible to deposit metal films onto the gel in a vacuum condition. In this work, we present a method to prepare ionic gels without water environment to construct microscale structures, such as pillars, lines, prisms and pyramids. We fabricate tactile sensors with ionic gels with various structures and conditions and compare the electrical characteristics. Furthermore, we use a model to explain the difference and find an optimum condition.

**Electrochemical, PCR-Mediated Biosensor for the Detection of pks Genomic Island in E. coli Samples Utilizing Custom Gold Flexible Electrodes**

Nadia E. Solis Marcano1, Marjorie Lopez-Nieves1, Ramon Gomez-Moreno2, Dina Bracho-Rincon1 and Carlos R. Cabrera1; 1University of Puerto Rico, Rio Piedras Campus, Carolina, Puerto Rico, United States; 2University of Puerto Rico Medical Science Campus, San Juan, Puerto Rico, United States.

The use of custom sensing platforms, such as electrodes, allows for the selection of optimum characteristics for the system such as: size, robustness, flexibility and biocompatibility, among others. ColicinB is a genotoxin produced by the polyketide synthase multienzyme (pks genomic island) encountered in the human gut microbiota. Many studies link colibactin production to different kinds of cancers, therefore making it a molecule of interest in the biomedical research field. More specifically, certain strains of *Escherichia coli* have been found to harbor pks genomic island that induced DNA damage. Here, we developed a PCR mediated-electrochemical protocol to successfully identify the presence of the pks genomic island in DNA samples utilizing a custom gold electrode platform. For this, pks and non-pks containing *E. coli* DNA were impedimetrically analyzed before and after amplification through polymerase chain reaction (PCR) protocol. Custom DNA primers where synthesized in order to selectively amplify a specific 400 base pair sequence from the cibN gene from the pks island. Impedance data showed a 97% increase in charge transfer resistance after the protocol was applied for the pks containing samples as opposed to the 15% increase for the non-pks containing DNA samples. Overall, effective identification of the pks genomic island was achieved.

**Dispersion Methods of Nanoparticles in Stretchable PDMS and Their Dielectric Constant to Fabricate Electroadhesion Gripper**

Hanwhu Lim1,2 and Baekjin Kim2; 1Yonsei University, Seoul, Korea (the Republic of); 2Green Chemistry and Materials Group, Korea Institute of Industrial Technology, Cheonan, Korea (the Republic of).

Polymer/nanoparticle (NP) composite is well known methodology to improve physical and chemical properties depending on its polymerization conditions and kind of NPs such as TiO2, SiO2, Al2O3, and BaTiO3. However, when we applied high amount of NPs, the aggregation was occurred due to its dispersion. To overcome this problem, we optimized the dispersion by choosing the suitable dispersion method according to the viscosity of composites. In less than 10,000 CPS, homogenizer and Ultrasonicator were used to mix NPs into polymers. Higher than 10,000 CPSs, however, it is almost impossible to mix NPs into polymer so we changed mixer to plenary machine in the high viscous condition. As a result, a well dispersed polymer/NP composite was fabricated with higher than dielectric constant of 4 via its equipment and observed by HR-SEM and TEM. Furthermore, the high dielectric constant layers were applied to an electrical adhesion robot gripper comprised of robot arm, skin layer and EA layer based on stretchable polymer. The gripper was controlled with voltage ON/OFF to attach and detach target materials.

**BM08.15.26**

**A Soft Self-Powered Microfluidic Sensor for Heavy Metal Ions Detection**

Peiwi Song2,3, Guang Yang2 and Ken-Tye Yong2; 1School of Physics, Huazhong University of Science and Technology, Wuhan, China; 2School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore, Singapore.

The detection of heavy metal ions is of great significance in healthcare, environmental monitoring and drinking water safety. The current states of strategies for heavy metal detection in water are mainly focusing on electrochemical and optical techniques, which are restricted to laboratory testing due to the bulky and expensive instrument involved. The emergence of the microfluidics technology coupled with flow-induced electrochemistry has boosted the development of innovative self-powered micro-sensors. We here demonstrate a soft self-powered microfluidic sensor mainly constructed by PDMS. The working mechanism of the sensor is based on liquid-solid contact electrification between the testing liquid sample and the sensing microfluidic channel that is modified with chelating molecules for metal ions coordinating. When flowing samples into the sensor, their electrification potentials can be determined by measuring the static induction current over an electrode patterned on the channel's outer surface. Once metal ions from the sample are captured onto the channel surface, the flowing electrification effects would be alerted due to the changes of surface potentials, which are highly sensitive to ions concentration. Only a small amount of liquid samples (< 30 μL) is needed in this method. By choosing different chelating molecules, the as-developed sensor shows excellent performance in the sensing of common heavy metal ions, such as Pb2+ and Cd2+, in a sensing range of 10 ppb to 100 ppm, with the sensitivity of 10 ppb. For selective sensing, we coat glutathione on the sensor as chelating molecule, under the same testing condition, the electrification potential generated from Pb2+ solution is more than 2.5 times larger than that from Cu2+, Zn2+ and Al3+, indicating selectively sensing capability of the sensor. This method can also be applied in detecting ions other than heavy metals (e.g. Na+ and K+) by coating certain coordinating agents such as crown ether onto the sensing layer, which will greatly broaden the sensor's applications. It is also worth noting that, the whole sensing process is self-powered which requires no external power source but only a current signal read-out. The sensor made by PDMS is soft, stretchable and biocompatible, making it suitable to be used in wearable or even implantable sensing applications.

**BM08.15.27**

**Small Molecules-Based, Water-Resistant Stretchable Organic Light-Emitting Diodes with Ag-Nanowire Elasticomer Substrates**

Chang Min Lee, Daekeun Choi, Dong Hyun Kim, Hassan Hafeez, Justin Jesuraj Periyanayagam and Seung Yoon Ryu; Korea University, Seoul, Korea (the Republic of).

Recently, the fabrication of stretchable organic light-emitting diodes (SOLEDs) has drawn a great attention due to development in the field of biomedical
devices and wearable electronics. Much of the device efficiency and stability investigations have been realized with polymer-based device layouts on plastic substrates. Even though polymer-based OLED is demonstrating a good mechanical stability, it suffers with low device efficiency due to large triplet-exciton loss. Moreover, even though the recently introduced small-molecule based, geometrically wavy-buckled SOLEDs approach demonstrated a high device efficiency, however revealed a shift in the emission color coordinates (CIE) in wavy form (without stretch) as compared to flat form (with stretch). This makes it difficult to achieve the luminance in an identical CIE (wavelength) region for the same device under different strain conditions.

In this work, we present the fabrication of small-molecule-based intrinsic (flat-form) SOLED capable of performing under various bend and strain values with a small decrease in efficiency. Silver nanowires (AgNW) embedded poly (urethane) (PU) was utilized as an anode, which maintained a high conductivity (low sheet resistance of 20 Ω/sqr) up to a strain of 50%. A degassing step was performed by annealing the AgNW-PU electrode at 120 °C for 2 hours, which removed the absorbed oxygen/moisture, and improved the stability of the device. The sandwiched OLED device was fabricated with small-molecules based layers (HAT-CN/NPB/TCTA/CBP+Irppy3/TPBi/LiF/Al) maintaining a strong advantage in terms of their processing in vacuum condition, with a small decrease in efficiency. Silver nanowires (AgNW) embedded poly (urethane) (PU) was utilized as an anode, which maintained a high conductivity (low sheet resistance of 20 Ω/sqr) up to a strain of 50%. A degassing step was performed by annealing the AgNW-PU electrode at 120 °C for 2 hours, which removed the absorbed oxygen/moisture, and improved the stability of the device. The sandwiched OLED device was fabricated with small-molecules based layers (HAT-CN/NPB/TCTA/CBP+Irppy3/TPBi/LiF/Al) maintaining a strong advantage in terms of their processing in vacuum condition, which provides uniform, high quality films with low triplet-exciton loss. The resulting SOLED devices demonstrated a current efficiency, quantum efficiency and power efficiency of 25 cd/A, 7% and 24 lm/W respectively, which is considerable in terms of small-molecule based intrinsic stretchable devices. (H.-B. Sun, group presented small molecule based geometrical, wavy SOLED with ~70 cd/A current efficiency). Due to the absence of any wavy/buckled structures and intrinsic form of SOLEDs, no shift in electroluminescence peak was observed demonstrating a stability in the emission CIE. Moreover, the polyurethane (PU) encapsulation was performed on the SOLED devices, which enabled it to be water-resistant and the device’s operation was confirmed in liquid atmosphere.

The approach mentioned in this work has the high potential to realize small molecule-based intrinsic water-resistant SOLEDs, which can provide high performance under strain without any shift in the CIE.

Soft Knee-Exoskeleton System Using Variable-Stiffness Magnetorheological(MR) Gel to Reduce the Energy Cost of Human Walking
JungHwan Youn1, YunSoo Back2 and KiUk Kyung1; 1Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Department of Mechanical Engineering, Yonsei University, Seoul, Korea (the Republic of); 3Department of Mechanical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Soft Knee-Exoskeleton System Using Variable-Stiffness Magnetorheological(MR) Gel to Reduce the Energy Cost of Human Walking

Wearable and Luminescent Oxygen-Sensing Films with Improved Sensitivity Based on Light Scattering by TiO2 Particles
Changjin Lim and Jin-Woo Park; Yonsei University, Seoul, Korea (the Republic of).

Dissolved oxygen (O2) is an essential element for energy production and cellular respiration in a human body. Insufficient O2 delivery can cause peripheral artery diseases (PAD) such as cancers, diabetic foot ulcer, and Raynaud’s disease. Based on the fact that transcutaneous oxygen pressure (tcpO2) is proportional to O2 concentration of tissues, research for measuring tcpO2 in real-time and in a large area have been done to diagnosis and monitor PAD. As a golden standard for sensing tcpO2, Clark electrode has been extensively used, which operates based on electrochemical reaction. However, this method is an invasive technique accompanying pain and consumes O2 during the measurement. Recently, luminescence-based O2 sensing mechanism has been studied as non-invasive method and for a large-area mapping of O2 distribution. The new concept of luminescent tcpO2 sensor consists of an O2 sensing film, a light source, and a photodiode as the photoluminescence (PL) detector. The luminescent oxygen sensors can be based on either the photoluminescence intensity or light-quenching lifetime of the sensing films. The ratiometric method based on the intensity analysis approach has been introduced to provide a low-cost technique capable of quantitatively and accurately measuring the oxygen distribution over large areas. However, to utilize the ratiometric method,
the sensitivity of intensity-based methods to ambient light, photobleaching, and self-quenching of dye molecules should be minimized for accurate analysis. To improve the signal-to-noise ratio and sensitivity ($I_{ph}/I_0$) of the oxygen sensor, in this study, we investigated the effects of embedded titanium dioxide (TiO$_2$) nanoparticles on the photocurrent and sensitivity of luminescent oxygen-sensing films based on platinum octaethylporphyrin (PtOEP), which is an indicator dye. The effects of the particle size and $n$ of the photocurrent and $I_{ph}/I_0$ of the oxygen sensor were investigated based on Mie light-scattering theory. The diameter and $n$ of the TiO$_2$ nanoparticles were varied by the simple processes of laser irradiation and thermal annealing. Finally, an integrated sensing platform (luminescent sensor) was made with the sensing film with TiO$_2$, and it was confirmed that the photocurrent and sensitivity of the oxygen-sensing films were greatly improved with increases in the size and refractive index ($n$) of the embedded TiO$_2$ nanoparticles. Furthermore, the improvements in the photocurrent and sensitivity of the oxygen-sensing films allowed the fabrication of a high-resolution oxygen-sensing film that can detect the oxygen distribution over large areas.

BM08.15.31
Fabrication of Flexible and Wearable Thermoelectric Fibers with Micro- and Nanoscale Structures Based on Laser-Induced In-Fiber Capillary Instability
Zing Zhang, Ting Zhang and Lei Wei; School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore, Singapore.

High-performance flexible and wearable thermoelectric (TE) devices are increasingly needed in many applications for thermal energy conversion. Well-designed thermoelectric devices open a path to recycle waste heat energy owing to its intrinsic capacity. Unfortunately, existing TE devices with high energy conversion efficiency are mainly constituted by inorganic TE materials, making those devices inflexible and bulky. Thus they are unsuitable for using on heat sources with irregular or curved surfaces. To bridge the gap, we develop a flexible and ultralong TE fiber with precisely patterned micro- and nanoscale in-fiber structures. The fabrication process that takes advantages in thermal drawing process and laser-induced in-fiber capillary instability phenomenon is designed and realized in this study.

Our process begins with the fabrication of a macroscopic preform, next we scale down the preform into micro- or nanoscopic fibers by thermal drawing. The prior issues in multi-materials fiber thermal drawing process are to match the melting/softening temperatures and the linear thermal expansion coefficients of the fiber core and cladding materials. Herein, we choose p-type Bi$_2$Sb$_3$Te$_6$ and n-type Bi$_2$Se$_3$ as the TE fiber core and the borosilicate glass as the fiber cladding. To achieve mechanical protection, a polymer layer is also coated onto the fiber outer surface. We calculate the thermal conductivities of 0.839 W/m K for the n-type fiber and 0.844 W/m K for the p-type fiber and obtain the ZT values of 0.23 for the n-type fiber and 1.25 for the p-type fiber at room temperature.

Furthermore, TE fibers with multiple functionalities and energy-storage capabilities could be achieved by patterning designed structures in fibers with functional materials such as metals and semiconductors. To avoid mixing and disrupting the device structures during the fiber thermal drawing process, we introduce a method that utilizes the in-fiber capillary instability phenomenon to define the inner structures of multi-functional TE fibers. A CO$_2$ laser serves as heating source induces the capillary instability occurring at certain positions of the fiber. The instability transforms continuous fiber core into designed and periodic micro- and nanoscale structures, such as spheres, rods, and spindles by carefully determining the laser treatment parameters. This step brings TE functional materials to interact with other materials (such as metal and semiconductors) in a precisely controlled procedure, forming a ladder-like structure in fiber. This structure makes energy conversion much feasible and efficient in the TE fiber. More importantly, the combination of fiber thermal drawing process and utilizing in-fiber capillary instability phenomenon could offer more design spaces and finally lead to high-performance, micro- and nanoscale, flexible and wearable TE devices to be available in the near future.

BM08.15.32
Highly Sensitive Flexible Capacitive E-Skins with Biomimetic Ionic Gel
Jingyi Yang and Chuanfei Guo; Southern University of Science & Technology, Shenzhen, China.

Flexible electronic skins (e-skins) with high sensitivity and low-cost fabrication have been intensively desired in human motion detection, health monitoring, soft robotics, etc. Capacitive type flexible e-skins usually improve sensitivity though introducing surface microstructures, but the change of the dimensions in dielectric layer is quite limited thus the improvement is also limited. Herein, we demonstrated a low-cost and highly sensitive flexible capacitive e-skin with biomimetic ionic gel (BIG). The BIG film with uniform cone-like microstructures, is templated from a Calathea zebrina leaf though soft lithography. Both the top and bottom electrodes are fabricated via spraying AgNWs onto a colorless polyimide (CPI). The device is in framework of CPI/AgNWs/BIG/AgNWs/CPI. Owing to the electrical double layer contributed by BIG film, this device exhibits a ultralow limit of detection around 0.1 Pa, and a ultrahigh sensitivity of 54.31 kPa$^{-1}$ in low pressure regime (0.5 Pa), and a strong response of larger than 1 kPa$^{-1}$ over a wide range of pressure from 0.1 Pa to 115 kPa. Such high performance e-skins have great potential in motion monitoring, health monitoring and human-machine interaction, etc.

BM08.15.33
Implanted Battery-Free Direct-Current Micro-Power Supply from In Vivo Breath Energy Harvesting
Jun Li, Lei Kang, Yin Long, Hao Wei, Weibo Cai and Xudong Wang; University of Wisconsin-Madison, Madison, Wisconsin, United States.

Majority of current IMDs are powered by conventional primary or secondary batteries that contribute up to 90% weight and volume of the entire device. [1,2] While replacement of or recharging the batteries requires substantial surgical or technical efforts, introducing additional suffering and complexity to the patients, other batteries potential issues such as overheat and leakage of toxic electrolyte further prohibit the advancement and miniaturization of IMDs. Therefore, increasing efforts are now being focused on the innovation of designated IMD power sources. Implantable nanogenerators (i-NGs) have been designed to convert biomechanical energy into electricity. [3,4] In spite of their numerous merits, the outputs of state-of-the-art i-NGs are always in a form of largely discrete pulses. Although their theoretical output power could be sufficient for IMDs, battery component is still needed in the i-NG design to produce a steady and useable direct current (DC) output. Moreover, most i-NGs are non-stretchable with incompatible mechanical properties compared to soft biological tissues, which further challenges their practical applications.

In this work, we reported an ultra-soft stretchable i-NG system that could function as a battery-free DC micro-power supply. The i-NG consisted of ultrafine micro-scale interdigital electrodes (IDEs) and multi tribo-active layers with a small working area (approximately 2 cm$^2$), packaged by biocompatible silicone elastomer. While the micro IDEs support the output of high frequency electricity (1 μA at 70 Hz) driven by slow mechanical stimulation, the silicone elastomer and an embedded cavity design enable i-NGs with extremely low Young’s Modulus (46 kPa), exactly matching the mechanical property range of most soft biological tissues. By implanted inside the abdominal cavity of Sprague Dawley (SD) adult rats, the i-NG could convert slow diaphragm movement during normal breath into stable high-frequency electrical spikes, which were readily transmitted into a continuous ~2.2 V DC output on a LED load after being integrated with a basic electrical circuit (rectifier and capacitor) for a relatively long period of time.

This electric output could continuously power the LED without any observable power decay, successfully demonstrating a constant operation of small electronics DC power free of the battery component. This solely biomechanical-energy driven DC micro power supply offers a very promising solution for
the development of self-powered IMDs in the near future.

Bio-Inspired Structural Designs for Bendable, Foldable and Stretchable Lithium-Ion Battery with High Energy Density Xiaoñbiao Liao1, Guoyu Qian2, Yuan Yang2 and Xi Chen2; 1Columbia University, New York, New York, United States; 2Earth and Environmental Engineering, Columbia University, New York, New York, United States.

Flexible batteries are attractive for wearable devices for various applications, such as health care. It is challenging to achieve high energy density and high mechanical flexibility simultaneously. In this work, we propose feasible and scalable strategies to fabricate flexible lithium-ion batteries, which can concurrently obtain high energy density and mechanical flexibility, including bendability, foldability, twistability and stretchability. Inspired by the structure of animal spine, the vertebræ-like hard segments with multiple layers of conventional anode/seperator/cathode stack to offer energy storage are interconnected by the soft components as marrow with the monolayer stack to provide flexibility. Its nonoptimized energy density of 242 Wh/L can be over 85% of a standard prismatic cell. It should be emphasized that the bioinspired design allows the battery to sustain stable electrochemical performance even upon continuous dynamic mechanical deformation including twisting and bending (Guoyu Qian, Bin Zhu, Xiangbiao Liao, et al. Advanced Materials 30.12 (2018): 1704947). Additionally, a wrinkling structure replacing the flat interconnector in between two hard segments is introduced to realize stretchability up to 50%. To further improve energy density and mechanical stability, we minimize the width of soft components by asymmetrically folding one long strip of electrode stack, where complex fabrication process of winding and cutting is not needed. Thanks to this improved design, the battery exhibits excellent mechanical and electrochemical stability upon up to 180 degree folding. Our facile and scalable designs of flexible lithium ion battery potentially play an important role in wearable electronics.

Applicable Phase Transition Capsule to Smart Fabric for Thermal Energy Storage Youngkwon Jung1, Taegu Do1, Youngsang Chun1 and Young Gun Ko2; 1Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2KAERI, Daejeon, Korea (the Republic of).

The need for the manufacturing of innovative fabric product has been required for using the waste heat. Fiber and fabric which have automatic acclimatising properties have recently attracted more attention. The phase transition capsules (PTCs), which can storage the thermal energy using the latent heat from solar heat and body temperature, have been highlighted. In order to apply the PTCs to industrial fields, the metallic, inorganic, or polymeric shell coated PTCs had been studied. However, metallic and inorganic shell is corrable in aqueous liquid such as water and perspiration, and polymeric shell has low thermal conductivity. Furthermore, because the previously studied capsules have low core content, the capsules have low thermal energy capacity. In this work, we used Pickering emulsion based encapsulation method to enhance the core content for high thermal energy capacity, and encapsulated the phase transition material (PTM) with water-absorbable polymeric shell to enhance the thermal conductivity. Paraffin wax was used as core thanks to its high heat storage capacity and nontoxic properties. And the poly[2-hydroxyethyl methacrylate] (pHEMA), a water-absorbable polymer, was used as a shell because the pHEMA can show high thermal conductivity after absorbing a water. The thermal conductivity of pHEMA were measured according to the water content by LFA, and the thermal conductivity of fully hydrous pHEMA was measured to be 0.45 W/m K which is far higher than the other polymers. The manufactured PTC showed good durability owing to the flexibility and elasticity of hydrous pHEMA. The thermal storage properties of the PTC were measured by DSC, and the thermal storage capability of the PTC was calculated to be 99.7%, which is higher than previously researched other PTCs thanks to its high core content.

Our study demonstrates that the PTCs with water-absorbable polymer are an attractive material for effective thermal storage and delivery. In addition to the use of the PTCs as thermal energy carrier, the PTCs can become an attractive material for various heat sensitive industrial fields, such as wall materials of buildings or houses, refrigerator vehicles, and outdoor wear by storage and release thermal energy.

BM08.15.36
Mapping Strain/Pressure with ZnO Nanowire Arrays by Piezotronic and Piezo-Phototronic Effect Caofeng Pan1, Xiaojia Zhang1 and Zhong Lin Wang2; 1University of Chinese Academy of Sciences, Beijing, China; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

Emulation of human senses via electronic means has long been a grand challenge in research of artificial intelligence as well as prosthetics, and is of pivotal importance for developing intelligently accessible and natural interfaces between human/environment and machine. In this talk, we present a novel design of ZnO nanowire arrays, which can be used to directly record the strain distribution by piezotronic and piezo-phototronic effect. First, we have reported large-area three-dimensional (3D) circuitry integration of piezotronic transistors based on vertical zinc oxide nanowires as active taxel-addressable pressure/force-sensor matrix for tactile imaging with a high resolution of 100 μm3. The device matrix has been demonstrated for achieving shape-adaptive high-resolution tactile imaging and self-powered, multi-dimensional active sensing. However, the signal of the piezotronic transistors array is the change of the resistance of each NWs, which can only be measured in a series way. That means such piezotronic transistors array can only mapping a static strain. Different with the electrical signal, the optical signal can be measured in a parallel way. In our previous work, we have demonstrated how the piezo-phototronic effect can be effectively utilized to enhance the emission intensity of an n-ZnO/p-GaN NW LED. Here, we extend the single NW device to NW LEDs array, for pressure/force sensor arrays for mapping strain with a resolution as high as 2.7 μm. Such sensors are capable of recording spatial profiles of pressure distribution, and the tactile pixel area density of our device array is 6250000/cm2. When the device is under pressure, the images unambiguously show that the change in LED intensity occurred apparently at the pixels that were being compressed by the molded pattern, while those were off the molded characters showed almost no change in LED intensity. Instead of using the cross-bar electrodes for sequential data output, the pressure image is read out in parallel for all of the pixels at a response and recovery time-resolution of 90 ns. This may be a major step toward digital imaging of mechanical signals by optical means, with potential applications in touch pad technology, personalized signatures, bio-imaging and optical MEMS.

Furthermore, our recent studies achieve such piezo-phototronic effect induced strain mapping in a flexible n-ZnO NWs/p-polymer LEDs array system composed of PEDOT:PSS and patterned ZnO NWs with a spatial resolution of 7 μm for mapping of spatial pressure distributions. The emission intensity of the LED array sensor matrix is dominated by locally applied strains as indicated by piezo-phototronic effect. Therefore, spatial pressure distributions are immediately obtained by parallel-reading the illumination intensities of LED arrays based on electroluminescence working mechanism. A wide range of pressure measurements from 40 MPa to 100 MPa was achieved through controlling the growth conditions of ZnO nanowire array.

BM08.15.37
Flexible all-solid-state supercapacitor is highly desired for integration with flexible electronic products. However, most current flexible supercapacitor electrodes show mediocre performance, especially for high mass loading electrodes. Herein, we report high performance chlorine-doped (Cl-doped) graphene films with either low or high mass loading prepared by a facile hydrothermal method. Benefiting from the enhanced electroconductivity and electrochemical activity resulted from Cl-doped effect, the film electrode with 1.06 mg cm^{-2} shows a high gravimetric capacitance of 210 F g^{-1} at 1 A g^{-1} and the capacitance of the electrode still remains 71.2% (149.5 F g^{-1}) at 100 A g^{-1}. Moreover, when the mass loading of the film increases to 10.1 mg cm^{-2}, the gravimetric capacitance can retain 92% (193.2 F g^{-1}) at 1 A g^{-1}, showing little decrease compared with that of low mass loading film. Besides, the film shows a high areal capacitance of 2110 mF cm^{-2} and 1487 mF cm^{-2} at 1 mA cm^{-2} and 50 mA cm^{-2}, respectively. Furthermore, a symmetric flexible all-solid-state supercapacitor is assembled by two films with 11.0 mg cm^{-2} mass loading. The flexible all-solid-state supercapacitor shows almost the same capacitance under different bending angles and can retain 98% capacitance after bending 500-time. The flexible all-solid-state supercapacitor also shows a high areal energy density of 160.7 μWh cm^{-2}. All the above results demonstrate Cl-doped graphene electrode is a promising material for flexible all-solid-state supercapacitor.

Flexible Ferroelectric Nanocomposite Film for Enhanced Triboelectric Effect

Hedong Zhu, Yucan Zhu, Xingke Ye, Ziyu Yue, Zhongquan Wan and Chunyang Jia; University of Electronic Science and Technology of China, Chengdu, China.

Supercapacitor is regarded as the ideal power source in wearable electronic device, the electrode materials of which are always research focus due to it is a key component in the supercapacitor. Among numerous electrode materials, graphene has attracted significant attention for its outstanding electrochemical performance and mechanical properties, which endows graphene films with great potential of applications in future flexible electronics. Therefore, effective preparing methods of graphene films were researched and reported extensively in recent years. Herein, we fabricate a novel graphene oxide (GO) film with excellent mechanical properties via foam film method. Its thickness can be simply regulated by changing the concentration of the surfactant. After chemical reduction, the reduced GO (rGO) films exhibit impressive electrical conductivity of ~172 S cm^{-1}. The supercapacitors based on the fabricated rGO films exhibit satisfied capacitive performance of ~56 mF cm^{-2} at 0.2 mA cm^{-2} with 6 M KOH solution. Furthermore, the flexible all-solid-state supercapacitors (FSSCs) based on the rGO films also show great volumetric capacitance of ~2810 mF cm^{-3} at 12 mA cm^{-3} (~1607 mF cm^{-3} at 613 mA cm^{-3}) with polyvinyl alcohol-KOH gel electrolyte, which indicates great rate performance of solid-state devices. Besides, the supercapacitor also show great cycling stability and flexibility: after 10000 cycles and continuously bent to 180° for 300 times, the volumetric capacitance of the FSSC remains at 81.4% and 90.4% of its initial capacitance value, respectively. All the results demonstrate the free-standing rGO films prepared via foam film method in this study could be considered as promising electrode materials for high performance flexible supercapacitors.

Chlorine-Doped Graphene Film for High Mass Loading Flexible All-Solid-State Supercapacitor

Jiang Hedong, Yucan Zhu, Xingke Ye, Ziyu Yue, Zhongquan Wan and Chunyang Jia; University of Electronic Science and Technology of China, Chengdu, China.

We introduce a strategy of materials synthesis, characteristic evaluations and manufacturing process for a mechanically elastic, biologically safe silicon-based dopamine detector that is designed to be completely transient, i.e. dissolved in the brain and/or other body organs after a desired period of operation. Dopamine is an electroactive neurotransmitter released by the brain, playing critical roles in the mammalian central nervous system. Abnormal lack of dopamine levels in the brain has been implicated in chronic neurological disorders such as Parkinson’s disease, Attention deficit hyperactivity disorder (ADHD), schizophrenia. Therefore, rapid and sensitive detection of dopamine has been required for accurate diagnosis and monitoring of such diseases. A fundamental mechanism responsible for dopamine detection is that dopamine molecules are adsorbed onto the CPPy surface of the hybrid NPs (Fe^{3+}-CPPy NPs) via pi-pi interactions and oxidized to form dopamine-derived quinone, i.e. dopamine-o-quinone, catalyzed by a number of transition metal (Fe) NPs. As a result, generated electrons from the reactions transferred to highly p-doped Si NMs-based electrodes contributed to modulations in electrical characteristics. Use of inexpensive, bioresorbable iron (Fe) nanoparticles (NPs) is one of attractive choices for efficient catalytic oxidation of dopamine as an alternative for noble, non-transient platinum (Pt) nanoparticles, based on extensive studies of synthesized materials and catalytic reactions. Arrays of transient dopamine sensors validate electrochemical functionality to determine physiological levels of dopamine and to selectively sense dopamine in a variety of neurotransmitters, illuminating feasibilities for a higher level of soft, transient electronic implants integrated with other components of overall system.

Free-Standing Graphene Films Prepared via Foam Film Method for Impressive Performance Flexible Supercapacitors

Zhu Yucan, Xingke Ye, Hedong Jiang and Chunyang Jia; University of Electronic Science and Technology of China, Chengdu, China.

In the present work, we have prepared a flexible nanocomposite film of polyvinylidene fluoride (PVDF) with hydrothermally synthesized ZnO nanorods embedded inside it. The flexible nanocomposite film shows an enhanced triboelectric effect. The triboelectric nanogenerator fabricated by coupling ZnO-PVDF flexible nanocomposite film with polytetrafluoroethylene (PTFE) shows a much enhanced triboelectric output of voltage of ~119 V and short circuit current of ~1.6 µA. The device gives an instantaneous output power of ~10.6 µW/cm². The instantaneous power is 65.6% more as compared to PVD/PTFE based TENG. Upon analysing the possible factors contributing the enhanced triboelectric effect of PVDF with the incorporation of ZnO into it, it is found that the enhancement in the triboelectric effect is due to (1) the increase in β-phase content of PVDF, which increases the polarizability of PVDF (2) increase in surface roughness and (3) increase in hydrophobicity of PVDF. Therefore, by embedding ZnO into the PVDF matrix, we achieved enhanced triboelectric effect of PVDF. This is a simple and novel approach for enhancing the triboelectric effect.

Flexible Ferroelectric Nanocomposite Film for Enhanced Triboelectric Effect

Huidrom Hemojit Singh and Neeraj Khare; Department of Physics, Indian Institute of Technology Delhi, New Delhi, India.

Triboelectric nanogenerators (TENGs) are the devices which can convert low-frequency mechanical vibrations into electrical energy. These devices can be used for sustainable energy source as there are abundant mechanical vibrations like muscle contraction, body movement, vehicular movements, ocean waves, etc.[1-3] Moreover, these devices are easy to fabricate, robust and not costly. However, there is a need to enhance their output power so that it can be used effectively for driving the electronic devices.[1][4] In the present work, we have prepared a flexible nanocomposite film of polyvinylidene fluoride (PVDF) with hydrothermally synthesized ZnO nanorods embedded inside it. The flexible nanocomposite film shows an enhanced triboelectric effect. The triboelectric nanogenerator fabricated by coupling ZnO-PVDF flexible nanocomposite film with polytetrafluoroethylene (PTFE) shows a much enhanced triboelectric output of voltage of ~119 V and short circuit current of ~1.6 µA. The device gives an instantaneous output power of ~10.6 µW/cm². The instantaneous power is 65.6% more as compared to PVD/PTFE based TENG. Upon analysing the possible factors contributing the enhanced triboelectric effect of PVDF with the incorporation of ZnO into it, it is found that the enhancement in the triboelectric effect is due to (1) the increase in β-phase content of PVDF, which increases the polarizability of PVDF (2) increase in surface roughness and (3) increase in hydrophobicity of PVDF. Therefore, by embedding ZnO into the PVDF matrix, we achieved enhanced triboelectric effect of PVDF. This is a simple and novel approach for enhancing the triboelectric effect.
Highly Conductive and Flexible Composite Integrated with Personal Earphone for Simple, Wireless, Real-Time Monitoring of Electrophysiological Signs

Suk-won Hwang1, 1KU-KIST Graduate School of Converging Science and Technology, Korea University, SEOUL, Korea (the Republic of); 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Kookmin University, SEOUL, Korea (the Republic of); 1Biomedical Engineering, Korea University, SEOUL, Korea (the Republic of).

Electroencephalogram (EEG) is one of most important noninvasive brain signal measurement method to diagnose various brain diseases on the scalp. With the advance of science and technologies, diverse EEG applications have been developed in various areas such as ubiquitous (U)-healthcare and brain computer interface (BCI). In addition, simple and insensible recording of EEG is highly required for EEG applications. Therefore, many different wearable EEG sensors have been developed for simple and comfortable EEG recording. However, conventional EEG sensors still have limitations such as ugly wearing, unreliability and inconvenience.

We introduce optimized elastomeric conductive electrodes using a mixture of silver nanowires (AgNWs) with carbon nanotubes/polydimethylsiloxane (CNTs/PDMS), to build a portable earphone type of wearable system that is designed to enable recording brain activities as well as listening to music at the same time. A custom-built, plastic frame integrated with soft, deformable fabric-based memory foam of earmuffs facilitates essential electronic components, such as conductive elastomers, metal strips, signal transducers and a speaker. Such platform incorporates with accessary cables to attain wireless, real-time monitoring of electrical potentials whose information can be displayed on a cell phone during outdoor activities and music appreciation. Careful evaluations on experimental results reveal that the performance of fabricated dry electrodes are comparable to that of commercial wet electrodes, and position-dependent signal behaviors provide a route toward accomplishing maximized signal quality. This research offers a facile approach for a wearable healthcare monitor via integration of soft electronic constituents with personal belongings.

Flexible PVDF Based Nanocomposite Piezoelectric Nanogenerators for Enhanced Performance

Neeraj Khare and Huidrom Hemojit Singh; Department of Physics, Indian Institute of Technology Delhi, New Delhi, India.

The number of electronic devices used in our daily life has been increasing tremendously since the last decades. Several devices require only few milli-watt power. Piezoelectric nanogenerators based on the flexible piezoelectric polymers mainly Polyvinylidene fluoride (PVDF) is a path-breaking device that can power these small-scale electronic devices directly [1-2]. Although the intrinsic piezoelectric property of PVDF is low, many methods have been employed to enhance the piezoelectric property like thermal treatment, mechanical stretching and electrical poling [3].

In the present work, we will compare the performance of piezoelectric nanogenerator fabricated using various PVDF nanocomposite films. We have achieved enhanced piezoelectric property of PVDF just by adding nanostructures such as ZnO, NaNO3, BaTiO3 without any further heat, electrical or mechanical treatment. XRD, polarization-electric field (P-E) measurement, Fourier transform infrared spectroscopy (FTIR) measurements have been performed, and the reason behind this enhancement in the piezoelectric property has been analyzed and discussed. We have compared the enhancement by adding a different amount of nano fillers of different shapes, and this gives a brief idea of choosing the appropriate nano fillers for enhancing the piezoelectric property of PVDF. Comparison of the performance of these nanogenerators fabricated from PVDF nanocomposites will be presented.

Stiffness Tunable (ST3R) Composite by Mechanical Actuation

Boyce S. Chang, Ravi Tutika, Michael D. Bartlett and Martin Thuo; Materials Science and Engineering, Iowa State University, Ames, Iowa, United States.

Smart responsive composites can be realized using various stimuli including heat, light, swelling, electricity, and magnetic fields to induce a change in material properties. Synthetic challenges, however, impede the fabrication of mechanically responsive materials. We report a thermodynamically driven mechanically responsive composite, exploiting irreversible phase-transformation (relaxation) of metastable undercooled liquid metal core shell particle fillers. As the composite is deformed, the core shell architecture is broken, leading to solidification of the undercooled liquid metal. This results in a 300% increase in Young’s modulus. In contrast to previous phase change materials, this dramatic change in stiffness occurs autonomously under deformation, is insensitive to environmental conditions, and does not require external energy sources such as heat, light, or electricity. We demonstrate the utility of this approach by transforming a flat, flexible composite strip into a rigid, 3D structure that is capable of supporting 50x its own weight. The ability for shape change and reconfiguration are further highlighted, indicating potential for multiple pathways to trigger or tune composite stiffness.

B008.15.45
Flexible Organic/Inorganic Hybrids for High-Performance Wearable Thermoelectrics

Zimeng Zhang and Shiren Wang; Texas A&M University, College Station, Texas, United States.

Flexible organic-inorganic hybrids are promising for high-performance wearable thermoelectric materials. However, current organic/inorganic hybrids suffer from inferior thermoelectric properties due to aggregate nanostructures. In this paper, we fabricate flexible organic-inorganic hybrids by incorporating monodispersed Bi2Te3 nanoparticles into the continuous conductive polymer phase at different loading fraction while no nanoparticle percolation is observed. Monodispersed and non-percolated nanoparticles significantly scatter phonons while continuous polymer phase facilitate the electronic transport, resulting in ultrahigh power factor of ~1350 µW m⁻¹ K⁻² and ultrawide in-plane thermal conductivity of ~0.7 W m⁻¹ K⁻¹. Consequently, figure-of-merit (ZT) of 0.58 is obtained at room temperature, outperforming all reported flexible thermoelectric materials. Thermoelectric properties of as-fabricated hybrids show negligible change for bending 100 cycles, indicating superior mechanical flexibility. These findings provide significant scientific foundation for shaping flexible thermoelectric functionality via synergistic integration of organic and inorganic components.

3D Printing of Kirigami-Inspired Structures for Flexible Electronics

Derrick Banerjee, Murithi-David Kem, Xochitl C. Hernandez and Konstantinos Sierros; Mechanical and Aerospace Engineering, West Virginia University, Morgantown, West Virginia, United States.

Direct ink writing allows for the low-temperature processing of soft 3D functional materials with a wide range of applications from flexible batteries to soft
Design and Synthesis of PS-b-PSS Block Copolymer for Ionic Electroactive Artificial Muscles that avoids the need of mold fabrication. The flexibility of the proposed method also offers a simple method of fabrication of flexible wearables and soft fabrication of different types of microchannels was demonstrated. The proposed method is simple and offers a great potential in fabricating microchannels of fabricated PDMS filaments. PDMS can be easily made functional and writing can be achieved. By extending the concept of the proposed method, in situ diameters, which was driven by the applied pressure. The proposed method has the capability of writing PDMS (addition curing, heat curing as well as UV curing) with a broad range of viscosity. We evaluated the effect of dispensing head velocity (v) and curing time (t) (in case of addition curing) on the diameter of filament extruded through the nozzle. Different types of substrates—including rigid, soft and wearable substrates—were evaluated for adhesion curing) with a broad range of viscosity. We evaluated the effect of dispensing head velocity (v) and curing time (t) (in case of addition curing) on the diameter of filament extruded through the nozzle. Different types of substrates—including rigid, soft and wearable substrates—were evaluated for adhesion procedures were designed according to the application requirements. PS-b-PSS-EMIm has two distinct blocks enabling to handle the antagonistic properties somewhat independently. While conducting block containing full PDMS-EMIm enhances ionic conductivity, structural block with cross-linked PS provides mechanical stability. This polymer was synthesized by RAFT polymerization, and characterized by 1H NMR spectroscopy, gel permeation chromatography, double aberration-corrected transmission electron microscopy, field emission scanning electron microscopy, differential scanning calorimetry, and electrochemical impedance spectroscopy [6].

 herein, we describe an unprecedented block copolymer, polystyrene-b-poly(1-ethyl-3-methylimidazolium 4-styrenesulfonate) (PS-b-PSS-EMIm), which was designed according to the application requirements. PS-b-PSS-EMIm has two distinct blocks enabling to handle the antagonistic properties somewhat independently. While conducting block containing full PDMS-EMIm enhances ionic conductivity, structural block with cross-linked PS provides mechanical stability. This polymer was synthesized by RAFT polymerization, and characterized by 1H NMR spectroscopy, gel permeation chromatography, double aberration-corrected transmission electron microscopy, field emission scanning electron microscopy, differential scanning calorimetry, and electrochemical impedance spectroscopy [6].

The as-produced actuator was investigated over wide-range conditions. At ultra-low voltage of 0.5 V, the actuator exhibited high displacement of 8.2 mm (0.37 % strain), no back relaxation, excellent durability over 14,000 cycles, and fast response of five seconds. Such short rise time is 12 and 120 times smaller than those of PSS-b-PMB and SSPB, respectively [4,5]. These excellent performances demonstrate the proper design and successful synthesis of PS-b-PSS-EMIm, together with the potential of the actuator for applications. We also expect the use of our approach in preparing novel polymers for related fields like fuel cells and solid-state lithium battery.

SESSION BM08.16: Wearable/Flexible Actuators/Sensors
Session Chairs: Kyu-Jin Cho and Wooshul Kim

Hynes, Level 2, Room 209

8:15 AM BM08.16.01
Low Power Flexible Electrostatic Transducers for Haptic Communication Jan Trase1, Zhe Xu1, Xiaomin Han1, Yin Liu1, Frances Lau2, Ali Israr2, Zi Chen1 and John X. Zhang1; 1Thayer School of Engineering, Dartmouth College, Hanover, New Hampshire, United States; 2Facebook Inc., Menlo Park, California, United States.

Introduction: Long-range communication has occurred exclusively through visual and auditory means, which disadvantages those for whom these modes of communication are inconvenient or impossible. Current social networking infrastructure does not adequately reproduce normal communication, which
can involve touch when face-to-face. No current integrated wearable technology enables touch-at-a-distance, where the transducer would allow a user's touch to be recorded, digitized, and represented on a remote device. We design a matrix of low-power flexible electrostatic transducers (FETs) with air-gap coupling to the skin for both actuation and sensing functionalities. We then demonstrate the usage of these wearable transducers, which can detect simple sensations from and transmit forces to the skin.

Materials and Methods: We use curved electrodes, flexible substrates, and mechanical buckling to create low-voltage electrostatic actuators that generate large forces over macroscopic distances. The actuators are composed of a pair of Kapton film insulators coated with gold electrodes. One film is buckled and affixed to the other, generating motion when voltage is applied as the films move together and apart. The force sensors are made of porous polyvinylidene fluoride (PVDF), a biocompatible piezoelectric polymer. The device was mounted to a group of subject's forearms to determine comfort and perceptibility.

Results and Discussion: We determined that for optimum perceptibility and comfort, the device should operate at voltages under 500V and frequencies under 100Hz. The electrostatic airgap transducers were found to deliver perceptible forces to the skin when operated with a 500V 1-100Hz signal. The actuator reached its maximum displacement at around 500V, and further increases in voltage did not lead to significant changes in perceptibility. The sensor had a minimum detection threshold of 0.5N, and the voltage output rose linearly with force until 1.5N. We also conducted a pilot user study in which force and comfort were measured at 1, 5, 10, 20, 50, and 100Hz. Users were able to feel the device and qualitatively characterize the frequencies at frequencies above 5Hz. Low frequencies were more comfortable than high frequencies, and maximum comfort was achieved at 5Hz. Conversely, frequencies above 100Hz were found to be less comfortable.

Conclusions: We demonstrated a wearable electrostatic transducer with significant potential to provide a new mode of communication using human touch. The displacement and force results indicated that perceptibility is achievable in low-power situations. The actuator was able to generate displacements of up to 4mm at 500V, and 2mm at 100V. This technology will both allow for communication in situations where auditory or visual communication is difficult, as well as greatly enhance the quality of remote communication for social networking.

8:30 AM *BM08.16.02
Exo-Glove Poly II—Soft Wearable Robot that Enables People with Hand Disabilities to Grasp
Kyu-Jin Cho, Soft Robotics Research Center, Biorobotics Lab. Dept. of Mechanical Engineering, Seoul National University, Seoul, Korea (the Republic of)

Recently, owing to the rapidly increasing number of individuals suffering from spinal cord injury (SCI) and stroke, many wearable devices have been developed to assist with activities of daily living (ADLs) or to help rehabilitation. But there is still a big gap between the users and the technologies that are available, to cope with the wide variety of needs for the people with disability to live an independent life. Seoul National University Biorobotics Lab has been developing soft wearable robots that can meet the unmet needs of the people with disability. Examples include a device that can be used to pressure the belly of people who lost the ability to use their abdominal muscles to help them breathe, speak and even sing, and a simple glove that can be worn by people who cannot move their fingers to enable them to hold various objects. In this presentation, we will present Exo-Glove Poly II, a polymer based soft wearable robot for the hand that enables people who lost their hand function to grasp various objects with their hand. Exo-Glove Poly II is built using polymer for comfort of the user and easy sanitization. Exo-Glove Poly II is composed of wearable body, a glove, and actuation system. Design features to allow adjustment to different hand sizes and to protect users from injury were implemented. To verify the grasping performance of the robot, various experiments were conducted with two SCI patients with lost hand mobility. By restoring the hand function with this assistive technology, we hope that more people with disability will be able to live a better independent life.

9:00 AM BM08.16.03
Mechanics-Guided Design of Active Material—Hard-Magnetic Soft Actuator Ruike Zhao1, 2, Yoonho Kim1, Shawn A. Chester1 and Xuanhe Zhao1, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2The Ohio State University, Columbus, Ohio, United States; 3New Jersey Institute of Technology, Newark, New Jersey, United States.

Composed of polymeric matrices embedded with magnetic responsive particles, magnetoeactive soft materials can rapidly and dramatically deform under magnetic fields. Since existing magnetoeactive soft materials mostly rely on paramagnetic or low-coercivity ferromagnetic particles, they usually give simple deformations such as elongation and compression under applied magnetic fields. Recently, high-coercivity ferromagnetic particles have been embedded in magnetoeactive soft materials, in which complex patterns of hard-magnetic domains can be programmed by three-dimensional printing. As the applied magnetic fields generate stresses and torques on hard-magnetic domains, the hard-magnetic soft materials with patterned domains can give rapid, untethered and complex modes of deformations, leading to new applications in soft robotics, flexible electronics and biomedical devices. This paper will aim to develop a framework of theory, constitutive law and computational model for hard-magnetic soft materials, in order to facilitate rational design of new materials, structures and devices. We adopt a nonlinear field theory that accounts for finite deformation coupled with magnetic fields in soft materials. We propose a new constitutive law named ideal hard-magnetic soft materials and implement it into numerical models with finite-element simulation. The theory, constitutive law and numerical model are validated with a set of experiments on various modes of deformations of hard-magnetic soft materials. In addition, the mechanics-guided complex structures of the 3D-printed hard-magnetic soft materials with programmed magnetic domains are demonstrated.

Supramolecular Biomimetic Skins Combining a Wide Spectrum of Mechanical Properties and Multiple Sensory Capabilities Peiwei Wu1, 2; 1Department of Macromolecular Science, Fudan University, Shanghai, China; 2Chemistry, Chemical Engineering and Biotechnology, Donghua University, Shanghai, China.

Biomimetic skin-like materials, capable of adapting shapes to variable environments and sensing different external stimuli, are of great significance in a wide range of applications including artificial intelligence, soft robots and smart wearable devices. However, such highly sophisticated intelligence has been mainly found in natural creatures while rarely realized in artificial materials. Herein, I will introduce several types of supramolecular polyelectrolytes with different molecular interactions to fabricate biomimetic iontronics and imitate natural skins. Their dynamic viscoelastic networks provide the biomimetic skins with a wide spectrum of mechanical properties, including flexible reconfiguration ability, robust elasticity, extremely large stretchability, autonomous self-healability and recyclability. Meanwhile, polyelectrolytes’ ionic conductivity allows multiple sensory capabilities towards humidity, temperature, strain and stress. Furthermore, in this presentation, I will share insights on the soft material design from the perspective of molecule-level dynamic interactions and hope they are inspiring for facile preparation of artificial neurosensory and neuromuscular systems.

9:30 AM BM08.16.05
Flexible Metasurfaces for Versatile Haptic Interfaces Osama Bilal1, Vincenzo Costanza1, Antonio Palermo1, Paolo Celli1, Ali Israr2, Frances Lau2 and Chiara Daraio1; 1California Institute of Technology, Pasadena, California, United States; 2Facebook, Palo Alto, California, United States.
Haptic feedback is the most significant sensory interface after visual cues. Developing thin, flexible skins that function as haptic interfaces is important for augmenting virtual reality, wearable devices, robotics and prosthetics. For example, adding a haptic feedback interface to prostheses could improve their acceptance among amputees. State of the art haptic technology is still limited by inadequate sensory feedback or complicated actuation mechanisms. Here, we present flexible metasurfaces designed for generic haptic interfaces. When actuated, the metasurfaces can produce complex tactile patterns on the human skin. The metasurfaces are composed of multiple resonant "pixels" that can locally amplify both input displacements and forces. Each of these pixels encodes various deformation patterns capable of producing different sensations on contact. The metasurfaces transform a harmonic signal containing multiple frequencies into a complex preprogrammed tactile pattern.

9:45 AM

Three-Dimensional Microporous Pressure Sensor Fabricated Using Droplet-Based Microfluidic Assisted Emulsion Self-Assembly Jin-Oh Kim and Steve Park; Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of).

Pressure sensors have been a subject of great interest over the past decade, with a wide-variety of exciting applications such as interactive wearable electronics, health monitoring systems, touch screens, and soft robotics with human-like functionalities. Large area processability, flexibility, high sensitivity, ability to sense both low pressure and high pressure range, and high spatial resolution and uniformity are some of the key features necessary for various pressure sensing applications. A variety of methods to detect pressure have been reported such as piezoresistance, capacitance, piezoelectric, optics, and inductance.

Polydimethylsiloxane (PDMS) is often chosen as the dielectric material due to its ease of processability, compliance with human body, and biocompatibility. However, PDMS has a relatively high compressive modulus, yielding devices with low sensitivity. To overcome this issue, PDMS has been microstructured using silicon mold. However, these devices generally lose their sensitivity when pressure exceeds tens of kPa. This restricts their applicability to devices that require large pressure sensing range (e.g. devices that mimic human skin require pressure sensing range of –0.1—100 kPa).

To expand the pressure sensing range, we present a novel droplet-based microfluidic assisted emulsion technique to generate 3-dimensional microporous structure for high performance capacitive pressure sensors. Our technique can generate uniformly sized pores assembled in an orderly close-packed manner over a large area without the use of any sacrificial template. The size of the pores can easily be tuned from 100 μm to 500 μm by adjusting the relative flow rates of the oil and aqueous solutions. The sensitivity of the sensors increased with increasing pore size to as high as 0.85 kPa⁻¹, which can be attributed to the relatively low pressure needed to induce buckling of the columns between the larger pores. Our sensor also exhibited high pressure sensing range up to 100 kPa and high spatial uniformity. Furthermore, we have combined our technique with standard replica molding to generate 3-dimensionally shaped microporous pressure sensors, through which sensitivity was further enhanced to 2.45 kPa⁻¹. Lastly, we have adhered our sensors to human body to detect subtle human motions. These demonstrations of facile and area-processability, high sensitivity, large pressure sensing range, and high spatial uniformity make our device unique and promising for many future pressure sensing applications.

10:00 AM BREAK

10:30 AM BM08.16.07 Highly Flexible Multi-Modal Capacitive Pressure Sensor Responsive to Tactile and Wide Pressure Range Haechang Lee, Hanul Moon, Hyukyun Kwon and Seunghyup Yoo; School of Electrical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Flexible pressure sensors have been attracting great amount of attention as they are key elements in realizing artificial skin, friendly human-machine interface, and wearable healthcare products. To apply pressure sensors to the aforementioned applications, they should not only be highly sensitive in low pressure region to detect tiny stimuli such as tactile or blood pulse, but be operable over a wide pressure range as well to catch up with the performance of human skin. In addition, they need to be thin enough as it can be applied to high flexible products. For this reason, film-type pressure sensors using a variety of materials and structures have been studied. However, it has been challenging to realize a wide pressure sensing range and high flexibility at the same time, because there is a trade-off relation between dynamic range and thickness of the pressure sensors. Furthermore, the problem becomes more difficult considering a multi-modal sensor having high sensitivity in low pressure region as well.

In this study, we propose a flexible capacitive pressure sensor using a structured ionic gel film as a dielectric layer whose capacitance is responsive to applied pressure. The ionic gel film is largely beneficial for high sensitivity attributed to ultra-high capacitance based on electric double layers, and it has suitable mechanical properties as a pressure sensing material because it has low Young’s modulus similar to that of rubber. By structuring the surface of the ionic gel film in several micro-meter scale to utilize confined air between the ionic gel and an electrode, linear response to large pressure range of over 100 kPa was secured. In addition, the complete pressure sensor can be highly flexible because the thickness of the ionic gel film can be reduced near or even below 10 μm. By using an appropriate surface structure of ionic gel film, the sensor shows distinguished response to low and high pressure regions, and it has multimodal sensing capability for tactile and pressure signals by adjusting high sensitivity in low pressure region, 1.1 kPa⁻¹ in the region below 700 Pa.

By using several μm-thick plastic substrates at both bottom and top sides of the ionic gel film, the overall thickness of the pressure sensor can be ca. 20 μm, thus finally the sensor has high flexibility, e.g. foldability or wrinklability. Together with multi-modal sensing capability with high sensitivity and large pressure range, we believe the proposed pressure sensor can be used for the applications requiring both high flexibility and high performance such as wearable or body-attachable devices, and thus will be a key role to realize artificial skin for prosthetic bodies and smart healthcare.

10:45 AM BM08.16.08 Programmable Artificial Muscles with a Feedback Mechanism Mehmet Kanik4, Sirma Orguc2, George Varnavides1, Jinwoo Kim1, Thomas Benavides3, Dani Gonzales4, Timothy Akintilo1, C. Cem Tasan1, Anantha P. Chandrakasan2, Yoel Fink3,4 and Polina Anikeeva1,4; 1Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 5Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Electrical Engineering and Computer Science, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 1Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Mammalian muscles exhibit exceptional strength, reliability, ability to self-heal, and responsiveness. Engineering actuators with comparable characteristics for robotics applications require developing materials with properties similar to biological muscles. Current robots use hydraulic and servo actuators; although recent studies have focused on ionic materials or elastomers that can be actuated by heat or electricity, none have yet surpassed the performance of the mechanical systems. Furthermore, fabricating such artificial muscles with high yield and at low cost remains to be demonstrated. Here, we report thermally actuated “artificial muscle” devices produced via a cost-effective iterative thermal fiber drawing technique, which mimics the strength and responsiveness of biological muscle. These fiber-based artificial muscles can be manufactured across size ranges from macro to micro.

To achieve actuation in fibers, we sought out to create bimorph structures by combining two materials with high and low expansion coefficients, respectively: for example, an elastomer and a high-performance engineering polymer. To prototype this approach, we have demonstrated several “muscle”
types using cyclic olefin copolymer elastomer (COCe) and polyethylene (PE). The bimorph fibers were thermally drawn from macroscale preforms and three subjects to elongation stress (cold drawing). Cold drawing created an excessive strain on PE and COCe components, and upon release, the strained fibers assumed a helical shape due to the high resilience of COCe and high plastic deformation in PE. The strained fibers could then be actuated thermally and were outfitted with silver nanowire mesh electrodes to provide feedback akin to the biological muscle. By controlling the fiber dimensions and the built-in strain, the strength and the temporal dynamics of the artificial muscles were engineered.

The observed actuation and feedback of the reported fiber-based artificial muscles indicate their potential utility in robotics, haptics, and prosthetics, at a significantly lower cost and higher throughput than existing actuator technologies.

11:00 AM BM08.16.09
Bioinspired, SWCNT-Coated, Micro-Hexagonal Array Based Electronic Skin for Mechanical Sensing Changwoon Jeong, Seonghwan Lee and Young-Bin Park; Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

Highly sensitive, flexible electronic skins (e-skins) with multi-modal, vibration sensing ability is of great interest for various applications, such as tactile sensing in robots, earthquake monitoring, human healthcare and wearable electronics. Here, we present an e-skin based on bioinspired, micro-hexagonal pillar arrays coated with single-walled carbon nanotubes (SWCNTs). The interlocking configuration between the meshed arrays allows stable sensing performance under both static and dynamic mechanical stimuli, including pressure, shear, and bending through the piezoresistive principle. Furthermore, the optimized interlocking geometries based on micro-hexagonal pillar arrays show enhanced sensitivity and ability to differentiate various modes of mechanical loading owing to the surface contacts between the microstructures, whose contact-separation behavior depends on the type of loading. We also showed that our e-skin can detect internal and external vibrations for various applications, including earthquake monitoring, smart phone detection and voice recognition, and demonstrated that they can measure different types and intensities of vibration.

11:15 AM BM08.16.10
Flexible Optomechanical Actuators Based on Light-Induced Demagnetization of Low Curie Temperature Composites Meng Li1, Yu Wang1, Aiping Chen1, Bradley Napier1, Wenyi Li1, Scott Crooker1 and Fiorenzo G. Omenetto1; TufTs University, Medford, Massachusetts, United States; 2Center for Integrated Nanotechnologies, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3National High Magnetic Field Laboratory, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

Actuators are components that are used to move a mechanical system or perform shape morphing under certain stimulus. Among various stimuli, light has distinguishing advantages of non-contact control, and being capable of localized actuation with high resolution. Most optomechanical devices can perform simple movement such as bending, twisting, or expansion with simple light modulation. However, it is only with complicated light patterning or structured design that they can achieve complex movement like rotating, folding, walking or waving. There are many situations where complex modulations cannot be enacted, and the versatility is limited by the specific design. In this work, we introduce an approach of wireless actuation based on optically-induced demagnetization which provides multiple opportunities for shape morphing and deformation in response to light to easy-to-use formats. We fabricate light-responsive magnetic composites by incorporating CrO2, in multiple flexible, elastomeric, and mechanically robust, durable materials. Because of their polymorphic nature along with their flexibility and high failure strain, biopolymers (silk fibroin) and elastomers (PDMS) are used as magnetically inert host material matrices for ferromagnetic dopants. When illuminated, the composite is capable of macroscale motion, through the interplay of optically-absorptive elements and low-Curie temperature magnetic materials (CrO2). These composites can be formed into films, sponges, monoliths and hydrogels, and can be actuated with light at desired locations. With no need for specific pattern design and complicated light modulation, we have successfully demonstrated a gripper that is activated by stationary light and is able to grab and release objects. The gripper experiences cyclic tightening and loosening, which has the potential for continuous object gripping and relocation. The combination of magnetic force and localized laser illumination can achieve more complex actuation patterns, other than bending and twisting. A Curie rotary engine powered by light is demonstrated at a rotation speed of 2 rpm. The concepts presented here represent a comprehensive baseline of a composite platform that merges optical and mechanical and magnetic functions. We believe that this approach offers an interesting platform to achieve delicate and desired light-induced motion with easily accessible equipment and facile manufacturing processes, opening opportunities for manufacturing flexible, simple, and cheap actuators at multiple forms from the micro- to the macro-scale.

11:30 AM BM08.16.11
Multifunctional Smart Electronic Glove for Robotic Prosthesis Controls Min Ku Kim1 and Chi Hwan Lee1, 2, 3; 1Biomedical Engineering, Purdue University, West Lafayette, Indiana, United States; 2Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States; 3Birck Nanotechnology Center, Purdue University, West Lafayette, Indiana, United States.

The human hand is one of the foremost part of the body in a physical interaction serving as an indispensable instrument to our daily lives. Therefore, any form of disfiguration or loss of the limb can negatively affect quality of life. Current evidence-based interventions demonstrates using robotic prosthetic hands as a supplementary movement aid to restore vital mobility. Recent developments of artificial electronic skin embedded with thin-film based flexible sensors can provide valuable functionality to sense external stimuli, thereby imitating humanlike sensory perception. Despite these technological advances, the devices suffer from difficulties in seamless integration of electronic skin with pre-existing robotic prosthetics, leading to poor physical bonding and degradation of sensor performance. Moreover, the price of these instrumented prosthetics remains consistently high due to the expensive materials used and limited production numbers due to advanced fabrication methods involved, ultimately discouraging its use and adaptation in cost affordable settings. This talk outlines materials, mechanistic design features and rapid prototyping fabrication methods employed for an innovative multifunctional smart electronic glove (or simply e-glove) that can be easily worn onto arbitrary robotic hands to simultaneously replicate the humanlike sensory perception, appearance, skin compliance, and body warmth in a simple, monolithic manner. A demonstrative e-glove system includes mechanically stretchable multimodal sensors that can detect changes in temperature, pressure, and hydration in a wireless fashion. Experimental and theoretical analyses reveal the underlying mechanics of the e-glove during prosthetic fitting and use.

11:45 AM BM08.16.12
Orthogonal Sensor Arrays by Selective Material Design Nicolay J. Pineau, Julia F. Kompalla, Andreas T. Güntner and Sotiris E. Pratsinis; ETH Zurich, Zurich, Switzerland.

Wearable devices for continuous monitoring of health parameters could allow personalized health care by guiding therapies, diets, exercise or detect diseases. Human chemical emissions through breath and skin are rich in physiological information, similar to blood assay. Especially the noninvasive monitoring of specific disease- or metabolic-related markers by nanostructured metal oxide gas sensors is promising, as they respond in real-time and feature sizes smaller than the tip of a match. Therefore, they could easily be incorporated into portable or wearable devices. Particularly interesting markers are ammonia, ethanol and acetone, being related to an impaired urea cycle due to kidney or liver disease, gut bacteria and fat metabolism, respectively. Here flame aerosol made nanostructured gas sensors were produced and systematically tailored (e.g. particle size, shape and film morphology) for distinct selectivity to ammonia, acetone and ethanol. An orthogonal array consisting of the individual materials was assembled and tested in 69 different 3-gas
mixtures containing random but realistic concentrations of ammonia (250-2000 ppb), acetone (250-1800 ppb) and ethanol (50-600 ppb), simulating human breath. The here presented array quantified all analytes in the realistic gas mixtures with high accuracy, precision, and high coefficients of determination ($R^2 > 0.88$) needed for real-life applications. As a result, this sensor array shows high potential as compact module for portable or wearable devices for the noninvasive monitoring of metabolic related ammonia, acetone and ethanol in real-time, or could be used to detect entrapped humans after an earthquake.\textsuperscript{a}

SESSION BM08.17: Energy Conversion/Transfer and Devices

Session Chairs: Svetlana Boriskina and Hong Wang

Friday Afternoon, November 30, 2018

Hynes, Level 2, Room 209
Enhancement and optimization of the receiving input power density is a key to many applications that requires maximizing the energy input, such as energy harvesting, small signal sensing, etc. Normal incidental illumination is the most direct way to maximize the input power density when the input energy is in a form of parallel electromagnetic wave. In nature, many plants have developed phototropism to spontaneously sense and track the light source and maintain their disk to be illuminated normally to the photonic input. By tracking the sun, the sunflowers are able to efficiently raise the temperature of their disk in the morning in time to attract more visits of the pollinators. Tree leaves could also track the sunlight to obtain the highest temperature they can to extract water from the root. Currently there is no synthetic material system can omnidirectionally sense, track and harvest the input emissive energy. In this work, we report a soft material system that can self-adaptively track the energy source whichever the direction of the source goes. We proposed a physically symmetric system based on photo-sensitive polymers. Input photonic energy shines on the geometrically symmetric hydrogel system and induce non-symmetric temperature gradient. The polymer will automatically bend toward the light source. The bending will be terminated when the top of the material points direct to the light source. We studied the tracking system with a simple mechanical model and FEA simulation. The hydrogel system has been optimized to achieve fast and omni-directional real-time tracking in all direction. The light tracking is as fast as 30 degrees per second and the tracking performance covers 360 degrees of azimuthal plane. The error of tracking accuracy is better than 1%. A demonstration of an omni-directional solar vapor generator that maintain > 90% solar energy harvesting even under large incident angles has been achieved. The enhancement of energy harvesting reaches as high as 423% over non-tropistic surfaces, indicating a significant compensation of energy harvesting in the case of the angular incidence attributed to the tracking functionality. We believe that the proposed material system can be applied in many applications that require maximizing their energy input.

2:30 PM BM08.17.04

3D Printed Flexible and Transparent Polymer Piezoelectric Generators for Powering Electronic Devices Nick Adamson1, Alexey Glushenkov1, Mitchell Sessio2, Vanessa Lussini1, Phillip Fox1, Greg Dicinoksl1 and Amanda V. Ellis1; 1Department of Chemical Engineering, The University of Melbourne, Parkville, Victoria, Australia; 2Department of Engineering, La Trobe University, Bundoora, Victoria, Australia; 3Note Issue Department, Reserve Bank of Australia, Craigieburn, Victoria, Australia.

The global need for sustainable and green power generation methods has resulted in renewable energy harvesting technologies such as photovoltaics. This method has low energy conversion efficiencies <15% and only operates at maximum efficiency in direct sunlight. For the purposes of always-on, self-powered sensors and wearable electronics, novel reliable energy scavenging techniques are required. Piezoelectric generators convert mechanical energy from external sources to electricity, with energy conversion efficiencies >35%.

Despite the promising nature of piezoelectric polymers, they are difficult to process into the polar (all- trans) β phase, with high energy methods commonly utilized as an additional step to orient dipoles after deposition as thin films. The β phase of fluoropolymers is desired as it exhibits the highest electromechanical coupling properties. Shear stresses have previously been found to reorient fluoropolymers into the polar β phase. Our computational fluid dynamics models show high shear stresses at the exit of pressure-based 3D printing nozzles, showing the potential for 3D printing techniques to induce the β phase. Increases in aspect ratio of the polymers are linked to an improved electrical output, further enhancing the potential of 3D printing as a deposition method for polymer piezoelectric generators. Recent literature investigating effects of ionic additives to fluoro polymers suggests increased re- orientation from non-polar to polar phase due to ion-dipole interactions, with further enhancement upon doping with low (<1 wt %) concentrations of graphitic carbon nanomaterials (such as carbon nanotubes).

This study presents the prospects of 3D printing of fluoropolymers for their use as piezoelectric generators, removing the requirement of post-processing to align dipoles. The scope for the use of 3D printed piezoelectric polymer microstructures as a method of enhancing voltage output up to 4.5x over that of thin films is discussed. Diffusion kinetics of solvent evaporation-assisted 3D printing is investigated and linked to nucleation into β phase and hence additional increases in voltage of 2x at optimised conditions. Further self-orientation of 3D printed fluoropolymers at room temperature is shown through the utilization of polymer-ionic liquid additive matrices, previously only used in high temperature processing such as melt mixing and extrusion.
Wearable electronics and smart textiles have attractive much attention, because they are expected to monitor biometric information with high precision. One of their major bottlenecks is a power solution to continuously supply electricity to health-monitoring sensors. In particular, it is important to solve this issue when long-term monitoring is required. In this presentation, we will report on recent progresses of ultraflexible organic photovoltaic cells and wireless power transmission for applications to smart apparel and wearables. First, we describe mechanical and environmental stability of ultrathin organic photovoltaic cells. Then, we will explain remaining issues and future prospects of power solutions for wearables.

4:00 PM BM08.17.07
Graphene-Based Nanocellulose Composites for 3D Printed Electrodes
Taylor J. Morrison¹ and Hani E. Naguib², ¹, ²; ¹Mechanical and Industrial Engineering, University of Toronto, Toronto, Ontario, Canada; ²Materials Science and Engineering, University of Toronto, Toronto, Ontario, Canada; ³Institute of Biomaterials & Biomedical Engineering, University of Toronto, Toronto, Ontario, Canada.

Academic interest in additive manufacturing (AM) is rapidly growing as researchers work to find new ways this innovative technology can be applied to revolutionize product prototyping and production in various industries. One of the fields in which there is excellent opportunity for advancement is energy storage. There is a growing demand for specialized energy storage devices due to the increased prevalence of integrated electronics across a wide range of applications. Rising technologies such as wearable electronics, internet-of-things products, and advanced biomedical devices could see significant benefit from mobile power supplies that are more physically versatile and energy dense than what is currently available. The performance and functionality of electrochemical energy storage (EES) devices, namely batteries and supercapacitors, could be significantly improved by the precise control and efficiency offered by AM technologies. AM enables intricately detailed design of both the physical structure and material composition of the final product. Therefore, by employing AM techniques, the components of EES devices could be precisely engineered to maximize performance while fulfilling the specific physical criteria required by the end application.

In this study, graphene-based nanocellulose composites suitable for direct ink writing are developed with the purpose of manufacturing EES electrodes with unique structures on both the macro and nanoscale. Cellulose was selected as the material of focus because of its natural abundance, which would allow cellulose-based inks to be made both sustainably and cost-effectively. Furthermore, when broken down to nanocellulose (NC), this advanced material offers high surface area nanostructures and viscoelastic properties advantageous to this application. In this work, graphene-based materials, including reduced graphene oxide and pristine graphene, are added to NC to create an electrically conductive network. The nanostructures of these inks are examined, and their printability assessed. Additionally, a variety of 3D supercapacitor geometries are printed and tested for electrochemical performance, achieving a maximum specific capacitance of 46 F/g at 5 mV/s.

4:15 PM BM08.17.08
The Role of Responsive Polymers and Hydrogels in ‘Smart’ Material Systems
Raymond Oliver¹ and Lynn Tandler²; ¹Northumbria University, Newcastle upon Tyne, United Kingdom; ²Fashion and Textiles, Royal college of Art, London, United Kingdom.

We are living in an age of technological convergence. Early 21st century materials science and fabrication, when coupled with creative design fundamentals, provide a new and compelling view that can drive innovative applications and manufacturing solutions that also meet human centred needs. This paper demystifies the idea of smart fabrics and discuss current and future developments in woven textiles, their formation and potential use in new product formation scenarios.

Woven textiles are material systems governed by the principles of structural hierarchy. It is this inherent structural complexity that attributes woven textiles with a unique set of properties and, which gives them a performance advantage over other textiles forms. Today, so-called ‘smart’ textiles are beginning to take centre stage due to the majority of accounts still holding to the belief that any piece of textile that presents properties over and above those of conventional textiles is worthy of the description smart. However, the problem here is that smartness in textiles is viewed as a synonym for responsive behaviour: something that is susceptible to changes in the environment such as moisture, temperature, light, electrical current, pH, chemical or pathogen driven external stimuli. This assumption is very misleading since we find from our own work that nearly all textile components are susceptible to changes in the environment to some extent and when we deal with worn apparel, the ‘around body’ stimuli become real and often spasmodic. Therefore, we set out to investigate the claim that a textile as a smart object is to order over claim and presume that the relationship between the inherent properties of materials and the technology on which the material systems are produced are in sync. We will present evidence based data that highlights the responsiveness of different fibres and yarns to support the argument that there are no smart textile materials, only smart textile material systems.

The study indicates revisiting the principles of woven纺织的材料系统是基于结构层次性的。它是由这种内在的结构复杂性所赋予的，赋予了纺织物一种独特的特性，赋予了纺织物性能的独特优势，赋予了纺织物与其他纺织物形式的不同之处。今天，所谓的“智能”纺织物正在崭露头角，因为大多数的账户仍然坚信，任何具有纺织物以外的纺织物自定义的纺织物是值得描述为智能的。然而，这里的问题是，智能性在纺织物中被视为一个同义词，即响应性行为：对环境的敏感性，如湿度、温度、光、电流、pH、化学或病原体驱动的外部刺激。这种假设是非常误导的，因为我们发现我们的工作表明，所有纺织物的组件都对环境的变化敏感，而且在处理穿着的服装时，这种“身体周围”的刺激会变得现实并经常是间歇性的。因此，我们设定的目标是，为了证明纺织物不是一个纺织物材料，只有一种纺织物材料系统。

4:30 PM BM08.17.09
Stretchable Thermoplastic Elastomer Optical Fibers for Sensing of Extreme Deformations in Wearable Devices
Andreas Leber¹, ², Beth Cholst¹, Joseph Sandt¹, Nicolas Vogel¹ and Mathias Kolle¹; ¹Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; ²Institute of Particle Technology, Friedrich-Alexander University Erlangen-Nürnberg, Erlangen, Germany.

The design of advanced materials with coupled optical and mechanical properties is an important challenge in materials science. Soft optical systems are particularly versatile for sensing applications in wearable technology, where large and repeated deformations require dynamically responsive materials. To this end, we present stretchable step-index optical fibers, which are capable of reversibly sustaining strains of up to 300% while guiding light. We form these fibers using a continuous and scalable melt-flow process to co-extrude two thermoplastic elastomers. The fibers can be stretched, bent, and indented, which induces detectable, predictable, reversible, and wavelength-dependent changes in light transmission. The fibers utility in sensing scenarios is demonstrated in a knee brace for continuous knee motion tracking, a glove for control of a virtual hand model, and a tennis racket capable of locating ball impacts. Such devices, integrated into wearable textiles could greatly improve quantitative assessment of human motion in rehabilitation, sports, and anywhere else where large deformations need to be monitored reliably.

4:45 PM BM08.17.10
Self-Powered Wireless Optical Transmission of Mechanical Agitation Signals
Wenbo Ding and Zhong Lin Wang; Georgia Institute of Technology, Atlanta, Georgia, United States.

The ubiquitous sensors have accelerated the realization of Internet of Things (IoT) but also raised challenges to the current overcrowding radio frequency
(RF) based communications. The optical wireless communications (OWC) that utilize the wide optic bandwidth can well solve the spectrum crisis and is an appealing complementary solution to the IoT applications. However, the additional direct current (DC) power supply and complicated modulating and power management circuits may limit the large-scale deployment of OWC systems. In this paper, by integrating with triboelectric nanogenerators (TENGs), the light-emitting diode (LED) could be directly transformed into a wireless transmitter that conveys the information associated with mechanical stimuli without additional power supply. With the customized TENG devices and the help of advanced image processing and machine learning techniques, three demonstrations with functions of optical remote control, pressure sensing, and security authentication, were demonstrated. The concept and results in this paper may greatly broaden the application of IoT through the integration of OWC and TENG.

SESSION BM09.01: Biomimetic Materials Based on Peptide Self-Assembly
Session Chairs: Chun-Long Chen and Nathaniel Rosi
Monday Morning, November 26, 2018
Sheraton, 2nd Floor, Back Bay A

8:00 AM BM09.01.01
Self-Organization of Peptides in Bioinspired Vesicles—Role of Relative Concentration and Helical Separation
Akash Banerjee and Meenakshi Dutt; Chemical and Biochemical Engineering, Rutgers University, Piscataway, New Jersey, United States.

Biological cells can inspire the creation of nanoparticles equipped to store and release hydrophobic drug molecules upon demand. Lipid vesicles impregnated with alpha-helical peptides have demonstrated the clustering of the peptides under equilibrium. The formation of thick, amphiphilic, transmembrane channels via the self-organization of the peptides could be potentially used for the on-demand release of small drug molecules from the hydrophobic core of a vesicle bilayer. We are interested in understanding the driving forces responsible for cluster formations and evaluating their effects using the Molecular Dynamics simulation technique. Coarse grained representations of the molecules are used to resolve the extended spatiotemporal scales relevant to the problem at hand. The bonded and non-bonded interactions between the particles is captured by the Martini force field. We investigate the role of peptide concentration and helical separation on the cluster formation. We find the cluster size to be dependent more on helical separation as compared to peptide concentration. Additionally, we test the role of hydrophobic mismatch to understand the effect of electrostatic interactions between the peptides and lipid molecules. Our results demonstrate negative mismatch to result in larger cluster sizes as compared to a zero hydrophobic mismatch condition due to larger perturbations in the vesicle monolayers.

8:15 AM BM09.01.02
Self-Assembly of Membrane-Active Peptides into Macromolecular-Size Pores
Kalina Hristova1, Sijia Li1, Sarah Kim1, Anna Pittman2, Gavin King2 and William Wimley1; 1Johns Hopkins University, Baltimore, Maryland, United States; 2University of Missouri, Columbia, Missouri, United States; 3Tulane University, New Orleans, Louisiana, United States.

Peptides that self-assemble into pore-like structures in lipid bilayers could have utility in a variety of biotechnological and clinical applications due to their ability to breach the barrier imposed by lipid bilayers. To empower such discoveries, we use rationally designed peptide libraries and high-throughput screens to select peptides based on a particular property, in this case macromolecular-size bilayer poration. Towards this goal, we designed a library based on the bee venom peptide melittin, and we developed a high throughput screen that reports on the passage of macromolecules across lipid bilayers. We identified two peptide families that efficiently assemble into large pore-like structures. One of the families is highly active at pH 7. The other peptide family is pH sensitive, as its self-assembly is triggered by low pH. The pH-triggered peptides could be used for endosomal release of uptaken polar molecules into the cell cytosol, upon endosomal acidification. They also could be used in cancer therapies to selectively permeabilize the plasma membranes of cancer cells, since the vicinity of solid tumors is often acidic. Additional generations can be screened to further fine-tune the properties of these peptides.

Exploring the Tubability of the Aggregation and Gelation Process of the Tripeptide Glycyl-Alanyl-Glycine (GAG)
David DiGuiseppi1, Lavenia Thursch2, Nicolas Alvarez2 and Reinhard Schweitzer-Stenner2; 1Department of Chemistry, Drexel University, Philadelphia, Pennsylvania, United States; 2Department of Chemistry, Drexel University, Philadelphia, Pennsylvania, United States.
Self-assembly of biomolecules is a prominent issue explored in biomedical, biophysical, and bio-material research. Understanding how and why certain peptides/proteins prefer to self-assemble into larger networks can reveal the mechanism of amyloid formation and assist in bottom-up designs of supramolecular structures like gels and nanotubes. Some low molecular weight di- or tripeptides with aromatic residues and terminal groups have been shown to form gels. Contrary to expectations, we recently discovered that cationic glycylalanylglycine (GAG), a tripeptide of low hydrophobicity, forms a gel in 55 mol% ethanol/45 mol% water at room temperature if the concentration exceeds 200 mM. The underlying structure is comprised of unusually long crystalline fibrils (in the 10^3 nm range), which do not exhibit the canonical β-sheet structure. Rheological data and vibrational circular dichroism spectra suggest the existence of two different gel phases, one formed between 15°C and 35°C with left handed twisted fibrils and G’ values at ca. 2*10^4 Pa and another one formed below 15°C with right handed twisted fibrils and G’ values close to 10^5 Pa. Results from DFT calculations indicate that the two phases might be underlie by rather differently structured fibrils. The fluorescence kinetics probing the incorporation of thioflavin T into the hydrophobic interior of fibrils indicate a retarded diffusion of the fluorophore into fibrils that formed rather quickly after incubation above 15°C, while fluorescence increase, and relaxation proceed on a similar time scale for the gel phase formed below this temperature. Upon increasing the temperature, it can preserve this capability until the melting temperature is reached, which suggests that this gel phase has all what it takes to function as a drug delivery system. The potential reformation process of the fibrils probed by UVCD, rheology, and microscopy show that after sitting for 16h above the melting temperature, the fibrils do not have the ability to grow back. Instead, microscopic images suggest the formation of a crystal-type structure that forms in its place. Our results therefore suggest that the gel phases are meta-stable states of the system that form more quickly at or below room temperature. We care currently working on optimizing the gelation/conditioning methods for specific biotechnological applications of the gel as well as characterizing the observed crystal-type structure.

Neutral Self-Assembling Multidomain Peptides—Steric Impediment Regulates Nanofiber Formation and Materials Properties Tanja L. Lopez Silva, David G. Leach, I-Che Li, Xinran Wang and Jeffrey Hartgerink; Chemistry Department, Rice University, Houston, Texas, United States.

Peptide-based materials have drawn high interest for their use in biomedical applications such as drug delivery, cell encapsulation, and tissue regeneration. Particularly, self-assembling peptide hydrogels have shown promising properties as biomaterials since their properties and functionality are tunable by their peptide sequence. For example, they are inherently biocompatible and biodegradable, their nanofibrinous structure resembles the extracellular matrix, and they form materials with high-water content. Generally, these peptides utilize ionic amino acids to control self-assembly by changing the pH or ionic strength. Included in these group are the self-assembling Multidomain Peptide nanofibers (MDP), composed of an amphiphilic β-sheet forming core and flanking charged domains, which increase peptide solubility and make the peptide material responsive to pH changes and the presence of ions.

It is known that the biological response and cell behavior is highly dependent on the chemistry of the materials. Positive polymers promote cell adhesion and proliferation while showing concentration-dependent cytotoxicity, whereas neutral polymers, such as PEG, are frequently inert, biocompatible and non-immunogenic. Previously, all MDPs were either positively or negatively charged; therefore, expanding the scope of MDNs to neutral, non-ionic peptides will make distinct biological properties available that are not present in highly charged peptides.

Strategies to control the self-assembly of non-ionic peptides is limited because these peptides tend to have low solubility, aggregate or precipitate in aqueous solutions, making the formation of finite supramolecular structures and self-assembled hydrogels challenging. In this project, we present an alternative mechanism to control the self-assembly of neutral, uncharged multidomain peptides by utilizing steric impediment. Through the study of a series of neutral peptides, we analyzed the effect of the steric interactions on the peptide solubility, aggregation, nanostructure, and hydrogelation. From the series, a novel neutral multidomain peptide hydrogel was developed, which is inert to pH variation and ionic strength. This novel material showed promising properties for biomedical, cell preservation and tissue regeneration applications.

Self-Assembly of 2D Peptide-Based Crystalline Nanomaterials Vincent P. Conticello; Emory University, Atlanta, Georgia, United States.

Structurally defined materials on the nanometer length-scale have been historically the most challenging to rationally construct and the most difficult to structurally analyze. Sequence-specific biomolecules, i.e., proteins and nucleic acids, have advantages as design elements for construction of these types of nanoscale materials in that there can be drawn between sequence and higher order structure, potentially affording ordered assemblies in which functional properties can be controlled through the progression of structural hierarchy encoded at the molecular level. The predictable design of self-assembled structures requires precise structural control of the interfaces between peptide subunits (proteins). However, control of quaternary structure has proven to be challenging to reliably predict, as conservative changes in sequence can result in significant changes in higher order, i.e., supramolecular, structure. We have employed single self-assembling peptides as building blocks for the construction of two-dimensional nano-scale assemblies. In contrast to filamentous assemblies (e.g., fibrils, ribbons, and tubes), protein-based two-dimensional assemblies occur relatively infrequently in native biological systems. We have demonstrated that extended and structurally defined two-dimensional assemblies can be constructed through lateral association of chiral rod-like subunits such as the collagen triple helix. The resultant assemblies can exhibit sequence-dependent control of structure, including growth in the lateral and/or axial dimensions. Moreover, the sheet-like assemblies can be integrated with other self-assembled biological structural motifs, such as DNA origami nano-tiles, to afford self-organized hybrid assemblies. Despite the potential for these two-dimensional assemblies as structurally defined nano-scale scaffolds, it remains challenging to reliably predict and control the structure of the assemblies based on sequence-structure correlations at present.

Supramolecular soft matter is a rapidly emerging field that encompasses the rational use of organic molecules to design function in materials. The most promising systems are “supramolecular polymers” since one-dimensional catenation of structural units is a critical feature to create mechanically robust macroscopic systems and directed transport of charge in aligned morphologies. Supramolecular polymers, in contrast to macromolecules in which every monomer is covalently linked through covalent bonds, supramolecular systems are designed using additive noncovalent bonds that are tunable over a very broad range of binding energies encoded in the molecular structure of the “mers”. Furthermore, a major gap in the design of synthetic soft matter is the rational integration of covalent and supramolecular polymers, a concept that is used to craft function in the structures of living organisms. This lecture will describe first entirely supramolecular systems based on peptides and nucleic acids in which dynamics of non-covalently bonded monomers can reversibly form superstructures linked to mechanical and biological functions. Within the domain of hybrid systems in which covalent macromolecules are integrated with supramolecular structures, the lecture will describe materials inspired by muscles that are capable of transferring thermal to mechanical energy, light to mechanical energy, and light to chemical energy in photocatalytic materials.
Macromolecular self-assembly in biological systems takes many forms and enables countless functions across multiple length scales. Often, the structure and function of these assembled structures are dictated by subtle changes in the composition of the molecular building blocks that make up these materials. For example, simple amino acid substitutions can impart significant changes in the structure and function of protein assemblies. Inspired by this theme, we explore here the self-assembly of an ABC triblock peptide-oligoethylene oxide amphiphile with hydrophilic A and C blocks and a hydrophobic B peptide block. By varying the amino acid side chain size and hydrophobicity within the B-block, we observe aqueous self-assembly into polymorphic cellular particles with hierarchical structure and porosity ranging from giant vesicles with foam-like membranes to porous tubular architectures. These structures are characterized microscopically and spectroscopically to determine the relationships between the varied peptide compositions, tunable intermolecular interactions, and the observed morphologies. Additional evaluation of these materials as vehicles for molecular encapsulation and as templates for secondary mineral templating reveal potential new strategies to control hierarchical materials synthesis and assembly through bio-inspired molecular building block design.

Modular Peptide-Polymer Conjugates—A Platform Technology for Mucin Analogues

Daniel French, Luis Navarro and Stefan Zauscher; Duke Univ, Durham, North Carolina, United States.

Mucins – the glycoprotein building-blocks of mucus – play diverse and crucial roles in the body. These functions range from lubrication of articular joints and the eye, to the protection of stomach endothelium from the harsh environment of the lumen, to modulation of microflora populations in the digestive and respiratory systems. Despite this diversity, these functions are all attributed to slight modifications in a general structure shared by all mucins: a telechelic triblock polypeptide comprised of terminal association moieties and a heavily glycosylated core which forms a hydrated bottle brush center. In vivo, these versatile functions are achieved by altering glycosylation patterns, crosslinking density, and targeting affinity in a modular fashion. Inspired by this adaptability, we have emulated this general architecture in a modular conjugate analogue mucin platform which engenders general structural features preserved among mucins which we, and others, have identified as key to their function. To recapitulate the mucin backbone, we genetically tether and co-express terminal binding modules with a lysine-rich, elastin-like polypeptide (ELP) central scaffold. Binding modules may include sequences designed to target surfaces of interest, to facilitate intramolecular associations, or to direct surface conformation of our construct. The regularly-spaced lysines in the ELP scaffold can be harnessed for grafting synthetic polymer bristles. Bristle chemistry may be chosen for a desired property (including non-fouling character and lubricity) independent of the binding and scaffold modules. Our platform is, to our knowledge, the first to adapt the modularity of the mucin architecture into a bio-synthetic platform technology.

To demonstrate the application of our platform to clinically-relevant problems, we have tailored our mCAMP to osteoarthritis and kidney stone disease, two conditions infamous for profound morbidity and high prevalence. In tailoring our analogue mucin to cartilage, we hope to rival the performance of lubricin, a natural mucin which provides lubrication and wear protection to articular joints. Moreover, we seek to harness the properties of natural mucins and apply them to systems not naturally protected by mucinous coatings. In doing so, we have adapted our platform to binding calcium oxalate kidney stones. Association modules are designed to direct assembly on mineral surfaces as well as inhibit further mineralization. Moreover, these modules are designed to form intramolecular associations, facilitating a robust surface coating. The inclusion of non-fouling synthetic polymer bristles provides a means by which to inhibit protein-mediated crystal aggregation. In this platform technology, we have begun to develop a means by which to replicate not only the in vitro function of mucins, but to harness that function to meet additional clinical needs.

11:00 AM BM09.01.09
Design of Bioreponsive Nanogels Inspired by Peptide-Glycan Interactions

Andrew Simonson1, Atip Lawanprasert2, Tyler Goralski3, Kenneth Keiler2 and Scott Medina1; 1Biomedical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; 2Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, Pennsylvania, United States.

Early investigations from The Medina Group identified that binding of cationic membrane-active peptides with negatively charged cell-surface glycans was a critical initiating step to potentiate the peptide’s lytic action. Inspired by this natural system, we have designed a family of biohybrid nanomaterials assembled via electrostatic association of cationic peptides and anionic carbohydrates. Screening a series of peptide-polysaccharide pairs under electrospray synthesis conditions identified that poly-L-lysine (PLL) and hyaluronic acid (HA) rapidly co-assemble to yield nano-scale gel-like particles. Binding modules may include sequences designed to target surfaces of interest, to facilitate intramolecular associations, or to direct surface conformation of our construct. The regularly-spaced lysines in the ELP scaffold can be harnessed for grafting synthetic polymer bristles. Bristle chemistry may be chosen for a desired property (including non-fouling character and lubricity) independent of the binding and scaffold modules. Our platform is, to our knowledge, the first to adapt the modularity of the mucin architecture into a bio-synthetic platform technology.

Template-Driven Peptide Assembly Yields Ultrasound Guided Phase-Changing Nanomaterials

Janna N. Sloan1, Scott A. Zinic2, Joel P. Schneider2, Julianna C. Simon2 and Scott H. Medina1; 1Department of Biomedical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; 2Department of Acoustics, The Pennsylvania State University, University Park, Pennsylvania, United States; 3Chemical Biology Laboratory, National Cancer Institute, National Institutes of Health, Frederick, Maryland, United States.

Phase-changing nanoparticles (PCNs) are a class of materials that undergo solid-liquid-gas transitions in response to various engineered stimuli, leading to their application in fields that include thermal energy storage, bioelectronics and precision medicine. In particular, liquid-shelled perfluorocarbon PCNs
Hierarchical organization across length scales is ubiquitous in the superstructures of living organisms. These highly functional structures form through self-assembly, and have therefore inspired significant research activity on synthetic supramolecular materials over the past decade. We report here on a new family of supramolecular polymers that are formed by peptide amphiphiles and each is labeled with a different small fluorescent dye, and based on earlier work on supramolecular polymers, we find that nano-peptisome size can be precisely controlled by simply modulating the starting peptide and fluorinated solvent concentrations during synthesis, leading to programmable acoustic properties of the final carrier. Further, biomolecular cargo, including peptides and proteins, can be encapsulated within the particle core and directly delivered to the cytoplasm of cells upon US-mediated rupture of the carrier. Bio-imaging studies demonstrate that nano-peptisomes can be tracked and guided using diagnostic B-mode US, while Doppler imaging allows for real-time monitoring of particle activation and rupture in tissue mimetic gels. These results establish nano-peptisomes as a novel theranostic platform capable of image-guided delivery of bioactive macromolecules into cells with spatial and temporal precision.

11:30 AM *BM09.01.11
Guiding Principles for Peptide-Based, Life-Like Nanotechnology  
Rein Ulijn; Advanced Science Research Center (ASRC) at the Graduate Center, Hunter College, Glasgow, New York, United States.

Life’s diverse molecular functions are largely based on only a small number of highly conserved building blocks- the twenty canonical amino acids. These building blocks are chemically simple, but when they are organized in three-dimensional structures of tremendous complexity, new properties emerge, giving rise to the extraordinary machinery of life. So, if just twenty simple building blocks- when appropriately assembled – give rise to the complexity and functionality that can sustain life- then this is clearly a very versatile construction set. Our overall goal is conceptually simple: to figure out how to make nanoscale systems and materials from biology’s building blocks, and to apply these materials to diverse problems, that require them to be interfaced, ideally seamlessly, with living systems, or the natural environment. Different from other research groups, we have an unbiased approach, that is not guided by copying biological systems, and we keep these systems as simple as possible, which lowers barriers to application. The talk will focus on our latest results in three areas: (i) directed discovery of peptide nanostructures with new functions, by searching the sequence space; (ii) application of peptide nanostructures as functional materials (including customizable melanin pigments); (iii) actively assembling systems, that continuously turn over chemical reactions, and the characterization of nanostructure as well as inherent material properties (e.g. extreme stiffness, responsiveness to temperature and pH, stability in aqueous and organic solvents).

1:30 PM *BM09.02.01
Large-Scale Self-Sorting in Supramolecular Assemblies  

Hierarchical organization across length scales is ubiquitous in the superstructures of living organisms. These highly functional structures form through self-assembly, and have therefore inspired significant research activity on synthetic supramolecular materials over the past decade. We report here on a novel bottom-up materials self-assembly design process, one can take advantage of inherently biomolecular attributes; intramolecular folding events, secondary structure, and electrostatic interactions; in addition to more traditional self-assembling molecular attributes such as amphiphilicity, to define hierarchical material structure and consequent properties. A new solution assembled system comprised of theoretically designed coiled coil bundle motifs will be introduced. The molecules and nanostructures are not natural sequences and provide opportunity for arbitrary nanostructure creation with peptides. With control of the display of all amino acid side chains (both natural and non-natural) throughout the peptide bundles, desired physical and covalent (through appropriate “click” chemistry) interactions have been designed to produce one and two-dimensional nanostructures. One-dimensional nanostructures span exotically rigid rod molecules that produce a wide variety of liquid crystal phases to semi-flexible chains, the flexibility of which are controlled by the interbundle linking chemistry. The two dimensional nanostructure is formed by physical interactions and are nanostructures not observed in nature. All of the assemblies are responsive to temperature since the individual bundle building blocks are physically stabilized coiled coil bundles that can be melted and reformed with temperature. Additional, novel nanostructures to be discussed include uniform nanotubes as well as the templated growth of metallic nanoparticles on and in peptide nanostructures. Included in the discussion will be molecule design, hierarchical assembly pathway design and control, click chemistry reactions, and the characterization of nanostructure as well as inherent material properties (e.g. extreme stiffness, responsiveness to temperature and pH, stability in aqueous and organic solvents).
artificial transmembrane pores with molecularly defined structures is instrumental for future bionanotechnology applications. In this work, thermoresponsive synthetic channels based on supramolecular metal-organic complexes (MOCs) have been constructed to transport cell impermeable cargo across the membrane. The channels can be reversibly controlled as they collapse when the temperature is increased and are simultaneously regenerated when the system is cooled down to room temperature. These ON/OFF molecular valves could be used to overcome multidrug resistance (MDR) in cancer cells and as building blocks for artificial cells.

2:30 PM BM09.02.04
Incorporating Hierarchical Structure within Hydrogel Biomaterials Using Multifunctional Collagen Mimetic Peptides Toward Directing Stem Cell Fate 

Eden Ford1, Amber Hilderbrand1, Chen Guo1 and April Kloxin1,2; 1Chemical & Biomolecular Engineering, University of Delaware, Newark, Delaware, United States; 2Material Science & Engineering, University of Delaware, Newark, Delaware, United States.

Extracellular matrix (ECM) properties are important regulators of cell function, particularly at early timepoints during bone healing. For example, physical and chemical properties of the ECM regulate cytoskeletal organization, proliferation, and migration of stem cells to the site of bone injuries for commencing repair. Controlling the presentation of such extracellular cues with molecularly engineered materials provides opportunities to direct bone regeneration. We hypothesize that engineering synthetic hydrogels to recapitulate aspects of the early stages of healing in healthy bone will promote stem cell invasion and remodeling processes toward improving bone regeneration of traumatic fractures or critical-sized defects. To test this, we have created well-defined materials to mimic the mechanical properties, biochemical content, and multiscale structure of native tissues, particularly the collagen-rich environment of the clot-like hematoma formed early in the wound healing process.

We have designed multifunctional collagen mimetic peptides (mfCMPs) that are variants of the Proline-Hydroxyproline-Glycine repeat unit of native collagen. Two variants of this peptide were synthesized: one promoting fibrillar assembly through ionic interactions using charged groups (CMP1a) and the other using hydrophobic interactions of aromatic groups on the C- and N-termini to promote end-to-end assembly (CMP2a). Circular dichroism was used to examine triple helical assembly of the peptides and measure associated melting temperatures, where melting temperatures of CMP1a and CMP2a were determined to be 45.0°C and 60.2°C, respectively. Further peptide assembly and fibril formation was investigated with transmission electron microscopy, where fibrils were observed that mimicked aspects of the hierarchical nanostructure of native collagen. For CMP1a, fibrils approximately 35 nm in width and on the order of 1 μm in length were observed, whereas for CMP2a, fibrils approximately 60 nm in width and on the order of 100 nm in length were observed. Toward studying cell response in vitro, these mfCMPs were covalently crosslinked within cell-degradable poly(ethylene glycol) hydrogels, and rheometry was used to characterize the resulting mechanical properties. Hydrogels with storage moduli in the range of 3500-4500 Pa were generated; further, good cell viability was observed within these unique matrices, with approximately 80% viable cells across conditions.

These studies support our hypothesis that incorporation of mfCMPs within a covalent hydrogel network captures aspects of the fibrillar structure of collagen on both the nano- and microscale toward providing a biomimetic matrix that recapitulates key cues found in ‘soft’ collagenous tissues. Ongoing studies of human mesenchymal stem cells within these materials support their relevance for multidimensional cell culture and suggest that the presence of mfCMPs influences cell-matrix interactions and observed cell response.

2:45 PM BM09.02.05
Tuning Bioinspired Macromolecular Assembly with Cation-π Interactions 

Matthew A. Gebbie1, Jacob N. Israelachvili2 and J. Herbert Waite2; 1Stanford University, Stanford, California, United States; 2University of California, Santa Barbara, California, United States.

Cation-π interactions govern the assembly of many bio-macromolecules, including the adhesion proteins of marine organisms. Increasingly, cation-π interactions are also implicated in pathological processes, like the formation of neurodegenerative protein aggregates. Thus, developing molecular level approaches for engineering cation-π interactions is of both fundamental and technological importance. Although cation-π bonding has been extensively studied for gas phase ion-aromatic pairs, the energetics of cation-π adhesion in biological and biomimernal interfaces, where many binding pairs are in close proximity, remains uncharted. In this seminar, I will discuss using molecular force spectroscopy, supplemented by solid-state NMR measurements, to show that the adhesive properties of simple aromatic- and lysine-rich peptides rival those of the adhesion proteins of the marine mussel. Surprisingly, we find that peptides with the aromatic amino acid phenylalanine, a functional group that is conspicuously rare in mussel proteins, exhibit adhesion that significantly exceeds that of analogous mussel-mimetic peptides. More broadly, we find that interfacial confinement fundamentally alters the energetics of cation-π mediated assembly, an insight that is relevant for diverse areas, from influencing bio-controlled crystal formation to engineering novel bioinspired medical adhesives.

3:00 PM BREAK

3:30 PM BM09.02.06
Nanomaterials for Nervous Regeneration 

Fabrizio Gelain; JSBREMIT, IRCSS Casa Solliello della Sofferenza, San Giovanni Rotondo, Italy.

Peptidic biomaterials have been receiving great interest because of their easiness of scale-up production, absence of pathogen-transfer risk, biomimetic properties, nanostructured morphology and customization potential for the specific tissue engineering application. However, their proper usage requires the understanding of the multiple-phenomena taking place at different scale levels during self-assembling. In this presentation, focused on the nanotech advancements in the field of nervous regeneration, we will see some multi-disciplinary researches and advances toward the regeneration of spinal cord injuries. This will bring us from coarse-grained molecular dynamics to electro-spinning of self-assembling peptides (SAPs), from cross-linking of SAPs to 3D high-density neural stem cells cultures. Lastly, in vivo tests of SAP prosthese in animal models of sub-acute and chronic SCI will be discussed.

4:00 PM BM09.02.07
Learning from Nature to Form New Organic Materials for Tissue Regeneration 

Lihi Abramovich; Oral Biology, Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

Molecular self-assembly is a key direction in current nanotechnology based material science fields. In this approach, the physical properties of the formed assemblies are directed by the inherent characteristics of the specific building blocks used. Molecular co-assembly at varied stoichiometry substantially increases the structural and functional diversity of the formed assemblies, thus allowing tuning of both their architecture as well as their physical properties. In particular, building blocks of short peptides and amino acids can form ordered assemblies such as nanotubes, nanospheres and 3D-hydrogels. These assemblies were shown to have unique mechanical, optical, piezoelectric and semiconductive properties. Yet, the control over the physical properties of the structure has remained challenging. For example, controlling nanotube length in solution is difficult, due to the inherent sequential self-assembly mechanism. Another example is the control of 3D-hydrogel scaffold’s physical properties, including mechanical strength, degradation profile and injectability, which are important for tissue engineering applications.
Pathogens can thrive in an abundance of environments, and pose a significant threat to human health when irrigation or drinking sources become contaminated. The ability to detect the presence of pathogens or biomarkers, such as proteases, using a biosensing platform that is passive and requires no power can help monitor and prevent outbreaks of infectious diseases. We have developed a tunable protease-responsive platform that demonstrated a red-to-blue color shift for all target molecule concentrations between 20 nM and 4000 nM. Structurally colored particle hydrogels were fabricated by centrifuging monodisperse silica particles along with a 4-arm polyethylene glycol (PEG) and a protease-specific peptide linker into a close-packed microstructure, followed by UV irradiation to polymerize the composite. These films swelled in aqueous solutions, and color shift towards the red region of reflected visible light in response to the degree of swelling. Upon degradation of the peptide crosslink, the particles reassembled into a close-packed structure with interparticle spacing less than the initially centrifuged material. This reduction in particle spacing produced a 240 nm color change from the swollen state to the reassembled state of the material for 205 nm particle composites.

To elucidate the mechanism responsible for the color change, we investigated the role of particle size and charge, and polymer concentration in reassembly after degradation. Both particle size and surface functionalization were varied to produce composites with a range of observable structural colors. The reassembled materials reflected shorter wavelengths than their initially fabricated counterparts, indicating that the interparticle spacing had decreased as much as 45 nm for hydrogels with 230 nm particles. In addition, the reassembled composites reflected nearly identical wavelengths independent of the starting polymer weight fraction in the hydrogel. Ultra-small angle x-ray scattering confirmed that the interparticle spacing decreased and the spacing was the same for the reassembled composites. While the particle size or polymer content did not inhibit the reassembly process, particle surface charge was crucial to the reassembly mechanism. Only highly negative (-60mV) particles reassembled to produce structurally colored composites. PEGylated particle hydrogels did not reassemble, and the corresponding composites degraded into the protease solution. Composites with positively charged (+30mV) particle surfaces aggregated irreversibly into a material that appeared white due to incoherent scattering of visible light. Interaction potential models demonstrated that depletion forces provide necessary attraction for reassembly, with a range of up to 120 nm. These findings offer insight into the parameters that will enable passive monitoring of proteases with precise control of structurally colored particle hydrogel responses.

4:30 PM BM09.02.09
Anti-Biofilm Activity of Graphene Quantum Dots via Self-Assembly with Bacterial Amyloid Proteins Yichun Wang, Usha Kadiyala, Zhi-Bei Qu, Paolo Elvati, Angela Violi, Scott VanEpps and Nicholas A. Kotov; Chemical Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Bacterial communities, known as biofilms, cause multiple technological and health problems and represent an essential part of Earth’s ecosystem. The environmental resilience and sophistication of the effects of biofilms acting as a multiscale organism is enabled by extracellular matrix (ECM) that creates a protective network of biomolecules around the bacterial communities. The current antibiofilm agents can interfere with ECM production but, being based on small molecules, they can be degraded by bacteria and diffuse away from biofilms, which reduce their efficacy. Here we show that graphene quantum dots (GQDs) can effectively suppress the growth of Staphylococcus aureus biofilms by preventing the self-assembly of amyloid fibers - the essential component of ECM. Mimicking peptide-binding biomolecules, GQDs form supramolecular complexes with phenol soluble modulins (PSMs), the peptide monomers of amyloid fibers. Experimental and computational results show that GQDs dock at the N-terminal of the peptide and change the second structure of PSM, which disrupts their fibrillation. Commitantly, the resulting free PSM monomers turn on biofilm dispersion signaling pathways that enhance the inhibitory effect. The two-prong anti-biofilm activity of GQDs offer a new strategy for manipulation of ECms of bacterial communities.

4:45 PM BM09.02.10
Soft to Hard Biomimetic Constructs Using Recombinant Proteins Undergoing Conformational Transition Hortense Le Ferrand, Bartosz Gabryeleczyk, Cai Hao and Ali Miserez; Nanyang Technological University, Singapore, Singapore.

Synthetic mechanical gradients based on synthetic and biocompatible hydrogels currently do not achieve the soft to hard transition found in many biological materials like squid beaks or osteochondral cartilage [1]. Indeed, it is difficult to obtain tight molecular packing and high crosslinking density using conventional polymeric building blocks. Here, we employ the recombinantly expressed protein HBP-1 found in the beak of squids, and make use of its folding in presence of polyelectrolytes to expel water and attain high packing density [2,3]. Under acidic pH and in the presence of chitosan, HBP-1 undergoes a conformational transition from predominantly random coil into β-sheet-rich. At increased ionic strength, this conformation change leads to a phase separation from soluble to liquid droplets and a hydrogel-like phase. At a constant volume fraction of chitosan, the elastic modulus of the HBP-1/chitosan composite increases with the protein content. After drying and cross-linking using catechol chemistry, the resulting organic material shows...
similar trend under fully hydrated conditions. This observation is reminiscent to what is observed in the native squid beak. Furthermore, concentration gradients can be controlled based on molecular diffusion and phase separation. With this knowledge, gradients of controlled stiffness can be obtained. The crosslinked gradient results in an increase of elastic modulus from 0.08 up to 1 GPa despite containing 60 vol% of water. The approach explored here may open new avenues for the fabrication of graded materials based solely on organic biomaterials with potential applications for orthopaedic devices and soft-to-hard attachment in hydrated environments.

CrystEM Reveals the Molecular Mechanism of Polymorph Selection in Protein Crystallization Mike Skeate¹, Alexander E. Van Driessche² and Nico Sommerdijk³; ¹ Vrije Universiteit Brussel, Elsene, Belgium; ² Univ. Grenoble Alpes, CNRS, ISTerre, Grenoble, France; ³ Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, Netherlands.

Macromolecular condensed phases such as protein crystals and gels bear great medical, scientific and industrial relevance, yet a molecular understanding of their initial stages of formation is still missing. Insights on the mechanism of nucleation have the potential to resolve one of the longest-standing questions of crystallization, i.e. polymorph selection. To gain control over the emerging polymorph one needs to have a molecular-level understanding of the pathways leading to the various macroscopic states and the underlying selection mechanisms that govern the process. Here we address the issue by capturing protein crystals at birth using time-resolved cryo-transmission electron microscopy and uncover at molecular resolution the nucleation pathways of the protein glucose isomerase into two crystalline and one gelled state. We show that polymorph selection takes place at the earliest stages of transformation and is based on the specific building blocks (monomers and nanorods) for each space group. Moreover, we demonstrate control over the system by selectively forming desired polymorphs through tuning of the directionality and specificity of inter-molecular bonding. These new insights on the mechanisms of nucleation and polymorph selection open new avenues towards the control of macromolecular phase transitions, which is crucial in the further development of protein-based drug delivery systems and macromolecular crystallography.

8:30 AM BM09.03.02
Building Hierarchically-Ordered 3D Nanomaterials Using 2D Self-Assembling Protein Arrays Francesca Manea and Caroline Ajo-Franklin; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Leveraging self-assembly to pattern proteinaceous crystalline arrays in 2D and 3D offers a highly scalable, bottom up approach to develop nanomaterials with new catalytic, optical or structural applications. However, introducing multiple sites of embellishment into existing 2D protein arrays currently utilizes weak interactions that are either sensitive to external conditions or challenging to re-engineer, limiting the ability to program in bifunctionality and new 3D configurations. Here we address these challenges by developing a means to introduce two orthogonal crosslinking linkages at multiple sites in a highly robust, thermostable 2D crystalline-forming protein. We first engineered the surface-layer (S-layer) protein SbsB from Geobacillus stearothermophilus to display SpyTag or SnoopTag at the C-terminal and two newly-identified locations within SbsB monomer. These regions were able to accommodate SpyTag or SnoopTag peptide tags without affecting the 2D lattice structure. The introduction of tags at distinct locations enabled orthogonal and covalent binding with high precision of SpyCatcher- or SnoopCatcher-protein fusions to micron-sized 2D sheets. By introducing different types of bifunctional crosslinkers, the dual functionalized nanosheets could be programmed to self-assemble into different 3D lamellae, all of which retain their nanoscale order. Additionally, these nanosheets can be functionalized to display two distinct nanomaterial, yielding nanomaterials with emergent optoelectronic properties. Thus, our work creates a modular protein platform that can be facilely programmed to create dual-functionalized 2D and lamellar 3D nanomaterials with novel catalytic, optoelectronic and mechanical properties.

Intracellular Phase-Separated Assemblies of Engineered Disordered Proteins Ming-Tzo Wei and Cliff Brangwynne; Princeton University, Princeton, New Jersey, United States.

There is currently a growing interest in biopolymer phase transitions, particularly those involving intrinsically disordered proteins/regions (IDPs/IDRs). It has been found that intracellular liquid-liquid phase separations underlie the assembly of many non-membranous organelles such as P granules, nucleoli, and stress granules. However, little is known about the physics of these organelles, including their internal molecular organization and feedback between their molecular and mesoscale properties. Progress on these questions has been hampered by the lack of detailed phase diagrams, which would elucidate how molecular interactions give rise to emergent droplet properties, particularly condensed-protein concentrations and their physical characteristics.

To answer these questions, we investigate the inter-molecular interaction strengths and the full binodal of a phase-separating disordered protein that induces in-vivo phase transitions, utilizing a novel technique, ultrafast-scanning fluorescence correlation spectroscopy. These measurements led to the recent discovery that phase-separated protein droplets have unusually low densities with large void volumes. The data demonstrate how sequence-encoded conformational fluctuations of IDRs give rise to low overlap volume fractions for driving phase separations. Using inter-molecular interactions of native non-membranous organelles, we develop an optogenetic platform that permits light activation of IDR-mediated phase transitions in living cells. Inter-molecular interaction strengths are quantified and demonstrated how IDR sequences determine intracellular phase separation. These studies can elucidate not only physiological phase transitions but also their links to pathological aggregates.
Our results provide a holistic picture of the dynamics and internal organization of phase separated organelles. By uncovering the relationship between molecular level interactions and emergent mesoscale material properties, this work is foundational for understanding the form, function and potential dysfunction of intracellular phase separated assemblies. Our study has significant impact for an extensive community of researchers, with interests spanning biomaterials, bio-inspired materials, macromolecular assembly, self-assembly, intracellular phase separation, disordered proteins dynamics, polymer chemistry, and bioengineering applications of synthesized intracellular biomimetic materials.

9:00 AM BM09.03.04
Altered Energy-Landscape and Self-Assembly of Protein Crystalline 2D Array at Solid-Liquid Interface Shuai Zhang1, Robert Alberstein2, E. Akif Tezcan3 and James J. De Yoreo4; 1Pacific Northwest National Laboratory, Richland, Washington, United States; 2Department of Chemistry and Biochemistry, University of California, San Diego, California, United States.

Protein 2D materials possess diverse sophisticated and synergistic structures, and inherent chemical and biological functions. Harnessing this paradigm of protein 2D materials for bottom-up biomaterial design, synthesis and application is an attractive task with promising perspectives in biomimetic and material science. Inspired by nature cases, various strategies have been developed to construct protein 2D crystals in bulk solution. Recently, computational protein design methodology has considerably improved the structural and functional complexities of protein 2D/3D supramolecular structures from scratch.1,2 Besides growth in solution, solid-liquid interface has also been used to template few-layer protein 2D materials. However, the solid-liquid interface that is used to artificially grow protein 2D supramolecular structures is generally limited to supported liquid bilayer. It is still not quite clear how solvent mediated protein-surface interactions to define protein thermodynamics, structure and function at solid-liquid interface. That is the obstacle for artificial design and functional applications of protein 2D crystalline arrays in future.

To address these issues, we assembled the variant of L-rhamnulose-1-phosphate aldolase (RhuA), C98RhuA[3], with incorporated Cys mutants, into crystalline 2D arrays on solid-liquid interface of mica. By carefully selecting cations and controlling their concentration, we create isotropic protein monolayer 2D crystals with controlled packing patterns. It is surprising that the crystallizations of the first and second layers is bimodal that follows non-classical and classical pathways, respectively. We also proved that solvent mediated protein-surface interactions can alternate the energy-landscape of protein self-assembly from that in bulk to stabilize the original intermediate and quasi stable phase. C98RhuA can epitaxially grow on top of the surface that has different symmetry. All the findings inspire the novel strategy to synthesize protein crystalline 2D arrays at solid-liquid interface artificially. They also help to elucidate the growth model of protein 2D architectures at solid-liquid interface. They remind us the importance of solvent mediated surface templating in the self-assembly of protein 2D structures both in nature and in human manner.

9:15 AM BM09.03.05
Microbial Factories for Programmed Production of Functional Biomaterials Avinash Manjula Basavanna1,2, Anna Duraj-Thatte1,2 and Neel Joshi1,2; 1Wyss Institute for Biologically Inspired Engineering, Boston, Massachusetts, United States; 2Harvard University, Boston, Massachusetts, United States.

Biological systems are highly complex and sophisticated with unparalleled structure-function correlations. Remarkably, biological systems produce materials with extraordinary properties and functions under ambient conditions, which is in total contrast to humans’ heat-beat-treat strategies. Thus, the capabilities of a technology by which biological networks of a cell can be programmed, offers tremendous potential as cellular factories and to produce biomaterials for various functional applications.

In this regard, we employ a novel technology entitled Biofilm-Integrated Nanofiber Display (BIND) that focuses on the curli system—the primary proteinaceous structural component of E. coli biofilms. Curli are highly robust functional amyloid nanofibers (diameter 4-7 nm) formed by the extracellular self-assembly of a small (13 kDa) secreted protein, CsgA. By genetic engineering, artificial peptide domains were grafted to the amyloid protein CsgA and the resulting CsgA fusion proteins were successfully secreted from the E. coli cells. Remarkably, these engineered fusion proteins were found to extracellularly self-assemble into amyloid nanofiber networks and also exhibited the characteristic functions of the grafted artificial peptide domains. By using BIND technology, E. coli biofilm matrix is conferred with several artificial functions for nanomedicinal, nanomechanical and nanoelectronics applications.

10:00 AM *BM09.03.06
S-Layers—Principles and Applications Uwe Sleytr and Dietmar Pum; Nanobiotechnology, Univ Bodenkultur, Vienna, Austria.

One of the key challenges in nanobiotechnology is the utilization of self-assembly systems wherein molecules spontaneously associate into reproducible aggregates and supramolecular structures. In this contribution, the basic principles of crystalline bacterial surface layers (S-layers) and their use as patterning elements will be described. The broad application potential of S-layers in nanobiotechnology is based on the specific intrinsic features of these monomolecular arrays which are composed of identical protein or glycoprotein subunits. Most important, physicochemical properties and functional groups on the protein lattice are arranged in well-defined positions. Many applications of S-layers depend on the capability of the isolated subunits to recrystallize into monomolecular arrays in suspension or on suitable surfaces (e.g. polymers, metals, silicon wafers) or interfaces (e.g. lipid films, liposomes, emulsomes). S-layers also represent a unique structural basis and patterning element for generating more complex supramolecular structures involving all major classes of biological molecules. Thus, S-layers fulfill key requirements as building blocks for the production of new supramolecular materials and nanoscale devices as required in nanobiotechnology and synthetic biology.

We acknowledge the financial support by the Air Force Office of Scientific Research (AFOSR) (Grant FA9550-15-1-0459).

10:30 AM BM09.03.07
Controlled Formation of Enzyme-Scaffold Complex for Biocatalysis Using a Self-Assembling Protein Template Samuel Ling1, Florence Barraud1, Sophia Prem1, Dominic J. Glover2 and Douglas S. Clark1; 1Department of Chemical and Biomolecular Engineering, University of California, Berkeley,
In nature, enzymes that catalyze multi-step reactions are often organized in close proximity to allow the efficient channeling of intermediates from one active site to another. Diverse synthetic scaffolds based on DNA and proteins have been designed to mimic such spatial control of enzymes, and have proven successful in facilitating cascade reactions. Recent studies revealed that such enhanced catalysis can also result from formation of enzyme agglomerates rather than direct channeling of intermediates between adjacent enzymes, highlighting the need to engineer the interactions that define metabolic clusters. Thus, there is a demand for scaffolds that can effectively crosslink with each other to form higher-order structures in a programmable manner, in addition to simply templating the enzymes.

The g-prefoldin (gPFD) is a filamentous protein isolated from the hyperthermophilic archaeon Methanococcus jannaschii; its remarkable stability, unique modularity, and self-assembly into filaments with chaperone activity render it an ideal building block for the bottom-up construction of functionalized protein nanostructures. Here we propose a strategy to utilize the gPFD to build enzyme agglomerates in tunable fashion. Using the combinations of orthogonal protein-peptide bioconjugation pairs, the gPFD filaments displaying the peptide tags are first conjugated with the enzymes, and then crosslinked using the linker proteins. Thus, the extent of crosslinking is tunable through simply varying the stoichiometry between the scaffold and linker proteins.

We verified the gPFD scaffold’s ability to cluster enzymes in proximity using FRET analysis of the filaments containing fluorescent protein pairs. Subsequently, we investigated the effect of agglomerate formation on the catalytic activities of multi-step reactions using two different model system pairings: glucose oxidase (GOX)-horseradish peroxidase (HRP) and alcohol dehydrogenase (ADH)-aldehyde dehydrogenase (ALDH). Ultimately, the ability to fabricate enzyme-scaffold complexes with programmable stoichiometry and dimensions will enable better control over single- and multi-step enzymatic catalysis.

Mimicking Dividing Cells by Assembly of Protein Structures Inside Aqueous Two-Phase Droplets

In this work, we demonstrate that assembly of macromolecules, such as proteins, can cause aqueous droplets to exhibit division, even in the absence of a cell membrane. The all-aqueous nature of the systems results in tunable interfacial tension, affinity partitioning and osmotic responses. The solubility of different types of macromolecules across the interfaces enables new strategies to assemble structures at the droplet interfaces. While the significantly lower interfacial tension can make stabilization of the interface difficult due to the slow adsorption dynamics by surfactants and particles, structures that have been assembled at the interfaces can be easily expelled. This contributes to the more sophisticated dynamics of the hierarchically structured all-aqueous droplets. These droplets have great potential to be utilized as templates for fabricating materials with novel properties.

Self-Assembly of Elastin-b-Collagen-Like Conjugates Mediated by Triple Helical Parameters

Physicochemical irregularities within extracellular matrix (ECM) proteins such as collagen can lead to a wide range of connective tissue disorders including osteogenesis imperfecta and osteoarthritis. Current pharmaceutical regimens to treat such diseases suffer from off-target effects, suggesting that new approaches for targeted delivery are necessary. In the last decade, ECM-inspired polypeptide materials have garnered significant interest for their ability to selectively mimic specific matrix components such as collagen and elastins, offering new opportunities to control drug delivery within specific tissues. For example, triple helix forming collagen-like peptides (CLPs) comprising (Gly-Pro-Hyp)ₙ amino acid repeats can hybridize with high efficiency to denatured collagen proteins in the body via thermal annealing of peptide and protein single strands into a stable triple helix. Additionally, elastin-like peptides (ELPs) that consist of (Val-Pro-Gly-Xₐₐₐₐ₋₁-Gly₁ₐ₁ₐ₁)ₙ (where Xₐₐₐₐ is any amino acid with the exception of proline) amino acid repeats possess a lower critical solution temperature in which aggregation occurs upon heating above this temperature, making ELPs ideal candidates for on demand drug delivery behavior.

Recently, our group has reported on the design of hybrid peptides with linked CLPs and ELPs, and the assembly of thermoresponsive, elastin-b-collagen-like peptide nanovesicles that are capable of dissociating at high temperature (70°C). These nanovesicles offer intriguing potential in drug delivery applications due to their dual thermoresponsivity and inherent ability to bind to degraded collagen protein. However, in order to make an ELP-CLP nanoparticle with optimal drug delivery properties such as physiologically relevant hybridization to degraded collagen protein, the critical parameters of their self-assembly must first be understood, specifically with respect to the CLP domain. To test the effects of the triple helical (CLP) melting temperature on temperature-dependent nanovesicle assembly and dissociation behavior a small library of ELP-CLP conjugates was made with varying numbers of CLP (G-X-Y) repeats and varied CLP sequences. These conjugates were characterized for their thermoresponsivity and their ability to form self-assembled structures. The melting temperature, repeat length, and overall hydrophilicity of the CLP domain were found to be of critical importance to nanoparticle function.
SESSION BM09:4: Bio-Inspired Materials Based on DNA or Peptide Building Blocks
Session Chairs: Xiang Yang Liu and Tiffany Walsh

1:30 PM *BM09.04.01
Colloidal Crystal Engineering with DNA—Creating a Genetic Code for Materials Design Chad A. Mirkin; Northwestern University, Evanston, Illinois, United States.

The materials-by-design approach to the development of functional materials requires new synthetic strategies that allow for material composition and structure to be independently controlled and tuned on demand. Although it is exceedingly difficult to control the complex interactions between atomic and molecular species in such a manner, interactions between nanoscale components can be encoded, independent of the nanoparticle structure and composition, through the ligands attached to their surface. DNA represents a powerful, programmable tool for bottom-up material design. The Mirkin Group has shown that DNA and other nucleic acids can be used as highly programmable surface ligands (“bonds”) to control the spacing and symmetry of nanoparticle building blocks (“atoms”) in structurally sophisticated materials, analogous to a nanoscale genetic code for material assembly. The sequence and length tunability of nucleic acid bonds has allowed us to define a powerful set of design rules for the construction of nanoparticle superlattices with more than 30 unique lattice symmetries, spanning over one order of magnitude of interparticle distances, with several well-defined crystal habits. Further, this control has enabled exploration of sophisticated symmetry breaking processes, including the body-centered tetragonal lattice as well as the clathrate lattice, the most structurally complex nanoparticle-based material to date (~20 particles per unit cell). The nucleic acid bond can also be programmed to respond to external biomolecular and chemical stimuli, allowing structure and properties to be dynamically tailored. Notably, this unique genetic approach to materials design affords functional nanoparticle architectures that can be used to catalyze chemical reactions, manipulate light-matter interactions, and improve our fundamental understanding of crystallization processes.

2:00 PM BM09.04.02
DNA-Programmed Assembly of Single Crystalline Nanoparticle Superlattices at Interfaces Robert J. Macfarlane; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The programmability of DNA makes it an attractive structure-directing ligand for the assembly of nanoparticle superlattices with unique structure-dependent physical phenomena. While DNA base pairing has enabled the development of materials with nanometer-scale precision in nanoparticle placement and independent control over particle size, lattice parameters, and crystal symmetry, manipulating the macroscopic shape of the lattices remains challenging. By pairing this “bottom-up” assembly method with “top-down” lithographic techniques and assembling nanoparticle superlattices on a patterned substrate, complete control over crystal size, shape, orientation and unit cell structure can be realized. The key challenges in developing this technique are to first understand how different design factors affect the assembly process in this broken-symmetry system that is assembled at an interface, and subsequently develop structure-property relationships that correlate the above mentioned design parameters with the resulting overall material structure. Here, we examine both at-equilibrium deposition processes capable of generating single crystals with well-defined shapes, as well as post-deposition annealing to transform disordered particle arrangements into crystalline arrays. Using a combination of X-ray diffraction and electron microscopy techniques, both surface morphology and internal thin film structure are examined to provide an understanding of the mechanisms of particle crystallization under conditions where crystal growth is anisotropic due to a boundary condition. This novel method for controlling particle assembly draws several strong analogies to traditionally atomic epitaxy/heteroepitaxy, providing a useful tool for understanding thin film growth processes. As a result, we are able to realize 3D architectures of arbitrary domain geometry and size, thereby making materials with unprecedented precision across multiple length scales.

Programmable DNA-Semiconductor Nanostructures for Molecular Delivery Libing Zhang; Leslie Dan Faculty of Pharmacy, University of Toronto, Toronto, Ontario, Canada.

Biotemplated nanomaterials offer great promise in multimodal imaging, biosensing, and molecular delivery. There remains an unmet need for traceable and biocompatible nanomaterials that can be synthesized in a precisely controllable manner. Here, we demonstrate a single-step fabrication method for Quantum Dot-DNA Hydrogels and their successful application in enzyme-responsive drug/siRNA delivery and cell-specific targeting, and the use of a new family of materials – programmable metal/semiconductor nanostructures – for drug delivery and mRNA sensing in drug-resistant cells.

2:30 PM BM09.04.04
Magnesium Stabilized Multifunctional DNA Nanoparticles for Tumor-Targeted and pH-Responsive Chemotherapy Leilei Tian; South University of S&T of China, Shenzhen, China.
Functional nucleic acids, that can target cancer cells and realize stimuli-responsive drug-delivery in tumor microenvironment, have been widely applied for anti-cancer chemotherapy. The high cost, unsatisfactory biostability, and complicated fabrication process are the main limits for the development of DNA-based drug-delivery nanocarriers. Recently, a kind of DNA-Mg2PPI (magnesium pyrophosphate) composite nanoparticles has been produced from rolling circle amplification (RCA), which combine advantages of the designate and high-throughput isothermal amplification technique and the high stability of DNA condensation structures, quickly becoming an attractive biomedical material with great potentials. Herein, instead of using MgPPI, we found that only Mg2+ is sufficiently enough to stabilize the functional DNAs for chemotherapeutic applications. The very long single-stranded RCA product with a high charge density is more prone to form a stable condensation structures compared with a short oligonucleotide. Moreover, the dynamic electrostatic interactions between Mg2+ and DNA can better preserve the functions of DNA, which is more suitable for the design of drug-delivery system. A tumor-targeting Dox-delivery nanoparticle (~ 100 nm) was synthesized by the condensation of RCA products in the presence of an excessive amount of Mg2+, which showed good bio-stability in serum, considerable Dox loading capability, specific cancer-targeting ability, and pH-responsive sustained Dox release. The DNA nanoparticle not only has a simple composition, but also it will keep intact after the excessive exterior Mg2+ is removed, making it safe and ideal for in vivo application. Through cellular and in vivo experiments, we thoroughly demonstrated that this kind of Mg2+ stabilized multi-functional DNA nanoparticles can successfully realize tumor-targeted Dox delivery.

DNA-Programmable Nanoparticle Lattices Assembled on Polymer-Patterned Surfaces
Shu Sun1, 2, Dmytro Nykypanchuk2, Gregory Doerk2, Charles Black2, Oleg Gang2, 3 and Diana Lopez2; 1Xi'an Jiaotong University, Xi'an, China; 2Center of Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 3Department of Chemical Engineering, Columbia University, New York, New York, United States.

Photonic and electronic devices require precise control of functional components at the nanoscale. The development of DNA nanotechnology offers a fascinating platform to direct the assembly of nanoparticles into well-organized architectures with prescribed distances and spatial arrangements. Here, we combine DNA-based assembly and diblock copolymer self-assembly to realize the multi-layer assembly of gold nanoparticles into large-area, three-dimensional arrays. Specifically, the assembly of gold nanoparticles is directed through binding with DNA origami that forms arrays, and the array growth is controlled by patterns formed via diblock copolymer on the surface. In our approach, DNA-programmable nanoparticle lattices are sequentially assembled with registry of polymer pattern. We show the potential to assemble functional nanoparticles in layer-by-layer manner with controllable interlayer distance and in-plane arrangements through a combination of surface patterns and DNA nanostructures.

Engineering Molecular Assembly for 3D Electronics
Thom LaBean, Nikolay Frick and Ming Gao; North Carolina State University, Raleigh, North Carolina, United States.

The ability to design and program complex molecular interactions between synthetic biomolecules (especially polynucleotides and polypeptides) has led to a revolution in artificial nanomaterials capable of self-assembly. For example, DNA-based nanotech entails the design of artificial nucleotide sequences capable of self-assembling into desired geometric shapes and patterns with nanometer-scale precision. These synthetic DNA nanostructures have been shown useful for organizing other materials including inorganic nanoparticles (metals and semiconductors), nucleic acid aptamers, and carbon nanostructures. We are working with DNA self- and directed-assembly to develop a general purpose molecular assembly toolbox useful for a wide variety of applications, especially in nanoelectronics and medicine. One promising future direction is the bottom-up fabrication of electronics components and devices including molecular assembly of wires and metal nanoparticles toward the construction of single-electron transistors, multicomponent devices, and artificial neural networks.

4:00 PM BM09.04.07
Self-Assembled Peptide Nano-Materials for Optics and Electronic Applications
Sharon Gilead and Ehud Gazit; Tel Aviv University, Department of Molecular Microbiology and Biotechnology, Tel Aviv, Israel.

In recent years, a key direction in the field of electronics and opto-electics involves the transition from inorganic to organic components, including organic light emitting diodes (OLED), thus paving the way towards flexible and wearable electronic and light emitting devices. Bio-inspired organic materials may be the next-generation of organic optoelectronic devices based on self-organization principles, which allow facile synthesis, eco-friendliness, resistance to oxidation and no need for heavy metal doping. Recent advances in bioorganic nanotechnology have established the notion that very simple building blocks, such as dipeptides, can form regular nanostructures with distinct mechanical, optical, piezoelectric and electronic properties. In particular, members of the diphenylalanine (FF) peptide archetypal family have been shown to form various morphologies and ordered nanostructures such as tubes, rods, fibrils, spheres, plates and macroscopic hydrogels with nano-scale order. Several studies have explored the piezoelectric properties of the diphenylalanine (FF) peptide. In the presence of an external electric field, vertically aligned FF microrod arrays can be organized on a substrate, resulting in enhanced piezoelectric response. Here we show the ability of FF and other similar peptide assemblies to be used in various electronics and optics application as new bioorganic materials. FF assemblies can act as an active optical waveguiding material, allowing locally excited states to propagate along the axis of the assemblies. In addition, Fmoc capped building blocks exhibit remarkable optical properties, such as quantum confinement and fluorescence. Other rod-like assemblies and toroid-like assemblies exhibit remarkable physicochemical features, including high thermal stability, metallic-like mechanical rigidity, luminescence, piezoelectricity and semi-conductivity. The ability of FF to self-assemble into ordered structures was discovered by a systematic reductionist exploration of biological recognition modules in an amyloidogenic polypeptide. We are applying a similar reductionist approach to expand our search for minimal building blocks towards single amino acids as well as other metabolites such as nucleobases, demonstrating their self-assembly into various ordered structures. Doing this we are enlarging our library of biological building blocks which bear the potential to be novel bio-inspired supramolecular materials for Optics And Electronic applications.

4:15 PM BM09.04.08
Amino Acid-Encoded Biocatalytic Self-Assembly for Transient Functional Nanostructures
Mohit Kumar and Rein Ulijn; Nanoscience, ASRC, City University of New York at the Graduate Center, New York, New York, United States.

One key feature of biological systems is the existence of chemically fueled, transient structure and function, like the on-demand formation/degradation of tubulin, actin fibers etc. Supramolecular polymers as synthetic mimic of such biomaterials has shown great promise in a number of areas, including...
biomedicine, sensing and energy harvesting. However, the main challenge is to actively regulate the shape, function and performance of these materials, while maintaining their physiological conditions. This has spurred recent research towards temporal control of nanostructures, which is achieved by using (bio-)catalysis to activate building blocks and thereby drive assembly. In this regard, potential for design of active supramolecular nanostructures based on peptide nanotechnology is increasingly appreciated. The objective of this work is demonstration of active encoding of nanostructures by using simple amino acids, resulting in transient conducting nanowires and in situ visualize time dependent dynamics of such structure.

We designed a self-assembling core molecule with two in-built competing reactive sites, consisting of the organic semiconductor naphthalenediimide (NDI), conjugated with D and L enantiomer of tyrosine methyl esters. The stereoselective fast enzymatic reaction at the L enantiomer compared to the D enantiomer provides the necessary kinetic competition to achieve temporal control over assembly. By simply adding one of a range of encoding amino acids in the presence of enzyme α-chymotrypsin, we achieve pathway selection between hydrolysis and acylation at both chiral ends. This results in an in situ modification of the amphiphilic structures, giving rise to unique self-assembly trajectories that are time programmed by the nature of encoding amino acid. Taking advantage of the semiconducting nature of the NDI core, electronic wires could be formed and subsequently degraded, resulting in temporally regulated electro-conductivity. Such a system holds great promise towards interfacing biology with electronics. Moreover, by appropriately functionalizing molecules with a fluorophore, the dynamic formation and degradation of nanofibers could be visualized with STED (Stimulated Emission Depletion microscopy) based super resolution microscopy. Such imaging significantly improved the resolution (39%) compared to traditional confocal. Interestingly, the lifetime of transient nanostructures can be completely controlled by simply choosing different amino acids. Overall, the biocatalytic incorporation of encoding amino acids around a functional core offers a general approach to modulate, switch or fine-tune supramolecular structures over time which can now be visualized in situ with superresolution microscopy.

4:30 PM BM09.04.09
DNA Origami-Assembled Light-Emitting Nanoclusters with Controllable Optical Output Honghu Zhang1, Mingxing Li1, Kaiwei Wang1,2, Ye Tian1, Jia-Shiang Chen1, Mingzhuo Liu1, Katherine T. Fountaine3, Donald DiMarzio1, Mircea Cotlet1 and Oleg Gang1, 4; 1Center for Functional Nanomaterials, Brookhaven National Laboratory, Upton, New York, United States; 2School of Science, Xi'an Jiaotong University, Xi'an, China; 3Department of Chemical Engineering and Department of Applied Physics and Applied Mathematics, Columbia University, New York, New York, United States.

Structural DNA nanotechnology has emerged as a powerful method to fabricate targeted nanoscale architectures. Using rationally designed DNA origami frames, nanoparticles can be coordinated in a prescribed manner in 3D. Here, we have designed DNA origami frames for assembling various nanoparticles in pre-determined locations. The DNA frames have enabled well-defined nanocluster assembly with nanometer-precision positioning, and controllable high-purity stoichiometry with tunable functionality. We have fabricated DNA origami-constructed nanoparticle clusters, consisting of spherical quantum dots (QDs) and gold nanoparticles (AuNPs) that exhibit controllable photoluminescence (PL) when the excitation wavelength is close to surface plasmon resonance of the AuNPs. Furthermore, these DNA-constructed nanoclusters emit highly polarized light. By varying the size and number of AuNPs in the nanoclusters, we have explored correlations between the assembled structures and the PL polarization magnitude and the overall PL enhancement. Our DNA origami based nanoclusters with precisely built 3D architectures provide an efficient route to control single emitter optical output.

4:45 PM BM09.04.10

Stimuli-responsive nanomaterials with reconfigurable structures and properties have garnered significant interest in the fields of optics, electronics, magnetics, and therapeutics. DNA is a powerful and versatile building material that provides programmable structural and dynamic properties, and indeed, sequence-dependent changes in DNA have already been exploited in creating switchable DNA-based architectures. However, rather than designing a new DNA input sequence for each intended dynamic change, it would be useful to have one simple, generalized stimulus design that could provide multiple different structural outputs. In pursuit of this goal, we have designed, synthesized, and characterized pH-dependent, switchable nanoparticle superlattices by utilizing i-motif DNA structures as pH-sensitive DNA bonds. When the pH of the solution containing such superlattices is changed, the superlattices reversibly undergo: (i) a lattice expansion or contraction, a consequence of the pH-induced DNA “bond breaking” and “bond forming” processes. The introduction of i-motifs in DNA colloidal crystal engineering marks a significant step toward being able to dynamically modulate crystalline architectures and propagate local molecular motion into global structural change via exogenous stimuli.

Tandem Molecular Self-Assembly in Liver Cancer Cells Jie Zhang1, Yanbin Cai1, Ling Wang2 and Zhimou Yang1; 1College of Life Sciences, Nankai University, Tianjin, China; 2College of Pharmacy, Nankai University, Tianjin, China.

Inspired by nature, stimuli-responsive self-assembly has been widely explored for spatiotemporally regulating diverse cellular functions. In situ formation (both pericellular and intracellular) of assemblies of man-made small molecular in cell milieu has been successfully applied for controlling the cell behavior and fate. The differences of the expression levels of bio-signals (i.e., enzyme or small molecule) between cells are favorable natural-source of inspiration for designing precursors to form sophisticated assemblies with enhancing selectivity to target and inhibit diseased cells. We herein describe the tandem molecular self-assembly of a peptide derivative NBD-GFFpYss-ERGD (Tandem Molecular Self-assembly Precursor, TMSP) that is controlled by a combination of enzymatic and chemical reactions. In phosphate-buffered saline (PBS), TMSP self-assembles first into nanoparticles by phosphatase and then into nanofibers by glutathione. Liver cancer cells exhibit higher concentrations of both phosphatase and GSH than normal cells. Therefore, the tandem self-assembly of TMSP also occurs in the liver cancer cell lines HepG2 and QGY7703; TMSP first forms nanoparticles around the cells and then forms nanofibers inside the cells. Owing to this self-assembly mechanism, TMSP exhibits large ratios for cellular uptake and inhibition of cell viability between
A tantalum oxide (Ta₂O₅) film was deposited on the lower electrode deposited by electron beam deposition (EB depo.), and the upper electrode was biomolecule-hostings gels and the chemical interactions between biomolecules and silica host have been investigated. Ethidium bromide (EtBr) high resistance state with low bias voltage and time. It is short-term plasticity well-known as synaptic movement. Also, manganese oxide is similarly deposited to fabricate a usual ReRAM. A structure in which manganese oxide (MnO₂) was sandwiched between the Ta₂O₅ film and the lower intervals of 40 to 50 nm by modifying PEG on the surface of ferritin.

A conceptually new fabrication technique has been developed for the fabrication of composite gel coatings containing commercially available drugs that of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. ZnO, a high mobility -type semiconductor, is a highly attractive transparent material for applications in optoelectronic devices. However, the manufacture of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. In this work we will demonstrate a biomimetic approach for the synthesis and deposition of ZnO films on Si substrates under mild ambient conditions. Simultaneous synthesis and deposition of ZnO nanoparticles (NPs) is achieved in this work by the use of dual affinity peptides (DAPs) as linkers. One segment of the DAP has a strong affinity to the substrate and the other promotes the synthesis of the NPs. The formation of 10-20 nm crystalline NPs in solution was confirmed by transmission electron microscope (TEM) electron diffraction analysis. Further X-ray photoelectron spectroscopy (XPS) and energy dispersive spectroscopy (EDS) characterization revealed 1[Zn]:1[O] stoichiometry. Initial results demonstrating the in-situ deposition of ZnO NPs on Si using the DAP linkers will also be presented. We will further show that the DAP monolayers reduce the work function of ZnO by ~260 meV. This work demonstrates the great potential of using low-cost and green biomimetic approaches for the fabrication of thin nanocrystalline inorganic films towards implementation in optoelectronic devices.

A tantalum oxide (Ta₂O₅) film was deposited on the lower electrode deposited by electron beam deposition (EB depo.), and the upper electrode was biomolecule-hostings gels and the chemical interactions between biomolecules and silica host have been investigated. A conceptually new fabrication technique has been developed for the fabrication of composite gel coatings containing commercially available drugs that of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. ZnO, a high mobility -type semiconductor, is a highly attractive transparent material for applications in optoelectronic devices. However, the manufacture of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. In this work we will demonstrate a biomimetic approach for the synthesis and deposition of ZnO films on Si substrates under mild ambient conditions. Simultaneous synthesis and deposition of ZnO nanoparticles (NPs) is achieved in this work by the use of dual affinity peptides (DAPs) as linkers. One segment of the DAP has a strong affinity to the substrate and the other promotes the synthesis of the NPs. The formation of 10-20 nm crystalline NPs in solution was confirmed by transmission electron microscope (TEM) electron diffraction analysis. Further X-ray photoelectron spectroscopy (XPS) and energy dispersive spectroscopy (EDS) characterization revealed 1[Zn]:1[O] stoichiometry. Initial results demonstrating the in-situ deposition of ZnO NPs on Si using the DAP linkers will also be presented. We will further show that the DAP monolayers reduce the work function of ZnO by ~260 meV. This work demonstrates the great potential of using low-cost and green biomimetic approaches for the fabrication of thin nanocrystalline inorganic films towards implementation in optoelectronic devices.

A tantalum oxide (Ta₂O₅) film was deposited on the lower electrode deposited by electron beam deposition (EB depo.), and the upper electrode was biomolecule-hostings gels and the chemical interactions between biomolecules and silica host have been investigated. Ethidium bromide (EtBr) high resistance state with low bias voltage and time. It is short-term plasticity well-known as synaptic movement. Also, manganese oxide is similarly deposited to fabricate a usual ReRAM. A structure in which manganese oxide (MnO₂) was sandwiched between the Ta₂O₅ film and the lower intervals of 40 to 50 nm by modifying PEG on the surface of ferritin.

A conceptually new fabrication technique has been developed for the fabrication of composite gel coatings containing commercially available drugs that of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. ZnO, a high mobility -type semiconductor, is a highly attractive transparent material for applications in optoelectronic devices. However, the manufacture of high quality ZnO thin films requires high temperatures and/or pressure, making the processes expensive. In this work we will demonstrate a biomimetic approach for the synthesis and deposition of ZnO films on Si substrates under mild ambient conditions. Simultaneous synthesis and deposition of ZnO nanoparticles (NPs) is achieved in this work by the use of dual affinity peptides (DAPs) as linkers. One segment of the DAP has a strong affinity to the substrate and the other promotes the synthesis of the NPs. The formation of 10-20 nm crystalline NPs in solution was confirmed by transmission electron microscope (TEM) electron diffraction analysis. Further X-ray photoelectron spectroscopy (XPS) and energy dispersive spectroscopy (EDS) characterization revealed 1[Zn]:1[O] stoichiometry. Initial results demonstrating the in-situ deposition of ZnO NPs on Si using the DAP linkers will also be presented. We will further show that the DAP monolayers reduce the work function of ZnO by ~260 meV. This work demonstrates the great potential of using low-cost and green biomimetic approaches for the fabrication of thin nanocrystalline inorganic films towards implementation in optoelectronic devices.
Self-assembly is widespread in nature. Supramolecular hydrogels formed by small molecular peptides that self-assemble in water through the noncovalent interactions have the advantages of simple chemical synthesis, easy modification of component units, good biocompatibility and low toxicity, and fluorescence probes have been applied for the detection of important analytes with high sensitivity and specificity. However, they cannot be directly applied for the detection in samples with auto-fluorescence such as blood.

Herein, we demonstrated a simple but effective method of surface-induced self-assembly/hydrogelation for fluorescence detection of an enzyme. First, the peptide precursor NBD-FFPY with fluorescent group NBD was synthesized by solid-phase synthesis method. Then NBD-FFPY could be dephosphorylated to form gelators NBD-FFY by alkaline phosphatase. After the peptide precursor NBD-FFPY was cleaved by the alkaline phosphatase, NBD-FFY can be embedded into the surface of positively charged glass plate. Therefore, the fluorescence intensity of NBD-FFY on the glass surface can be calculated through detecting the fluorescence intensity of NBD-FFY deposited on the surface of the glass was linearly related to the incubation time and the concentration of the enzyme. Even in the complex environments such as blood and cell lysate, our method can still quickly detect the activity of the enzyme.

As a result, surface-induced self-assembly for fluorescence not only expands the application of molecular selfassembly but also provides a useful method that can be applied for direct detection of enzyme activity in complex biological samples such as blood and cell lysates.

Studies on Synthesis and Fluorescence Spectroscopy of Hybrid Magnetic Nanoparticles (Fe3O4-Au) Linked with Fluorescent Molecule

Magnetic and fluorescent nanoparticles are widely studied in biomedical research for their use in drug delivery, cell separation, magnetic resonance imaging (MRI), hyperthermia, various multimodal techniques, etc. In this study, we report a recent work on nanoparticles incorporating with a fluorescent molecule and a superparamagnetic core via nanoscale engineering. Fe3O4-Au hybrid nanoparticles are synthesized via a solution phase chemical reaction in an inert N2 atmosphere. These synthesized hybrid nanoparticles are characterized by UV-Vis-NIR spectroscopy, fluorescence spectroscopy, XRD, TEM, etc. Optimal synthesis conditions are also highly relevant in producing stable and uniform hybrid nanoparticles without impurities. Fluorescence spectroscopy show the correlations between the lifetime and intensity of fluorescence and sizes, compositions, shapes of hybrid nanoparticles as well as the conjugation process to link the nanoparticles to fluorescent molecules. By carefully engineering the growth conditions, such as altering growth temperatures and precursor reagent ratios, functional hybrid magnetic nanoparticles can be optimized for hyperthermia, MRI and other multimodal biomedical applications.

Self-Assembly of Peptide with Polyoxometalates into Nanostructured Materials

Polyoxometalates (POMs) are one of the structurally-characterized anionic oxide nanoclusters that have been frequently used as building blocks to self-assemble organic-inorganic hybrid materials. POMs-based hybrid materials have received attractive attention owing to their applications in catalysts, photovoltaics, molecular magnetism, and biochemistry. Peptoids, a type of sequence-defined synthetic molecules, are composed of repeating N-substituted glycine monomer units and developed as attractive protein-mimetics to combine the advantages of both synthetic polymers and biopolymers. Moreover, peptoids are more thermally and chemically stable in comparison with peptides and proteins. The lack of both intra- and intermolecular backbone hydrogen bonds make peptoids as unique building blocks for controlled self-assembly1-4 and tuning the function of peptoid-based materials. In this presentation, we will report the two alternative approaches to self-assemble organic-inorganic hybrid materials from POMs and peptoids. For the first approach, peptoids containing cationic residues are co-assembled with anionic POMs via electrostatic interaction. Peptoid sequences and the ratio of POMs and peptoids are varied to tune the morphology of the self-assembled hybrid materials. The second approach is based on building POM-containing peptoids by having POMs as peptoid side chains, then these hybrid sequences are self-assembled into hierarchically-structured organic-inorganic hybrid nanomaterials. Comparing to the first approach, the second approach offers the precise control the location and stereochemistry of POMs within peptoid assemblies.

As a result, surface-induced self-assembly for fluorescence not only expands the application of molecular selfassembly but also provides a useful method that can be applied for direct detection of enzyme activity in complex biological samples such as blood and cell lysates.

involving van der Waals force, must be working at the basic level. The thickness of the film implies an alignment of a few poly-Glycine helices in the vertex as attraction and many of them into an ordered side-side arrangement. Such a uniformly flat structure suggests its possible role as a reliable and well-defined platform for further assembly with other molecules as a composite film.

We also found that some short peptides and alpha-hydroxy acids self-assembled into long strings as well as a hydrogel structure under an aqueous condition at specific pHs. The hydrogel has a nano-mesh like structure that can be reconstructed on mineral surfaces and visualized with AFM. We are particularly interested in possible roles of these structures as potential functional biomaterial in the origin of life on the Earth.

**BM09.05.10 Catalytic Self-Assembly of Peptidic Bolaamphiphiles Coordinated with Transition Metal Cofactors** Sang-Yun Lee, Min-Chul Kim and Changjoon Keun; Yonsei Univ, Seoul, Korea (the Republic of).

Peptidic bolaamphiphile is an biomimetic amphiphilic molecule whose biochemical activity can be tuned by the designer peptides. The peptidic bolaamphiphiles have peptide or amino acid segments as hydrophobic moieties that are associated with the central alkyl chain to display amphiphilic property. Similar to other amphiphilic molecules, these peptidic bolaamphiphiles self-assemble to form complex structures while exposing the biological component to the surface in an aqueous medium. Here, assembled structure of histidyl bolaamphiphiles was exploited as a biomimetic host matrix whose histidine imidazoles are exploited as ligands to coordinate with transition metal ions. By coordinating with transition metal ions, metalloenzyme-mimetic catalysts could be built. In particular, catalytic activity for CO2 hydration and oxidation of organic compounds could be realized by coordinating various transition metal ions to the histidyl bolaamphiphile assembly. Furthermore, the catalytic water evolution was achieved by introducing iridium to the histidyl bolaamphiphile assembly. The prepared metal-bolaamphiphile catalyst was surveyed with spectroscopic studies to verify the origin of the catalytic activity. This assembly of peptidic bolaamphiphiles will be beneficial for the building of catalyst mimicking various metalloenzymes.

**BM09.05.11 Thermodynamic Properties of Pluronic F127 Micelles with Added Cefepime Determined by Differential Scanning Calorimetry** Lydia M. Menah1 and Brian J. Love1, 2; 1Material Science and Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 2Biomedical Engineering, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Aqueous amphiphilic copolymer solution have been made with varying amounts of a third constituent with the notion of forming drug loaded gels. Our research group is interested in how additive molecules perturb the structure of amphiphilic copolymers that are known to form colloidal crystals. We are investigating whether likely correlations exist between how strongly the drug interacts within the hydrophobic and hydrophilic regions of micelles and colloidal crystals and how bioavailable the drug is as it elutes from within the gel. We have made 25% aqueous solutions of PEO-PPO-PEO copolymers (F-127, BASF) formulated and tested between -5°C and 50°C. Rheology, and DSC have been the primary tools of measurement and we have focused our initial efforts on cefepime to observe how its presence affects micelle formation and colloidal crystallization. Drug-loaded polymers are of interest as schemes within the drug delivery community for controlled release and other studies have been done using dendrimers, and responsive polymers contained within other polymers. We have found that when Cefepime has been added in concentrations ranging from 2-8% of the mass of a 25% PEO-PPO-PPO copolymer solution, the onset temperature for micelle formation systematically drops with increasing cefepime concentration. The change is not dramatic, 9.1°C ±5.1 for neat, while 4.5°C ±5.1 for 8%, the trend is apparent. The size of the endotherm does not show the same systematic trend and within the realm of statistical analysis, the size of the endotherm is invariant to cefepime concentration. At 2°C/min, the energy of the gel formation is masked by the rest of the endotherm linked with micelle formation. We are testing a lower ramp rates in order to observe the transition linked with the gel. Separately we have resolved that the gel is clearly forming and requires a cold re-equilibration to break up the gel structure. It can be inferred that cefepime is acting as a chaperone to allows micelles to nucleate more easily at lower temperature. We will present on the gel formation temperatures, enthalpies, and transitions to show the structural formation and development of the other polymers-drug complexes beyond cefepime/F-127.

**BM09.05.13 β-Sheet Crystallization-Driven Supramolecular Peptide Nanoagents with Structure-Dependent Theranostic Functions** Inhye Kim1, 2 and Eunji Lee1; 1School of Materials Science and Engineering, Gwangju Institute of Science and Technology, Gwangju, Korea (the Republic of); 2Graduate School of Analytical Science and Technology, Chungnam National University, Daejeon, Korea (the Republic of).

Versatile, one-dimensional (1D) supramolecular theranostic nanoagents were developed by β-sheet crystallization-driven-assembly of peptide amphiphiles (PAs) attached with paramagnetic metal ion (gadolinium, Gd3+)-chelating moiety and tumor cell-targeting segment, respectively. Paramagnetic metal-attached scaffolds have attracted much attention as magnetic resonance imaging (MRI) contrast agents (CAs). Many efforts have been devoted to enhance MRI efficacy of commercial CAs by adopting supramolecular scaffolds to overcome the disadvantages with low sensitivity and specificity. Here, fibrils, driven by the assembly of PA with hydrophobic β-sheet-forming peptide block, were utilized as a theranostic nanoscaffold with drug-loading within their robust core. The resulting 1D nano-aggregates allowed successful intracellular delivery of doxorubicin (DOX) to target cancer cells and contrast-enhanced MR imaging by high longitudinal (T1) relaxivity of water protons. Correlation between the structural nature of fibrils formed by PA-assembly and its diagnostic efficacy was elucidated. The nanostructured theranostics with desirable functions may thus be a useful strategy for the generation of tailor-made biocompatible nanomaterials.

**BM09.05.14 Graphitization and Strength of Annealed Silks and Synthetic Polymer Fibers** Thomas Dugger1, Sourangsu Sarkar2, Sandra Correa-Garhwal1, Mikhail Zhernenkov1, Hourng Kim Chea1, Cheryl Hayashi4 and David Kisailus1; 1University of California, Riverside, Riverside, California, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States; 3Brookhaven National Laboratory, Upton, New York, United States; 4American Museum of Natural History, New York, New York, United States.

Silks have been proposed as superior carbon fiber precursors to synthetic polymers. β-sheet nanocrystals, the main contributor to silk's strength, have a favorable structure to graphitize upon annealing. Due to their uniform dispersion throughout the fiber and preferential alignment along the long axis of the fiber, silk-precursor carbon fiber could be stronger than traditional carbon fiber made from polycrylonitrile (PAN). To investigate this theory, we compare the degree of graphitization, graphite crystal orientation, and tensile strength between spider silks, silkworm silk, PAN, and poly(vinyl alcohol).

**BM09.05.15 Fabrication of 2D Protein Films and 3D Protein Hollow Spheres via Alternative Self-Assembly of α-Synuclein and Their Applications** Sookkoo Lee1, Ghibom Bhak2 and Seung R. Paik1; 1Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of); 2Organic Chemistry University of Santiago de Compostela (USC), Center for Research in Biological Chemistry and Molecular Materials (CIQUS), Santiago de Compostela, Spain.
Understanding the self-assembly process of amyloidogenic proteins is valuable not only to find their pathological implications but also to prepare protein-based biomaterials. α-Synuclein (αS), a pathological component of Parkinson’s disease, producing one-dimensional (1D) amyloid fibrils, has been employed to generate two-dimensional (2D) protein films and three-dimensional (3D) protein hollow spheres (PHS) via its alternative self-assembly at either high temperature or rapid-freezing condition, respectively. At a high temperature of 50°C, αS molecules self-assembled into the 2D film whereas 1D amyloid fibrils were produced at 37°C. This alternative self-assembly phenomenon could be attributed to structural plasticity of the intrinsically disordered protein of αS which turns into a surface active agent at the air-water interface at the high temperature. The αS 2D film was also routinely prepared at the oil-water interface and used as a framework of molecular assembly to give rise to a polydiacetylene-based sensing material. 10,12-Pentacosadiynoic acids (PCDA) were aligned on the film in a spatially organized way and then photo-polymerized to induce the n-conjugated molecular assembly yielding blue color. Its colorimetric transition to red was induced by increasing temperature. This functionalized protein film increased its height to 60 nm from 40 nm upon the PCDA immobilization and exhibited enhanced physical and chemical stability. In addition, the modified film showed remarkable high electrical conductivity only in the red state. Under frozen condition, on the other hand, PHS were produced from αS oligomers via rapid freezing, frozen incubation, and freeze-drying process. PHS prepared with αS-eosin conjugates and focused ion-beam severance of PHS confirmed their empty core structure. While PHS were stable at room temperature, they were immediately converted into amyloid burs comprised of protein nanofibrils upon heating. Therefore, PHS could be considered a constrained spherical structure transformable into biocompatible matrix material in nanoscale which could be used as a fill-in agent to improve mechanical strength of living tissues like skin as well as hydrogels in general. In this study, we have demonstrated selective fabrication of the amyloidogenic protein of αS into either 2D or 3D structures and their use as potential protein-based biomaterials.

BM09.05.16

Chain-Like Superstructures of Macromolecular Micelles for Linear Assembly of Plasmonic Nanoparticles and Fluorophores

Kyungtai Kim, Sukwoo Jang, Jonghyuk Jeon, Donghwi Kang and Byeong-Hyeok Sohn; Seoul National Univ, Seoul, Korea (the Republic of).

In living organisms, we can find various chain-like structures in microscale, which are usually self-assemblies of biomacromolecules. For example, fibrils in a tissue consist of collagen as a biomacromolecular building block. Assemblies of collagens by controlled hydrogen bonding produce elongated supramolecular chains of fibrils. Similarly, colloidal nanoparticles having patches can be employed as effective building blocks for chain-like superstructures. Well-defined patches on nanoparticles can serve bonding parts for assembling process of linear chains. Especially, macromolecular micelles can have distinct patches on their surface so that they can be assembled into linear superstructures. In this presentation, we polymerized chain-like superstructures with patchy micelles of diblock copolymers and then utilized them for linear assembly of plasmonic nanoparticles and fluorophores. The growth of nanoparticles was controlled within the cores of macromolecular micelles in chain-like superstructures. In addition, fluorescent dyes were selectively attached to the core-forming blocks of macromolecular micelles to organize them into linear assemblies. We also produced red-, green-, and blue-emitting linear superstructures by varying the dyes attached to the core-forming block. We characterized optical properties of chain-like superstructures functionalized with plasmonic nanoparticles and fluorophores.

8:00 AM *BM09.06.01 Biominalization-Inspired Self-Organized Organic/Inorganic Composites—Stimuli-Responsive Ordered Nanorod Materials and Aligned Thin Films Formed with Macromolecular Templates

Takashi Kato; The University of Tokyo, Tokyo, Japan.

Biomimeralization-inspired synthesis of organic/inorganic composites has attracted attention. We have been developing a variety of composite materials based on macromolecular templates.[1] Here we report hydroxyapatite and calcium carbonate nanorods composites that exhibit liquid-crystalline properties and zine oxide thin-films with controlled aligned structures. The TEM observations of the nanorod composites show that they have crystalline structures covered with acidic macromolecules.[2] These nanorods exhibit colloidal liquid-crystalline states. Hydroxyapatite nanorod materials are aligned under application of an external magnetic field.[2] Magneto-optical response has been achieved for the liquid-crystalline states under crossed polarizers. Liquid crystalline materials are also obtained for calcite nanorods.[3] We have also applied bioinspired synthesis to the development of functional ZnO thin-film materials with oriented structures.[4] We have succeeded in the biomeralization-inspired synthesis of composite thin films comprising of zine hydroxide carbonates that are not found in biominalers. The composite thin films are converted to ZnO thin films with ordered structures through thermal treatment. Bioinspired syntheses are useful approaches to the development of new functional materials by low-energy consumption and environmentally friendly processes.

8:30 AM BM09.06.02

Utilizing GLC-TEM to Elucidate Magnetosome Biominalization in Magnetotactic Bacteria

Emre Firlar1,2, Meagan Ouy1, Agata Bogdanowicz2, Leigha Covnot1, Boao Song2, Yash Nadkarni2, Reza Shahbaziyan-Yassar2 and Tolou Shokuhfar1; 1Bioengineering, University of Illinois at Chicago, Chicago, Illinois, United States; 2Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, United States.

Biomimicking of Fe3O4 magnetosome synthesis ex situ is of interest due to the potential uses in the physical and medical field, and is thus important to understand the biominalization pathway for the magnetosomes in magnetotactic bacteria. Conventional TEM approaches use fixation of bacteria preventing monitoring the dynamics or using fluid cell TEM holder which does not have enough spatial resolution. Therefore, in this work, graphene liquid cells (GLC) were used to encapsulate magnetotactic bacteria after mixing them with iron rich growth medium, thus maintaining the native environment. For the first time, the formation of these nanoparticle and increased nanoparticle contrast due to advancing biominalization using GLC-TEM was monitored.
Through electron energy loss spectroscopy (EELS) analysis, the presence of graphene optical gap, water exciton peak and graphene σ+π bond were monitored at 6 eV, 8.5 eV and at 14 eV, respectively. Formation of radiation induced H2 bubbles and magnetosomes were observed as well, indicating the presence of liquid during electron imaging. Fe2o (octahedral), Fe3o (tetrahedral), Fe(III) (octahedral) and FeOOH reference spectra were used to fit the experimental data. Relative ratio of Fe2+ to Fe3+ was calculated to be 0.35. Magnetite was known to be able to be converted to first maghemite and then to hematite via the electron beam exposure. Considering this ratio will be 0.5 for a perfect Fe3O4 (1x Fe2+, 2x Fe3+), hematite is the strongest candidate to be present in addition to magnetite in magnetosomes contributing to higher Fe3+ content. At different time scales after iron induction, (i) an increase of the magnetosome image contrast was reported by the line profile drawn across the magnetosome and increased TEM contrast showed increased mass-thickness in the image, which indicates progression in biomineralization and incorporation of more Fe3O4 molecules to this particle; and (ii) an increase in the number of magnetosomes were observed.

8:45 AM BM09.06.03

In nature we can find many examples of organic-inorganic nanocomposites with exceptional properties. For example, diatoms are unicellular algae whose cell walls are formed form hierarchical nanostructured silica. Euplectella sp. is a siliceous sponge that can assemble a mechanically resistant glass cage with nano- to macro- hierarchical organization. In both cases the formation process occurs by the intricate interactions between macromolecules and the silica precursors. These beautiful examples provide inspiration for the controlled formation of structurally complex silica based materials under ambient conditions.

In this paper we present a detailed study on the use of synthetic macromolecules to control silica morphology using two strategies: 1) mineralization of silica in pre-assembly macromolecular templates with defined pores and 2) the co-assembly of silica precursors and nanoparticles with macromolecules. Using (cryo)-electron microscopy, (cryo)-electron tomography and liquid phase electron microscopy we investigate the formation processes and characterize the hierarchically porous silica structures.

We discuss the underlying principles of silica mineralization in confinement and design strategies for making hierarchically porous silica based materials. Such porous materials have many potential applications including insulators, sensors, catalysts and drug delivery vehicles. We hope the insights provided by our detailed investigation will help towards the rational design and understanding of mechanisms formation of porous silica based materials.

9:00 AM BM09.06.04
Mineralization in Bio-Inspired Metal-Coordinate Polymer Hydrogels Niels Holten-Andersen, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Biominerals have been widely studied in part due to their unique mechanical properties, afforded by their inorganic-organic composite structure and well-controlled growth in macromolecular environments. More recently, growing concerns over climate change and environmental sustainability and the emerging relevance of green chemistry make biomineralization an even more attractive process to study. Here, we focus on the earlier stages of mineral nucleation and growth in macromolecular environments, where an organic, hydrogel matrix dominates the bulk properties of the material and the mineral is distributed throughout the matrix as nano- and/or microparticles. The phase, morphology, and size of the particles can be controlled using the choice of the hydrogel, functional moieties on the gel polymer backbone and soluble additives. Depending on the choice of organic matrix and inorganic mineral, the matrix can be dissolved to leave highly uniform particles, or the matrix can be left intact, creating a hydrogel-mineral composite with improved mechanical properties through organic-inorganic interfacial interactions or additional functionality, such as magnetic properties.

9:15 AM BM09.06.05
Towards Templating 2D Magnetite Platelets via Bio-Inspired Approaches Bernette Oosterlaken1, 2, Giulia Mirabello1, 2, Yifei Xu1, 2, Joseph P. Patterson1, 2, Heiner Friedrich1, 2 and Nico Sommerdijk1, 2; 1) Laboratory of Materials and Interface Chemistry, Eindhoven University of Technology, Eindhoven, Netherlands; 2) Institute for Complex Molecular Systems, Eindhoven, Netherlands.

Magnetite, Fe3O4, is a naturally occurring iron oxide. Magnetite has excellent mechanical properties, as well as magnetic properties. Its magnetic properties depend on crystal size and shape. In nature, the formation of magnetite is precisely regulated, as controlled size and shape crystals are specifically tuned depending on the biological function, even at ambient and aqueous conditions.

Inspiration for this work was found in nature, where specialized vesicles with associated transmembrane proteins are directing nucleation and growth of the magnetite crystals. Achieving a similar level of control over crystal shape and size thus far has been challenging in synthetic procedures and the processes behind templated magnetite mineralization are still poorly understood.

Little work has been done on templated magnetite formation so far. In a bio-inspired approach, we are investigating templated magnetite growth, to precisely tune the size and shape of the magnetite crystal into a certain shape. The targeted crystal shape in this project is 2D platelets. 2D platelets of magnetite might have appealing magnetic properties, such as magnetic vortices, which result in in-plane magnetization.

A suitable template to direct magnetite growth into 2D crystals is collagen. Collagen is known to template the formation of calcium phosphate into 2D platelets, but also lepidocrocite (γ-FeOOH) (Xu et al., in preparation, 2018). By growing magnetite into a collagen template, we are creating a novel collagen-based hybrid material with excellent mechanical and magnetic properties. To the best of our knowledge, we are the first to explore the possibilities of growing magnetite in a collagen template.

To template magnetite inside a collagen matrix, magnetite formation outside the collagen template should be inhibited. Acidic (bio-)molecules, like polypeptides, are shown to influence magnetite crystal growth. As such, those polypeptides are used to assist in mineral formation inside the template, similar to what has been exploited for calcium phosphate mineralization in a collagen matrix before.

Combining spectroscopic techniques such as Raman spectroscopy with advanced electron microscopy techniques might provide us with new insights in the mechanisms behind magnetite formation inside the template. CryoTEM already has been shown to be of great value when addressing mineral formation mechanisms. Liquid phase electron microscopy (LP-EM) allows to visualize the processes in-situ and therefore is an appealing complementary technique to CryoTEM. Preliminary experiments in the confined space of the liquid cell that is used for LP-EM measurements show that magnetite indeed has formed inside the liquid cell. After optimization of the experimental conditions, LP-EM allows for in-situ visualization of templated magnetite formation.

9:30 AM BREAK
of incubation in phosphate buffered solutions (PBS), BSA immobilized and aligned exclusively along the biosilica micropatterns, while the FITC-BSA was noted, while the response on the unpatterned controls was randomized. Additionally, FTIC-labeled BSA and R5 were printed together and after 6 days biomineralization was demonstrated. This cost-effective micropattern design scheme can meet a wide range of needs in the biomedical field with labeled R5 and observed by fluorescence microscopy. hMSCs were cultured on the micropatterned hydrogels and specific alignment along the printed lines showed limited guidance of cell orientation in relatively short culture periods. Silica-based micropatterns are popular in many biomedical fields.

The organisation and function of biological systems is based on compartmentalisation. Biomimeralisation processes, which lead to the generation of mineral-based structures such as bones, teeth and seashells are no exception to this. Biominerals form within the confines of “privileged environments” delineated from the organism, where spatial constraints and chemical conditions can be precisely controlled. Despite this, the influence of confinement on crystallisation processes is poorly understood. This talk describes a series of systematic investigations into the effects of confinement on the formation of a range of important crystal systems including calcium carbonate, calcium sulfate and calcium phosphate. Rods of controlled glassy gels (CGs) with sponge-like structures were used to access thin nanoscale confinement. X-ray absorption and diffraction tomography were used to study the precipitation of a population of calcium sulfate particles within these environments and we show that bassanite (CaSO4·0.5H2O) whose existence as a precursor to gypsum (CaSO4·2H2O) has been disputed – is stable in the CGs for periods of at least three weeks. We can also monitor the transformation from bassanite to gypsum and investigate how this leads to fracture of these porous media. At larger length scales, microfluidic devices including a novel “crystal hotel” that comprises a series of “rooms”, are used to grow larger crystals. These offer many features including flow, confinement and the possibility of changing reaction conditions with time that are common to biological systems. These devices were used to image the development of crystals within confined volumes and to study the effects of soluble additives on calcium carbonate precipitation at early times. Our results show that the additives have no effect on crystal morphologies until the crystals reach at least 100 nm in size. Finally, the cylindrical pores of track-etched membranes were used to study the effects of confinement on calcium carbonate and calcium phosphate precipitation. We show that the polymorph of CaCO3 changes from calcite to aragonite as the pore diameter decreases, and that aragonite is the major polymorph in 200 nm pores when low concentrations of magnesium and sulfate ions are also present. Finally, calcium phosphate precipitation in this system generates highly orientated single crystal of hydroxyapatite in small pores, where the degree of orientation is comparable to that seen in bone. Confinement therefore enables effective control over crystallisation processes, and as such promises the ability to optimise the synthesis of crystalline materials.

In the development of the invertebrate calcium carbonate skeletal elements, protein families are involved in the coordination of mineralization events. In many instances this process begins with the formation of amorphous calcium carbonate mineral nanoparticles which are assembled into mesoscale crystals (calcite, aragonite, vaterite) and this assembly process creates many mechanistic features of these crystals that are important for material integrity. We have observed that in the mollussk shell and sea urchn spicules that this mineralization process is guided by the formation of matrix protein hydrogel phases that stabilize, assemble, and organize mineral nanoparticles, create nanotextured crystal surfaces, and form intracrystalline nanoainclusions within the mineral phase that introduce elastic deformability to the mineral phase. These protein hydrogels form in response to protein-protein interactions that are entropically driven by intrinsically disordered and modified globular protein domain sequences, as well as protein-carbohydrate interactions involving glycoproteins. We hope that materials science will develop similar principles to create the next generation of composite materials under ambient conditions.

Well-designed micropatterns present in native tissues and organs involve changes in extracellular matrix compositions, cell types and mechanical properties to reflect complex biological functions. However, mimicking these micropatterns in vitro remains a challenge and the patterning strategies often showed limited guidance of cell orientation in relatively short culture periods. Silica-based micropatterns are popular in many biomedical fields including in vitro tissue models, due to the biocompatibility and high versatility of silica. Yet, harsh conditions (e.g. extremely high temperature and/or pressure) are often required to create silica patterns, and bonding between substrates is not strong enough. In this work, a de novo design strategy to code functional micropatterns to engineer cell alignment through the integration of aqueous-peptide inkjet printing and site-specific biomimeralisation is presented. Inkjet printing provides direct writing of macroscopic biosilica selective peptide-R5 patterns, which allow site-specific growth of silica nanoparticles through in situ biomineralisation, with micrometer-scale resolution on the surface of a biopolymer (silk) hydrogel to achieve the alignment of human mesenchymal stem cell (hMSCs) and enhanced immobilization of bovine serum albumin (BSA). To create the micropatterns, peptide-R5 was inkjet printed on the surface of enzymatically crosslinked silk hydrogels, followed by subsequent silicification to induce biosilica deposition. Linewidth and gap distance between each printed line were manipulated by adjusting drop spacing and drop volume during printing. Biomimeralisation was confirmed by examining silica nanoparticles covering the printed lines but not elsewhere. A 20 µm pattern gap distance and 1 µm linewidth were achieved. Well-defined peptide patterns on the substrate were also evidenced by printing fluorescein isothiocyanate (FITC)-labeled R5 and observed by fluorescence microscopy. hMSCs were cultured on the micropatterned hydrogels and specific alignment along the printed lines was noted, while the response on the unpatterned controls was randomized. Additionally, FITC-labeled BSA and R5 were printed together and after 6 days of incubation in phosphate buffered solutions (PBS), BSA immobilized and aligned exclusively along the biosilica micropatterns, while the FITC-BSA alone extended over the surface, which suggests improved protein stability and alignment on micropatterns. A de novo strategy to design functional micropatterns to engineer cell alignment and protein immobilization through inkjet printing and site-specific biomimeralisation was demonstrated. This cost-effective micropattern design scheme can meet a wide range of needs in the biomedical field with implications for broader material designs.

The production of crystalline materials with structures and properties resembling those of biominerals is a challenging synthetic goal. Biominerals are invariably composite materials in which organic matrices are associated with the inorganic phase, even single crystal biominerals contain proteins embedded within the crystal lattice. Biominerals therefore provide a unique inspiration for the design and synthesis of new materials.

This talk explores how this biogenic strategy can be used to generate synthetic crystals with novel composite structures and properties and to determine the “design rules” which govern the occlusion of additives within crystals. Using polymer particles rather than proteins as simple crystal growth additives, High levels of particle occlusion is achieved by tuning the particle surface chemistry and the crystal growth conditions within calcite single crystals.
Our strategy is extended to generate nanocomposites in which inorganic nanoparticles are distributed throughout a crystal matrix with true nano-scale mixing. Highly effective incorporation of gold and magnetic nanoparticles was achieved within host carbonate- and sulfate-minerals by controlling the nanoparticle surface chemistry using a physically-adsorbed double hydrophilic diblock copolymers. This methodology can potentially be applied to a huge number of nanoparticle/ host crystal systems, where its experimental simplicity makes it an attractive and general method for generating composite materials.

Exploring the Abiotic-Biotic Interface—From Fundamentals to Biomimetic Composites Carole C. Perry; Nottingham Trent Univ, Nottingham, United Kingdom.

Events occurring at the solid/aqueous interface (i.e. molecular recognition, adsorption, desorption etc.) underpin a variety of technologies used in the biomedical and biotechnological fields. The use of nanoparticles and multifunctional nanoparticles that combine recognition and targeting with specific properties is widespread for the development of clinical diagnostic tools or therapeutic platforms. Although we are developing understanding of how materials are made in nature there is a long way to go in applying that knowledge in a systematic and predictive fashion to develop new composite materials.

This presentation will highlight (a) aspects of our recent exploration of the effect of surface chemistry on peptide material interactions using both simulation (DFT) and experiment, and (b) show how we can apply this understanding to the development of novel biomimetic composites based on Pt/Au and MOFs.

In all our studies we use a wide range of experimental techniques to characterise our (bio) materials and measure their behaviour at interfaces. The research presented will include new methods being developed specifically to probe such interactions.

SESSION BM09.07: Biomimetic Crystallization
Session Chairs: Chun-Long Chen and Nico Sommersdijk
Wednesday Afternoon, November 28, 2018
Sheraton, 2nd Floor, Back Bay A

1:30 PM *BM09.07.01
Creation of Hierarchical Material Structures Using Molecular Specificity Yu Huang; University of California, Los Angeles, Los Angeles, California, United States.

Material formation in nature is precisely controlled in all aspects from crystal nucleation, growth to assembly to deliver superior functions. Specific biomolecule-material interactions have been hypothesized to play important roles in these processes. Proteins, polymers and small molecules have been extensively explored to replicate the degree of control in material formation in vitro and for nonbiogenic materials. However the organic-inorganic interfacial interaction is still far from being understood which hinders the further advancement of biomimetic material formation. In this talk I will share our efforts on decoding the myth of biomolecular specificity to material surface and their roles in controlling crystal nucleation and growth. The selection of facet specific short peptides and their abilities in guiding predictable morphology control of Pt nanocrystals will be first demonstrated. Then detailed experimental and theoretical studies on binding mechanism will be discussed. These studies open up opportunities in understanding the molecular details of inorganic-organic interface interaction, which can one day lead to the development of a library of molecular functions for biomimetic materials design and engineering.

2:00 PM *BM09.07.02
Leveraging Molecular-Level Control of Peptide Constructs to Direct the Synthesis, Structure and Properties of Chiral Nanoparticle Superstructures Nathaniel Rosi; University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

Replacing one atom or linkage in an organic molecule or polymer can dramatically affect its structure and properties. Chemists have leveraged the power of synthesis to adjust and fine tune the properties of molecules. Nanoparticles are a class of fundamental structural and functional building blocks for the construction of new materials. The properties of these materials depend intrinsically on the size, shape, and composition of the constituent nanoparticles as well as the precise organization of the nanoparticles within the material. In order to fine tune the properties of the material, we must be able to carefully adjust the organization of its component nanoparticles. Can we use the power of synthetic chemistry to program and carefully adjust the structure and properties of hierarchical nanoparticle-based materials? This talk deals with peptide-based methods for controlling the synthesis and assembly of nanoparticles into well-defined chiral helical architectures. Rigorous molecular models of peptide assemblies will be detailed. It will be demonstrated that the atomic make-up of the peptide constructs can be carefully adjusted and that these subtle yet purposeful modifications lead to non-trivial structural changes to the chiral nanoparticle superstructure assembly and properties.

Engineering Biology for Design and Assembly of Functional Materials Rajesh Nair; Joseph Slocik, Kristi Singh, Maneesh K. Gupta, Kuang Zhifeng and Patrick B. Dennis; Air Force Research Laboratory, Dayton, Ohio, United States.

Biological systems offer inspiration and exciting opportunities for creating biomimetic materials, structures and devices. The assembly of individual biomolecular units into well-defined, higher-order functional structures is a hallmark of biological systems, and is exemplified in the self-organization of biological building blocks into supramolecular structures (e.g. peptides, proteins, nucleic acids, viruses). Such biological materials/systems offer inspiration and exciting opportunities for creating biomimetic materials, emulating processes and inspiring the design of devices. Furthermore, the ability to use synthetic biology tools to manipulate the genetic information encoding for biomolecules of interest allows one to design materials with tailored functionalities and properties. I will describe in my talk our research on engineering biology to create designer biomolecules or enabling the assembly of functional materials for various applications.

4:00 PM BM09.07.04
Investigations into the Mechanism of Biosilicification Under In Vitro Conditions Sai Maddala1, Ernst van Eck2, Paul H. Bonans1, Heiner Friedrich1 and Nico Sommersdijk1; 1TU Eindhoven, Eindhoven, Netherlands; 2Radboud University, Nijmegen, Netherlands.
Diatom biosilicas possess intricate organization, whilst requiring only ambient synthesis conditions. Their remarkable morphological properties have been a source of intense interest for chemists and biologists. Understanding the mechanisms involved in the morphological control of biosilica could inspire the production of new functional materials.

Here, we present results from our in vitro investigations into biomineralization of silica. Our investigations focus on mimicking the conditions present in the silica deposition vesicle of the diatoms; high silicic acid concentration (0.10 to 0.34 M), salinity, the presence of polyamines and mildly acidic pH (pH 5.5). Understanding the silica formation in these conditions is key to unravelling the mechanism of silica biomineralization. Tetramethy orthosilicate (TMOS) was used as silica precursor, as it readily hydrolyses to give metastable silicic acid solutions. pH was maintained at 5.5 using an autotitrator. Silicic acid consumption was monitored using ammonium molybdate assay. In the absence of polyamine additives, and under high salt conditions (NaCl concentration 0.45 M) free silicic acid was consumed in two stages, first a portion of it undergoes rapid condensation within 5 minutes, and the remainder stays unreacted for the next 27 minutes, followed by complete reduction in concentration by 43 minutes. Previous investigations into silica formation were generally performed in pure water, and this two-stage silicic acid consumption process was not observed. The role of polyamines on silica particle formation was monitored under real-time conditions using Dynamic Light Scattering (DLS). We used polyallylamine hydrochloride (PAH, Mw 15000 g/mol) as polyamine mimic. In the absence of PAH, silica particles were observed as soon as TMOS completely hydrolysed in water. In the presence of PAH, the particle formation wasn’t observed for the first 76 minutes, suggesting that the polyamines could potentially inhibit silica formation. Argon sorption porosimetry of silica gels obtained in the absence of PAH had a surface area of 170 m²/g and a pore size of 7.05 nm. Whereas in the presence of PAH, the surface area was 230 m²/g and pore size of 3.36 nm. Further analysis was performed using Cryo-TEM and solid state ²⁹Si NMR.

Our results indicate that under the conditions found in silica deposition vesicle of diatoms, silicic acid undergoes rapid condensation and that the presence of polyamines retard this process. This suggests that the polyamines could crucially help stabilize and store silicic acid. While the exact mechanism will be the subject of future research, our results help explain an important intermediate step in silica biomineralization.

4:15 PM BM09.07.05
Building Biomimetic Bone at Higher Level of Organization Eléa Besson¹,², Clement Sanchez³, Marco Faustiní¹,² and Nadine Nassif³,⁴; UMR 7574 - Laboratoire de Chimie de la Matière Condensée de Paris, Paris, France; ²Sorbonne Université, Paris, France; ³CNRS, Paris, France; ⁴ESPCI, Paris, France; ⁵Collège de France, Paris, France.

Bone is a composite material which closely associates a dense and organized collagen organic matrix (mainly type I collagen fibrils) with an apatite mineral network. From nanometers to millimeters and beyond, bone is hierarchically structured to provide maximum strength with a minimum of material. The structure/function relationship being crucial in bone, attention needs to be paid to the long-range collagen/hydroxyapatite (HA) structure in models set in vitro. Recently, the cholesteric geometry was reproduced in the laboratory (Wang and al., Nat Mater 2012).

The aim of this work is to reach higher levels of bone hierarchical organizations enlarging the relevance and applications of bone models. We are working on two different organizations: the trabecular and the cylindrical motif (osteons) of the cortical bone. Both imply the texturization of the liquid-crystalline collagen liquid-crystal phases to control the spatial arrangement of the oriented domains. Thanks to the geometry, the direction of the flow or and the confinement, the shear forces involved may have an effect on the resulting organization.

The resulting hybrid biomimetic materials and their hierarchical organization require various characterization techniques (e.g. in-situ observations by polarized optical microscopy (birefringence) and investigation by SAXS/WAXS of the directed co-assembly of the organic/inorganic phases, electronic microscopies, mechanical tests etc).

By using an original strategy, we aim to improve our knowledge on processes involved in the bone tissue (morphogenesis) as well as build new biomimetic hierarchically-structured materials that offers remarkable scaffolds to repair larger defects for bone tissue engineering.

4:30 PM *BM09.07.06
Harnessing the Precision of Biorecognition for the Development and Assembly of Responsive, Functional Inorganic Nanomaterials Marc R. Knecht, Univ of Miami, Coral Gables, Florida, United States.

Nature has exploited the precision of biorecognition events for the development inorganic materials for critical applications ranging from protection against predation to structural support. These materials are generated under sustainable conditions where the translation of such approaches to material compositions of technological importance could provide pathways to address current needs in applications ranging from energy harvesting and storage to biological sensors and theranostic systems. At present, only minimal understanding is known concerning the direct interaction between biological and bio-inspired molecules (e.g. peptides, DNA, peptoids etc.) with inorganic materials, where the ability to predictably design these biomolecules with affinity for the target system remains unachieved. By having such capabilities, the ability to fabricate functional materials with desired properties on demand could be accessed for immediate use in targeted applications. In addition, due to the great complexity achievable from biosystems, the biomolecules could be designed with secondary functionalities beyond inorganic material affinity, thus generating final structures with multifunctional capabilities. Our research has focused on the design of new bio-inspired systems with the ability to fabricate functional inorganic materials and drive their assembly in three dimensions. This assembly process is accessed based upon the multifunctional capability of the peptides to recognize and bind the inorganic surface, while simultaneously self-organizing in three dimensional space. In one instance, the self-assembly process is driven through biomolecule-biomolecule interactions, while in a second case, the assembly process is achieved through crosslinking of multiple inorganic materials from a single biomolecule. This research demonstrates multiple, disparate pathways from which biorecognition events can be exploited to drive inorganic material assembly, which could be tailored to different systems based upon biomolecular affinity.
Dehydration Stability Analysis of DNA-Guided Nanoparticle Superlattices

Yakuto Sumi, Takumi Isozai, Shoko Kojima, Shunta Harada, Toru Ujihara, and Miho Tagawa
Graduate School of Engineering, Nagoya University, Nagoya-shi, Japan; Institute of Materials and Systems for Sustainability, Nagoya University, Nagoya-shi, Japan.

Supramolecular hydrogels hold great promise for controlled drug delivery. We reported on a supramolecular hydrogel based on an aldehyde-terminal peptide. The hydrogelator could form Schiff base with amine drugs. The resulting hydrogels showed an ultra-stable property in highly acidic or basic aqueous solutions. Due to the pH-responsive property of Schiff base, the hydrogels could be applied for controlled release of encapsulated amine drugs (doxorubicin).

As a result, doxorubicin released faster at acidic pH values (5.5, 6.5) than neutral pH value (7.4) in the hydrogels (The 24 hours accumulative released percentage of Dox at pH 5.5, 6.5 and 7.4 was 15.38, 13.45 and 10.98%, respectively.). Tumor microenvironment was reported having acidic pH values from pH 5.8 to pH 7.6. We think our strategy provides a novel peptide-based hydrogel that may be applied in controlling delivery of amine containing therapeutics.

Catalyzed Organic Reactions in Aqueous Media Using Hierarchically-Structured Nanomaterials Assembled from Sequence-Defined Peptoids

Tengyue Jian and Chun-Long Chen; Pacific Northwest National Laboratory, Richland, Washington, United States.

Natural enzymes are highly efficient and selective catalysts that present unique catalytic microenvironments. Development of highly stable enzyme- mimic catalysts using sequence-defined synthetic molecules is of great benefit to the area of biomimetic catalysis and facilitate our understanding of the structure-dependent catalytic performance. Here we report the design and synthesis of peptoid-based biomimetic materials with hierarchical structures for catalyzing the direct asymmetric aldol reaction and hydrolysis reaction in aqueous media. First we synthesized and assembled 20 proline-containing membrane catalysts, and demonstrated their catalysis of asymmetric aldol reaction with high conversion yields and good enantio- and diastereoselectivities. We further showed that both the enantio- and diastereo-selectivities of this aldol reaction are highly dependent on the hydrophobic microenvironment built around catalytic sites. For the hydrolysis reaction, we found that imidazole and pyridine-containing 2D membranes catalyzed this reaction in aqueous media with high efficiency. We demonstrated the use of peptoid nanomembranes for degradation of nerve agent simulants: 4-nitrophenyl phosphate and acyl ester (nitrophenylacetate and pyrene ester). In this catalyzed hydrolysis reaction, we found that the addition of Zn²⁺ and Cu²⁺ significantly accelerated the hydrolysis rate. We further demonstrated that these catalyzed organic reactions are highly dependent on the morphology and crystallinity of peptoid assemblies.

Ultrastable Supramolecular Hydrogel of Hydrophobic Peptides Prepared by a Hydrolysis Process

Guojuan Pu; State Key Laboratory of Medicinal Chemical Biology, Nankai University, Tianjin, China.

Supramolecular hydrogel based on peptides self-assembly have attracted extensive research interests in recent years, but its application in the field of nanomedicine is still limited by its poor stability in extreme environments. The number of hydrophobic amino acids directly affects the solubility of the peptides and the properties of the hydrogel. Peptides FF (F: Phenylalanine) has strong assembly capability, those hydrogels based on dipeptide of FF are the most widely investigated. Organic solvent is always required to dissolve peptides because of its strong hydrophobic properties. However, there is no hydrogel containing more than three Phenylalanine currently in aqueous solution.

Therefore, we describe a method for the preparation of hydrogels containing hydrophobic FFFF and FFFFF sequences by ester bond hydrolysis, which resulted in two highly potent peptide hydrogels formed by Nap-GFFFF-GP-EE and Nap-GFFFF-GP-EE (GP: Glycolic Acid). Then the transparent hydrogel containing more than three Phenylalanine currently in aqueous solution.

In conclusion, a novel method was constructed to promote hydrophobic peptides to dissolve in water and form a supramolecular hydrogel by the ester and the bond hydrolysis method, even if the molecule itself is unable to form a hydrogel and there is low solubility with ultrasound or heat means. This approach should be applicable for exploring supramolecular assemblies formed by other hydrophobic peptides. From the above, useful information for

Organic-Inorganic Bio-Hybrid Nanoparticle for Systemic Cellular Delivery of Superoxide Dismutase to Prevent Acetaminophen-Induced Hepatotoxicity and Liver Injury
Min Sang Lee and Ji Hoon Jeong; Sungkyunkwan University, Suwon-si, Korea (the Republic of).
Direct delivery of proteins into cells has been considered an effective approach for treating the protein-related diseases. However, clinical use of proteins has still been limited due to their instability in the blood and poor membrane permeability. To achieve an efficient cellular delivery of the protein to target cells via a systemic administration, a multifunctional carrier system having desirable stability both in the blood stream and the cells, specific cell-targeting property and endosomal escape functions may be required.
In this study, we designed organic-inorganic bio-hybrid nanoparticle containing an active enzyme by cross-tethering multiple superoxide dismutase (SOD) molecules with 3,4-dihydroxystyrenylamine (L-dopa)-derivatized hyaluronic acid (d-HA). SOD was conjugated with d-HA by reacting surface amines of SOD with catechol moiety of d-HA through Michael-type addition and Schiff base formation, which forms a hydrophilic network mesh pouch containing multiple SOD molecules tethered with HA chain networks. The free catechol groups that were not involved in the conjugation chelated calcium ions, resulting in formation of ultra-small calcium phosphate nanoparticles (USCaP, 2-5 nm) decorated on the surface of the nanoparticle. The permeable shell of hydrophilic HA chains effectively protects the enzyme from degradation in the blood after intravenous administration and provides an additional function for targeting hepatocytes expressing HA receptor (CD44). The structure and catalytic activity of the enzyme molecules in the nanoparticle were not significantly compromised in the nanoparticle. In addition, dissolution of USCaP in acidic environment efficiently improved the endosomal escape after cellular uptake, resulting in the rapid release of d-HA/SOD into the cytoplasm. The SOD-containing nanoparticle fortified with USCaP was used for the treatment of acetaminophen (APAP)-induced fulminant hepatotoxicity and liver injury. The systemically administrated nanoparticle achieved the efficient hepatic cellular delivery of SOD and resulted in efficient removal of reactive oxygen species (ROS) in the liver and remarkable improvement of APAP-induced hepatotoxicity and liver injury in animals.

Fine-Tuning Core-Shell Nanoparticle Growth by Exploiting Ions Doping
Jianxiong Zhao, Xian Chen, Bing Chen and Feng Wang; Materials Science and Engineering, City University of Hong Kong, Hong Kong, Hong Kong.
Predicting and tailoring the morphology of core shell nanoparticle is indispensable in obtaining desirable properties for optical and biological applications. However, the incomplete and discontinuous shell growth induced by heterogeneity in structure and chemical bonding may reduce the luminescence intensity and detriment to particle uniformity. Here, we demonstrate a strategy of ions doping for forming continuum NaREF4 (RE= rare earth) shell growth on heterogeneous core.
Compared to those un-doped shell which formed homogeneous nucleation surround the core. We show that doping can greatly reduce the energy barrier of heteronucleation, making shell successfully deposit on core. The core shell structure are distinguished by using high-angle annular dark-field scanning transmission electron microscopy. The shell growth process at different reaction stages are revealed by transmission electron microscopy observation on nanoparticle extracted during the reaction. We show that nascent shell layer formed at low energy crystallographic facets, afterward, shell extended and merged together over entire core surface.
We applied the strategy on core particle with different size and dimensions. All shell growth is stabilized but with some morphology variation for different core shape. The TEM analysis show that shell growth is not only strongly dependent on the nature of the different facet, but also reliant on mechanical flexibility of core. Moreover, the strategy improves both upconversion emission and lifetime of core shell nanoparticle and simultaneously provide novel platforms for building multifunctional self assembled composites.
BM09.08.07
Liquid Crystalline Disubstituted Polyacetylene-Preparation, Properties and Possible Applications for Biomimetic Materials
Kyoka Komaba2, Masashi Otaki1 and Hiromasa Goto1; 1University of Tsukuba, Tsukuba, Japan.
Many polymers mimicking ecosystem such as DNA have been synthesized. Synthesis of helical macromolecules has been inspired by such natural polymers. In this report, we synthesized disubstituted polyacetylenes using tantalum based catalyst. Chemical structure and optical properties of the polymer thus synthesized in this study are characterized with infrared absorption spectroscopy (IR), gel permeation chromatography(GPC), UV-vis absorption (UV) spectroscopy, circular dichroism (CD), fluorescence spectroscopy, and polarized optical microscopy analyses. Polyacetylene as a conductive polymer has some drawbacks such as poor stability in the air, no solubility, low processability. Introduction of substituent to the polyene backbone allows improvement of its disadvantages. Introduction of liquid crystal group can improve such drawbacks. We synthesized liquid crystal polyacetylenes for potential applications in biological field.
We succeeded in synthesis of disubstituted polyacetylene using tantalum chloride catalyst (Y = 41%). GPC result indicated that number average molecular weight (Mn) of the polymer is to be > 1,000,000 and degree of dispersion (Mw/Mn) ca.1.4.
The IR spectroscopy measurements confirmed that polyene was successfully produced by opening of the C≡C bond of the monomer in the polymerization. Polymer shows two absorption maxima at around 370 nm and 430 nm in the UV-vis. These absorption bands are derived from p-p* transition of the main chain. The polymer shows no CD signals. This result indicates that the polyacetylene derivative synthesized in this report contains equimolar amount of right-handed and left-handed helical structures, resulting in racemic state. This polymer shows fluorescence signal at around wavelength 500 nm. Polarizing optical microscopy observations for the drop cast film from toluene solution deposited on a glass substrate was carried out. This polymer shows fan-shaped texture of smectic liquid crystal with lyotropic liquid crystallinity. The layer structure has similarity to biological membrane. This unique structure may be artificial lipid bilayer membrane.
In this work, we achieved synthesis of disubstituted polyacetylenes with large molecular weights, showing lyotropic liquid crystallinity with layer structure. We evaluated that the simple synthesis of liquid crystal polyacetylene derivatives having no mesogenic group from readily available monomers affords to producing of the biomimetic lipid bilayer membrane.
BM09.08.08
Selenium- and Tellurium-Containing Block Copolymer with Multi-Hierarchical Oxidation Response
Lu Wang and Huaping Xu; Department of Chemistry, Tsinghua University, Beijing, China.

We evaluated that the simple synthesis of liquid crystal polyacetylene derivatives having no mesogenic group from readily available monomers affords to producing of the biomimetic lipid bilayer membrane.

Nanomaterials with hierarchical responsiveness are of great significance for not only fundamental science but also future biomedical applications due to sophisticated and hierarchical physiological environments. Here, we report a selenium- and tellurium-containing block copolymer that can be stepwise oxidized by both chemical methods and electrochemical methods. Differences in sensitivity to the oxidation of selenium and tellurium were employed. By tuning the concentration of the oxidant and oxidation periods, self-assembly behaviors of the copolymer were tuned by stepwise chemical oxidation. After
Stimuli-responsive DNA hydrogels, albeit the potential advantages like biocompatibility and ease to functionalize, problems remain in the reconciliation between facile fabrication and stimuli-responsiveness. In this study, by rationally designing the sequence of DNA chains, pH-responsive sites-namely, i-motif forming sequences (IFSs)—were introduced during rolling circle amplification. At pH 5.0, the resultant gelation occurs driven by the formation of intermolecular i-motifs as crosslinkers.

To better evaluate the sequence influence on the responsiveness, three IFSs were designed and named as I1, I2, and I3 whose sequences are CCCCTCCCCC, CCCTCCCTCCCT, and CCAATCCCAATCCCAATCCCC. Three IFSs form primarily inter-molecule, both inter-and intra-molecule and primarily intra-molecule i-motif structure respectively. The difference in sequence reflects on the pH-responsiveness during sol-gel transition. When adjusting the pH from 5.0 to 8.0, I1 quickly dissolved while I2 became softer but remain intact and I3 became more dispersed in the buffer. We draw a conclusion that the gelation process can be tuned via sequence design. An IFS favoring intramolecular i-motif leads to mechanically weak, thermally unstable yet pH-sensitive hydrogel while for IFS favoring intermolecular i-motif structure, gelation may occur along with quick condensation which promotes non-specific interactions within the gel.

The microstructure of the hydrogel was investigated to dig some evidence of the gelation mechanisms. RCA products at neutral (pH 7.5) and acidic condition (pH 5.0) were observed under scanning electron microscope. Of all three samples, flower-like microstructures (FMs) with diameter of 2-3 μm was observed in a large amount. FMs were believed to be a in situ formed by-product of DNA polymerization and performs a crucial role in gelation process. Form the SEM images, the hydrogel morphology featured with thick DNA matrix embedded with FMs. For sol, the FMs is more visible due to the lack of matrix surrounding. Also, the different properties of specimen can be explained. For I1, dense matrix already formed in neutral pH indicating many crosslinking sites that are not i-motif structures. For I3, the matrix is in acidic buffer is relatively looser which is consistent with the weak stability. Worth noting that there is no RCA matrix in I2 after redissolved in pH 8.0 buffer yet the FMs remain unchanged. This proves that FM, as a condensed complex of DNA and magnesium pyrophosphate (MgPPi), has no pH-responsiveness and that the pH-adjusting gelation exclusively relies on introduced i-motif sequences.

To summarize, this work proposed a facile method to produce pH-responsive DNA hydrogel. Also, the influence of three different IFS sequences on gelation mechanism as well as their interaction with flower-like microstructures were investigated.

BM09.08.10

Hybrid Thin-Film Formation of Zinc Layered Hydroxides with Intercalated Organic Molecules Through a Biominalization-Inspired Approach

Satoshi Kajiyama, Takashi Kato and Fumiya Katase; Univ of Tokyo, Tokyo, Japan.

Biominalization-inspired crystallization is one of effective approaches for the development of hierarchical structures from nano- to macro- scales under ambient conditions [1-3]. In biominalization, acidic polymers induce amorphous states of inorganic crystals with the interaction between acidic groups and metal ions. The amorphous states are useful as precursors for inorganic crystals with ordered structures [4,5]. We have achieved the formation of hybrid thin films based on zinc hydroxide carbonate (ZHC) with ordered nanostructures through biominalization-inspired approach utilizing amorphous precursors. ZnO thin films have been obtained with ordered structures from ZHC ordered hybrid thin films through thermal treatment [6]. In the present study, we demonstrate that hybrid thin-film formation composed of zinc layered hydroxides with intercalated organic molecules through the biominalization-inspired approach utilizing amorphous states as precursors. The amorphous precursors for zinc layered hydroxides with intercalated organic molecules were prepared in the presence of poly(acrylic acid). Polymer thin-film matrices were immersed in aqueous solution containing the amorphous precursors in order to develop hybrid thin films. The structures of resultant hybrid thin films composed of layered zinc hydroxides have been examined with polarizing optical microscopy, scanning electron microscopy and X-ray diffraction. These characteristics revealed that the hybrid thin films of layered zinc hydroxides exhibit macroscopically ordered structures. Hybrid thin films comprising of the layered zinc hydroxides are converted to ZnO thin films through thermal treatment. The resultant ZnO thin films exhibit macroscopically ordered structures. It is elucidated that ordered structures of ZnO thin films depend on the molecular structure of intercalated guest molecules as well as the original structures of hybrid thin films of layered zinc hydroxides. These results suggest that the biominalizationapproach is useful for the development of functional ZnO materials with ordered structures.

Macromolecular Assembly of DNA into Complex Nanostructures via Hybridization Chain Reaction

Laura A. Lanier and Harry Bermudez; Univ of Massachusetts-Amherst, Amherst, Massachusetts, United States.

Through the use of a macromolecular self-assembly technique called hybridization chain reaction (HCR), we have created complex, well-defined nanostructures. HCR is a supramolecular polymerization of DNA that proceeds as an isothermal cascade of strand displacement reactions. Two DNA monomers are kinetically trapped in hairpins until the addition of an initiator strand opens the hairpin of one monomer through a strand displacement reaction. The unhybridized end then opens the hairpin of the other monomer through a strand displacement reaction. This cascade of strand displacement reactions continues, producing a supramolecular DNA polymer. This project aims to demonstrate the living mechanism of HCR. Further, the living nature of HCR is used to create well-defined nanostructures of DNA by HCR in order to expand the design toolbox of DNA for potential applications in such fields as nanomedicine, sensing, synthetic biology.

References
We have demonstrated that HCR produces supramolecular polymers of DNA in a controlled manner through a living polymerization mechanism. Through molecular assembly by HCR, DNA polymers of narrow dispersity are produced whose molecular weight is controlled by the stoichiometric ratio, consistent with a living polymerization mechanism. Additionally, HCR polymerization can be continued by the addition of further monomer, demonstrating its living nature by the absence of termination and chain transfer reactions. Identification of the living character of HCR presents new opportunities in macromolecular assembly of structural DNA nanotechnology and molecular biology.

Utilizing the demonstrated living nature, complex, well-defined nanostructures are created via HCR. Bottlebrush structures are created by modifying the monomer to include an additional overhang that initiates a secondary HCR polymerization with aspect ratio controlled by the stoichiometric ratios of the initiator and monomer strands of each HCR sequence. Supramolecular star polymers are created by modifying a four-arm star to initiate HCR from each arm. The growth of each arm is independently controlled, allowing for the creation of asymmetric DNA star polymers. The creation of these complex nanostructures is demonstrated by gel electrophoresis and atomic force microscopy.

**Enzymatically Activated Aggregation and Cell-Adhesion of Peptide-Nanoparticle Conjugates for Surface-Enhanced Raman Spectroscopy (SERS) Based Diagnostics and Imaging**

Hailing Huang1, 2, 3, Stephen O’Brien1, 2, 3, Duncan Graham4 and Rein Ulijn5, 2, 3, 4

1 The City College of New York, New York, New York, United States; 2 CUNY Advance Science Research Center, New York, New York, United States; 3 The Graduate Center, City University of New York, New York, New York, United States; 4 Applied and Pure Chemistry, University of Strathclyde, Glasgow, United Kingdom; 5 Chemistry, Hunter College, New York, New York, United States.

In cancer research, multi-functionalized gold nanoparticles (GNPs) have advanced to realize simultaneous diagnosis and therapy (i.e. theranostics) due to their excellent optical properties and accessibility of surface modification. An example of GNPs used for cancer theranostics is to functionalize the surface using Raman reporter molecules for surface enhanced Raman spectroscopy (SERS) and incorporate anti-cancer drug molecules on the surface. One critical aspect of using nanomedicines for cancer treatment is to ensure that the administered drugs reach and accumulate at the tumor site, rather than retaining at healthy parts of the body or being eliminated by the reticuloendothelial system. Unfortunately, during the past 10 years, the delivery efficiency of nanoparticles has not been improved significantly, and only a median of 0.7% of injected dose of nanoparticles reached the tumor. Increasing the delivery efficiency is therefore one of the greatest challenges for the development of cancer nanomedicines.

In this study, an enzyme responsive peptide functionalized GNP is designed to target metastatic tumor cells with a new dual-action targeting mechanism. Immobilized peptides with which contain an enzyme- cleavable linker which incorporates a cysteic acid adhesive ligand are immobilized onto GNP and recognized and cleaved by collagenase MMP-9. MMP-9 is overexpressed by malignant tumor cells and plays a central role in metastatic cancer progression by degrading proteins in the extracellular matrix (ECM). The enzymatic product fragments retained on the surface of GNP, LRGIDC, trigger nanoparticle self-assembly and enhances SERS signals. Moreover, the RGD motif binds preferentially to αvβ3 integrins which are protein receptors overexpressed on tumoral endothelial cells primarily during angiogenesis. The advantage of this design is that the surface functionalized GNPs remain an inactive state through the blood circulation and become active once they reach the tumor ECM, not only exposing the RGD surface for cell binding, but also enabling tumor diagnosis by SERS. This active targeting mechanism can potentially reduce the binding of RGD to non-tumoral integrins and increase the delivery efficiency of the nanoparticles.

**Octopus-Inspired Adhesive and Conductive Patch Sensor for Biosignal Monitoring**

SeungHoon Choi1, HeonJoong Lee2 and Changhyun Pang2, 3

1 Sungkyunkwan University Advanced Institute of NanoTechnology, Suwon, Korea (the Republic of); 2 School of Chemical Engineering, Sungkyunkwan University, Suwon, Korea (the Republic of); 3 Samsung Advanced Institute for Health Science and Technology, Suwon, Korea (the Republic of).

The attachment phenomena of various hierarchical architectures found in nature have extensively drawn attention for developing highly biomimetic adhesives for skin or wet inner organs. Scientists have reported biospired skin adhesives with various multiscale architectures including patches with mushroom-shaped tips with or without conductive materials, microneedles, and miniaturized octopus-like suction cups. Adhesives with mushroom-shaped tips have demonstrated enhanced attachment by van der Waals interactions on dry skin, and stabilized contact to active skin surface underwater by embedding the patch underneath swimwear. These adhesives, however, cannot maintain adequate adhesion on wet skin or skin under flowing water. Microneedle patches have indicated striking adhesion performances through mechanical interlocking, but they are more appropriate for wound closure or invasive therapies rather than reversible and residue-free dermal attachment. In recent years, hierarchical structures of octopus suckers have been investigated for their unique reversible adhesion in both dry and wet conditions. The octopus sucker can be divided into two parts: 1) the protruded cup-like upper portion (infundibulum) and 2) the lower portion with a dome-like protuberance (acetabulum). For such adhesive capabilities, suction cups of octopi have been mimicked to develop reusable and residual-free skin patches for versatile medical applications. Here, we present an octopus-inspired skin-adhesive with meniscus-controlled unfoldable 3D microsuckers in micropillars, as well as its application to a stretchable patch sensor composed of carbon-based conducting polymer composite (CPC) films. Mimicking the rim and infundibulum of octopus suction cups, the microsuckers are fabricated by controlling the wetting properties of a liquid precursor during simple molding. Moreover, the adhesive shows strong dry/wet adhesion performances in both pull-off and peeling-off directions against a wafer and rough, hairy skin. Finally, the patch sensor incorporated with 3D microsuckers displays sensitive and reliable piezoresistive responses to lateral strain and vertical pressure. With high conformity on human skin and water-resistant nature, our patch sensor demonstrates efficient detection of not only electrocardiogram (ECG), but also the motion of a human finger even in an underwater environment. We believe that this work represents a timely, methodological advance in nature and breakthrough in the fields of wearable and skin-attachable sensor devices for future healthcare applications.

**Antimicrobial Modification of K-Wires via Novel Polymer Grafting Technology**

Mikhail A. Bredikhin1, Dmitry Gil2, Christopher Gross3, Igor Luzinov4 and Alexey Vertegel1; 1 Bioengineering, Clemson University, Clemson, South Carolina, United States; 2 Medical School, Harvard University, Boston, Massachusetts, United States; 3 Department of Orthopedics, Medical University of South Carolina, Charleston, South Carolina, United States; 4 Materials Science & Engineering, Clemson University, Clemson, South Carolina, United States.
**Introduction:** Kirschner wires are the external smooth stainless-steel pins that are used today in bone fracture fixation. These wires provide the surface for bacteria to adhere onto and form a biofilm, which makes them considerably less-susceptible to antibiotics. The solution to this problem has been an active area of research.

Surface coatings of implants with bioactive molecules is a modern approach to modify implant’s function. However, in the case of K-wires, coating the pin with an antibiotic would not have much effect in vivo since this coating is poorly adherent and would be easily removed when the wire is drilled by a surgeon. In this work, we propose a novel method of grafting the K-wires with highly adherent polymer. Specifically, this study utilizes cross-linkable random “brush” copolymer of OEGMA, GMA, and LMA, which can be covalently attached to solid surfaces. Such polymeric coating can be loaded with an antibiotic, allowing both the protection of the antimicrobial coating during insertion into the bone and optimal release over time.

**Materials & Methods:** Gentamicin sulfate (GS), butanone-2 (MEK) and other materials were purchased from Sigma-Aldrich. The polymeric “brush” is synthesized via solution polymerization. grafting of the polymer onto the surface was performed by dip-coating. The wires were dipped in the MEK solution of the polymer. Following thermal cross-linking of the polymer, the polymer-coated wires were submerged and kept in aqueous GS solution for 24 hours. Finally, the wires were washed with DI water to remove weakly-bound drug, and then air-dried. For the negative controls, the wires were dipped in the plain MEK solution and the MEK-Chloroform solution of polyactic acid (PLA). The next steps were the same as for the polymer-coated wires. Surface of the wires was then characterized using AFM, SEM, and FT-IR.

Antimicrobial in vitro studies were carried out with *S. aureus*. We have tested the ability of the prepared wires to kill planktonic bacteria exposed to them and to prevent biofilm formation on the wire surface by colony forming unit (CFU) plate count method using standard FDA protocols.

Finally, coated wires were drilled into human femur model. Their antimicrobial efficacy was assessed again after this procedure.

**Results and Discussion:** While the uncoated wires showed no anti-bacterial activity, the polymer-coated wires were highly antimicrobial showing maximum inhibiting concentration of 10⁻⁵ CFUs/ml/cm of wire. The PLA-coated wires exhibited similar antimicrobial effect. However, only the polymer-coated wires retained bactericidal properties after drilling into human femur bone model. PLA layer was almost completely removed after the mechanical shear stressing by drilling, which was confirmed by FT-IR analysis of the surface. Thus, the polymer coating of K-wires provides an appropriate drug-carrying and drug-protecting system for the bone implant, where the shear stress during implantation plays a significant role.

**Ultra Long-Scale Silver Nanowire with Self-Templating M13 Bacteriophage**

Kyoung Lim¹, JongMin Lee¹, Vasanthan Devaraj¹, Yeong Ju Lee¹ and Jin-Woo Oh¹, ², ³, ⁴

¹Research Center for Energy Convergence and Technology Division, Pusan National University, Busan, Korea (the Republic of); ²Department of Nanoenergy Engineering, Pusan National University, Busan, Korea (the Republic of); ³Institute of Physics, Pontificia Universidad Catolica de Chile, Santiago, Chile; ⁴Departamento de Física, Universidad Tecnica Federico Santa Maria, Valparaiso, Chile.

These days, electron devices demand high performance electrode. Ag nanowire is the most promising candidate because it has excellent electrical property, however, the process of Ag nanowire synthesis is complicated and it is difficult to obtain long-scale Ag nanowires in traditional methods. M13 bacteriophage is a helical structured biomaterial with 6.6 nm of the diameter and 880 nm of the length. M13 bacteriophage can be reproduced through self-cloning and modified the chemical properties by genetic engineering. According to these properties, M13 bacteriophage is very useful as a template. In this work, we fabricated ultra long-scale Ag nanowire using genetically engineered M13 bacteriophage. We observed that the crystallinity of Ag nanowire (length or diameter) was affected as changing the engineered chemical structure on major coat protein of M13-bacteriophage. The range of Ag nanowire was around 50 nm to 200 nm and the average length and diameter were around 100 um and 1 um, respectively. The maximum length of Ag nanowires that was observed was 300 um. The existence and morphology of Ag nanoparticles and nanowires were confirmed by FE-SEM (field emission scanning electron microscope) and high resolution TEM (transmission electron microscope). To examine the components of Ag nanoparticles and nanowires, map profiling was conducted by EDS (energy dispersive spectroscopy).

**High-Density Enzyme Array on Self-Assembling Protein Template for ELISA-Type Detection of Biomarkers**

Gi Ahn Jung, Samuel Lim and Douglas S. Clark; University of California, Berkeley, Berkeley, California, United States.

Enzyme-linked immunosorbent assay (ELISA) provides a simple and convenient way to detect biomarkers, and is widely used as a diagnostic tool. The components of ELISA consists of a primary antibody specific to the target antigen, and a secondary antibody that binds the primary antibody to render it detectable; commonly, the secondary antibody is coupled to an enzyme that allows for a colorimetric assay. Although conventional ELISA has proven very useful in both research and clinical applications, it can suffer from poor sensitivity when the biomarker concentration is too low.

We propose a strategy to enhance the sensitivity of ELISA based on the self-assembling filamentous protein g-prefoldin (gPFD), which was isolated from the hyperthermophilic archaean *Methanocaldococcus jannaschii*. Using the streptavidin-biotin interaction, gPFD was engineered to template horseradish peroxidase (HRP) enzymes in high density and close proximity along its filamentous backbone; subsequently, the HRP-gPFD complex was fused to the secondary antibody. Each secondary antibody is coupled to the array of HRP enzymes, with the aim of increasing the antigen sensitivity compared to conventional ELISA. The strategy demonstrated here may further improve currently used ELISA techniques, allowing for the efficient detection of biomarkers in both research and clinical settings.

**Study of the Behavior of an Artificial Membrane Immersed in Aqueous Medium**

Marcelo A. Cisternas¹, ², ³, Sebastian A. Molina¹, ², ³, María J. Retamal², ³, ⁴, Nicolás H. Moraga¹, ², ³, Hugo I. Zelada¹, ², ³, Tomas P. Corrales¹, ², Diego I. Diaz¹, ², Rodrigo E. Catalan¹, ², ³ and Ulrich G. Volkmann¹, ², ³

¹Instituto de Física, Pontificia Universidad Catolica de Chile, Santiago, Chile; ²Facultad de Quimica, Pontificia Universidad Catolica de Chile, Santiago, Chile; ³CIEN-UC, Pontificia Universidad Catolica de Chile, Santiago, Chile; ⁴Departamento de Fisica, Universidad Tecnica Federico Santa Maria, Valparaiso, Chile.

Self-assembly of artificial membranes on solid substrates has gained importance due to the potential applications in the field of BioNanotechnology. Artificial membranes represent models for study of the behavior of biological membranes, which are the base of the cell membrane structure. The cell membrane is composed by different kind of lipids and proteins that change their behavior when they are stimulated physically and/or chemically.

Samples were made using a silicon substrate to support the lipids that compose the membrane. First, the substrate were cleaned using the Tidswell method to remove all organic material from the surface. Second, we evaporated the DPPC phospholipid that self-assembled in bilayers when hydrated. The growth of the DPPC layer on the substrate was controlled in situ using Very High Resolution Ellipsometry (VHRE) to obtain the specific thickness of the film.

In our previous work, we measured the capacitive response of the system composed by a phospholipid bilayer on a thin chitosan (CH) layer, both deposited onto silicon substrate and immersed into a protein solution of gramicidin. The change of the capacitive response permit us to confirm the gramicidin ion channel formation across the membrane, to transform our phospholipid bilayer into an artificial membrane. Our results showed a change in the system response due to the protein insertion across the membrane, but it was necessary to perform a detailed study of the membrane immersed into an aqueous medium.
In this work, the behavior of the artificial membranes immersed into an aqueous medium was studied. This medium simulates the natural environment of the biological membrane in laboratory conditions. For this purpose, was designed and constructed an aqueous cell as an accessory of our VHRE. In this cell we immersed the substrate and applied temperature ramps to measure the phase transitions of the phospholipid bilayer.

The Differences Between Colloidal and Crystalline Evaporative Deposits

Samantha McBride, Kripa K. Varanasi and Rachael S. Skye; 1Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Michigan, United States; 2Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Michigan, United States.

Evaporative deposits (for example, the well-known coffee-ring) are widely studied to improve technologies such as inkjet printing or to understand crystal fouling of infrastructure. Evaporative deposition can also be used as a tool for micro-scale assembly, as precipitates self-assemble into structures on extremely small length scales. Altering the conditions of evaporation allows for a large amount of control over the properties and structure of the resultant deposit. The morphology of inorganic crystalline patterns deposited from evaporating drops of saline solution are largely dependent on the wetting properties of the solid substrates they are placed on, with hydrophobic surfaces yielding localized deposits and hydrophilic surfaces causing larger, ring-shaped deposits. However, to date, little attention has been given to the role of surface energy on the crystal formation itself, with the crystal being treated as a simple product of the fluid flow rather than a separate entity that also interacts with the substrate chemistry. Here, we test the hypothesis that the surface energy of the burgeoning crystal faces will also contribute to the morphology of the crystalline deposits left from evaporating drops. To this end, experiments were performed on six different substrate chemistries. Substrate surface energy was analyzed by polar and non-polar components. We will show how the interactions between the growing crystals and the substrate affect the morphology of the resultant deposit. For drops containing colloidal nanoparticles, the deposit shows two modes, precipitating either in a ring or in a condensed disk, while drops containing crystals can also show intermediate modes of small or partial rings. These results have important implications for evaporative self-assembly as they present a method for tuning deposit morphology based on both substrate chemistry and the crystal chosen.

Influence of the Formation Time of Amorphous CaCO3 on Its Degree of Hydration and Stability

Huchuan Du, Mathias Steinacher, Camelia Borca, Thomas Huthwelker, Anna Murello, Francesco Stellacci and Esther Amstad; 1Paul Scherrer Institut, Villigen, Switzerland; 2Institute of Materials Science, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland.

Calcium carbonate (CaCO3) is an abundant biomineral that nature often uses as a structural material because of its excellent mechanical properties. Inspired by the excellent mechanical properties, a lot of work has been devoted to producing CaCO3-based functional materials. However, the structures and properties of these biomimetic CaCO3-based materials significantly differ from those of natural counterparts. To gain a closer control over the mechanical properties, a better understanding of the influence of processing conditions on the formation and stability of amorphous CaCO3 (ACC) particles, that serve as transient precursors for CaCO3 crystals, is crucial. Here, we will present a new method to study the early stages of ACC particles formation using a microfluidic spray-drier. The microfluidic spray-drier forms Ca(OH)2 containing aqueous drops that react with CO2 and rapidly dry, thereby quenching the formation of ACC particles at early stages without the need of any organic solvent. We show that the amount of mobile water contained in ACC particles increases with increasing formation time and hence with increasing particle size. As a result, larger particles are less stable against temperature-induced solid-state crystallization and electron beam-induced decomposition than smaller counterparts. The amount of mobile water contained in ACC can be strongly reduced if certain organic additives, such as poly(acrylic acid) (PAA), is incorporated into ACC particles. As a result of the reduced mobility of water, these additive-stabilized particles are much more stable against crystallization and electron beam-induced decomposition. These insights might open up new opportunities to fabricate biomimetic CaCO3-based materials with tunable structures and hence with properties that can be adapted to the specific needs of the different applications.

Synthesis of Ion Substituted Ceramic Core-Shell Particles for Dental Applications

Camilla Berg, Wei Xia and Håkan Engqvist; Engineering Sciences, Uppsala University, Uppsala, Sweden.

Calcium phosphate spheres are interesting alternatives for dental applications due to their chemical similarity to teeth and biocompatibility.1 A spherical shape with a hollow core allows for loading of therapeutic agents for drug delivery which potentially could be combined with other applications such as tooth remineralization and treatment of hypersensitivity.1 Precipitation reactions are one of the techniques used for synthesizing spherical particles, but little is known about the mechanism behind the sphere formation, which makes tuning of the material properties challenging. Previously, it has been shown that substituting ions can influence the crystallization process, which can enable greater control during the synthesis.4 In this study, several different substituting ions has been used in the synthesis of alkaline earth phosphates, to further investigate their role in sphere formation and to develop a robust synthesis technique.

Particles of alkaline earth phosphates (Ca, Sr and Ba) were synthesized with a precipitation reaction. Solutions with constituent anions and cations were mixed at room temperature, and substituting ions (Mg, Ca or Sr) were added before heating at 60-100 °C. Reaction times varied between 10 minutes to 24 hours. Characterization of precipitates was performed with SEM, DLS and FIB to analyze morphology, size and cross-sections of the spheres. Crystal structure and atomic composition was analyzed with XRD and ICP-OES.

Without substituting ions, precipitates had no specific shape and crystallized in an apatitic structure or as a hydrogenated phosphate. Substituting ions stabilized the initial amorphous phase during the reaction, hindering rapid crystal growth which allowed for self-assembly into hollow, spherical particles with a diameter between 300-700 nm. The phase composition and degree of ion substitution in the precipitates depended on the size and concentration of the substituting ions. The amount of substitution was determined in the range between 5-30 %, where precipitates with a low degree of substitution crystallized in a structure similar to β-tricalcium phosphate, whereas materials with a higher degree of substitution had an amorphous structure.
In this study it was shown that it was possible to obtain hollow, spherical particles of calcium-, strontium- and barium phosphate, by using substituting ions during a precipitation reaction. This indicates that the approach can be used to tailor the properties of spherical particles intended for dental applications.

BM09.08.22
Self-Assembly of Nematic Liquid Crystals in Drops of Dried Lysozyme

Amusya Pal and Germano S. Iannacchione; Physics, Worcester Polytechnic Institute, Worcester, Massachusetts, United States.

In the recent years, an active area of research involves using liquid crystals (LCs), e.g. 5CB (4-Cyano-4’-pentylbiphenyl), for sensing biological and chemical analytes. Another active area of research studies drying drops of liquid revealing a rich interplay of fundamental mechanisms resulting in emergent patterns at the final dried state. In this presentation, these two areas are bridged by asking a basic question of the influence and the self-assembly, in the final dried state, of adding the liquid crystal, 5CB, with the initial protein solution of lysozyme and de-ionized water. The investigation is done using bright-field and cross-polarizing microscopy and quantified using image processing software- ImageJ and Fiji. It is observed that the crack patterns in the final dried state of the protein is influenced by the presence of small amounts of 5CB. Since the protein lysozyme is not birefringent, cross-polarizing microscopy closely monitors the distribution of the LC, while the bright-field microscopy probes the crack patterns that emerge. To understand the final deposits, the time evolution of the drying dynamics of the drops with and without 5CB are monitored. It is found in both drops that all the particles move to the drop edge due to convective flow, but with the LC, partial phase separation into droplets occurs while some LC remains mixed and dispersed into the channels formed by the protein particles. This work demonstrates the utility of using a bulk thermotropic LC as a probe material in a protein solution, revealing new information on the protein self-assembly during the drying process.

BM09.08.23
Scalable Colloidal Self-Assembly by Deionization, Coacervation and Epitaxy

Rodrigo Guerra and Paul M. Chaikin; New York University, New York, New York, United States.

Charging and ionic conductance are ubiquitous properties of biomolecular and colloidal dispersions that also profoundly affect their stability and phase behavior. Rigorous deionization of macromers induces long-range electrostatic forces that can drive colloidal crystallization, and small changes in salinity can drive large changes in the assembly of oppositely charged particles, polyelectrolytes, and polyelectrolyte complexes. Here we demonstrate a new technique to control the salinity of colloids and solutions in-situ, and show how it may be combined with polyelectrolyte coacervation and epitaxial templating to produce self-assembled crystals of oppositely charged colloidal particles using materials techniques that are inexpensive and scalable.

BM09.08.24
Active Control of Calcium Carbonate Heterogenous Nucleation Using Mechanically Tunable Elastic Surfaces

Jay M. Taylor, Abhiteja Konda and Stephen A. Morin; University of Nebraska-Lincoln, Lincoln, Nebraska, United States.

Biological systems are capable of sophisticated and active control over the nucleation and growth of crystalline material. Their ability to control and direct the mineralization process enables the formation of intricate biological minerals with complicated micro-/nanoscale architectures with inanimate physical properties. Synthetic systems capable of such active control over crystal nucleation remain limited. Herein, a simple synthetic system that uses macroscopic physical strain in soft, elastic, silicone surfaces is used to control the rate of heterogeneous calcium carbonate nucleation in mild aqueous solutions. As the rate of heterogeneous nucleation is governed by the specific interfacial energies of system (i.e., calcite, water, and silicone surface), the application of mechanical stress to the chemically modified silicones alters the surface chemical composition and by relation the interfacial energies, thus altering the rate of heterogeneous nucleation. In this system the rate more than doubles between the lowest and highest strain state on the silicone surface. The ability to tie nucleation rate to physical mechanical strain can enable temporal and spatial control over the nucleation process. The results presented herein provides a level of control over nucleation that has not yet been demonstrated, and will be of interest to those studying nucleation, biomineralization, and crystal engineering, and will have applications in adaptive materials, anti-fouling surfaces, and ice prevention.

BM09.08.25
Amoeba-Like Self-Oscillating Polymeric Fluids with Autonomous Sol-Gel Transition

Michika Onoda1, Takeshi Ueki4, Ryota Tamate2, Mitsuhiro Shibayama2 and Ryo Yoshida; 1 The University of Tokyo, Tokyo, Japan; 2Yokohama National University, Kanagawa, Japan; 3Institute for Solid State Physics of the University of Tokyo, Chiba, Japan; 4National Institute for Materials Science, Ibaraki, Japan.

One of the important feature of living organisms is the dynamic behavior based on the hierarchical spatio-temporal structuration of building blocks driven by chemical signals. For example, spontaneous assembly and disassembly of actin networks play a central role in muscle contraction, cell division, and motility of protists. Despite these concepts are widely accepted as key components of biological systems, there are few reports that reproduce the dynamic behaviors based on the hierarchical spatio-temporal structuration by using only synthetic materials.

In contrast, we have reported structural oscillations of micelles and vesicles by totally synthetic AB diblock copolymer (di-BCP) incorporated a catalyst site of the Belousov-Zhabotinsky (BZ) reaction, without applying any on-off switching. In addition, we recently succeeded in realizing autonomous viscosity oscillation induced by microscopic self-oscillation between formation and break-up of the micellar network structure by preparing ABA tri-BCP. However, the viscosity amplitude was still limited (~2 mPa s).

Herein, we describe the self-oscillating ABC tri-BCP exhibiting autonomous sol-gel transitions assisted by dynamic structural oscillations between association and dissociation of the percolated network structure similar to a living amoeba. The target multiblock copolymer is synthesized by sequential reversible addition-fragmentation transfer (RAFT) polymerization incorporating a thermoresponsive A segment, a hydrophobic B segment, and a self-oscillating C segment. Unique oscillation behaviors of the multiblock copolymer are investigated in terms of time-resolved dynamic light scattering techniques for a dilute polymer solution and dynamic viscoelastic measurements for a concentrated polymer solution. As a result, novel oscillation behaviors among large viscosity oscillation, sol-gel oscillation, and viscoelastic oscillation are successfully demonstrated. The maximum amplitude of the viscosity is about 2,000 mPa s, which is 1,000 times larger than previous report and equal to the oscillation amplitude in a living amoeba. We also demonstrate an intermittent forward motion of a droplet of the polymer solution synchronized with the autonomous sol-gel transition. This marvelous polymer solution bears the potential to become the base for a type of slime-like soft robots that can transform their shape kaleidoscopically and move autonomously, which is associated with the living amoeba that move forward by a repeated sol-gel transition.
8:00 AM *BM09.09.01

In the idealized laboratory environment crystallization from pure solutions can follow either a single or a multistep nucleation pathway. The latter case involves the formation, aggregation and transformation of precursor particles to the final crystals [e.g. 1-3]. But, in most natural and industrial crystallization environments additives play a key role and are a central part of biomineralization, of functional material synthesis or of anti-scaling strategies, to name just a few. To gain full understanding and therefore control over crystallization, the possible interactions between additives and the precursor particles, intermediate and final phases need to be precisely unraveled.

In order to elucidate how additives get the job done we studied in situ and at the nanoscale the early stages of mineral formation in the presence of additives and compared them to the pathway observed for the additive free system [e.g. 4,5]. In this presentation, an overview of nucleation in the presence of additives will be given. Special emphasis will be placed on the interaction of organic molecules with precursor particles and how this affects the dynamics of the nucleation pathway.

8:30 AM BM09.09.02

Liquid coacervate is a metastable state where biopolymers assemble into densely packed droplets of low interfacial energy. In biology, coacervates may form inside the cells under variation of physiological conditions, for example under chemical stress [1]. Liquid coacervates form through spinodal decomposition but yet little is known about the path by which coacervate micro-droplets are formed: nucleation and growth, coalescence of smaller droplets, or formation of intermediate states? Here, we use as a model system a protein from the squid beak (HBP-2), whose recombinant version was recently shown to exhibit coacervation triggered by variations of pH and ionic strength [2]. Optical observations indicate that far from the spinodal conditions, coacervation occurs after a lag time and exhibits a linear increase in droplet density. Furthermore, time-dependent circular dichroism reveals that droplet formation coincides with the folding of HBP-2 into β-rich structures. Finally, direct observations under liquid transmission electron microscopy (liq-TEM), shows the nucleation of droplets of 1.5 to 2 nm in diameter, 20 nm entities and a network-like structure. At high ionic strength, the hydrogel-type of network shrinks, leading to the formation of dense discrete droplets. To the best of our knowledge, our study is the first example of in-situ observation of liquid-liquid phase separation under TEM. Understanding the precise assembly pathway of proteins into coacervates may help developing tools to prevent its occurrence when coacervates are the precursors of phases (such as amyloids) associated with pathological diseases [1].

8:45 AM BM09.09.03

Interfacially-Driven Nanoparticle Nucleation—A New Pathway to Mesocrystal Formation Guomin Zhu1, 2, Maria Sushko2, Jinhui Tao2, John Loring2, Benjamin Legg1, Jennifer Solits2, Chongmin N. Wang2 and James J. De Yoreo1, 2; 1University of Washington, Seattle, Washington, United States; 2Pacific Northwest National Laboratory, Richland, United States.

A diverse class of materials, including many biominerals, exhibit characteristics of mesocrystals: single crystals composed of distinct nano-sized domains that are atomically aligned. The formation of such structures is often attributed to crystallization through oriented attachment (OA). However, many unanswered questions about the fundamental drivers and dynamic progression of this process remain. Here we focus on the crystallization of hematite (hem, Fe2O3) from ferrihydrite (fh) as an example. In pure solution the resulting hem crystals are well faceted cuboctahedra, but in the presence of oxalate hem particles, the ligands bias the growth process towards oriented attachment. The common observation of crystals that appear to have formed via OA in solutions that are largely devoid of individual particles, suggesting this growth scenario may be widespread.

Negative Poisson’s Ratio of a Natural Nanocomposite Studied by In Situ TEM Mechanical Testing Jinkyung Kim, Jinsol Seo, Jiwon Jeong, Jeehun
The teeth of limpets are reported to be the strongest natural material, with tensile strength values ranging from 3 to 6.5 GPa. However, the origin of ultrahigh strength of limpet teeth is still unknown. Lipmets use conveyor belt-like radula to scrape rocks and extract algae during feeding. These processes require extremely strong teeth. Limpet teeth show characteristic composite nanostructures consisting of high volume fraction of reinforcing goethite crystals and softer amorphous hydrated silica matrix. The volume fraction and morphology of goethite crystals are heterogeneous at different locations of the tooth, which leads to site-specifically heterogeneous mechanical properties. The present work reports on the relationship between microstructures and deformation mechanisms of limpet teeth, using transmission electron microscopy (TEM) and in-situ TEM deformation. At the leading part of a limpet tooth, goethite crystals are mainly aligned along the principal direction of a tooth. The goethite crystals are rod-shaped, with approximately 30 nm in diameter and 300 nm in length. The volume fraction of the goethite crystals is approximately 50 %. TEM characterization of a longitudinal section at the tip of a limpet tooth shows both normally and laterally aligned goethite crystals, with some clusters of the normally aligned crystals. In addition, transition areas at the interfaces between goethite crystals and amorphous matrix are frequently observed. Atomic scale scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) analyses show that the transition areas have different atomic structures and chemical composition from the original goethite crystals. The trailing part of a limpet tooth shows larger goethite crystals, with lower volume fraction than the leading part. To understand deformation behavior of limpet teeth, in-situ TEM deformation experiments were conducted using the samples taken from the tip of a limpet tooth. Upon tension, the samples show both positive tensile and transverse strain, which indicates negative Poisson’s ratio. The rotation of laterally-aligned goethite crystals appears to result in observed negative Poisson’s ratio. When the sample fractures, a crack propagates very fast right after its initiation. The ultrahigh strength of limpet teeth is expected to delay initiation of cracks. The present work will discuss the relationship among microstructures, deformation/fracture behavior and mechanical properties of limpet teeth. This could provide an insight into design of bioinspired engineering composite materials with superior strength and toughness.

9:15 AM BM09.09.05
Barrier-Free Nucleation of 2D Phage-Selected Peptide Films on MoS2 Surfaces Jiajun Chen1,2, Enbo Zhu1, Juan Liu4, Hendrik Heinz4, Yu Huang2 and James J. De Yoreo1-2, University of Washington, Richland, Washington, United States; 3Pacific Northwest National Laboratory, Richland, Washington, United States; 4University of California, Los Angeles, Los Angeles, California, United States; 5University of Colorado Boulder, Boulder, Colorado, United States.

Directed assembly of two-dimensional molecular arrays on crystal surfaces has been widely investigated to reveal the structural and energetic relationships between the substrate and overlying architecture. Progress has been achieved in understanding and controlling their assembly, yet little is known about the mechanism by which they nucleate. Understanding the dominant pathways and formation kinetics would enable precise control over phase and morphology during synthesis of 2D materials. In our study, short peptides were selected for their ability to bind to MoS2(0001). We studied nucleation and growth of 2D films of these peptides directly with in situ atomic force microscopy and compared our results to molecular dynamics simulations. We find the peptide arrays exhibit an epitaxial relationship to the underlying hexagonal lattice, but assemble one row at a time from dimeric units, and grow along three equivalent directions. The nuclei are ordered from the earliest stages without evidence for a transient precursor phase. Although the final crystals are 2D, due to the 1D nature of the constituent rows, there is no critical size, and the nucleation rate varies linearly with concentration and is finite for all concentrations above the solubility limit. Our results verify long-standing but unproven predictions of classical nucleation theory while revealing the key interactions responsible for ordered assembly.

9:30 AM BREAK

10:00 AM *BM09.09.06

Self-assembled macromolecular architectures exhibit a range of structural motifs such as particles, fibers, ribbons and sheets with functions that include selective transport, structural scaffolding and mineral templating. Although the sequence of the molecules dictates their governing interactions, function emerges from the mesoscale organization that arises from assembly. In the classical picture of assembly, order develops concomitantly with condensation as part of the microscopic density fluctuations inherent to all systems. However, establishment of long-range order in macromolecular structures almost always requires significant changes in conformation away from that seen in the monomeric state. Moreover, the presence of hydrophobic regions drives aggregation events that compete with ordered assembly. The impact of such structural transformations and transient states on the assembly process are a current subject of intense research. Using in situ techniques including AFM and optical and dynamic force spectroscopy, we have investigated the dynamics of assembly and intermolecular interactions for a number of natural protein and synthetic sequence-defined polymer systems assembling from solution on surfaces. In non-rigid systems, the results show that conformational transformations impose kinetic limitations on the nucleation of order. Transient fluctuations no longer provide a pathway to order; instead, the system must be driven to stabilize amorphous or liquid-like precursors. Moreover, once ordered structures nucleate within these precursors, conformational changes of the remaining solution-phase monomers are catalyzed by the presence of the ordered nucleus. However, the final architecture depends strongly on the interplay between protein-protein, protein-surface, and protein-solvent interactions. In particular, the introduction of high salt concentration, which screens electrostatic repulsion and introduces large entropic effects, leads to ordering processes reminiscent of colloidal systems. Small changes in sequence that alter the balance of hydrophobic and electrostatic interactions can induce a switch in assembly pathway between the multi-stage process described above and direct formation of the ordered structure. Finally, building 2D structures at interfaces out of molecules that assemble one row at a time, eliminates the barrier to nucleation and creates an asymmetry in nucleation kinetics for the first row and all subsequent rows, creating a simple means to tune the aspect ratio of the resulting 2D materials. The results of these studies suggest that the requirement of conformational transformation introduces a timescale for structural relaxation that differs from that of the density fluctuations and thus alters the pathway and kinetics of assembly, but that the details of macromolecular sequence, solvent interactions, and the architecture of the ordered phase can be used to influence barriers, pathways and outcomes.

10:30 AM BM09.09.07
In Situ Atomic Force Microscopy of DNA-Mediated Nanoparticle Assemblies in Solution Mikhail Shekhirev, Eli Sutter and Peter Sutter, Univ of Nebraska-Lincoln, Lincoln, Nebraska, United States.

Self-assembled nanoparticles into crystalline superlattices is an attractive approach toward fabricating metamaterials with tunable properties. Synthetic DNA as a “bonding agent” provides programmable crystallization of nanoparticle superlattices according to well-defined rules [1]. Remarkable progress has been made in fabricating 3D architectures with different crystal symmetries and consisting of different building blocks. Recently, research interest has shifted towards tuning structural parameters of the superlattices in response to external stimuli to creative adaptive materials architectures. Techniques for following such complex processes in the native solution environment have so far been limited mostly to X-ray scattering methods, with real space imaging (e.g., by liquid cell electron microscopy [2,3]) still in its infancy.

Jeong, Zhen Wang and Sang Ho Oh; Sungkyunkwan University, Suwon, Korea (the Republic of).
Here we present results of an investigation of DNA-mediated nanoparticle superlattices using in-situ atomic force microscopy (AFM). AFM is a powerful technique for direct imaging of soft samples, including DNA, in solution. However, AFM on DNA-bonded nanoparticle superlattices is challenging due to the weak base-pairing interaction between oligonucleotides and possible damage by the scanning probe. We demonstrate that by using peak-force tapping with precise control over the imaging forces, we can achieve continuous imaging without any significant perturbation of the nanostructures. Such non-invasive imaging in solution revealed a close-packed hexagonal arrangement of nanoparticles in surface-bound single- and few-layer superlattices. In contrast to direct imaging, indirect imaging of the assemblies allows the identification of particle arrangements within individual ordered and disordered domains, thus providing local information not accessible in reciprocal space. This approach shows systematic differences in the equilibrium distance of the DNA-coupled nanoparticles, for example in different layers of multilayer crystals or between central and edge regions in single-crystalline monolayer domains. Finally, we discuss in-situ AFM experiments toward understanding the reconfiguration of DNA-mediated nanoparticle superlattices in response to external stimuli, e.g., changes in solvent polarity and addition of DNA intercalants. Our in-situ real-space observations provide unprecedented insight into the behavior of DNA-nanoparticle conjugates as “programmable atom equivalents”.

**Towards Colloquen—Zinc Oxide Hybrid Materials**

Mark M. van Rijt1, 2, 3, Heiner Friedrich1, 2, 3 and Nico Sommerdijk1, 2, 3; 1Laboratory of Materials and Interface Chemistry and Centre for Multiscale Electron Microscopy, Eindhoven University of Technology, Eindhoven, Netherlands; 2Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, Netherlands; 3Institute for Complex Molecular Systems, Eindhoven University of Technology, Eindhoven, Netherlands.

In biology hierarchical organic-inorganic composites show highly tailored properties due to their precise control over shape and structure. One example is the mineralization of collagen with calcium phosphate in bone which results in remarkable mechanical properties. Its highly-defined pores make collagen a template of interest for more inorganic phases than only calcium phosphate.

One of these inorganic phases is Zinc oxide (ZnO). ZnO is a metal oxide with a range of electro and opto-electronic properties, among them piezo-electric behavior. By mineralizing ZnO in the confinement of collagen enhanced and selective control of its piezo-electric behavior should be achievable. ZnO has previously been synthesized under mild “bio-friendly” conditions using hydrothermal synthetic strategies; aqueous environment, low temperatures (50–80 °C) and ambient pressure. However, the initial stages and the mechanism of ZnO formation are rather poorly understood, making the incorporation of ZnO into collagen at this stage rather challenging.

The current steps in this work therefore focus on understanding the initial stages of ZnO formation. Preliminary results using conventional transmission electron microscopy (TEM), cryogenic TEM (cryoTEM) and selected area electron diffraction (SAED) studies suggest a multi-step precursor assisted mechanism. The formation of a nano-platelet precursor phase is observed by cryoTEM within the first minutes, showing no crystallinity with SAED. These platelets evolve into irregular sheets. At this stage nucleation of ZnO particles ~2-3 nm in diameter on the surface of the precursor sheets is observed, with SAED confirming the presence of ZnO. These primary particles subsequently grow into ZnO pillars via particle attachment. By elucidating this mechanism of formation using advanced cryoTEM and liquid phase TEM studies and by further studying the use of charged polymers and polypeptides as crystallization directing agents, we aim at obtaining new insights for the design and formation of collagen–ZnO hybrid materials.

**Iron Sulfide Supraparticles as Artificial Viruses for Gene and Gene Editing Therapies**

Emine Turali-Emre, Ahmet Emre and Nicholas A. Kotov; University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Gene and gene editing therapies have been widely investigated for treatment of inherited or acquired genetic diseases. Efficient delivery of therapeutic agents has become a significant barrier in clinical applications due to the toxicity and instability of the vectors in the complex intracellular environment. Among non-viral vectors, individual inorganic nanoparticles (NPs) have become a popular strategy for nucleic acid delivery. However, the nanoshell geometry of viruses is advantageous for the geneCRISPR cargo protection. Therefore, we synthesized L-cysteine stabilized iron-based inorganic nanoparticles which self-assemble into supraparticles with nanoshell geometry. Transmission electron microscopy (TEM), TEM tomography and dynamic light scattering (DLS) were used to characterize the virus-like supraparticles’ size, shape, and charge. Our results indicate that virus-like supraparticles contain continuous compartments, are positively charged (25±7.2 mV) and 74±21 nm in diameter. We loaded the DNA in the compartments during the formation of supraparticles. We tested these complexes in circular dichroism, UV-Vis spectroscopy, electrophoretic mobility shift and protection assays. Since iron sulfide is a natural material, it presumably has low cytotoxicity and high biocompatibility. Supraparticles can condense DNA, protect it against degradation, penetrate through cellular membranes and facilitate endolysosomal escape in gene therapy. Therefore, development of these particles can be used as an effective cargo delivery tool for gene and gene editing therapies.

**11:15 AM BM09.09.10**

**Biomimetic Molecularly Imprinted Photonic Crystal for Small Molecule Detection**

Prathyushakrishna Macha1, Abigail Juhi1 and Milana C. Vasilyev1; 1University of Massachusetts Dartmouth, Dartmouth, Massachusetts, United States; 2Materials and Manufacturing Directorate, Air Force Research Laboratory, Dayton, Ohio, United States.

In recent times, an increase in opioid related deaths have occurred due to the addition of synthetic opioids such as Fentanyl and carfentanil. Though there are conventional techniques, they are not designed for on-site detection of these molecules and are tedious. Photonic crystal structures have garnered significant interest in the fields of antireflective coatings, gas sensors, omnidirectional mirrors and label-free biological sensing. These have advantage over the conventional techniques as the structural enhancement and local changes in the refractive index (RI) allows for highly sensitive label-free onsite small molecule detection. The species *Bosere Cucumis* and *Ameniopsis Leidyi* of phylum Ctenophora have two-dimensional (2D) photonic crystals in their combs, which occur relatively less frequently in nature. The structures which occur in the eutomorphs were studied by embedding and morphology studies using cross-sections created using an ultratome and studied them to understand the nanoscale arrangements with the help of a transmission electron microscope.

Two-photon lithography, ebeam lithography, and nainoimprint lithography, were used to replicate these arrangements. The photonic crystal templates formed were observed using scanning electron microscopy and their reflectivity, Raman scattering, refractive indices were analyzed and further used for designing a molecularly imprinted photonic crystal (MIPC) to detect the target molecules as a colorimetric sensor.

**11:30 AM BM09.09.11**

**3D Self-Assembly of Nanocrystals via Co-Crystallization with Proteins**

Hyewon Kim, Xiaoting Guo, Yasutaka Nagaoka, Ou Chen and Vicki L. Colvin;
It has been a challenge to develop a facile and versatile method to achieve the 3D arrangement of nanocrystals. On the other hand, nature utilizes self-assembly process to produce the complex structured functional materials. Here, we present how the process of protein crystallization can provide a means for achieving the 3D arrangement of nanocrystals. By controlling the interaction between nanocrystals and protein, we achieved incorporation and the 3D arrangement of nanocrystals within protein crystals.

We chose hen egg white lysozyme (HEWL) and gold nanocrystals as a model system. For co-crystallization, weak attraction between nanocrystals and HEWL is required. We controlled interaction between gold nanorods (AuNRs) and hen egg white lysozyme (HEWL) by functionalizing AuNRs with poly (ethylene glycol) (PEG). When gold nanorods are functionalized with large molecular weight PEG, weak attractive interaction between AuNRs and HEWL arises. This weak interaction leads to facilitate nucleation of HEWL crystals and incorporation of AuNRs into HEWL crystals. Controlling directed self-assembly of nanoparticles requires understanding interactions between nanoscale building blocks. We used HPIC to understand the interaction between the gold nanocrystals and HEWL. Single crystal x-ray scattering confirms that the lattice parameter of HEWL is preserved when AuNRs are incorporated. We used SAXS, TEM, and the polarized optical microscopy to show that AuNRs are incorporated into lysozyme crystals and AuNRs inside the crystals have some ordered arrangement within HEWL crystal structure.

The phenomenon was independent of nanoparticle shape and type. We found other nanoparticles, such as iron oxide, quantum dots, and spherical gold nanoparticles also proceed co-crystallization with HEWL when the surface grafting density of PEG was low. This confirms that the surface properties of NP-PEG conjugates, rather than the nanoparticle itself, dictates the protein-nanoparticle solution interactions and the subsequence incorporation of nanoparticles into biomolecular crystals. In addition, proteins other than HEWL shows co-crystalization with these NP-PEG conjugates, which indicates this process can be applied to various 3D arrangement of nanocrystals.

11:45 AM BM09.09.12 Bioinspired Templating and Assembly of Heme Crystals for High-Performance Energetic Materials Chia Hung1, Andrea R. Poole1,2, Joseph Slocik1,2, Rajesh Naik1, Patrick B. Dennis1, Wendy J. Crookes-Goodson1 and Maneesh K. Gupta2, 1Air Force Research Laboratory, Wpafb, Ohio, United States; 2UES, Inc., Dayton, Ohio, United States.

Thermite reactions with nano-scale particles have attracted much study due to their high flame temperatures and combustion velocities. Mixing chemically synthesized heme crystals (hemoozoin) with aluminum nanoparticles (nAl), Slocik and co-workers (Slocik, 2015) demonstrated nanocomposites with increased energy output and combustion rates. Hemozoin are naturally produced by malaria parasites Plasmodium falciparum through bio-templated crystallization of heme B by Histidine-Rich Protein II (HRPII). Proteins with high histidine content with metal-coordinating functions are present in many organisms, including the Nereis virens jaw protein 1 (Nvjp1). Although rich in histidine and natively found to coordinate Zn(II), Nvjp1 does not share similar histidine-repeat motifs as HRPII. Here, we demonstrate the ability of Nvjp1 proteins to template hemozoin formation. Recombiantly produced Nvjp1 was incubated with iron-containing heme and efficiently formed hemozoin crystals. X-ray diffraction confirmed the crystal structure of the templated hemozoin crystals. Additionally, Nvjp1 was utilized to assemble hemozoin crystals directly on the surface of nAl yielding thermite nanocomposites. Results demonstrated that hemozoin formation is feasible with orthogonal proteins, therefore expanding the repertoire of candidates for bio-templated heme crystal formation. Through engineering of these proteins, the ability to control the size and shape of hemozoin crystals and hence the energy output of thermite nanocomposites could be realized.

Reference:
Elastin is the dominant building block of elastic fibers that impart structural integrity and elasticity to a range of important tissues, including the lungs, blood vessels and the skin. The elastin polymer is assembled from its molecular precursor tropoelastin. Historically, elastin’s dynamic nature has precluded traditional approaches such as X-ray crystallography to understand its detailed features. Here, I describe recent work using atomistic and coarse-grained models for predicting elastin’s multiscale structure and mechanical properties. We use the models to probe the function of key molecular regions, investigate disease etiology and explore implications for hierarchical assembly. The elastic fiber assembly process begins with a coacervation stage where monomers reversibly self-assemble into n-mer structures. Starting with the monomer as the basis for coarse-graining, we map the atomistic model to a MARTINI-based coarse-grained framework fortified with an elastic network. We show that directed assembly takes place through nucleation events and resulting aggregates display preferential domain positioning for enhanced cross-linking. Our results suggest that the irreversible coalescence of n-mer assemblies into higher-order fibrillar structures may be reinforced in the initial stages of coacervation by directed assembly.

Designing Hybrid Biological Materials—Controlling Morphology via Molecular Composition
Srinivas Mushnoori1, Cassandra Schmidt1, Vikas Nanda2 and Meenakshi Dutt1; 1Biomedical Engineering, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States; 2Center for Advanced Biotechnology and Medicine, Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States.

Peptide self-assembly is a field that shows great promise in the domain of controllable and shape tunable biomaterials. Their unique properties allow for a building blocks approach to materials design. In this study, mixed systems of two carefully selected peptides (i.e. diphenylalanine and phenylalanine-asparagine-phenylalanine) are explored for their self-assembly properties. We report a rich polymorphism in the assemblies of these peptides and explain the relationship between peptide molecular structure and the morphology of supramolecular assembly.

2:30 PM BM09.10.04
Simulating the Effect of Organic Molecules on Clustering in Calcium Carbonate and Phosphate—A Key Stage in Bioimineralisation
Aaron Finney1, Riccardo Innocenti Malini2, Colin L. Freeman1 and John H. Harding1; 1University of Sheffield, Sheffield, United Kingdom; 2Empa, Swiss Federal Laboratories for Materials Science and Technology, St. Gallen 9014, Switzerland.

Calcium carbonate and calcium phosphate are the most important biominerals in nature but there is still no consensus on how they form. Many nucleation and growth mechanisms have been and continue to be proposed. An amorphous phase is known to preceed both calcite and phosphate phases. It is also known that both inorganic and organic additives can affect the crystallisation process, the polymorphs formed, and the physical properties of the resulting materials. Simulations have frequently been used to try to unravel the complex mechanisms involved but require considerable computer resources to reach the long timescales required.

Recent work on calcium carbonate solutions at low concentration in the presence of amino acids has shown that they exhibit behaviour typical of that expected by classical nucleation theory with free ions, ion pairs and other small clusters present. At high concentration the amino acids self-assemble into aggregates, facilitated by ‘spectator’ ions and usually by bicarbonate ions. Liquid-like clusters form from the remaining calcium carbonate. These are also seen at the surface of the amino acid aggregates. When simulations are performed in the presence of oligopeptides (amino acid hexamers) liquid-like networks are formed, seeming to stabilise a dense liquid phase. Calcium phosphate also forms liquid-like clusters in the presence of amines, in this case the buffer tris(hydroxymethyl)aminomethane (TRIS). The simulations suggest that TRIS favours the formation of negatively charged complexes, and we believe that these are responsible for the inhibitory effect of TRIS. More generally, the formation of charged large aggregates could explain the formation of dense liquid phases in phosphate solutions.

We discuss the implications of these results for the role of a dense liquid phase in the nucleation mechanism for calcium carbonates and phosphates, connecting with the long-established proposal by Gower of the importance of a polymer-induced liquid phase (PILP) in the nucleation of biominerals.

2:45 PM BM09.10.05
Understanding Polymorph Selection in Calcium Carbonate
Colin Freeman1, Aaron Finney1, Riccardo Innocenti Malini2 and John H. Harding1; 1University of Sheffield, Sheffield, United Kingdom; 2Empa, Swiss Federal Laboratories for Materials Science and Technology, St Galen, Switzerland.

Within biomineralisation we frequently see the expression of both calcite and aragonite with the later being common in many marine organisms probably due to its enhanced material properties. These two polymorphs are very similar and differ only marginally in thermodynamic stability to favour calcite [1]. Despite its abundance in the natural world, aragonite is difficult to synthesise in the lab, requiring Mg or other additives. An alternative method is to raise the solution temperature above 70°C [2] despite the fact that the actual thermodynamic stability is unchanged at this these temperatures. The lack of aragonite and even its general absence from a solution during crystallisation implies that the nucleus must be unstable and quickly dissolve. This is at odds with recent simulation work that demonstrates that the surfaces of aragonite may be more stable in water than their calcite counterparts [3].

Computational molecular dynamics provides an ideal tool to study this unusual phenomena. We have studied the interfacial energies of a range of calcium carbonate polymorphs in contact with water and amorphous calcium carbonate with varying water concentrations. We use this data to demonstrate the stability of the different calcium carbonate nuclei. Using a statistical analysis of the structure we are able to identify the first stages of nuclei formation and discuss the potential structural features of these. This investigation reveals that kinetics rather than thermodynamics may be dictating the phase selection.

3:30 PM BM09.10.06
Hierarchical Assembly of Computationally Designed Coiled Coils into Tunable 1D Architectures
Nairiti J. Sinha1, Dongdong Wu1, Chris Kloxin1, Jeff Saven2 and Darrin J. Pochan1; 1University of Delaware, Newark, Delaware, United States; 2University of Pennsylvania, Philadelphia, Pennsylvania, United States.

Computational design guided self-assembly of biomolecules such as peptides has emerged as a new paradigm for engineering novel biomaterials in a bottom-up fashion. We exploit lithographic computationally designed homotetrameric antiparallel coiled coils as modular cylindrical Legos for assembling hierarchical 1D architectures using a hybrid physical-covalent assembly pathway. Specifically, the coiled coils are functionalized at the N-termini with either thiol-containing cysteine or maleimide functional groups and subsequently linked together via the Thiol-Michael ‘click’ reaction to form novel 1D...
chains of coiled coils. While the aspect ratio of these chains can be easily manipulated by changing the stoichiometric ratio of cysteine to maleimide functionalized coiled coils, the flexibility of the chains can also be tuned by the linker type between the coiled coils. Thus, a short linker results in stiff rods with large persistence lengths while a longer flexible linker yields flexible fibers, both of which are clearly visible in Transmission Electron Microscopy (TEM) analyses. Small Angle Neutron Scattering (SANS) has confirmed that these 1D chains of coiled coils are ca. 2 nm in diameter that is comparable with the designed cross-section of a coiled coil. Furthermore, stiff rods that are ca. 100 nm in length form liquid crystal domains at high concentrations that have a smectic like birefringence texture. The addition of sodium chloride salt changes the liquid crystal phase to one having a mosaic like birefringence texture. We propose that this is because the rods are net negatively charged in pure water and addition of salt screens the charge on the rod exterior which results in the observed change in the liquid crystal phase. This is supported by SANS of rods which exhibits a correlation hole in the intensity curve due to repulsion between rods in low ionic strength solution which disappears when salt is added.

3:45 PM BM09.10.07
Computational Design of Hierarchically-Assembled Multi-Component 2D Protein Materials Ariel J. Ben-Sasson1, William Sheffler1, 2, David Baker1, Fang Jiao2 and James J. De Yoreo2; 1Biochemistry, University of Washington, Seattle, Washington, United States; 2Physical Sciences, Pacific Northwest National Laboratory, Richland, Washington, United States.

The major advances in computational engineering of symmetric protein assemblies and characterization methods forms the basis for the design of novel materials, systems, and devices. A grand challenge that remains is the ability to generate multi-component assemblies with unbound symmetry that could theoretically grow infinitely either in vivo or in vitro. In other words, the challenge is to design protein components that would never self-assemble but co-assemble under a variety of conditions: in living cells, Eppendorf tube, or an advanced 3D printer.

In this work, we developed a computational method for the design of multi-component 2D protein assemblies by combining a number of design principles: Introducing plane symmetry constraints into the Rosetta software suite to engineer assembly pathways for hierarchical assembly of protein arrays. Computational interface design of multi-component non-covalent, weak, interactions to create a highly geometrical specific interaction. Use of dihedral building blocks whose internal symmetry favors planar assemblies. As a first milestone, we show in vivo assembly of ordered arrays that are obtained by introducing a multistronic vector carrying the genes of both proteins. Post lysis TEM characterization resolves the structure to 14 Angstrom, and pre-lysis optical characterization confirms the assembly takes place while proteins are expressed within the cells. As a second milestone we show in vitro assembly, which offers a controlled assembly environment that can be tuned, optimized, and applied to different practical purposes. We show that ordered micrometer scale arrays are robustly formed when the components are mixed in concentrations that are two orders of magnitude below those in which they are stably stored. Finally we show that multiple functional components can be either genetically fused or attached post-expression to the arrays, offering a direct route to introduce emerging, assembly-related, functionalities.

These recent achievements in the design, control, and optimization of the assembly process of complex protein 2D arrays, offers a new platform to generate biologically synthesized, synthetic materials, with custom designed functions beyond those found in nature.

4:00 PM BM09.10.08
Kinetically Dependent M13 Bacteriophage-Based Self-Assembled Nanostructures for Dynamic Gap Plasmonics Vasanthan Devaran1, JongMin Lee1, Jiye Han1, Kyoungh Lim1, Yeong Ju Lee1 and Jin-Woo Oh1, 2; 1Research Center for Energy Convergence and Technology Division, Pusan National University, Busan, Korea (the Republic of), 2Department of Nano Fusion Technology, Pusan National University, Busan, Korea (the Republic of).

Significant progress on the fabrication of highly ordered and hierarchically organized nanostructures through self-assembly methods had received greater attention in recent years. One of the critical highlights of processing a fabrication using self-assembly was its ability to surpass the critical structural and functional complexity issues occurring with current bottom-up and top-down approaches. In this work, a bacterial virus – M13 bacteriophage (phage) is used to fabricate self-assembled nanostructures based on drop-cast fabrication technique. The employed drop-cast fabrication method is simple, straightforward and cost-effective and doesn’t require any post-processing methods like etching or lithography to demonstrate (gap – tunable) plasmonic nanostructures. Upon drop-casting M13 phage solution on the substrate, by exploiting natural evaporation kinetics at the meniscus, different distance-dependent nanostructures were formed in a single fabrication attempt: networking-like structure close to the center, bundled or single nanowire in the middle, and an island (or dot) close to sides. Reproducibility of these nanostructures was possible even when changing few fabrication parameters such as follows: when using different types of phages like wild-type, WHW-type, and metalized (silver- or gold- coated) M13 phages; depositing on different substrates like glass slide, silicon, and gold coated silicon. Size control of networking nanowires (diameter range – 10 nm – 150 nm) and islands (diameter range – 200 nm – 1000 nm) was possible by varying the concentration of M13 phages or with changes in humidity. Experimental plasmonic studies like scattering, absorption, electric field enhancement were carried out and verified by three-dimensional finite difference time domain simulations (3D FDTD). M13 phage-based nanostructures exhibited an excellent dynamic plasmonic properties using above-mentioned size control conditions. In that, mainly, it was possible to demonstrate a clear tunable gap based plasmonic scattering using humidity control. By varying the humidity, the gap between two nanowire structures or islands were either increased or decreased leading to dynamic changes in scattering resonances or in near-field enhancement. We hope our kinetically controlled self-assembled fabrication approach utilizing M13 phage will open exciting applications in the field of sensors, plasmonics, photonics, lithography-free fabrication of highly ordered nanostructures, and so on.

4:15 PM BM09.10.09
Liquid Crystalline Behaviour of Surface Modified Laponite Clay Suspensions Peicheng Xu; University of Cambridge, Cambridge, United Kingdom.

We present two new routes to surface modify either the negatively charged flat surfaces of Laponite discs with the comb-polymer, PLL-PEG (polylsine-polyethylen glycole) or the positively charged rims of these particles with the cucurbit[7]uril, CB[7], a barrel shaped molecule. We demonstrate that the PLL-PEG coating can completely suppress the ageing typically observed in aqueous Laponite solutions, thus allowing for the first time to access the dichotic liquid crystalline phases of these clays. We distinguish between three scenarios, insufficient coatings, perfect and excess coatings leading to different liquid crystalline textures. In the case of the functionalization with CB[7] we observe a very different evolution into the formation of lamellar sheets of laponite particles leading to a smectic like texture, with a large spacing between the lamellas caused by the long-ranged Coulomb repulsion between the negatively charged particles.

4:30 PM BM09.10.10
Insights into the Interaction of Select Amino Acids with Anatase TiO2 via DFT Calculations Sai Phani Kumar Vangala and Parag A. Deshpande; Department of Chemical Engineering, Indian Institute of Technology Kharagpur, Kharagpur, India.

Design of biocompatible materials with improved properties have found increasing attention due to the effective interaction of biomolecules with inorganic surfaces in their applications in implantology, biosensors and bioelectronics. TiO2 has been widely studied for this purpose as an inorganic support to
Flow Imaging Technology for Evaluation of Polymer Microparticles—Analyzing Millions of Elastin-Like Polymer Coacervates One at a Time
Laura Marvin, James Vesenka, Wynter Paiva and Eva Rose M. Balog; Chemistry and Physics, University of New England, Biddeford, Maine, United States.

Biological and bioinspired polymer microparticles have broad biomedical and industrial applications, including drug delivery, tissue engineering, surface modification, environmental remediation, imaging, and sensing. Full realization of the potential of biopolymer microparticles will require methods for rigorous characterization of particle sizes, morphologies, and dynamics, so that researchers may correlate particle characteristics with synthesis methods and desired functions.

Toward this end, we evaluated biopolymer microparticles using dynamic imaging particle analysis, also known as flow imaging. This technology is becoming more widely used in the biopharmaceutical industry but is not yet well-known among the materials community. Our polymer, a genetically engineered elastin-like polypeptide (ELP), self-assembles into micron-scale coacervates.

We performed flow imaging of ELP coacervates using two different instruments, one with a lower size limit of approximately 2 microns, the other with a lower size limit of approximately 300 nanometers. We validated flow imaging results by comparison with dynamic light scattering and atomic force microscopy analyses. We explored the effects of various solvent conditions on ELP coacervate size, morphology, and behavior, such as the dispersion of single particles versus aggregates. We found that flow imaging is a superior tool for thorough and statistically powerful particle analysis of ELP coacervates in solution. We anticipate that researchers studying many types of microscale protein or polymer assemblies will be interested in flow imaging as a tool for rapid, quantitative, solution-based particle characterization.

Bioinspired Assembly of Small Molecules in Cell Milieu
Zhaoqiazi Feng, Hninmin Wang and Bing Xu; Brandeis University, Waltham, Massachusetts, United States.

Self-assembly, the autonomous organization of components to form patterns or structures, is a prevalent process in nature at all scales. Particularly, biological systems offer remarkable examples of diverse structures (as well as building blocks) and processes resulting from self-assembly. The exploration of bioinspired assemblies not only allows for mimicking the structures of living systems, but it also leads to functions for applications in different fields that benefit humans. In the last several decades, efforts on understanding and controlling self-assembly of small molecules have produced a large library of
candidates for developing the biomedical applications of assemblies of small molecules. Moreover, recent findings in biology have provided new insights on the assemblies of small molecules to modulate essential cellular processes (such as apoptosis). These observations indicate that the self-assembly of small molecules, as multifaceted entities and processes to interact with multiple proteins, can have profound biological impacts on cells. Here we illustrate that the generation of assemblies of small molecules in cell milieu with their interactions with multiple cellular proteins for regulating cellular processes can result in primary phenotypes, thus providing a fundamentally new molecular approach for controlling cell behavior.

Enamel Proteins for Guided Mineral Growth Karina M. Carneiro; Dentistry, University of Toronto, Toronto, Ontario, Canada.

Dental enamel is the outermost layer of teeth and is the hardest, most mineralized tissue in the human body. Its high crystallinity and hierarchical organization provide function and form the critical protective interface against external factors. Enamel formation involves a multi-step process guided by a complex mixture of proteins secreted by specialized cells. Key features of the underlying biomineralization mechanism remain unknown, primarily because the matrix is completely degraded during tissue formation. Amelogenin (AMEL) is the main protein present during enamel formation, with a suggested role in acting as a scaffold for mineralization to occur. Amelotin (AMTN) is a recently discovered enamel matrix protein that is secreted in small amounts during tissue maturation. Previous studies have shown its role in enhancing mineralization in vitro. In this presentation, I will describe the hierarchical self-assembly of AMEL and AMTN, their functional relationship, and their individual and combined effects on calcium phosphate mineralization. Specifically, I will show evidence that AMTN promotes directional crystal growth on AMEL supramolecular structures under biomimetic conditions, suggesting a similar guided mineralization mechanism may occur in vivo during enamel formation.

Chiral Tartaric Acid Can Selectively Regulate Brushite Bioceramic Crystallization Hanan M. Moussa1,2; Wenge Jiang1; Alaa Mansour1; Amir El Hadad1; Hailua Pan1; Jun Song1; Marc McKee1 and Faleh Tamimi3

In natural biomineralized structures such as bone, teeth and nacre, remarkable mechanical properties result from the control of growth and organization of inorganic brittle crystals by specialized biomolecules (i.e. proteins); this interplay provides high-performance material strength and toughness. These biomolecules found in biominerals are homochiral, one of the most distinctive biochemical signatures of life, where they are composed exclusively of L-enantiomers of amino acids enriched in acidic carboxyl groups. Brushite bioceramics have been attracting great attention as a bone substitute material because they are biocompatible and resorbable under physiological conditions. However, brushite bioceramics alone are brittle, and their mechanical properties are far inferior to bone.

We have discovered that brushite crystals have a chiral dynamic growth step susceptible for interaction with matching chiral molecules. Indeed, the growth of the chiral brushite step can be inhibited by stereochemical matching with the L-enantiomer of tartaric acid (L-(+)-Tar), hence inhibiting crystal precipitation and growth. Following on this discovery, here we also show that the simple addition of L-(+)-Tar can decrease the subunit crystal size of brushite bioceramics, and endow the bioceramic with high compressive strength and fracture toughness. In contrast, addition of the D-(−)-Tar enantiomer had an inverse negative affect on the mechanical properties, resulting in lower compressive strength and fracture toughness due to increased porosity. These observations are predicted by mathematical models that precisely described the inverse relationship of the mechanical properties with both subunit crystal size and total porosity content. These findings provide insight into the role of chiral L-biomolecules in biomineralization, and they inform the rational for fabrication of bioceramics having controlled crystallographic structure and enhanced mechanical properties.

Large Surface Plasmon Enhanced Fluorescence of Organic Dye Using M13 Virus-Based Framework and Its Application for In Vitro E.coli Detection Shengnan Huang1,2; Jifa Qi3,2; Dane W. deQuilettes3,4; Xiangnan Dang3; Neelkanth M. Bardhan3,2 and Angela Belcher1,3,2

Fluorescence spectroscopy is a powerful tool for studying biological processes, but its applicability is often limited by the fluorophores, which should have high specific binding and emission efficiency. In this regard, M13 virus, a versatile biotemplate, has been used to assemble fluorophores on its viral capsid with molecular precision and to target various cells. Although the M13-fluorophore ensembles have high targeting specificity, these systems suffer from poor detection sensitivity due to low quantum yield of the fluorophores. To address such limitations, we demonstrate a new, simple method to fabricate arbitrary arrangements of flexible high-aspect-ratio nanopillars using a combination of two-photon lithography and oxygen plasma etching. We show that the method can create millimeter-size arrays of nanopillars with tunable dimensions, cross-sections, bending stiffnesses, tilt angles and aspect ratios. In particular, we demonstrate aspect ratios up to 500, more than 15 times larger than has been shown in other fabrication methods such as replica molding, photolithography and e-beam lithography. We also show that high-aspect-ratio nanopillars assemble into chiral twists through kinetically controlled evaporation.

BM09.11.08
Fabrication and Self-Assembly of Hierarchical Nanostructures Moha M. Shahjamali and Vinothan N. Manoharan; School of Engineering and Applied Science, Harvard University, Cambridge, Massachusetts, United States.

In nature, hierarchical structures such as arrays of pillars are source of various functionalities and have inspired broad applications in surface engineering, heat/electron transfer and sensing. However, traditional top-down fabrication approaches suffers from low control over their aspect ratio, tilt angle, lattice arrangement and flexibility.

To address such limitations, we demonstrate a new, simple method to fabricate arbitrary arrangements of flexible high-aspect-ratio nanopillars using a combination of two-photon lithography and oxygen plasma etching. We show that the method can create millimeter-size arrays of nanopillars with tunable dimensions, cross-sections, bending stiffnesses, tilt angles and aspect ratios. In particular, we demonstrate aspect ratios up to 500, more than 15 times larger than has been shown in other fabrication methods such as replica molding, photolithography and e-beam lithography. We also show that high-aspect-ratio nanopillars assemble into chiral twists through kinetically controlled evaporation.
How do polymer crystals differ from small molecule crystals? With the recent advent of sequence-defined peptoid polymer chemistry, we can now readily synthesize molecularly pure, peptoid polymers, with precision, atomic control of their molecular structure. This allows us to systematically explore how the chemical structure of a polymer chain effects its ability to crystallize and pack into well-defined assemblies. It allows us to explore the impact of main chain length and side chain shape on molecular crystallization. Here we used X-ray scattering and cryo-TEM to examine a series of crystalline, sequence-defined peptoid diblock copolymers, where we varied the main chain length, side chain chemistry and size, terminal groups and monomer composition. The peptoids assemble into both 2D and 3D lattices, depending on solvent conditions, allowing a variety of characterization tools to be used to elucidate the molecular structure and packing configuration. Interestingly we found that in over 22 crystalline peptoid polymers reported in the literature, all of them likely share a similar packing motif, where the chains are extended, and the backbones are in an all-cis conformation. This common structural motif over a wide variety of structures, suggests favorable backbone-backbone interactions resulting in chain alignment, and provides great opportunities to engineer these crystals by using synthesis to introduce point mutations to introduce specific function.

Universal Backbone Conformation in Peptoid Polymer Assemblies**

Sunting Xuan, Doug Greer, Nitash Balsara and Ronald N. Zuckermann; Lawrence Berkeley National Lab, Berkeley, California, United States.

In recent years, block copolymers have attracted much attention for they can be used as building blocks to fabricate 1/2D nano-/micro- architecture driven by crystallization, electrostatic interaction and crosslinking. We combine conjugated fluorescent block poly (phenylene vinylene) (PPV) and poly (2-vinyl pyridine) (P2VP) to build rod-coil type diblock copolymer PPV-P2VP with strong fluorescence and self-assembly property. Nano-/micro-supramolecular fluorocent architectures of the copolymers were obtained by dissolving-cooling-aging process. The obtained structures could be transformed from one-dimensional (ribbons) to two-dimensional (square micelles) by changing the alkyl side chains of PPV blocks, and the scale of the structures could be controlled by changing the block length ratio of PPV and P2VP in the copolymer. The self-assembled morphology of the low block ratio exhibits a significant concentration dependence, and the concentration dependence disappears as the block ratio increases. The morphological characterization and kinetic studies of the formed nano-/micro-architectures show that the conjugated forces play an important role in self assembling process.

The Controlled Self-Assembly of Fluorescent Block Copolymers Driven by π-π Interaction**

Feng He; Department of Chemistry, Southern University of Science and Technology, Shenzhen, China.

Many applications in tissue engineering, flexible electronics, and soft robotics call for approaches that are capable of producing complex three-dimensional (3D) architectures in soft materials. Uncovering the principles that biological systems utilize to develop complex 3D shapes and patterns (i.e. morphogenesis) is a promising route. Although the general principles dictating how differential cell growth leads to the formation of 3D shapes in plant tissue morphogenesis have been identified, an in vitro system that can closely mimic the process of tissue growth and morphogenesis is still missing. In this work, we use polyacrylamide hydrogel as a model system to mimic plant tissue growth. Our strategy takes advantage of the detrimental effect of polymerization inhibitors (i.e. oxygen) by turning it into an effective way to manipulate hydrogel formation. We demonstrate that the polymerization of polyacrylamide hydrogel is able to faithfully resemble all the essential features of plant tissue growth and morphogenesis. During polymerization, the oxygen plays a role mechanistically similar to the role of growth factors in tissue growth, and the continuous growth of hydrogel enabled by diffusion of monomers/cross-linkers into the porous hydrogel is similar to the mechanisms of tissue growth enabled by nutrient transport through vascular networks. The cross-linked hydrogel structure enabled by covalent bonds resembles the concept of interconnected cell walls in plant tissues. Similar to the differential growth in plant tissues facilitated by non-uniformly distributed growth factors and/or different growth rates among different constituent parts, accumulated residual stress as a result of differential polymerization of hydrogel leads to the formation of 3D structures. Our technique opens up new avenues to studying many growth phenomena found in nature and generating complex 3D structures to benefit diverse applications.

Universal Backbone Conformation in Peptoid Polymer Assemblies**

Sunting Xuan, Doug Greer, Nitash Balsara and Ronald N. Zuckermann; Lawrence Berkeley National Lab, Berkeley, California, United States.

Two-dimensional (2D) nanostructures, typified by graphene or metal dichalcogenide nanosheets, are of interest in a broad range of applications including optoelectronics and photovoltaics. Solution-phase block copolymer (BCP) self-assembly is a widely-studied method to produce nanostructures using soft materials, although examples of dimension control using such methods are rare. Crystalline-coil BCPs can undergo living crystallization-driven self-assembly (CDSA), resulting in BCP micelles of controlled size and low polydispersity. Furthermore, length control over amphiphilic 1D BCP micelles have allowed access to complex superstructures, such as “windmill” supermicelles and large micelle superlattices. Recently we have extended living CDSA to the formation of 2D structures, through seeded-growth of BCP/homopolymer blends and charge-terminated crystallizable homopolymers. Various 2D platelet morphologies of controllable area and aspect ratio are now accessible. These methods can be applied to bio-compatible or optoelectronic crystalline polymers, providing materials with potential application in nanomedicine or nanoelectronics.
References
domains, our group recently reported their self-assembly into highly crystalline membrane-mimetic 2D nanomaterials and 1D nanotubes. We demonstrated that the peptoid-based nanomaterials are highly stable and a wide range of functional groups can be precisely placed within these materials as peptoid side chains. Furthermore, our mechanistic studies indicate that the packing of hydrophobic side chains is the key for the stabilization of these biomimetic nanomaterials. To gain the atomic level of understanding the self-assembly of these 2D and 1D nanomaterials, herein, we report the design and synthesis of short peptoid oligomers for self-assembly of biomimetic nanomaterials with similar structures. X-ray diffraction data indicate that nanomaterials assembled from these short sequences are highly crystalline and the change of one side-chain group at the N-terminal can significantly influence the materials formation process. By analyzing the XRD data of a number of biomimetic materials assembled from peptoids with similar chemistries, and the assistance of CryoEM and AFM characterizations, we gained a better understanding of peptoid assembly process and the structures of 2D and 1D peptoid-based nanomaterials.

Self-Assembly and Supramolecular Chirality Reversal of a Sophorolipid-Functionalized Chromophore Kyle C. Peters1, Shekar Mekala2, George Heidbreder1, Richard A. Gross3 and Kenneth Singer1; 1Physics, Case Western Reserve University, Cleveland, Ohio, United States; 2Center for Biotechnology and Interdisciplinary Studies, Rensselaer Polytechnic Institute, Troy, New York, United States.

Bio-based, self-organizing molecules are of considerable interest as functional materials due to their structural versatility, mildly-sustainable bio-synthesis, and sophisticated nano-architectures that introduce chirality. This work is focused on molecules designed to exploit the light-absorbing and macromolecular self-assembly abilities of Nature for potential organic materials. Among these potential candidates, photoactive chromophores show promise for providing (opto)electronic and highly tunable structure and morphology. Additionally, a distinct class of microbially produced glycolipid biosurfactants, known as sophorolipids, show promise for providing the driving mechanism for self-assembly through carbohydrate hydrogen bonding. Herein, we explore the self-assembly and optical properties of a novel series of sophorolipid-functionalized zinc porphyrin molecular geometries that provide an intricate interplay among steric, π-π and hydrogen bonding interactions. We have investigated the delicate interplay of these non-covalent self-organizing interactions and their influence on multi-chromophoric aggregation by precise structural modification of the sophorolipid’s hydrogen bonding moiety and steric interactions through hydrocarbon chain modulation. Spectroscopic studies reveal solvent-promoted self-assembly in dilute methanol/water solution. It was found that helical supramolecular structures form by strong carbohydrate hydrogen bonding interactions, in contrast to nanosphere formation with acetyl-group substitution that eliminates hydrogen bonding interactions. Temperature-dependent UV/vis absorption and circular dichroism show that helical supramolecular polymerization proceeds through a cooperative mechanism of self-assembly for compounds that contain free hydroxyl groups capable of hydrogen bonding interactions. Further, it was discovered that shortening of the sophorolipid hydrocarbon chain promotes helical reversal accompanied with a large increase in the cooperative nature of assembled structures.

Anti Fatigue-Fracture Hydrogels by Forming Percolated Crystal Domains Shaoting Lin, Hyunwoo Yuk, Ji Liu, Xinyue Liu, Hyun C. Loh, Admir Masic and Xuanhe Zhao; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Natural materials in human body (e.g. heart valves, cartilages and muscles) can undergo millions of cycles without losing their functionality. However, synthetic hydrogels including recent developed tough hydrogels are susceptible to fatigue-failure even under a few thousands of cycles. To date, there are no unraveled mechanisms proposed yet to design anti fatigue-fracture hydrogels, which limits synthetic hydrogels’ applications that require long-term robust performance. Here, we report a biomimetic strategy to design anti fatigue-fracture hydrogels via controlled crystal domains. The strategy is to form percolated crystal networks in semi-crystalline hydrogels, retarding crack initiation under cyclic loading owing to high-strength crystal. To validate the proposed strategy, we use the poly(vinyl alcohol) (PVA) hydrogel as an exemplar material system and adopt a new experimental method to measure the fatigue threshold of the semi-crystalline networks with controlled crystal morphology. We show that the critical fracture energy for fatigue-fracture (i.e. fatigue threshold) can increase up to 1000 J/m² as the crystallinity in semi-crystalline network reaches the percolation threshold, higher than that of existing reported hydrogels in the order of 1-100 J/m². Following the design strategy, we further demonstrate two approaches to improve long-term mechanical performance: enhancing fatigue threshold via inducing local crystal domains around crack tip and achieving long-term high strength with crystal reinforcement.

11:45 AM BM09.12.12
Small Angle Neutron Scattering Analysis of Gold Induced Gel Formation of Chitosan Radha Perumal Ramasamy1 and Vinod K. Aswal2; 1Department of Applied Science and Technology, ACT Campus, Anna University, Chennai, India; 2Solid State Physics Division, Bhabha Atomic Research Centre, Mumbai, India.

Biopolymers are studied extensively due to its wide applications in the field of bio-technology, micro fluids and lab on chip devices. Chitosan is natural biopolymer derived from chitin. It has wide applications in bio-medical engineering because of its biocompatibility and biodegradability. Also, chitosan act as reducing and stabilizing agent for the metal ions. Chitosan is also a good candidate in batteries as membranes. It is therefore important to study the conformational changes of chitosan. Understanding the conformational changes in chitosan will help us better understand the microstructural modifications taking place inside membrane made using chitosan. In this research work, SANS was used to understand the modifications in the radius of gyration (Rg) values of chitosan in (i) solution, (ii) in presence of HAuCl₄ and (iii) in presence of LiClO₄. Small Angle Neutron Scattering is a useful technique for the characterization of biological materials. SANS experiments involve scattering of a monochromatic neutron beam from the sample and measures the scattered neutron intensity as a function of scattering vector. The wavelength of the neutron beam used was 5.2 Å with a resolution (Δλ/λ) of about 15%. All of the data were collected in the accessible Q range of 0.017−0.35 Å⁻¹. All of the SANS data were corrected for the background, the empty cell contribution, and solvent contribution, and were normalized using standard procedure. Chitosan solution was prepared by adding 1% (w/v) of chitosan powder, 1.5% (w/v) of acetic acid to D₂O. When HAuCl₄ was added to chitosan solution, higher concentrations of HAuCl₄ (more than 3mM) gave rise to gels. When chitosan solution was dried in a dish it gave rise to films. SANS shows that the chitosan solution (liquid) had greater Rg value than the chitosan film. For chitosan-gold gels the Rg value did not change in gels from that of solution. There was no correlation length for the fitting for chitosan in solution, however there was correlation length observed in the gels. This indicates that in gels the chitosan units are more localized than in solution phase. To chitosan solutions and chitosan-gold gels LiClO₄ was also added. The films formed by solution casting chitosan-LiClO₄ solution and gels formed using Chitosan-3mM HAuCl₄-LiClO₄ were also analyzed using SANS. The Interestingly, chitosan-Au-Li film shows the formation of star like structures which are not observed in case of gels. The correlation length for Chitosan-3mM HAuCl₄-LiClO₄ was less than that of Chitosan-3mM HAuCl₄ gels while the Rg in gels is nearly same for both Chitosan-3mM HAuCl₄-LiClO₄ and Chitosan-3mM HAuCl₄ gels. Hence we conclude that HAuCl₄ can localize chitosan units in solution leading to formation of gels and the incorporation of LiClO₄ in chitosan-gold gels can make the correlation length smaller and thereby affect the gels mechanical properties.
Changing the chemical and physical properties of a surface is important for many fields. This includes the design of new medical devices, antifouling materials and smart surfaces. Surface chemistry and topography determine the interactions of biomolecules with an implant and therefore govern its fate in the body. It also controls the interactions of surfaces with other biological entities such as bacteria and cells that lead to the undesirable process of biofouling.

This lecture will present a new platform for the formation of functional coatings. The coating is based on simple peptides that self-assemble into a layer on various surfaces. The functionality of the coating is controlled by the sequence of amino acids of the peptide. This peptide-based coating can resist biofilm formation and direct cell attachment. It could be useful in hospitals to prevent health-associated infections, in water desalination facilities to arrest membrane blockage by biofouling and in the design of implants.

2:00 PM BM09.13.02
Aerosol-Assembled Re-Entrant Textures for Superamphiphobic Coatings and Devices William S. Wong¹, Zuankai Wang², Antonio Tricoli³ and Vincent Craig⁴; ¹Physics at Interfaces, Max Planck Institute for Polymer Research, Mainz, Germany; ²Department of Mechanical and Biomedical Engineering, City University of Hong Kong, Hong Kong, China; ³Research School of Engineering, The Australian National University, Canberra, Australian Capital Territory, Australia; ⁴Applied Mathematics, The Australian National University, Canberra, Australian Capital Territory, Australia.

Top-down fabricated re-entrant profiles are ubiquitous in the field of superamphiphobicity. However, their complex geometrical design and poor scalability presents significant challenges. Alternatively, bottom-up assembled superamphiphobic surfaces do exist, but true evidence of re-entrancy is, to our knowledge, never demonstrated. Inspired by these limitations, we propose the use of aerosol-assemble for achieving stochastic agglomerate textures with distinct and potentially tunable re-entrant profiles. Modifications to deposition parameters enabled a transitional-shift from quasi-pillar shaped geometries to quasi-inverted trapezoidal configurations. For the first time, re-entrancy and stochastically developed superamphiphobicity were correlated, validated using experimental wetting and computationally simulated particle assembly. Coatings developed were superamphiphobic-functional, preserving the Cassie-Baxter state (CA > 150°, SA < 10°) with fluids down to surface tensions of ca. 25 mN/m. Owing to the dimensional- and geometry-independent self-assembly, this technique is capable of producing functional coatings on highly complicated substrate profiles, even within fine needle capillaries. To this end, a series of contamination-proof, contact-free micro(fluid)mechanical devices were fabricated. They culminated in the unprecedented demonstration of producing and manipulating nano-liter droplets from ultra-low surface tension fluids. We hope that our findings could take root within and beyond the field of functional superdewettability, advancing progress in emerging fields such as high-resolution 3D printing, tissue- and biomedical engineering.

Understanding the Impact of Ligand Composition on Protein Corona Formation around Au Nanoparticles Sam Hoff¹, Desiré Di Silvio², Sergio Moya², Ronald Ziolo³ and Hendrik Heinz³; ¹University of Colorado Boulder, Boulder, Colorado, United States; ²Soft Matter Nanotechnology Group, CIC biomaGUNE, San Sebastian, Spain; ³Centro de Investigación en Química Aplicada, Saltillo, Mexico.

The makeup of coatings on nanoparticles in biological systems has an important impact on the fate and stability in cells and tissues. Ligands attached to nanoparticles, as well as protein coronas which form around nanoparticles in physiological environments, can be altered to change the destination of the nanoparticles, the time in the blood stream, and potential therapeutic functions. In this study, molecular dynamics is employed to study how the chemistry of end groups and length of ligands attached to gold nanoparticles affects the accessible surface structure. The structure and end groups have a marked change on the binding ability and binding conformation of Bovine Serum Albumin and Concanavalin A. PEGylated chains ending in a butanamide present a much smoother surface structure on the nanoparticle compared to that of PEGylated ligands ending in glucosamine which forms a rough surface capable of forming many weak unspecific non-covalent bonds. We use the CHARMM27 Interface force field which yields interfacial properties directly comparable to measurements. The study is being driven by experimental results and is expected to give insight into how protein - ligand interactions work, as well as an advanced understanding of ligand conformations, opening doors to designing ligands with the purpose of forming specific protein coronas to control the destination of nanoparticles for therapeutic activity.
Plasmmonic nanoparticle/semiconductor composites hold promise for optoelectronic applications ranging from solar cells to photocatalysts. There are two typical morphologies for such heterostructures, core-shell nanoparticles and pre-formed semiconductor nanostructures that are decorated with nanoparticles, but both have significant limitations on the degree to which the absorption and charge transfer can be enhanced. A composite architecture in which multiple nanoparticles can be incorporated into a crystalline rod without the insulating barriers associated with ligands could allow us to further enhance optoelectronic performance. BiomimORIZATION routinely creates composite crystals, where second phases are incorporated within single crystalline domains, thereby imparting improved functionality to the composite compared to a pure single crystal. Organisms use a combination of strategies (chemical and physical) to form these composites. Here, we focus on the bio-inspired growth strategy of crystallization in physical confinement as a means to create composite plasmimonic nanoparticle/semiconductor nanostructures. Our group previously showed that track-etched membranes could be used as a template for the formation of composite CuO/Au nanoparticle rods, where a large number of Au nanoparticles are encapsulated within crystalline cuprite nanorods (Chem. Mater. 2017). In this work, we show the generalizability of this physical confinement-based approach to create other semiconductor/nanoparticle composites, such as Cu2O/Ag and ZnO/Au. First, we load the track etched membrane with nanoparticles of an appropriate diameter with respect to the diameter of the pores such that the nanoparticles jam within the pores of the membrane. Then, using low-temperature, aqueous growth methods, we grow metal oxide semiconductors, which grow into the membrane pores and encapsulate the nanoparticles. By incorporating collections of nanoparticles into crystalline rods, we access a relatively unexplored morphology of plasmimonic nanoparticle/semiconductor heterostructure that we predict may have enhanced light collection and charge separation compared to the current typical morphologies.

Precisely programmed block copolymers self-assemble nano-structures such as micelles, vesicles and nanotubes in aqueous solution, have attracted increasing interests from all over the world as the biomaterial which has potential mainly for medical applications. Most typical example is the polymeric micelles with distinctive core-shell architecture, have great potential as drug delivery systems (DDS) to cancer and other intractable diseases. Hydrophilic shell provides polymeric micelles with stealth effect against foreign body recognition system in the body, while inner core works as a nano-reservoir of various cargo compounds. The polymeric micelle provides a promising system for delivery of therapeutic or diagnostic agents to diseased parts of the body, particularly solid cancers which have blood vessels with enhanced permeability, and some clinical trials are currently in progress. Meanwhile, designing a polymeric micelle that transports nucleic acid-based drugs such as siRNA, mRNA and pDNA have great potential for the therapy of central nervous system (CNS) disorders, through the barrier of a normal blood vessel with unenhanced permeability remains a challenging task. For the development of DDS to the CNS, blood brain barrier (BBB) is the obstacle, which excludes most drugs with the tight junction between brain capillary endothelial cells (BCECs). Recently our group developed glucose decorated polymeric micelles (Gluc/m) targeting glucose transporter 1 (GLUT1). GLUT1 is highly expressed on the BCECs and its localization can be manipulated by controlling the blood glucose level. Optimizing glucose ligand density on the surface of Gluc/m and glycemic control, Gluc/m achieved 6 % dose/g accumulation in the brain and attained its BBB penetrating ability. Although glucose-decorated micelles with short length PEG chains (2 kDa) can be recognized by GLUT1 and observed accumulating in brain, micelles with long length PEG chains (12 kDa) cannot recognize GLUT1. For increasing stability of micelles and loading various drugs, the development of ligand-loaded micelles with high molecular weight PEGs which maintains the ligand accessibility is needed. Previous research hypothesized that the ligand mobility is restrained by the neighboring PEG chains and the accessibility of ligands to the receptor is reduced when longer ligand-installed PEG chains attached to nanoparticles. In this research, for the purpose of overcoming PEG dilemma, the novel polymeric micelle consisting of long PEG conjugated to the glucose ligand and short PEG was developed. This technique is called cocktail PEGylation, and mixing short PEG is expected to increase the mobility of ligand molecules. The interaction between Target Membrane Proteins and Ligand-Decorated Polymeric Micelles Penetrating Blood-Brain Barrier Noriko Nakamura1,2, Yasutaka Anraku1,2, Shigeto Fukushima2, Kazuko Tou1, Horacio Cabrall1,2 and Kazunori Kataoka1,2; 1The University of Tokyo, Tokyo, Japan; 2Innovation Center of NanoMedicine, Kanagawa, Japan.

Nitrile oxide (NO) is a physiological molecule that plays a key role in our body such as, vasodilation and inflammation. In respect of inflammation, NO is known to be related with RA which is a chronic inflammatory autoimmune disease that involves the joints. NO from abnormal macrophage upregulates osteoclasts to destroy a cartilage and recruits other immune cells inducing inflammation. In our group, we already reported NO-responsive macro-sized hydrogel by synthesizing NO-cleavable crosslinker. Herein, we further investigate NO-responsive nanogel for treating RA. The abnormal macrophage in the RA lesion secretes much higher concentration of NO compared with normal one. Thus, we designed NO-responsive nanogel that removes NO in abnormal joint and then alleviates a progress of RA. We represented the formation of the nanogel using acrylamide and NO-cleavable linker and showed its swelling behavior responding to NO through transmission electron microscopy (TEM) and dynamic light scattering (DLS). We also confirmed higher NO capturing efficiency of NO-cleavable crosslinker than N, N'-methylene bis-acrylamide via gries assay. For in vivo study, we prepared a collagen-induced arthritis mouse model in DBA/1 mice. The therapeutic effect of the nanogel in suppression of the onset of arthritis in each paw of mice was as effective as dexamethasone, a commercial anti-rheumatoid arthritis drug. Therefore, our findings may suggest a potential biomedical application for clinical translation.
nanostructured carrier is not orthogonal, which affects not only the structure of carrier but also the loaded amount of each cargo molecule. Therefore, development of a nanostructured carrier which facilitate orthogonal loading of the cargo molecules has been highly demanded. Herein, we report an ingeniously designed Pt(IV)-mediated polymeric architecture (Pt-PA) for combinatorial gene and chemotherapy to address the issue. The Pt(IV) prodrug, which has two reaction site, enabled the crosslinking of low-molecular-weight (MW) polyethyleneimine (PEI) to form high-MW PEI. Accordingly, the Pt-PA exhibited successful self-assembly into nano-sized complex with therapeutic gene (i.e. siRNA) without any influence on the loading of Pt(IV), because Pt(IV) has been already incorporated in a polymer architecture by chemical conjugation. The self-assembled complex could be dissociated specifically under redox environment due to an inherent characteristic of the Pt(IV) crosslinker. Therefore, simultaneous release of both active Pt(II) drug and gene was monitored at intracellular reducing environment, resulting in enhanced gene silencing effect and anticancer effect. In animal study, an improved therapeutic effect of the nano-sized complex was observed, which can be explained by tumor targeting via EPR effect of nano-sized complex as well as enhanced intracellular release of drug and siRNA at reducing environment. Taken together, overall results from in vitro and in vivo studies strongly manifest the therapeutic potential of our nanostructured Pt(IV)-mediated polymer architecture.

Facile Formulation of poly(phenylboronate) Nanoconstruct by Simple Mixing with Diol-Containing Hydrophobic Chemotherapeutics and Its Biomedical Application
Junseok Lee, Jinhwan Kim, Yeong Mi Lee and Won Jong Kim; POSTECH, Pohang, Korea (the Republic of).

To date, self-assembled nanostructures have drawn enormous attention for biomedical application. Since nano-scaled particulates are known to be accumulated into the tumors easily via an enhanced permeation and retention (EPR) effect, such nanostructures have been exploited as delivery system for therapeutic small molecules. However, convoluted synthetic process of conventional nanostructures has impeded to achieve feasible and reproducible clinical applications. Herein we report a facile formulation of self-assembled nanostructure for systemic delivery of diol-containing hydrophobic chemotherapeutics, andrographolide (AND) and doxorubicin (DOX). In these studies, formation of a stable nanoconstruct enabled to enhance the water solubility of AND or efficiency of DOX. Phenylboronic acid (PBA) was grafted on the hydrophilic polymer to form poly(phenylboronate) (pPBA) and nanoconstruct was easily formulated by simple mixing with drug through the formation of phenylboronic ester with 1,3-diol of drugs. The release profile of drug was pH-responsive owing to the intrinsic property of phenylboronic ester. Moreover, tumor targeting ability of nanoconstruct was demonstrated in vitro and in vivo driven by an inherent property of residual PBA. Finally, antitumor effect of nanoconstruct was highly effective in vivo even in comparison with free drug. Taken together, our judiciously designed pPBA/drug nanoconstruct suggests a new paradigm of self-assembled nanostructure with variant potential in biomedical application.

SESSION CM01.01: Perovskites and Beyond
Session Chairs: Kirill Kovnir and Corey Thompson
Monday Morning, November 26, 2018
Hynes, Level 2, Room 203
8:00 AM #CM01.01.01
Lone Pairs in the Halide Perovskites, Hidden and Otherwise
Douglas Fabini¹, Geneva Lauria², Constantinos Stoumpos², Mercouri G. Kanatzidis³ and Ram Seshadri¹; ¹Materials, University of California, Santa Barbara, Santa Barbara, California, United States; ²Chemistry, Bates College, Lewiston, Maine, United States; ³Department of Chemistry, Northwestern University, Evanston, Illinois, United States.

The ABX₃ halide perovskites that have attracted so much renewed attention mostly possess B = Sn²⁺ or Pb²⁺, with m² lone pairs of electrons. These lone pairs are frequently hidden, in the sense that the crystal structures are not consistent with the presence of a stereochemically active lone pair that would result in certain characteristic distortions of MX₆ polyhedra in the structure. The influence of such hidden lone pairs can be found in numerous perovskites including the hybrids with methylammonium [4 = CH₃NH₃⁺] and formamidinium [4 = CH(NH₂)₂⁺], where the lone pairs are associated with proximal instabilities that can profoundly influence materials properties. We will discuss the understanding that we have developed from extensive real and k-space studies of local and average structure in these materials using synchrotron and neutron scattering, DFT calculations and NMR studies complement the structural studies to obtain a coherent picture of what is happening, and where all the red herrings are. This work was supported by U.S. DOE, Office of Science, through DE-SC-0012541.

8:30 AM CM01.01.02
A Study of Dynamic Tilt in Perovskites—Bridging the Gap Between Simulation and Experiment
Christopher M. Handley, Robyn Ward, Colin L. Freeman, John H. Harding and Ian M. Reaney; University of Sheffield, Sheffield, United Kingdom.

Tilting in perovskites is a well-documented structural phenomenon, which occurs due to the mismatch in the A and B site ion sizes. We can observe the influence of these tilts through selected area diffraction patterns (SADP), and classify them using Glazer notation. However, Glazer notation is limited as it only classifies tilt for the time-averaged system structure, and assumes that the octahedra are regular in shape. Attempts have been made to simulate transmission electron microscope (TEM) patterns for SADP for each perovskite titling motif, but it has been limited to static simulations and assumes ideal SADPs.

We have developed a new methodology that uses a combination of commercial (CrystalMaker) and in-house (PALAMEDES) programs, to analyse the dynamics of perovskite tilts from molecular dynamics simulations, and in turn use these simulations to simulate time averaged TEM and X-ray diffractions (XRD).

Simulations of CaTiO₃, BaTiO₃, and solid solutions of BCT and BST have been performed using DL_POLY 4. The calculated diffraction patterns and spectra for these materials compare well to experiment. In addition, we are able to use PALAMEDES, to extract dynamic measures of structural features, such as the magnitudes and oscillations of the tilt angles, volumetric distortions, local dipoles, and the phase of the tilts - both locally and at longer ranges.

Through our methodology we are able to demonstrate the influence that temperature and dopants have on perovskite structure, in particular their dynamical traits, and how these dynamics are detected or masked by experimental TEM and XRD, and ultimately have a basis for how it is the dynamics of structural features that underpins the material properties.

6. 8:45 AM CM01.01.03
Tunable Emission in Multinary Halides
Bayrammurad Saparov¹, Mao-hua Du² and Rachel Roccanova¹; ¹University of Oklahoma, Norman, Oklahoma, United States; ²Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

One of the projects in our group targets the synthesis, modeling, single crystal growth, and characterization of low cost multinary halides for light emission applications (e.g., solid-state lighting, scintillators etc.). Taking advantage of the simple processing and rich chemistry of multinary halides including hybrid organic-inorganic halides, we controllable prepared a series of 2D, 1D and 0D crystal structures featuring perovskite-derived and non-perovskite crystal structures. Tunable light emission properties of the obtained materials were characterized using UV-vis absorption, photoluminescence (emission, excitation, time-resolved, temperature-dependent, quantum yield etc.) and density functional theory calculations.

In luminescent hybrid Sn- and Pb-based halides, the inorganic Sn/Pb-halide networks (or clusters) are usually responsible for the observed luminescence due to their relatively small energy gaps of the inorganic substructures compared to those of organic molecules. The low energy gaps of the inorganic substructures in such cases are ensured by the relatively small electronegativity difference between Sn/Pb and halogen elements, which results in valence bands dominated by halogen orbitals and conduction bands primarily made of metal orbitals. In principle, the band alignment in hybrid halides can be altered by (1) combining pairs of metal and halogen elements with large electronegativity difference to accommodate organic molecules’ frontier orbitals, or (2) by utilizing low-gap aromatic molecular cations. The hybrid metal halides studied in our group feature electropositive metals such as Zn and Cd, among others, and aromatic organic cations, yielding unusual band alignments at the organic-inorganic interface. Thus, we were able to obtain compounds showing type-I band alignment with bands near the band gap originating from the inorganic component, type-I band alignment based on organic molecules, and also type-II band alignment featuring both organic and inorganic states. Therefore, depending on the specifics of their band structures, highly tunable light emission of our compounds are attributed to inorganic or organic substructures, or a combination of both.

In this talk, I will provide fresh examples of highly luminescent multinary halides prepared in our group including several examples of broadband white-light emitters, and efficient deep blue emitters, both of which are sought for solid-state lighting applications. The highest room temperature photoluminescence quantum yield (PLQY) values measured in our lab include 3% for a white-light emitting hybrid zinc bromide compound, and 26% for blue-emitting all inorganic Cu halides. Importantly, this work paves the way to band alignment engineering of organic and inorganic components in hybrid organic-inorganic halides to controllably create type I and type II band alignments, and to fabricate materials where the emission originates from organic, inorganic or both components.

9:00 AM CM01.01.04
Tuning the Magnetic Anisotropy in the Layered Chromium Mixed Halides
Fazel Fallah Tafti, Mykola Abramchuk, Samantha Jaszewski, Kenenth
Magnetic anisotropy is the tendency of spins to align in a certain crystallographic direction - the easy-axis. Without anisotropy, thermal fluctuations prevent magnetic ordering in two dimensions according to the Mermin-Wagner theorem. In layered materials, the two limits of the easy-axis are in-plane (XY) and out-of-plane (Ising). Recent advances in exfoliation and device fabrication have led to the discovery of ferromagnetic ordering with Ising anisotropy in CrI₃ monolayers. It is theoretically conjectured that spin-orbit coupling (SOC) provided by halide atoms on the super-exchange path yields the magnetic anisotropy. Here, we design a unique experiment to probe this idea by growing a series of CrIₓBr₃ and CrIₓBr₄ crystals where SOC is tuned between CrI₃ with XY and CrI₄ with Ising anisotropy. We discover a continuous rotation of the easy-axis from XY to Ising with increasing x. Remarkably, the magnetic ordering temperature, optical gap, and inter-layer spacing are also tuned linearly with x. This is the first observation of a continuous rotation of the easy-axis and the effect of SOC on the super-exchange path. Methods presented here can be extended to produce other metal mixed halides to fabricate tunable heterostructures and spintronic devices.

Colloidal nanocrystals of APbX₃ perovskites \( A=\text{Cs}^+, \text{CH(NH}_2\text{)}_2^+, \text{Br}^-, \text{I}^- \): structural aspects, self-assembly and potential applications Maksym Kovalenko M. V. Kovalenko et al. *Chemistry and Applied Biosciences, ETH Zurich, CH-8093, Switzerland; Empa—Swiss Federal Laboratories for Materials Science and Technology, CH-8600, Dübendorf, Switzerland*.

We survey the synthesis methods for colloidal lead halide perovskite nanocrystals (APbX₃, NCs, A=Cs⁺, FA⁺, FA= formamidinium; X=Cl, Br, I), structural chemistry and structural dynamics, and prospects of these NCs for optoelectronic applications such as in television displays, light-emitting devices, and solar cells, emphasizing the practical hurdles that remain to be overcome. The spontaneous and stimulated emission spectra of these NCs are readily tunable over the entire visible spectral region of 410-700 nm [1-2]. The photoluminescence of these NCs is characterized by narrow emission line-widths of 12-42 nm, wide color gamut covering up to 140\% of the NTSC color standard, high quantum yields of up to 100\%. Cs\(_2\)FA\(_x\)Pb\(_{1-x}\)I₃ and Cs\(_x\)FA\(_{1-x}\)Pb\(_2\)I₅ reach the near-infrared wavelengths of 800 nm [3]. Their processing and optoelectronic applications are, however, hampered by the loss of colloidal stability and structural integrity due to the facile desorption of surface capping molecules during isolation and purification. A new ligand capping strategy utilizing common and inexpensive long-chain zwitterionic molecules such as 3-(N,N-dimethyldecylammonio) propanesulfonate, resulting in much improved chemical durability had been developed [4]. Perovskite NCs also readily form long-range ordered assemblies, known as superlattices. These assemblies exhibit accelerated coherent emission (superfluorescence), not observed before in semiconductor nanocrystal superlattices [5].

10:30 AM CM01.01.07
First Principles Investigation of Metal-Insulator Transitions in Rare-Earth Nickelates Induced by Chemical Doping Pilsun Yoo and Peilin Liao, Purdue University, West Lafayette, Indiana, United States.
Chemical doping driven metal-insulator transitions (MIT) can be adopted for solid-state field effect devices, solid electrolytes for solid oxide fuel cells, and active terahertz spectrum photonic devices. The electrical conductivity of SmNiO$_3$ decreases by ~8 orders of magnitude when it is chemically modified by hydrogen atoms. We applied first principles calculations to study geometric, electronic and optical properties of perovskites during chemical doping induced MIT. We showed that the DFT+U method with the PBEsol functional and $U_{\text{eff}} = 2$ eV produced results in good agreement with experiments for both insulating and metallic phases of SmNiO$_3$. We further examined changes in geometry and electronic structures for hydrogen doping in a series of rare earth nickelates. These current findings provide physical insights for future experimental investigation to develop efficient metal-insulator switching devices.

10:45 AM CM01.01.08
Exploring Tunable Persistent Luminescence in Chromium-Substituted Spinel Phosphors Erin Finley; University of Houston, Houston, Texas, United States.

Developing new persistent luminescent phosphors, which have applications ranging from emergency signage to children’s toys, requires an improved understanding of the mechanism that drives their distinctive optical properties. The current consensus is that the long luminescence lifetime stems from a relationship between the inorganic host crystal structure’s band gap and the position of defects that form electron trap states. Fortunately, investigating the crystal chemistry and electronic structures of well-known persistent luminescent phosphors based on the chromium substituted spinel ZnGa$_2$O$_4$ offers a platform to study this mechanism. Substituting Cr$^{3+}$ into this host crystal structure produces a long lifetime red emission as a result of the spin forbidden $^2E \rightarrow ^4A_2$ transition of the $5d$-orbitals. This electronic transition results in a phosphorescence emission decay that is further extended by anti-site defects that act as electron traps. Research has shown that substituting aluminum onto the gallium site can change the luminescence lifetimes by varying the size of the band gap and presence of structural defects. Therefore, this work presents the preparation and investigation of persistent luminescence in the solid solution Zn(Cr$_{6-x}$Al$_x$)$_2$O$_4$Cr$^{3+}$ ($x = 0-1$). Employing a combination of luminescence spectroscopy, extended X-ray absorption fine structure (EXAFS) spectroscopy, and density functional theory this work provides valuable insight into the relationship between the inorganic host crystal structure and the persistent luminescence mechanism. These results provide a pathway to aid in the discovery of new persistent luminescent phosphors with a range of both emission wavelengths and luminescence lifetimes.

11:00 AM CM01.01.09
The Magnetic Properties of Triple Perovskites—Spin Glasses, Ferrimagnets and Relaxors Peter D. Batlle1, Emily C. Hunter1, Chun-Mann Chin1, Yuwei Tang2, Mylene Hendrickx2, Joke Hadermann2 and Maxim Avdeev3, 4; 1Oxford Univ, Oxford, United Kingdom; 2Physics, University of Antwerp, Antwerp, Belgium; 3ANSTO, Lucas Heights, New South Wales, Australia; 4The University of Sydney, Sydney, New South Wales, Australia.

This contribution is centred on the magnetic properties of so-called triple perovskites having the general formula La$_{3-a}$A$_a$B$_2$O$_9$ where $A$ is Ca, Sr or Ba, $B$ is Fe or Ni; $B'$ is Nb, Ta, Sb or Te and $0 \leq x \leq 3$. Many of these compounds adopt a cation-ordered, monoclinic perovskite-like structure in which there are two crystallographically-distinct six-coordinate sites with equal multiplicities. The cation ordering over the octahedral sites thus involves arranging two cation species that are present in a 2:1 ratio over two sites that are present in a 1:1 ratio. We have shown, by a combination of neutron diffraction and electron microscopy, that one of the two sites is usually occupied entirely by the more abundant cation, $B$, while the other is occupied in a ratio of 0.333:0.666 by $B$ and $B'$, respectively. If $B$ is magnetic and $B'$ is diamagnetic and the nearly-linear nearest-neighbour $B - O - B$ interaction is dominant and antiferromagnetic, then the imbalance in the concentration of magnetic $B$ cations on the two sites would be expected to lead to ferrimagnetism and a net magnetisation below the Curie temperature. This idealised behaviour is rarely observed in practice. Magnetometry data collected on La$_3$Ni$_2$SbO$_9$ were consistent with the model but no magnetic Bragg scattering was observed in a neutron diffraction experiment carried out below the magnetic transition temperature until a magnetic field was applied; we therefore described this compound as a relaxor ferrimagnet. La$_3$Ni$_2$TaO$_9$ behaves in a similar manner but La$_3$Ni$_2$NbO$_9$ is a spin glass. However, the magnetisation of the latter composition increases markedly when 12.5 % of the Ni$^{2+}$ cations are replaced by Cu$^{2+}$. In the case of SrFe$_2$TeO$_6$ the six-coordinate cations order in a different, trigonal pattern, although domains of a 1:1 tetragonal phase were revealed by electron microscopy. The monoclinic structure is adopted by the Co-doped composition Sr$_2$LaFeCoSbO$_9$, which shows a novel cation ordering pattern: all the Sb$^{5+}$ cations are on the same six-coordinate site and all the Co$^{3+}$ cations are on the other; the Fe$^{3+}$ cations are distributed evenly across both sites. This results in the observation of long-range magnetic order by neutron diffraction, with a Curie temperature of ~215 K and a saturation magnetisation of ~1 Bohr magneton per formula unit. Attempts to synthesize the calcium and barium analogues of this composition, or to replace cobalt by nickel, resulted in samples that were shown to be amorphous.

11:15 AM CM01.01.10
Reassessing Pauling’s Rules Janine George, David Waroquiers, Davide Di Stefano, Gian-Mario Rignanese and Geoffroy Hautier; Institute of Condensed Matter and Nanosciences (IMCN), Université catholique de Louvain, Louvain-la-Neuve, Belgium.

Pauling’s rules are essential for solid state chemistry [1,2]. In the first publication of the rules, Pauling has already stated several of their drawbacks [2]. For instance, they are presumed to only work for very ionic compounds such as oxides and fluorides [2]. Surprisingly, there is no statistical sound answer on how well all Pauling’s rules perform for oxides up to today in literature. In this contribution, we will provide such an answer. To do so, all five Pauling rules are checked on thousands of oxides from the Materials Project [3] that originally stem from the experimental database ICSD. We will start from a very recent analysis of the statistics of the coordination environments of oxides [4]. A special focus will be on the rules describing the connections of the coordination polyhedra because the knowledge on the performance of these rules is especially sparse. Deviations from Pauling’s rules and their origins will also be discussed.

Materials Discovery and Reaction Design Tyrel McQueen; Johns Hopkins Univ, Baltimore, Maryland, United States.
A grand challenge in solid state materials chemistry is to achieve the same level of control over bond-making and bond-breaking as afforded by well-known organic reaction paradigms. In this talk, I will present recent work on the discovery of new organo-halide electronic materials and mineral-derived quantum spin liquids. Despite disparate synthetic approaches, these subjects are unified by having progress made through an enhanced understanding of reaction pathways, and demonstrate systematic approaches to solid state materials synthesis. The importance of tightly coupling experimental characterization with theoretical modeling will be highlighted.

1:30 PM CM01.02.01
Synthesis and Thermoelectric and Magnetic Properties of Novel Borides Takao Mori1, 2; 1WPI-MANA, National Institute for Materials Science (NIMS), Tsukuba, Japan; 2Graduate School of Pure and Applied Sciences, University of Tsukuba, Tsukuba, Japan.

Boron atoms in boron-rich materials have the tendency to form clusters or 2D sheets. As a synthesis method we have discovered that small amounts of third elements like C, N, and Si in borides can function as bridging sites, and result in the formation of novel and varied boron cluster structures. In addition to thermal stability and high hardness derived from the strong covalent bonding of boron, these structured borides possess strong structure-property relationships, leading to interesting properties in thermoelectrics (TE) and magnetism. Borides are promising for high temperature TE applications in thermal power plants, steelworks, incinerators, focused solar power, etc. [3]. Recent topics will be presented. Discovery of TE enhancement in Sm [4] and Yb phases in RB66 is indicated to be due to mixed valency, while carrier delocalization is indicated as the enhancer for metal-rich YB48. Conventionally difficult p, n control has been achieved for elemental boron [5], and also AIB-type analogous 2D layered borides. Borides have exhibited several novel structure-based mechanisms for intrinsic low thermal conductivity, and I will also present very strong phonon blocking behavior discovered in a 2D layered boride [6]. In regard to magnetism, unexpectedly strong magnetic coupling was previously discovered in dilute f-electron insulating borides, leading to interesting 1D dimer-like, 2D spin glass, 3D behavior [7]. The boron icosaahedron cluster has been indicated to function to dramatically strengthen the magnetic interaction, and will be presented, in addition to recent developments in 2D layered borides.

2:00 PM CM01.02.02
Disorder in Semiconducting Ternary Nitrides Stephanie Lany1, Jie Pan1, Jacob Cordell2, Wenhao Sun3, Aaron Holder1, Sage Bauers1, Angela N. Fioretti1, Elissabeta Arca1, Gerbrand Ceder1, Adele Tamboli1 and Andriy Zakutayev1; 1National Renewable Energy Laboratory, Lakewood, Colorado, United States; 2Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Oxides comprise a large number of insulators or semiconductors, often with rather poor electronic properties. In contrast, nitrides have often better electronic properties, but have much smaller number of known phases, in particular regarding ternary or multinary compounds. Due to the inherent relative instability of nitrides relative to N2, such ternary nitrides are often grown as thin films at relatively low temperatures, leading to crystal structures with atomic disorder. Using first principles and Monte-Carlo calculations, we investigate the effects of disorder on the electronic structure. Case studies include ZnSnN2, which has attracted interest as photovoltaic material, and which tolerates large off-stoichiometry without adverse effects on the electronic properties. We discuss the possibility to remove undesirable electronic localization effects by controlling short range order, even when the material remains long-range disordered. A second example are the Mg-TM-N (TM = Ti, Zr, Hf, Nb) nitrides, which have recently been identified as a particularly stable region in the map of ternary nitrides. First principles structure search and electronic structure calculations predict rocksalt structure semiconductors with low effective masses and large dielectric constants. Disorder not only affects the electronic properties directly, but it also can tip the balance between competing structure types, thereby playing a crucial role in the phase formation and the ensuing materials properties.

2:15 PM CM01.02.03
Lithium Alkaline-Earth Metalide-Nitrides—From Simple to Complex Peter Hoehn, Matej Bobnar, Manisha Pathak, Yuri Prots and Yuri Grin; MPI-CFPS, Dresden, Germany.

Depending on preparation conditions and composition, phases obtained in the quaternary systems Li–AE–M–N (AE = Ca, Sr, Ba; M = Ga, In, TI, Ge, Sn, Pb) range from nitridometalates (e.g. (Ca,N3)[GaN4] 24, Ca[Ge,N2] 23) via nitride-metalides (e.g. (Ca,N4)[M2] 13, to intermetallic species without nitrogen (e.g. LiBa[Sn] 4). They may contain nitrogen as isolated N3– anions or complex anions [M,N3–] of different dimensionality with coordination numbers M by N typically between two and four, respectively. Whereas the bonding within these complex anions and frameworks is essentially covalent, nitridometalates are stabilized by predominantly ionic bonding through counterions like alkali (A) or alkaline-earth (AE) cations. In contrast, bonding in metalide-nitrides is dominated by metallic and ionic interactions. Structural data for the majority of phases reported up to now had been derived from X-ray single crystal data, whereas single-phase powder samples had to be employed for investigation of physical properties, since no sufficiently large single crystals were available.

Here we report on crystal growth experiments in lithium melts by modified high-temperature centrifugation aided filtration (HTCAF) 3, which resulted in specimens of up to 5 mm in length and 50 mm2 in volume. Generally, due to the mode of preparation the thermodynamically most stable phases are precipitated from the reaction mixtures of Li, Li3N, AE, N2 or AE3N, and M, which leads to significantly different results concerning composition of products with respect to reaction temperatures and the alloying ratio, which is illustrated by the following set of examples: (Sr,N0.5)[Pb] 6 crystallizes in the perovskite type with a 2×2×2 superstructure, Li4(Li3Sr)[NiPb] 7 features an ordered variant of the ScAl12 type structure, whereas Li4+(Sr,N)[Ga4]+[Ga] crystallizes in a new structure type. Li2[Sn,N]{Ga2} (8) is isotypic to the σ-carbide Fe3W3C. Most phases show diamagnetic behaviour and electrical resistivities of about 1×103 Ωm.
mechanism that is not present in a typical hard material. The understanding gained by studying the electronic structure as a function of strain explains the unique coexistence of high hardness and ductility in Mo$_2$BC. These results provide a new perspective on the design of future mechanical materials by crystal structure reveals an unusual strain-stiffening due to the formation of pseudo-gaps with a remarkable bond-breaking and concurrent bond-formation.

### 3:00 PM *CM01.02.04*

**Boron—Enabling Metal-Rich Structures and Magnetic Materials**  
Boniface Fokwa; University of California, Riverside, Riverside, California, United States.

Boron tends, like carbon and silicon, to form covalent molecular as well as extended compounds, but boron’s ‘electron deficiency’ enables the formation of multicenter B-B bonds, and therefore unexpected compounds. Boron reacts with most metals to form the large class of metal borides, ranging from the boron-richest YB$_6$ monochromator up to the metal-richest Nd$_8$Fe$_2$B permanent magnet. This huge composition range, coupled with the unusual chemical bonding, makes this class of materials an ideal playground for unexpected discoveries. In this seminar, I will present our recent works on “designing” new materials, all of which contain boron. I will show that boron does not help build new crystal structures but it also plays a prominent role on the studied properties. Furthermore, I will present a new reaction developed recently that enables the synthesis of these materials at the nanoscale, a major step toward fulfilling their huge potential.

### 3:30 PM *CM01.02.05*

**Stoichiometric B$_{13}$C$_2$—Structural Stability and Mechanism of Compression up to 68 GPa**  
Irina Chuvashova$^{1,2}$, Elena Bykova$^3$, Maxim Bykov$^2$, Volodymyr Svitlyk$^4$, Leonid Dubrovinsky$^5$ and Natalia Dubrovinskaiia$^1$; 1Laboratory of Crystallography, University of Bayreuth, Bayreuth, Germany; 2BGI, University of Bayreuth, Bayreuth, Germany; 3Photon Science, Deutsches Elektronen-Synchrotron, Hamburg, Germany; 4European Synchrotron Radiation Facility, Grenoble, France.

Boron carbide is a ceramic material with unique properties widely used in numerous, including armor, applications. Its mechanical properties, mechanism of compression, and limits of stability are of both scientific and practical value. The structure of boron carbide consists of icosahedra (B$_2$: or B$_3$:C), located in the corners of the rhombohedral unit cell, and linear chains (C-B-B or C-C-B or C-C-C) oriented along its body diagonal. According to numerous early studies, boron carbide exists as a single-phase material within a wide homogeneity range, from ~7 at. % (B$_3$:C) to ~20 at. % (B$_3$:C) of carbon. Synthesis and investigations of single crystals of boron carbide have been reported for “nearly stoichiometric B$_3$:C”, B$_2$:C, B$_3$:C, and B$_3$:C$_2$. On the basis of studies of single crystals, there is a dispute in the literature data whether there is or is not a phase transition in this material. Bulk compressibility of boron carbide compared to compressibility of icosahedra has been a matter of debate. Nelmes et al. reported the crystal structure to be more rigid than the icosahedron cluster, whereas Dera et al. observed an opposite relation. In the present work we have studied the compressional behavior of the stoichiometric boron carbide B$_3$:C$_2$ in the pressure interval up to 68 GPa. Unlike the previous experimental observations, our single-crystal synchrotron X-ray diffraction investigations revealed structural stability of the boron carbide in the studied pressure range. A comparison of the compressional behavior of B$_3$:C$_2$ with that of α-B, γ-B, and B$_3$:C showed that it is determined by the types of bonding involved in the course of compression. Neither ‘molecular-like’ nor ‘inverted molecular-like’ solid behavior upon compression was detected that closes a long-standing scientific dispute.

### 3:45 PM *CM01.02.06*

**Unexpected Origin of Strength in Mo$_2$BC**  
Aria Mansouri Tehrani, Amber Lim and Jakob Brsgoch; University of Houston, Houston, Texas, United States.

In the search for new superhard materials using machine learning, we recently prepared the high hardness, ultraincompressible compound, Mo$_2$BC. This compound is not only extremely hard but according to the calculated bulk and shear moduli ratio (G/B) it is also ductile, which is contrary to most superhard materials like diamond or ReB$_6$. Mo$_2$BC crystallizes in a highly anisotropic, pseudo-layered orthorhombic crystal structure containing alternating layers of boron and carbon rich planes. The complexity of this compound and its exceptional mechanical properties motivated an in-depth examination of the structure-property relationship using density functional theory. Calculating the tensile and shear stress-strain behavior to probe the ideal strength of the crystal structure reveals an unusual strain-stiffening due to the formation of pseudo-gaps with a remarkable bond-breaking and concurrent bond-formation mechanism that is not present in a typical hard material. The understanding gained by studying the electronic structure as a function of strain explains the unique coexistence of high hardness and ductility in Mo$_2$BC. These results provide a new perspective on the design of future mechanical materials by contrasting the notion of avoiding materials with pseudo-layered structures.

### 4:00 PM *CM01.02.07*

**Understanding the Crystal Structures of In$_2$Se$_3$**  
Philipp M. Konze$^1$, Michael Küppers$^1$ and Richard Dronskowski$^{1,2}$; 1Institute of Inorganic Chemistry, RWTH Aachen University, Aachen, Germany; 2Juelich-Aachen Research Alliance (JARA-HPC), RWTH Aachen University, Aachen, Germany.

Phase-change memories (PCMs) are promising candidates for storage class memories, bridging the gap between traditional DRAM and Flash storage. Their targeted synthesis and characterization therefore become an interesting field for chemists, physicists, and material scientists alike. Traditional PCMs, such as GeSbTe, use the differences in reflectivity or resistivity between an amorphous and a crystalline phase, where switching is performed using heat, either through radiation or Joule heating. This local melting and quenching has become a limiting factor for the energy efficiency of these materials. Switching, instead, between two closely related crystalline structures, as proposed for chalcogenide superlattices (CSLs), promises to increase their energy efficiency and reduce mechanical stress within a device. One possible candidate as a CSL is In$_2$Se$_3$. In$_2$Se$_3$ was first characterized over 100 years ago, but only recently attracted interest as a promising candidate for applications such as solar cells, photodiodes, and phase-change memories. Despite the growing interest for possible uses, its polymorphism and structures remain poorly understood. Combining X-ray diffraction and transmission electron microscopy, we will present the crystal structures of In$_2$Se$_3$ and rationalize their local environments using chemical bonding analysis. We aim to understand different coordination environments through covalent, as well as ionic contributions, comparing them to prototypical structure types such as B$_2$:Se$_2$. In doing so, we will highlight some new features of our chemical bonding analysis tool LOBSTER.

Cation-Ordering in Tri-Rutile Ternary Antimony Oxide Systems

Winnie Leung1, Elizabeth Martin1, Robert Palgrave1 and David O. Scanlon1, 2, * 1Department of Chemistry, University College London, London, United Kingdom; 2Harwell Science and Innovation Campus, Diamond Light Source Ltd., Didcot, United Kingdom; 3University College London, Thomas Young Centre, London, United Kingdom.

The search for novel, earth abundant materials to be used as transparent conductors and/or in thermoelectric devices has resulted in recent interest in the ternary Sb(V)-oxides. A key example is ZnSb2O6, known to have an ordered tri-rutile structure which consists of Mo6 octahedra (where M is Zn or Sb) and edge-sharing atoms in the order of Zn-Sb-Sb-Zn. Early reports demonstrated the potential of ZnSb2O6 as a new transparent-conducting oxide (TCO) due to its high carrier concentration in the near-IR region and wide band gap of 3.5 eV. While recent calculations by our group indicate a large thermopower and low thermal conductivity at elevated temperatures, once sufficient carrier concentrations are present, making the system of interest for thermoelectricity (TE). Pure ZnSb2O6, however, is non-conductive; hence to enhance the electrical conductivity one needs to dope it with metal ions such as Co, Ni, Cu, Al and In. Indeed, these doped systems have been shown to possess higher electrical conductivity than the nominally pure material. Nevertheless, the mechanism of doping and associated cation ordering in ZnSb2O6, upon which the structural and chemical properties are strongly dependent, remain unknown.

In this study, we have successfully doped ZnSb2O6 with various metal ions such as Ni(II), Ga(III), Cr(III), Al(III), In(III) and Nb(V), and have investigated the structural properties of these doped samples via powder x-ray diffraction (PXRD), x-ray photoelectron spectroscopy (XPS), ultraviolet and visible spectroscopy (UV-vis) and energy-dispersive x-ray spectroscopy (EDXS). Where applicable, we make comparisons with computational work done within our group. Our results help elucidate the cation ordering and doping mechanisms in each case, allowing us to determine the optimum doping strategies to facilitate TCO and TE applications.

Borates as Cathodes for Li- and Mg-Ion Batteries

Sian E. Dutton; University of Cambridge, Cambridge, United Kingdom.

Polyanion materials are attractive for use as electrodes in Li-ion batteries due to their chemical stability and high operating voltages. Studies of polyanion compounds doped with Mg, typically assume that there is no Mg-ion transport and that the dopant Mg-ions are electrochemically inactive. In this talk I will present our results on the structure and electrochemical properties of magnesium, transition-metal borates. Despite their being cation disorder between the magnesium and transition-metal sites I will show that it is possible to remove electrochemically remove Mg and subsequently intercalate Li ions. The role of the crystal structure on the ion transport will be discussed and the results of testing MgMnB2O6 vs. a Mg metal anode will be presented.

SESSION CM01.03: Poster Session I: Solid-State Chemistry of Inorganic Materials

Session Chairs: Ashfia Huq and Antoine Maingnan

Monday Afternoon, November 26, 2018

8:00 PM - 10:00 PM

Solvothermal Intercalation of Iron-Amine Complexes into Iron Sulfide Layered Materials

Colin Harmer and Kirill Kovnir; Iowa State University, Ames, Iowa, United States.

Recent interest in the intercalation chemistry of layered iron chalcogenides has led to the discovery of many new compounds with magnetic properties ranging from simple paramagnetism to antiferromagnetism and superconductivity. The parent superconducting compounds, mackinawite-FeS and β-FeSe, are composed of iron-chalcogen layers stacked via van der Waals forces. These relatively weak interlayer forces make iron chalcogenides suitable candidates for intercalation studies. Numerous reports have shown that drastic changes to magnetic behavior can arise from intercalation by a variety of species, such as, simple cations, metal hydroxides, metal-amine complexes, and neutral organic molecules. Although a wide variety of intercalates are possible, their diversity can pose a challenge when trying to assess direct relationships between the intercalated species and bulk properties. One approach towards a more systematic study is to intercalate iron-chalcogenides with a coordination complex and subsequently tune the complex while assessing structural and property variations. Our study focuses systematically modifying the ligand of the previously reported [FeS3]2–[Fe(en)]●en compound, while observing changes to the structure, stability and bulk thermodynamic properties. [FeS3]2–[Fe(en)]●en consists of [FeS3]2– layers intercalated by tris(ethylenediamine)iron(II) and a free ethylenediamine. Through solvothermal synthesis, we have made two new compounds intercalated with bidentate amines, 1,2-diaminopropane and 2,2’-bipyridine. We show that the interlayer spacing increases with the size of the coordination Fe-amine complex. This work will focus on the solvothermal synthesis, structure, and properties of the ethylenediamine, 1,2-diaminopropane and 2,2’-bipyridine-containing compounds.

CM01.03.02
Need for a SCAN+U Framework to Describe the Oxidation Energetics of Transition Metal Oxides

Sai Gautam Gopalakrishnan and Emily A. Carter; Princeton University, Princeton, New Jersey, United States.

Transition metal oxides that can tolerate a large number of oxygen vacancies, specifically systems containing the redox-active Ce, Mn, and Fe atoms, are crucial ingredients for generating renewable fuels via two-step, oxide-based solar thermochemical reactors. However, any predictive modeling such as using density functional theory (DFT) calculations, needs to accurately describe the energetics of redox reactions (and, subsequently, defect formation) involving transition metals, if new candidate materials are to be found. Recently, the strongly constrained and appropriately normed (SCAN) exchange-correlation (XC) functional was developed, which impressively satisfies all the 17 known constraints for the behavior of any XC functional. However, the ability of SCAN to describe redox energies involving transition metal atoms thus far has remained unexplored. Based on calculated enthalpies for oxidation reactions involving binary Co-, Mn-, and Fe-oxides, we find that SCAN systematically overestimates measured oxidation enthalpies, due to remaining self-interaction errors in the description of their ground-state electronic structure. Adding a Hubbard U term to the transition metal centers, where the U is...
derived from oxidation enthalpies, significantly improves the qualitative agreement of the calculated electronic structure with experiments. Also, the SCAN+U-calculated lattice parameters exhibit marginally better quantitative agreement with experimental values. Importantly, SCAN+U predicts the right ground state polymorph for all transition metal oxides considered in this work, unlike SCAN, which yields erroneous predictions for CeO₂, MnO₂ and Fe₂O₃. Hence, we conclude that the DFT-SCAN+U framework with an appropriately determined U, is required to describe accurate ground-state energies and qualitatively consistent electronic structures for most transition metal oxides and sulfides.

CM01.03.03 Magnetic and Dielectric Properties of Single Crystal GaFeO₃ Mitsuhiro Itoh¹, Shintaro Yasui¹, Tsukasa Katayama², Hiroki Moriwake³, Ayako Konishi³, Jianding Yu¹ and Yosuke Hamasaki⁴; ¹Laboratory for Materials and Structures, Tokyo Institute of Technology, Yokohama, Japan; ²Department of Chemistry, The University of Tokyo, Bunkyo-ku, Japan; ³Nanomaterials Research Laboratory, Japan Fine Ceramics Center, Nagoya, Japan; ⁴Center for Materials Research by Information Integration, Research and Services Division of Materials Data and Integrated System, National Institute for Materials Science, Tsukuba, Japan; ⁵Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China; ⁶Department of Applied Physics, National Defence Academy, Yokosuka, Japan.

κ-Al₂O₃-type GaFeO₃ is a promising multiferroic material due to the coexistence of a large spontaneous magnetization and polarization near room temperature. Currently, the physical properties of GaFeO₃ are not clearly verified, making it an interesting study. Quite recently, a study on ε-Fe₂O₃ which is isostructural to GaFeO₃, Garcia-Munoz et al. (Chem. Mater. 2017, 29, 9705) unveiled a new magnetic ordering at 850 K, higher than the conventional T_N at 480 K. In order to design κ-Al₂O₃-type GaFeO₃ multiferroics, it is essential to know the similarities in the properties between κ-Al₂O₃-type ε-Fe₂O₃ and ε-Fe₂O₃. In the current study, we present the magnetic, electric, and thermal properties of single crystalline GaFeO₃ (space group Pnã2₁) and compare it with that of ε-Fe₂O₃. The as-grown GaFeO₃ crystal was found to have modest, anisotropic electrical resistivities of 5.7×10³, 3.6×10³, and 5.7×10³ Ω m at room temperature along the crystallographic axes of a, b, and c, respectively. Dielectric measurements revealed that the dielectric constant is largest for the a-axis, around 31 when below 50 K, and the dielectric loss abruptly increases above 50 K. Polarization switching could not be observed even at extremely large electric field of 350 kV/cm at 77 K, due to the high coercivity, although the value of polarization by ab initio calculation is ~21 μC/cm² and polarization switching energy is ~100 meV/f.u.. Magnetic measurements revealed that spontaneous magnetization appears below 540 K in two steps, similar to that reported for ε-Fe₂O₃. Partial magnetic ordering takes place at 540 K (T_N1), with Fe³⁺ ions in regular distorted octahedral Fe₁d and Fe₂d positions ordering antiparallel to one another. Upon further cooling at 200 K (T_N2), the remaining Fe³⁺ ions in regular octahedral Fe₁d and tetrahedral Fe₄d order antiparallel to one another. Heat capacity measurement by the relaxation method and differential scanning calorimetry revealed that there are faint heat anomalies around T_N1 and T_N2, corroborating that spin alignment at these temperatures is fairly diffuse. These results are consistent with the data of XMC. Substitution of Ga for Fe in ε-Fe₂O₃ leads to a decrease in T_N1 and T_N2 from 850 to 540 K and from 480 to 200 K, respectively, caused by a dilution of magnetic Fe by nonmagnetic Ga and preferential site occupation of Ga in Fe₁d and Fe₄d sites. All the data will be compared with those for κ-Al₂O₃-type ε-Fe₂O₃ (A=Al, Cr, Ga, Fe, Rh, Sc, and In) thin films.

CM01.04 Hydrothermal Synthesis of New Pentavalent Bismuthates Md Saiduzzaman, Nobuhiko Kumada, Takahiro Takei and Sayaka Yanagida; Centre for Crystal Science and Technology, University of Yamanashi, Kofu, Japan.

The hydrothermal method is a useful synthetic route for the preparation of new bismuthates with a variety of crystal structures like ilmenite, perovskite and pyrochlore-type structures. Some of these exhibit unique properties such as photocatalysis and superconductivity. In our research, we synthesis highly crystalline BaBi₂O₆ and two new pyrochlore-type metallic bismuthates (Ca₂Bi₂O₇ and Sr₂Bi₂O₇) by hydrothermal reaction using Na₂BiO₃·nH₂O. The crystal structure of these compounds were refined by using synchrotron X-ray powder diffraction (SXRPD) data. We investigated their photocatalytic property.

All hydrothermal reactions were performed in Teflon-lined autoclaves. Na₂BiO₃·nH₂O with Ba(OH)₂·8H₂O, Ca(OH)₂, Sr(OH)₂·8H₂O with 1:1, 1:1, 1:1.8 molar ratios were placed in Teflon-lined autoclaves and heated at 80 °C, 90 °C and 120 °C respectively for 2 days. Samples were filtered, washed and dried. Crystal structure was determined by XRD using monochromated CuKα radiation (RINT-2000, Rigaku). SXRPD measurements were performed using beam line BL02B2 at the SPring-8 facility. RIETAN-FP and VESTA were used for crystal structure refinement and drawing respectively. The thermal stability was investigated by TG-DTA (RIGAKU Thermo Plus). Band gap were measured by diffuse reflectance spectroscopy (JASCO V-550 spectrometer). DFT were performed using Vienna ab initio Simulation Package (VASP). The temperature dependent electrical resistivity was measured between 300.0 K and 1.8 K using a standard four-probe method (PPMS, Quantum Design). The photocatalytic activities were examined for the decomposition of phenol (20 ppm) under visible light from a 300 W Xe lamp (UXR-300DU, Ushio Inc.).

The XRD patterns of Ca and Sr bismuthates could be indexed with the cubic system (pyrochlore-type, Pd-3m) and that of Ba bismuthate with the trigonal system (P3bSbO₃-type, P-31m). From the chemical analysis (ICP) Ca:Bi, Sr:Bi and Ba:Bi molar ratios were 1:1, 1:1 and 1:2 respectively. The Rietveld refinements of BaBi₂O₆, Ca₂Bi₂O₇ and Sr₂Bi₂O₇ from SXRPD data led to the final reliability (R) factors were (R_p=5.53%, R_w=4.28%) and (R_p=6.40%, R_w=4.83%) respectively. The lattice parameters of BaBi₂O₆, Ca₂Bi₂O₇ and Sr₂Bi₂O₇ were a=5.57534(6) Å, c=5.7381(1) Å, a₀=10.7642(6) and a₀=10.9413(6) respectively. Above 200 °C all the bismuthates decomposed consequently mass loss being due to the reduction of Bi³⁺ to Bi²⁺. BaBi₂O₆ exhibited photocatalytic activity for phenol degradation under visible light. However, Ca₂Bi₂O₇ and Sr₂Bi₂O₇ showed strong oxidation property for the degradation of phenol under dark condition. This is due to the metallic behavior evidence by DOS calculation and supported by temperature dependent resistivity data indicated that these compounds possessed very low resistivity at room temperature. While BaBi₂O₆ is a semiconductor exhibited by band gap energy estimation and supported by DOS calculation.

CM01.03.05 Cluster Analysis of a Cast Aluminum Alloy Utilizing an Atom- Probe Tomography Won Sang Shin, Kyo Jin Hwang, Dong Hyuck Jung and Yoon Jun Kim; Material Science Engineering, Inha University, Nam-gu, Korea (the Republic of).

Cast Aluminum alloys are widely used in the automotive and aerospace industries, due to their high strength to weight ratio, good corrosion resistance and recyclability. An A356 cast aluminum alloy (Al – 7 wt.%Si – 0.3 wt.%Mg), contains approximately 50% eutectic microstructure. Such a high content of Si with various casting conditions plays a significant role in strengthening of A356 alloy by controlling eutectic morphology and precipitate other intermetallic compounds. Understanding the way to form Si nanoclusters soluble in the α-matrix is necessary in order to provide high strength and fatigue properties to the A356 alloys. Quantification of nanoclusters' size, distribution, and composition gives insight into how type of atoms in the aluminum matrix migrate and attract or repel other types of alloying elements. The morphology of Si nanoclusters in A356 alloy is analyzed using an Atom Probe Tomography (APT). Samples were differently aged at the temperatures of 110°C, 130°C, and 150°C for 2 hours. Although typical size of nanoclusters is a few nanometers or even less than nanometers which makes characterization difficult, APT can provide not only a nano- or sub-nano scale clusters’ information such as size, distribution, and composition but also three-dimensional (3-D) chemical and spatial information.

APT raw data can be further analyzed using the well-known maximum separation algorithm in order to define and characterize the nanoclusters. The input
parameters required for this algorithm, for example dmax and Nmin, were carefully selected for agglomerated Mg and Si ions in an α-aluminum matrix. Applying those cluster parameters along with additional correction variables, such as envelopment and erosion distances for Al, Si, and Mg ions, Mg-Si nanoclusters in an α-aluminum matrix were quantitatively analyzed determining their size distributions and average sizes, etc. Obtained clusters’ information can be correlated the age-hardening process of the A356 alloy comprising types of solid solution aluminum prior to decomposition sequence commenced.

CM01.03.06 Atomic Diffusion in the Low Temperature Synthesis of Perovskite-Type (A$^+$B$^-$)O3 (A, B = Sr, Ba; B$^+$ = Ti, Zr) Using Hydroxides and Hydroxal Gels at 50 °C

Y. Yamaguchi

Synthesis of perovskite-type oxides in a solid state reaction requires high-temperature heat-treatment at around 1000 °C to cause sufficient diffusion of metal ions. Therefore, various synthesis methods such as sol-gel method have been studied to reduce a reaction temperature and obtain fine-particles. Until now, we have successfully synthesized perovskite-type ABO3 (A: alkaline earth; B = Ti, Zr) by only leaving the mixture of A(OH)x-nH2O and BO2 hydroxal gel at around 50 °C for several days. The SrTiO3 synthesized by this method at room temperature had a highly crystallized fine particles and exhibited higher photocatalytic activities than that synthesized by sintering at 1000 °C[1]. The reaction mechanism was considered that BO2 hydroxal gel worked as an acid to react with A(OH)x which worked as a base. In addition, SrTiO3 synthesized at room temperature by this method in this study, (A$^+$B$^-$)BO3 (A, B = Sr, Ba; B$^+$ = Ti, Zr) were synthesized to investigate further detailed reaction mechanism, especially cation diffusion in A- and B-sites.

Starting materials for (A$^+$B$^-$)BO3, A(OH)x-8H2O and BO2 hydroxal gel prepared by precipitation method. The water content of hydroxal gel was determined by TG-DTA. Mixed A(OH)x-4H2O and BO2 hydroxal gels were sealed in a vial bottle. The vial was kept at 50 °C for several days. In order to investigate the diffusion of A-site cations, we attempted to synthesize (Ba,Sn)3 TiO5 using Sr(OH)2, Ba(OH)2, and TiO2 hydroxal gel. A-site substituted perovskite phase was obtained, this is the first time to synthesize perovskite solid solution by this low temperature synthesis method. Though Sr and Ba were present in separate particles as starting materials, both the elements were mixed at the atomic level in reacted compound to form A-site disordered perovskite phase. This result indicated that alkaline earth cations diffused long range even at low temperature of 50 °C. We also attempted to synthesize Ba(Zr0.5Ti0.5)O3. When Ba(OH)2, ZrO2 hydroxal gel, and TiO2 hydroxal gel were used as starting materials, mixture of perovskite-type BaZrO3 and BaTiO3 were obtained. On the other hand, when Ba(OH)2 and (Zr0.5Ti0.5)O2 solid solution hydroxal gel were used as starting materials, perovskite solid solution Ba(Zr0.5Ti0.5)O3 were obtained. The obtained phases depended on the starting materials. If all the ions diffuse long range, thermodynamically stable phase must be obtained. Therefore, B-site cations diffuse only short range in contrast to A-site cations. It is concluded that the A cations diffuse into the B cation network to form a perovskite phase at low temperature of 50 °C.

CM01.03.07 Investigating the Effects of Surface Ligand Concentration on the Magnetic Properties of Semiconductor Nanocrystals

Alex Khammang1, Robert W. Meulenberg2

Semiconducting nanocrystals (NCs) have been utilized in optoelectronic devices like solar cells and laser emitting diodes and semiconductor materials have biomedical applications such as biological markers. These types of materials typically consist of an inorganic core, which dictates most of the physical properties, and an organic layer on the surface, which helps dictate chemical stability. While much work has been performed towards understanding the fundamental physics of the core NC, the surface science of these materials remains relatively unexplored. Although we stated that the surface of NCs help drive chemical stability, recent reports have suggested that the surface layer does much more, including effecting photoluminescence (PL) quantum yields, PL lifetimes, and electrical properties. Quite remarkably, the surface layer even has shown to convert nominally non-magnetic materials, such as CdSe and ZnO, into “magnetic NCs”. This result is curious, as the bulk state of these materials exhibit diamagnetic properties. These exciting results suggest that it may be possible to pair these induced magnetic properties with the inherent PL properties of these materials. This multi-functionalization of CdSe and ZnO, into “magnetic NCs”. This result is curious, as the bulk state of these materials exhibit diamagnetic properties. These exciting results suggest that it is possible to pair these induced magnetic properties with the inherent PL properties of these materials. This multi-functionalization of CdSe and ZnO, into “magnetic NCs”.

To gain further insight on how the surface layer affects the magnetic properties, this work alters the surface chemistry by controllably varying the surface ligand concentrations and by systematically varying the types of ligands (i.e. headgroup) on the surface of spherical NCs. In addition, we will study how the NC shape and interface can affect the magnetic properties by examining materials like nanowires and core/shell materials. This study will provide detailed information on how the surface ligands and interfacial layers in a NC can lead to unique magnetic properties.

CM01.03.08 Citrate-Controlled Optical Properties of Solution Deposited PbSe Thin Films

Michael Shandalov1, Maayan Perez2, Eyal Yahel1 and Yuval Golan2

Chemical bath deposition is an efficient method to reproduce high quality thin films. Extensive work has been done on deposition of lead chalcogenides due to their technological importance as infrared detectors and emitters [1]. Our group has previously reported on the ability to obtain desirable optical and microstructure of lead selenide at high pH (>13) by optimizing reactants concentration, temperature and growth duration [2,3]. There is an important advantage in understanding the kinetics influencing the deposition of PbSe at relative low pH (<13) and gaining further control on film's morphology related to optical properties. Trisodium citrate (TSC) is a commonly used co-complexing agent during chemical deposition of the lead selenide, which allowed us to deposit films at lower pH, yet its exact role has not been systematically studied [3]. This work focuses on the effect of citrate and pH on the kinetics involved in the deposition of PbSe and on microstructure related optical properties of the films.

CM01.03.09 High Pressure H2 and D2 Annealing Effects on the Interface Characteristics Between H2O2 and SiGe:

Soongheum Choi1, Jinyong Kim1, Jinbum Kim1, and Hyungsup Kim1

As a next-generation channel material for high performance transistors, such as fin and gate-all-around field-effect transistors, Si1–xGe, has been considered
to be the most promising due to its high carrier mobility and excellent compatibility with the current Si-based integration processes [1]. However, for successful implementation of Si$_x$Ge$_{1-x}$, it is imperative to improve the interface properties with the adjacent high-k gate dielectrics. For the high-k dielectrics on both Si and III-V compounds, post-metalization annealing (PMA) in high pressure H$_2$ and D$_2$ ambient was demonstrated to be effective in lowering the interface state density [2, 3]. However, its application to the high-k/Si$_x$Ge$_{1-x}$ structure has been rarely studied.

In this presentation, we compared the electrical and interface characteristics of the HfO$_2$ films grown on Si$_{0.7}$Ge$_{0.3}$ after different PMA: conventional forming gas annealing (4% H$_2/96%$ N$_2$ at 1 atm), and high pressure H$_2$ and D$_2$ annealing (20 bar). Immediately after native oxide cleaning of epitaxially-grown of Si$_{0.7}$Ge$_{0.3}$, films on Si, the HfO$_2$ (nominally 5 nm) films were grown using atomic target deposition at 250 °C. Following the metal electrode formation, PMA was conducted at 300 °C for 30 min, and then various electrical measurements were conducted. The detailed electrical properties of the capacitors after different PMA, including the interface state density, will be discussed. In addition, the chemical analysis results of the high-k/Si$_x$Ge$_{1-x}$ interface will be presented.

CM01.03.10
Sterically Controlled Solid-State Mechanocatalysis Under Hydrostatic Pressure Hao Yan1, 2, Fan Yang1, 2, Jing Pan1, 2, Wendy L. Mao1, 2, Giulia Galli1, 2, Peter R. Schreiner1, Zhi-Xan Shen1, 2 and Nicholas A. Melosh1, 2, Materials Science and Engineering, Stanford University, Stanford, California, United States; 1SLAC National Accelerator Laboratory, Menlo Park, California, United States; 2Geophysical Sciences, Stanford University, Stanford, California, United States; Chemistry, Hong Kong University of Science and Technology, Hong Kong, Hong Kong; 1Institute of Molecular Engineering, The University of Chicago, Chicago, Illinois, United States; 4Physics, Stanford University, Stanford, California, United States; 1Institute of Organic Chemistry, Justus-Liebig University, Giessen, Germany.

Mechanical stimuli can modify the energy landscape of chemical reactions and enable new reaction pathways, offering a complementary synthetic strategy to conventional chemistry. Mechanocatalytic mechanisms under tensile stress have been extensively studied in one-dimensional polymers. In these systems, the pulling force stretches chemical bonds, initiating the reaction. Recently, it has also been shown that forces orthogonal to the chemical bonds can alter the rate of bond dissociation. However, these bond activation mechanisms have not been possible with isotropic, compressive stress (i.e., hydrostatic pressure) in three-dimensional solids. Here we show that mechanochemistry through isotropic compression is possible by molecularly engineering structures that can translate macroscopic isotropic stress into molecular-level anisotropic strain. We engineer molecules with mechanically heterogeneous components consisting of a compressible (‘soft’) mechanophore and an incompressible (‘hard’) ligands. In these ‘molecular anvils’, isotropic stress leads to relative motions of the rigid ligands, anisotropically deforming the compressible mechanophore and activating bonds. Conversely, rigid ligands in steric contact impede relative motion, blocking reactivity. We combine experiments and computations to demonstrate hydrostatic-pressure-driven redox reactions in metal-organic chalcogenides incorporating molecular elements with heterogeneous compressibility, where bending of bond angles or shearing of adjacent chains activates the metal-chalcogen bonds leading to formation of elemental metal. These results reveal an unexplored mechanism and enable new possibilities for high-specificity mechanosynthesis. Recent results applying the molecular anvil strategy to the activation/reduction of carbon dioxide will also be discussed.

CM01.03.11
High-Mobility N- and P-Type Cu$_3$N Thin Films Realized by Novel Direct Nitriding Synthesis and Computational Doping Design Kosuke Matsuoka1, Kou Harada1, Yu Kumagai1, Shogo Koshiya2, Koji Kimoto2, Shigenori Ueda2, Masato Sasa1, Akhiro Maeda1, Tomofumi Susaki1, Masaki Kitano1, Fumiyasu Oba1, 2 and Hideo Hosono1, 2, Tokyo Institute of Technology, Yokohama, Japan; 1National Institute for Materials Science, Tsukuba, Japan.

Copper nitride (Cu$_3$N) has an indirect bandgap of ~1.0 eV and a high absorption coefficient of ~10$^5$ cm$^{-1}$ above ~2.0 eV, and therefore is considered as an earth-abundant and environmentally-benign absorber candidate in thin-film photovoltaics. Its self-doping mechanism has been discussed theoretically, but a comprehensive understanding of the doping mechanism and intrinsic behavior of pure Cu$_3$N is still lacking owing to the low crystalline quality. We show that bipolar doping with high electron and hole mobilities in high-quality Cu$_3$N is realized by our novel gaseous direct nitriding reaction utilizing a catalytic ammonia oxidation to form Cu$_3$N from Cu metal. This reaction overcomes the thermodynamic constraint associated with its high positive formation enthalpy (~83.7 kJ mol$^{-1}$) and provides high-quality Cu$_3$N films showing resistive n-type behavior. P-type conduction is realized by flowing doping into the interstitial site as predicted by density functional theory calculations and directly proven by electron energy loss spectroscopy combined with scanning transmission electron microscopy. The electron and hole mobilities of undoped n-type and F-doped p-type films are as high as 200 and 80 cm$^2$(Vs)$^{-1}$, respectively. Our synthetic methodology for high-quality n- and p-type films applicable to uniform and large-area deposition would open up the possibility for Cu$_3$N as an alternative photosorbber in thin-film photovoltaic cells.

CM01.03.12
Defects Behavior in Disordered Iron Oxide Synthesized from Grain-Oriented Iron Foils Karen A. Neji1, José Alfredo Andrade Adame2, Ramón Pelá1, 2, Roberto Baca1, 2, Dr. of Nanoscience and Micro-Nanotechnology, ENCB, Instituto Politecnico Nacional, Mexico City, Mexico; 1IPHII, Instituto Politecnico Nacional, Mexico City, Mexico; 2Department of Electrical Engineering, Solid State Electronics Section, Centro de Investigacion y de Estudios Avanzados del Instituto Politecnico Nacional, Mexico City, Mexico; 3Department of Electronics, ESIME, Instituto Politecnico Nacional, Mexico City, Mexico.

Disordered iron oxide thin-films synthesized from grain-oriented iron foils were grown on both glass and Si (100) n-type substrates by vacuum evaporation followed by thermal oxidation at low temperatures. Defects such as vacancies formation has been studied using Atomic Force Microscopy (AFM) and Raman Spectroscopy. The kinetic of oxidation as a function of surface parameters was investigated by AFM studies. The vibrational modes (bands) connected with the vacancies formation and magnetic ordering into the iron oxide structure were validated by Raman spectroscopy. Space-charge effects can be influenced by discontinuous growth of iron oxide and correlated with their structure parameters. Finally, the disordered iron oxide will be useful for the next generation of adaptive oxide devices.

CM01.03.13
Chemical, Structural and Photovoltaic Properties of Graded CdS$_x$Se$_{1-x}$ Thin Films Grown by Chemical Bath Deposition on GaAs(100) Ofrs Friedman, Omri Moscovitch and Yuval Golan; Department of Materials Engineering and the Ilse Katz Institute for Nanoscale Science and Technology, Ben-Gurion University of the Negev, Beer-Sheva, Israel.
CdS$_x$Se$_{1-x}$ films are direct band gap ternary semiconductors that can harvest photon energy in an energy range from 2.42 eV (CdS) to 1.74 eV (CdSe) by compositional tuning or chemical gradation. Growth of such films using chemical bath deposition (CBD) is advantageous due to low production costs and the ability to easily control initial bath composition. We have recently demonstrated monocrystalline CdS and CdSe deposited on GaAs substrates by CBD. In this work we present the chemical, structural and photovoltaic properties of Cd(S,Se) solid solution thin films deposited on GaAs(100) substrates by CBD. The structural and chemical properties of the films were characterized using x-ray diffraction (XRD), scanning electron microscopy (SEM), analytical transmission electron microscope (A-TEM) and energy dispersive spectroscopy (EDS) mapping. We present evidence of chemically graded films that were formed by controlling the initial anion concentrations in the bath, which affect nucleation and growth of the films. The films are polycrystalline in nature, with a thin zinc blende layer formed directly onto the GaAs substrate, on top of which a highly oriented nano-columnar layer of wurtzite Cd(S,Se) is obtained. Finally, current-voltage measurements of GaIn-eutectic/GaAs/Cd(S,Se)/In device were conducted at room temperature under 1 sun. We demonstrate the photo-response dependence on the S/Se ratio in CdS$_x$Se$_{1-x}$ based photovoltaic cells.

CM01.03.14

Revealing the Atomic Arrangement of Dopants in the Layered Oxide Cathode Structure

Soroosh Sharifi-Asl,1 Jason Croy,2 Mahalingam Balasubramanian3 and Reza Shabbazian-Yassar1; 1Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago, Illinois, United States; 2Chemical Science and Engineering, Argonne National Laboratory, Argonne, Illinois, United States; 3Advanced Photon Source, Argonne National Laboratory, Argonne, Illinois, United States.

The positive electrode of rechargeable-ion battery, which is normally a layered oxide ceramic material, is known as the bottleneck of this technology. Based on the numerous studies focused on the degradation mechanisms of cathode materials, it has been proposed that cationic doping with electrochemically-inactive metals such as Al, Ti and Mo improves the cycling stability and electrochemical performance of cathode materials. LiCoO$_2$ is one of the most widely used cathode materials in Li-ion batteries. It has a layered hexagonal (R3m) structure, which allows for free Li-ion mobility during the electrochemical cycling. LiCoO$_2$ has a very high theoretical capacity of 270 mAhg$^{-1}$, only half of which can be reversibly utilized to maintain a stable cycling condition. The reason is, Li deintercalation higher than a certain extent results in migration of Co ions into the Li sites that leads to the layered to spinel/rock-salt phase transition, an irreversible reaction that results in rapid capacity fading. To combat this issue metal doping has been pursued as a promising direction in the literature. The electrochemically inactive cations act as stabilizing skeleton in the cathode structure and resist against the structural collapse upon high extent of Li-deintercalation. However, the dispersion of such dopant cations in the cathode structure is not truly investigated and it is normally assumed that dopants will disperse uniformly into the cathode structure.

In this study, we utilized aberration-corrected scanning transmission electron microscopy (AC-STEM) together with analytical electron energy loss spectroscopy (EELS) and energy dispersive spectroscopy (EDS) to study the atomic structural arrangement of W-doped LiCoO$_2$. High angle annular dark field imaging (z-contrast imaging technique) that can distinguish between Co and W atoms is utilized in our investigation. Interestingly, our results indicate that in the W-doped LiCoO$_2$ sample, W atoms prefer to occupy a distinct Co layer and form separate LiWO$_2$ layers inside the LiCoO$_2$ matrix. The mechanism of such abnormal atomic arrangement is being investigated by computational calculations. Furthermore, structural analysis at various state of charge and cycling conditions is studied to reveal the role of W layers on the structural stability of W-doped LiCoO$_2$. In addition, to test the structural stability of such local W rich layers, controlled beam damage experiments have been carried out that demonstrate higher stability of W layers against beam knock-on damage. Overall, presenting the first atomic demonstration of dopant arrangement inside the layered-oxide cathode structures can explain many questions regarding the role of dopant on the electrochemical performance of the cathodes and can have a great contribution in designing superior cathode materials for next generation of Li-ion batteries.

Towards the Application of Large Zeolite Particles as PEPT Tracers

Dan Parsons2, Joe Hriljac3 and Andy Ingram1; 1School of Chemical Engineering, University of Birmingham, Birmingham, United Kingdom; 2School of Chemistry, University of Birmingham, Birmingham, United Kingdom.

PEPT (Positron Emission Particle Tracking) is a powerful technique used to elucidate dynamics in chemical engineering processes[1]. Visualizing dynamics with PEPT relies on incorporating tracer particles, radioactively labelled with a $\beta^+$-emitting isotope, into the system under study. The most commonly applied tracer particles are resin or glass beads with diameters in the range 0.1 – 4 mm. Large glass beads (> 1 mm) may be activated directly in a cyclotron, converting some oxygen in the glass to F$^{-}$; however, this is not possible for smaller glass beads and resin particles (< 1 mm), instead these are labelled by surface adsorption or ion-exchange, respectively, from aqueous solutions containing F$^{-}$[2]. Low affinities for F$^{-}$ in existing tracers limits the ability to label particles smaller than 100 μm, hence tracer particles are often much larger than the granular material they represent, and the properties of the tracer material are also often atypical of the granular material in true systems, ultimately limiting the applications of PEPT studies and potentially the accuracy of results obtained[3]. The aim of the current work is to develop syntheses that provide control of particle size and morphology for materials with high affinities for the $\beta^+$-emitting isotopes of interest.

Our work has applied established methods to successfully synthesize large crystals, or particles, of zeolites with the faujasite, LTA and mordenite structures in the size range of interest, 10 - 100 μm. Methods employed have included the addition of tetraethanolamine to gels, retarding the crystal growth thus producing larger crystals over extended periods of time, synthesizing large zeolite crystals with faujasite and LTA topologies. Moreover, the use of tetraethylammonium ions as structure directing agents in siliceous gels has produced large particles of zeolites including mordenite. The most commonly used $\beta^+$-emitting isotopes for labelling tracers in PEPT are F$^{-}$ and Ga-68, owing to ease of production and suitable half-lives. We have demonstrated the affinity of large zeolite particles for uptake of both cationic and anionic species, viz. Ga$^{3+}$ and F$^{-}$, from aqueous solution by ion-exchange and adsorption, respectively.

Ultimately, we have produced crystalline tracers in the size range of interest which may be labelled by exploiting the innate affinity of the material for the species of interest. The application of crystalline tracers that are smaller than any previously used in PEPT studies have the potential to provide more accurate information on dynamics in many industrially important processes including mixing and fluidization phenomena.

CM01.03.16
Solid Electrolytes Particle Size Effect in All-Solid-State Batteries

Qingsong Tu, Gerbrand Ceder and Tan Shi; University of California, Berkeley, California, United States.

All-solid-state battery (SSB) is a promising candidate to replace the conventional lithium ion batteries. It not only has improved safety, but also could have larger energy density by utilizing Li metal anode. However, two factors limit the cathode loading in current SSBs and lead to low energy density. 1) Large amount (30 wt% - 50 wt%) of solid electrolyte (SE) in the cathode composite is required to provide sufficient ionic diffusion pathways. 2) Cathode composite thickness is limited by the poor ionic diffusion in the cathode composite.

We address these two issues by improving the Li ion conduction network through cathode morphology optimization. Our theoretical calculation and experimental data both show the relative particle size of cathode and SE greatly modifies the ionic percolation in the cold pressed cathode composite. Through simple SE particle size optimization, we were able to reduce the SE needed in the cathode composite and increase the cathode composite thickness without sacrificing specific capacity, resulting in an increased full cell energy density.

Field-Induced Magnetic Order Switching of A'-site Iron Spins in CaFeTiO₄

Midori Amano Patino¹, Fabio Denis Romero², Masato Goto¹, Takashi Saito³ and Yuichi Shimakawa⁴; ¹Institute for Chemical Research, Kyoto University, Kyoto City, Japan; ²Hakubi Center for Advanced Research, Kyoto University, Kyoto City, Japan.

Materials which adopt the ABO₃ perovskite lead to a significant tilting of the corner sharing BO₆ octahedra and give way to square-coordinated units or “A” sites. In this work we got particularly interested in the quadruple perovskite phase CaFe₂TiO₄ in which the B-site Ti³⁺ ions are nonmagnetic therefore allowing the investigation of the unusual magnetic behaviour of the Fe²⁺ spins forming the A’-site sublattice. We synthesized this compound using high-temperature high-pressure techniques, and characterized its magnetic properties for the first time. This phase had been previously observed, but not fully characterized. [3] Here we confirm the presence of Fe²⁺ S = 2 centers at the square planar A’ sites in CaFe₂TiO₄ from Curie-Weiss magnetic susceptibility and Mössbauer data. Magnetic susceptibility data show a maximum at 2.8 K suggesting AFM (antiferromagnetic)-like behaviour of the Fe²⁺ spins. Interestingly, such state switches to a ferromagnetic-like behaviour under the application of magnetic fields H ≥ 1 T. Therefore, the applied magnetic field is capable of inducing a FM-like structure on the A’-site Fe²⁺ S = 2 spin sublattice. DFT calculations for the AFM and FM spin arrangements for the Fe²⁺ spin sublattice in CaFe₂TiO₄ reveal that the two states are very close in energy. We propose that the comparable energies of the AFM and FM states lead to competition between the two spin configurations.

CM01.03.18

Synthesis of Alumina-Doped Zirconia Microparticles for High-Temperature Applications

Gregor T. Dahl¹, Sebastian Döring¹, Tobias Krekeler², Martin Ritter², Horst Weller¹ and Tobias Vossmeyer¹; ¹Physical Chemistry, University of Hamburg, Hamburg, Germany; ²Electron Microscopy Unit, Hamburg University of Technology, Hamburg, Germany.

Zirconia and similar ceramics are widely used in high-temperature applications. In the past decades, significant efforts have been focused onto the synthesis and characterization of well-defined ceramic particles in terms of size, shape and composition in order to control their properties precisely. Current research aims at the application of ceramic microparticles in advanced thermal barrier coatings, structure-based colorants for ceramics and thermophotovoltaics.[1-4] Most of these application environments require materials with a high resistance against thermal degradation, which is usually achieved to some degree by doping of the bare ceramic material. Hence, our research addresses the development of synthetic routes for doped zirconia microparticles with accurate tunability of the product’s size and morphology, as well as the examination of the mechanisms underlying the structural degradation under thermal stress.

Recently, we focused on the sol-gel fabrication of well-defined spherical alumina-doped zirconia microparticles and their high-temperature behavior. This material system is to date far less understood than related materials, e.g. yttria-stabilized zirconia, regarding their synthesis and thermally induced structural changes. However, rare and contradictory results in the literature provide a profound understanding of the involved fundamental physical processes highly desirable. Here, we examine the role of the reaction conditions during particle fabrication and the dopant concentration using ex situ characterization of particle samples before and after annealing at different temperatures.

TEM/EDX analyses suggest that homogenous alumina-doping of zirconia microparticles fabricated via a stabilizer-assisted sol-gel protocol at Al/(Al+Zr) molar concentrations between 2 % and 50 % can easily be achieved by using mixed Zr- and Al-alkoxide precursors. The degree of doping can be precisely adjusted by the precursor ratio. Evident effects of the latter on the resulting particle size can be compensated in a controlled way by a variation of the amount or composition of involved stabilizing agents. TEM images of particle samples annealed at temperatures between 800 °C to 1200 °C imply that their structural integrity is progressively maintained with increasing amount of Al. Qualitative XRD analysis using Rietveld refinement reveals a correlation between the Al amount and the stabilization of the tetragonal polymorph against the destructive martensitic transition to the monoclinic phase and inhibited grain growth. Evident dopant segregation after annealing revealed by EDX mappings suggests a reduction of the propagation of grain boundaries during sintering (solute drag effect).

CM01.03.19

Structural and Functional Investigations of Substitutions in the Ionic Conducting Li-Argyrodite Family

Nicolò Minafra and Wolfgang G. Zeier; Justus-Liebig-Universität Gießen, Giessen, Germany.

Inorganic solid electrolytes have garnered considerable attention as separators in lithium-ion battery applications as they may solve the safety problems and improve energy and power density of the conventional devices using liquid electrolytes.¹ Inspired by such technological interest, in this work we studied an inorganic crystalline solid that belongs to the Li-argyrodite family,² with the general formula Li₆PS₄Br. While this compound is known for its high ionic conductivity of Li⁺ ions, the influence of aliovalent and isoelectronic substitutions on the structure and transport properties are unknown.

In this work, we will present the influence of aliovalent substitution of P⁵⁺ with Si⁴⁺ and isoelectronic substitution of Se²⁻ for S²⁻ on the structure-transport
correlation in lithium conducting argyrodites. Structural changes arising from the substitution were monitored through Rietveld refinements of the experimental X-ray powder and neutron diffraction data, and severe changes in the lithium substructure and site ordering can be found. The found changes in the lithium substructure and site ordering can be used to explain the changes in the Li+ ionic conductivities as measured by impedance spectroscopy. This work provides an approach to a better understand structure-property relationships in solid electrolytes. The herein found correlations between composition, structure and functional properties contributes towards a general framework and universal strategy to design solid materials with fast ionic diffusion.

Synthesis and Characterization of ZrO2@SiO2/Al2O3 Core-Shell Particles for Application as Structural Colors and Thermal Barrier Coatings
Maik Finsel1, Jil Rüter1, Maria Hemme1, Kaline F. Furlan1, Guoliang Shang4, Robert Blick3, Robert Zierold3, Alexander Petrov4, Manfred Eich4, Hoest Weller1 and Tobias Vossmeier1; 1Physical Chemistry, University of Hamburg, Hamburg, Germany; 2Advanced Ceramics, Hamburg University of Technology (TUHH), Hamburg, Germany; 3Center for Hybrid Nanostructures, University of Hamburg, Hamburg, Germany; 4Optical and Electronic Materials, Hamburg University of Technology (TUHH), Hamburg, Germany; 5ITMO University, St. Petersburg, Russian Federation; 6Materials Research, Helmholtz-Zentrum Geesthacht Center for Materials and Coastal Research, Geesthacht, Germany.

In recent years, zirconia (ZrO2) micro- and sub-microparticles gained considerable attention due to their outstanding properties, including chemical inertness, thermal stability and high refractive index. These excellent features of zirconia-based materials enable a broad variety of applications ranging from fuel cells, catalysis, sensors to electro- and bioceramics. Furthermore, zirconia (sub-)microparticles are interesting for applications as building blocks of photonic glasses for high-temperature applications, including structural colors (SC) and thermal barrier coatings (TBC).

For structural colors, well-defined monodisperse core-shell particles with smooth surface and strong refractive index contrast are needed. These requirements can be achieved by encapsulation of spherical zirconia submicroparticles with a suitable shell material. For example, to achieve the desired properties for structural colors Al2O3, SiO2, and polymers are attractive materials to form the shell. Most synthesis methods for such core-shell particles use organic ligands (e.g. polymer, citric acid) as adhesive layer between the core and the shell. One of the main obstacles of this approach is that it precludes high-temperature applications. Here, we developed a straightforward approach to prepare ZrO2@SiO2 core-shell composites without using additional organic coupling agents. First results show that changing the silica shell thickness varies the optical properties in the visible region. Furthermore, we demonstrate that the ZrO2@SiO2 core-shell particles withstand temperatures up to 1000 °C whereas size-comparable zirconia particles and core-shell particles using polyvinylpyrrolidone (PVP) as interfacial layer disintegrate when heated up to 800 °C as shown by XRD, SEM and cross-sectional TEM characterization.

For thermal barrier coatings, low-thermal conductivity ceramics such as Y-stabilized zirconia (YSZ) are used to provide thermal insulation of the underlying superalloy in gas-turbine engines operated in aircrafts. One of the main obstacles of this system is the oxygen diffusion through the ceramic TBC due to oxygen vacancies, which leads to corrosion and failure of the turbine blade. We show that YSZ microparticles are interesting for TBC application with broadband thermal radiation reflection and decreased thermal conductivity at temperatures up to 1500 °C. Furthermore, we used a sol-gel synthesis and atomic layer deposition (ALD) for Al2O3 deposition on YSZ and ZrO2 microparticles to decrease oxygen diffusion and thus to improve high-temperature stability. These core-shell microparticles were characterized by XRD, SEM and IR-reflection measurements.

Mechanical and Microstructural Characterization of a 3003 Aluminum Alloy Processed by Repetitive Corrugated-Straightening (RCS)
Carlos A. Reyes Ruiz1, Carlos G. Figueroa Alcantara2, Jose G. Gonzalez Reyes1 and Armando Ortiz Prado1; 1Departamento de Diseño y Manufactura, Facultad de Ingeniería, Universidad Nacional Autónoma de México, Mexico, Mexico; 2Centro Tecnológico Aragón, Facultad de Estudios Superiores Aragón, Universidad Nacional Autónoma de México, Mexico, Mexico; 3Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México, Mexico, Mexico.

Repetitive corrugated-straightening (RCS) is a severe plastic deformation technique that has been applied to an extensive amount of materials due to its capability to generate ultra-fine grain microstructures. Through remarkable grain size reduction, this process led to improved mechanical properties such as strength, hardness, endurance, etc. The aim of the present work was to study the mechanical and microstructural effects of a repetitive corrugated-straightening process using a novel die geometry. A 3003-O aluminum alloy sheet was processed at room temperature up to 6 RCS passes. Deformed samples showed improvements in yield strength. Nonhomogeneous deformation zones were determinate by means of microhardness tests and were correlated to low (LAGB) and high (HAGB) grain boundary and regions measured by means of electron backscattered diffraction (EBSD) mapping. Samples did not change at increasing the number of passes. However, surface quality showed that root mean square roughness (Rrms) increased after the first RCS pass. Initial texture components were not modified at early stages of the processing, but showed an orientation spread at latest stages. Grain lattice distortion, obtained by Williamson–Hall plots, exhibited a maximum after one RCS pass, decreasing as passes number increased. Crystallite size decreases as function of RCS passes.

Fast Interfacial Li+ Diffusion in Nanostructured LiF and LiF-Al2O3 Composites as Seen by NMR Spectroscopy
Stefan Breuer, Veronika Pregartner and Martin Wilkening; Institute for Chemistry and Technology of Materials, Graz University of Technology, CD-Laboratory for Lithium Batteries, Graz, Austria.

Understanding ionic diffusion in solids is a very vital topic in material science. Currently we put much effort into finding suitable materials that meet the
needs to develop leading-edge energy storage devices and sensors. Besides studies driven directly by applications, also fundamentally oriented investigations are required to shine further light on the structure-property relationships determining fast ion transport.\textsuperscript{2-3} LiF attracted our attention as it has a versatile range of application. It can be used as a component for electrode materials with high capacity;\textsuperscript{2} moreover, it is a fundamental component of the solid electrolyte interface (SEI).\textsuperscript{4} Understanding ionic transport in and across the SEI is a topic of utmost importance.\textsuperscript{5}

Here we studied ionic transport in nanocrystalline LiF and nanocrystalline LiF:Al\textsubscript{2}O\textsubscript{3} composites to study interfacial ion transport properties. It is well known that the properties of materials with nm-sized structures, particularly if we consider ionics transport, can be significantly different from those of their coarse-grained counterparts.\textsuperscript{6} To investigate the relationship between macroscopic and microscopic ion dynamics, we used conductivity spectroscopy and \textsuperscript{7}Li, \textsuperscript{9}F nuclear magnetic resonance (NMR) spectroscopy. The former method, which is sensitive to long-range ion transport, reveals significant higher conductivity values for the nanocrystalline LiF compared to the microcrystalline sample. Joint milling the ionic conductor with an insulator successfully enhances the conductivity even more. We observed an increase in ion transport by up to three orders of magnitude for LiF:Al\textsubscript{2}O\textsubscript{3} (70:30 vol %). Variable-temperature NMR line shapes recorded under static conditions reveal a fast and a slow Li spin reservoir at elevated temperatures. Obviously, the interfacial regions at the LiF:Al\textsubscript{2}O\textsubscript{3} contacts provide fast diffusion pathways for the Li ions. These atomistic insights available by NMR support earlier concepts that interfacial disorder and strain as well as space charge zones considerably influence overall ion transport in (nanocrystalline) conductor:insulator composites.\textsuperscript{8-11}

Microwave Synthesis of Transition Metal Oxide Nanoparticles Adsorbed on Silica Nanosprings for Energy Applications

Pierre Magri\textsuperscript{1}, Noura Zahir\textsuperscript{1}, Sara Soltni\textsuperscript{1}, Jean J. Gaumet\textsuperscript{1}, S\ébastien Dilliberto\textsuperscript{2}, David N. McIlroy\textsuperscript{1}, Wen Luo\textsuperscript{3} and Liqiang Ma\textsuperscript{4}; 1Jean Barriot Institute, University of Lorraine, Metz, France; 2Jean Lamour Institute, University of Lorraine, Nancy, France; 3Physics, Oklahoma State University, Stillwater, Oklahoma, United States; 4Wuhan University of Technology, Wuhan, China.

SiO\textsubscript{2} nanosprings (NS) are used not only for support and substrates in various chemical, biological and medical applications, but also for photovoltaic development and hydrogen storage depending on the choice of the coating on the NS\textsuperscript{[1,2]}. SiO\textsubscript{2} NS are now readily coated with metal oxides, which make them interesting devices for sensors based on redox processes, particularly with semiconducting elements\textsuperscript{[3]}. The use of microwave (MW) chemistry has become more and more common as a means to synthesize nanoparticles on the silica NS using two joint mechanisms for heating, dipolar polarization and ion conduction. However, to ensure the stability of the SiO\textsubscript{2} NS, it is better to first synthesize the nanoparticles by MW reaction before adding them to the NS. In this context, we present herein some MW synthesis of transition metal oxide (TMO) and mixed metal oxide (MMO) nanoparticles (Zn, Co, V) followed by direct absorption on SiO\textsubscript{2} NS. Defect-rich TMO and MMO nanoparticles are synthesized by preparing various metal acetylacetonate solutions in different H\textsubscript{2}O/EtOH volume ratios. After MW irradiation up to 1 h, the resulting precipitates were filtered, washed with EtOH, and dried at 80°C \textsuperscript{[4]}. Finally, the nanoparticles were added to various NS in EtOH. SEM, TEM and X-Ray diffraction confirmed the presence of metal-oxide nanoparticles in a different size range and shapes depending on the solvent ratio and the MW irradiation time. The quantification of ligands originating from the precursors was determined by Thermogravimetric Analysis (TGA) and Differential Scanning Calorimetry (DSC). After SEM and TEM characterizations, the optical properties of the different TMO and MMO nanoparticles were carefully measured by UV-Visible photoluminescence and absorption spectroscopy. The same analytical protocol was performed after adsorption on SiO\textsubscript{2} NS. It shows that integrity of defect-rich TMO or MMO nanoparticles (constant visible light emission for ZnO at 570 nm for example) is preserved when deposited onto the NS. Such results on this stability show the potential of using a metal-oxide shell with a silica NS core as an absorber/emitter when connected to a metal contact.

Impact of the Isovalent Alloying on the Thermoelectric Properties of Yb\textsubscript{1-x}MnSb\textsubscript{x}

Giacomo Cerretti, Sabah K. Bux and Jean-Pierre Fleurial; Jet Propulsion Laboratory, Pasadena, California, United States.

Yb\textsubscript{1-x}MnSb\textsubscript{x}, with a zT of about 1.2 at 1200 K, is the highest performing p-type materials for high temperature thermoelectric applications. Structurally it belongs to the Zintl phase family A\textsubscript{4}MnP\textsubscript{4}, (where A = Ca, Sr, Ba, Eu, and Yb; M = Al, Mn, Zn, Ga, Nb, In, and Cd, Pn = P, As, Sb, Bi), which is formed by 14 A\textsuperscript{2-}\textsuperscript{2} cations, a MPn\textsubscript{4} tetrahedron, a linear Pn\textsubscript{3} trimer, and 4 Pn\textsubscript{3} anions. This chemical configuration gives the possibility to independently manipulate the electronic and thermal transport properties of the compound by using different alloying species and adjusting their concentrations. In this contribution, we want to show how different alloying approaches affect the chemical and structural properties of the Yb\textsubscript{1-x}MnSb\textsubscript{x}, and how this translates into the manipulation of the thermoelectric properties. Specifically, we studied the impact of the isovalent partial substitution on the Yb and Mn sites with Sr and Co/Pd respectively. The lack of filled f-orbitals in Sr could result in large changes in the DOS due to the different nature of the chemical bonding. Additionally, the bigger cationic radius of Sr compared to Yb will decrease the bond length generating a higher chemical pressure, and in turn altering the thermal transport properties of the material. Partial substitution of the Mn\textsuperscript{2+} ions by isovalent elements could increase the covalent nature of the bonding to reduce the effective mass and hence to increase the carrier mobility. The results of the isovalent substitution study will be presented and discussed.

Negative Magnetisation in A\textsubscript{4}T\textsubscript{2}Cr\textsubscript{2}B\textsubscript{2}O\textsubscript{6}, Perovskites

Emily C. Hunter\textsuperscript{1}, Peter D. Battle\textsuperscript{2}, Maxim Avdeev\textsuperscript{3, 4}, Mylene Hendrickx\textsuperscript{5} and Joke Hadermann\textsuperscript{6}; 1The University of Oxford, Oxford, United Kingdom; 2ANSTO, Lucas Heights, New South Wales, Australia; 3The University of Sydney, Sydney, New South Wales, Australia; 4Physics, University of Antwerp, Antwerp, Belgium.
This research explores the compositional sensitivity of the magnetic properties of $A^2'\text{Sr}_2\text{Cr}_2\text{SbO}_9$ perovskites where $A^2'$ is La or Pr; $A^2'$ is Sr or Ca and $B$ is Nb, Nb or Ta. In monophasic compounds of this type the cations occupying the B sites can be partially ordered or fully disordered. Alternatively the material can phase-separate to give regions in which the cations are ordered and others in which they are disordered. Neutron diffraction and electron microscopy have shown that in compositions where there is cation order two crystallographically distinct B sites are present in a 1:1 ratio, despite the two cation species being present in a 2:1 ratio.

The extent of the cation ordering affects the magnetic properties of the perovskite. For example, $\text{LaSr}_2\text{Cr}_2\text{SbO}_9$, which has a high degree of cation order, is a ferrimagnet while $\text{PrSr}_2\text{Cr}_2\text{NbO}_9$ and $\text{PrSr}_2\text{Cr}_2\text{TaO}_9$, which contain both cation-ordered and disordered regions, are spin glasses. $\text{PrSr}_2\text{Cr}_2\text{SbO}_9$ still behaves as a ferrimagnet, despite containing disordered regions. We shall focus on $\text{PrCa}_2\text{Cr}_2\text{NbO}_9$ and $\text{PrCa}_2\text{Cr}_2\text{TaO}_9$ which are both fully disordered, adopting the space group $\text{Pmnr}$. In these compounds the Ct cations order antiferromagnetically below ~120 K, however, magnetometry studies show that the field-cooled magnetisation becomes negative below 50 K for $\text{PrCa}_2\text{Cr}_2\text{NbO}_9$ and below 80 K for $\text{PrCa}_2\text{Cr}_2\text{TaO}_9$. The direction of the net magnetisation can be flipped by applying magnetic fields of 1000 Oe to $\text{PrCa}_2\text{Cr}_2\text{NbO}_9$ and 3000 Oe to $\text{PrCa}_2\text{Cr}_2\text{TaO}_9$ and both compounds show a large degree of hysteresis in $M(H)$.

In these compounds the Cr cations order antiferromagnetically below ~120 K, however, magnetometry studies show that the field-cooled magnetisation becomes negative below 50 K for $\text{PrCa}_2\text{Cr}_2\text{NbO}_9$ and below 80 K for $\text{PrCa}_2\text{Cr}_2\text{TaO}_9$. The direction of the net magnetisation can be flipped by applying magnetic fields of 1000 Oe to $\text{PrCa}_2\text{Cr}_2\text{NbO}_9$ and 3000 Oe to $\text{PrCa}_2\text{Cr}_2\text{TaO}_9$ and both compounds show a large degree of hysteresis in $M(H)$.

In metallic fuels, fission products generated during operation react with the cladding materials leading to fuel-cladding-chemical interactions (FCCI). The FCCI results in degradation of the cladding wall and eventual rupture of the cladding if the fuel is operated for higher burnup. Use of a dopant in the fuel matrix, which can form intermetallic compounds with lanthanide fission products (e.g., Nd, Ce, Pr, and La), is proposed to be one of the effective ways of mitigating FCCI. Here we used ab-initio calculations based on density functional theory (DFT) to study the interactions between different possible dopants (such as Se, As, Pd, In) and the lanthanide fission products. Based on the calculations, arsenic and selenium were identified as potential dopants to arrest the major lanthanides within the uranium matrix effectively. The relative preference of identified novel dopants in binding with another fuel component, Zr, is also evaluated. Finally, we present an approach that can be used in selecting a dopant to bind a particular lanthanide inside the fuel matrix based on their intrinsic properties such as electronegativity and atomic size. The approach used in this study is generic; so it has implication in other areas of research related to alloy design. This research is being funded by DOE-NEUP, grant # DE-NE0008557.

**Ozone-Mediated Synthesis of Ceria Nanoparticles**

Anuja Bhalkikar and Chin Li Cheung; Chemistry, University of Nebraska–Lincoln, Lincoln, Nebraska, United States.

Numerous methodologies have been developed for the synthesis of cerium oxide or ceria, a commercially important lanthanide oxide. Some of the techniques employ long reaction times, elevated temperatures and/or pressures, expensive metal alkoxides and caustic alkalis. This necessitates the need to develop milder, environment friendly synthetic routes for cerium oxide generation. Herein, we report a rapid, room temperature methodology to synthesize fluoride-structured ceria nanoparticles using cerium (III) salts and ozone in the presence of short chain primary, secondary, and tertiary alcohols. This simple technique produced nanoparticles with higher oxygen vacancy compared to that of bulk ceria. Chemical species in the reaction mixtures were studied to elucidate a possible growth mechanism of these nanoparticles from ozonating alcoholic solutions of cerium salts. The catalytic activity of ceria nanoparticles towards the oxidation of carbon monoxide (CO) was further evaluated and compared with that of commercial bulk ceria.

**How to In Situ Follow the Evolution of Dislocation Configurations During Mechanical Testing on Bulk Specimen?**

Ben Haj Slama Meriem1, 2, Hana Kriaa1, 2, Julien Guyon1, 2, Nabilal Maloufi1, 2, Jean-Jacques Fundenberger1, 2 and Antoine Guittion1, 2;

1Université de Lorraine – CNRS – Arts et Métiers ParisTech – LEM3, Metz, France; 2Labeix Damas - Université de Lorraine, Metz, France.

In the aim of following the fast evolution of the industrial demands, developing innovative techniques that allow to understand and to predict the mechanical properties of materials has become a necessity for the Materials Science community. For instance, mechanical tests followed by microstructural investigations provide engineers with the necessary information to computationally predict the mechanical performance of components. In situ mechanical testing combined with microscopy techniques (SEM and TEM) [1,2] is well known for studying the instantaneous evolution of microstructures during exposure to stress. Such experiments allow capturing footprints of the deformation mechanisms responsible for the changing microstructure. For instance, in-situ testing combined with TEM is generally required for studying the instantaneous evolution of defects during exposure to stress. Today various approaches inside a TEM exist: TEM holders with a simple mechanical actuation [3], elaborated testing units that fit inside the pole pieces [4,5] or by playing with various coefficients of thermal expansion [1]. Nevertheless, in-situ TEM mechanical testing is experimentally very tough. In addition to the difficult control of the deformation conditions, the space available is generally less than one centimeter and statistics on physical mechanisms is scientifically very weak. Indeed, TEM needs an electron transparent specimen with a thickness of ~100 nm with a useful field of view of few µm².

Therefore, fundamental questions on the representativeness of observed phenomenon must be raised when extrapolating discussions to a millimeter-size specimen.

In this framework, we have successfully combined mechanical testing of bulk specimen with an in-situ avant-gardist dislocation-scale characterization technique; the accurate Electron Channeling Contrast Imaging (aECCI) [6]. aECCI is a non-destructive groundbreaking procedure that provides, inside a TEM, diffraction contrast imaging of sub-surface defects (at a depth of about one hundred of nanometers) on centimetric bulk specimen with still unsurpassed resolutions [7,8]. Firstly, technological challenges such as defect contrast comprehension and experiment procedure will be presented. Secondly first in-situ results will be discussed and they clearly show the full potentialities of this groundbreaking and powerful testing set-up.

**Fundamental and Experimental Aspects of Diffraction for Characterizing Dislocations on Bulk Materials by Electron Channeling Contrast Imaging in Scanning Electron Microscope**

Hana Kriaa1, 2, Antoine Guitton1, 2 and Nabila Maloufi1, 2; 1CNRS, Arts et Métiers ParisTech, Université de Lorraine, Metz, France; 2Labex Damas, Université de Lorraine, Metz, France.

The SEM is an easier way to use electron microscope compared to TEM essentially because of the possibility to observed centimetric bulk specimen and the larger space available in the chamber. SEM can access diffraction contrast on bulk materials with the phenomenon of electron channeling [1]. The Electron Channeling Contrast Imaging (ECCI) is a non-destructive groundbreaking technique offering the ability to provide, inside a SEM, TEM-like diffraction contrast imaging of sub-surface defects (at a depth of about one hundred of nanometers) on centimetric bulk specimen with still unsurpassed resolutions [2, 3]. Electron channeling contrast is produced from electrons, that channel down the crystal planes. Strain and defects distort the crystal planes, which produce changes in backscattered electron intensity leading to a contrast on the image. Dislocations for example can be characterized by ECCI using the well-known TEM $g \cdot b = 0$ and $g \cdot b_{x}u = 0$ extinction criteria [4] where $g$ is the diffraction vector and $b$ the Burgers vector. In this study, fundamental and experimental aspects of electron diffraction for characterizing dislocation by ECCI in SEM are reported [5]. The $(g \cdot g - g)$ method is explored on several dislocation configurations in an Intertistitial-Free steel sample. Moreover, the first detailed characterization of a dislocation dipole by ECCI [4, 5] is presented.

**Structural, Raman and Electrical Characterization of Nanocrystalline ZnSe Thin Films Deposited by Pulse Laser Deposition**

Pawan Kumar1, 2, Arvind Kumar1, Trilok Pathak1, Sita Dugu1, Rajesh K. Katiyar1, Alvaro Instan1 and Ram Katiyar1; 1Department of Physics, Institute for Functional Nanomaterials, University of Puerto Rico, San Juan, Puerto Rico, United States; 2Department of Physics, Gurukul Kangri Viswavidyalaya, Haridwar, India; 3Department of Physics, Kalindi College, Delhi University East Patel Nagar, Delhi, India.

Thin films of group II–VI semiconductor compounds have attracted considerable attention due to their novel physical properties. As a wide band-gap material, ZnSe is a potential candidate showing compatibility for optoelectronic devices based on the thin film technology [1, 2]. Zinc Selenide (ZnSe) thin films were deposited by Pulse Laser Deposition (PLD) technique on Si-p type substrates at different substrate temperatures. The substrate temperatures were fixed at 150°C, 200°C, 250°C, & 300°C respectively during the growth of the samples. The structure of ZnSe was confirmed by using X-ray diffraction pattern. The surface morphology and roughness of thin films were investigated by atomic force microscopy. The atomic bond behavior at room temperature and at lower temperatures (30°C to -190°C) were studied by Raman spectroscopy. The n-ZnSe/p-Si hetero junction thin films were characterized by current-voltage (I-V) and capacitance-voltage (C-V) measurements at different temperatures (273K to 373K). These films are promising candidates for applications in solar cells and sensors.

**Development of Highly Hydrogen-Sensitive Thermal Desorption Spectroscopy System—For Detection of Extremely Low Concentration Hydrogen in Oxide Semiconductors**

Hidenori Hiramatsu1, Taku Hanna1, Isao Sakaguchi1 and Hideo Hosono1; 1Tokyo Institute of Technology, Yokohama, Japan; 2National Institute for Materials Science, Tsukuba, Japan.

Hydrogen is the most unavoidable and uncontrollable impurity in semiconductor devices because of the ease of contamination during fabrication processes, even under an ultra-high-vacuum (UHV) atmosphere. This impurity results in serious problems such as instability of thin-film transistors and unintentional carrier doping. The detection limit of various techniques strongly depends on the sample volumes because a larger total amount of hydrogen facilitates detection. Thus, many quantitative and sensitive hydrogenic semiconductor device technology is generally based on thin-film deposition and fine-scale processing technologies, for which material purification and refinement of processing techniques have been rapidly advancing. Thus, the development of highly sensitive hydrogen detection techniques for small-volume samples such as thin films with nanometer-scale thicknesses is critical to investigate the effects of hydrogen impurities for practical semiconductor devices.

In this study, we developed a highly hydrogen-sensitive thermal desorption spectroscopy (HHS-TDS) system to detect and quantitatively analyze low hydrogen concentrations in thin films [REF]. The system was connected to an in situ sample-transfer chamber system, manipulators, and an rf magnetron sputtering chamber under an UHV atmosphere of ~10^-8 Pa. The following key requirements were proposed in developing the HHS-TDS: (i) a low hydrogen residual partial pressure, (ii) a low hydrogen exhaust velocity, and (iii) minimization of hydrogen thermal desorption except from the bulk region of the thin films. To satisfy these requirements, appropriate materials and components were selected, and the system was constructed to extract the maximum performance from each component. Consequently, ~2000 times higher sensitivity to hydrogen than that of a commercially available UHV-TDS system was achieved. Quantitative analysis of an amorphous oxide semiconductor InGaZnO4 (IGZO) thin film (hydrogen concentration of 4.5 × 10^17 atoms/cm^2), which is the minimum concentration among previously reported IGZO was demonstrated using the HHS-TDS system. This concentration level cannot be detected using UHV-TDS or secondary ion mass spectroscopy (SIMS) systems. The hydrogen detection limit of the HHS-TDS system was estimated to be ~1 × 10^17 atoms/cm^2, which implies ~2 orders of magnitude higher sensitivity than that of SIMS (~10^19 atoms/cm^2). This detection limit is the most sensitive among various conventional analysis techniques, to our knowledge, in the case of thin-film samples. We will also discuss role of hydrogen in oxide semiconductors such as IGZO, which are practically applied to channel layers of thin-film transistors in electronic display devices such as organic light-emitting diode displays and smartphones.

**Role of Surface Oxidation in the Dehydrogenation of Complex Metal Hydrides**

James L. White1, Andrew J. Rowberg2, 3, Liwen Wan4, 4, ShinYoung Kang2, Tadashi Ogitsu2, Robert D. Kolansinski3, Josh A. Whaley1, Timothy C. Wang1, A. A. Baker2, Jonathan R. Lee2, Yi-Sheng Liu4, Lena Trotochaud4, Jinghua Guo4, Vitalie Stavila1, David Prendergast4, Hendrik Bluhm4, Mark Allendorf1, Brandon Wood2 and Farid El Gabaly1; 1Sandia National Labs, Livermore, California, United States; 2Lawrence Livermore National Laboratory, Livermore, California, United States; 3University of California, Santa Barbara, Santa Barbara, California, United States; 4Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Complex metal hydrides have high hydrogen storage capacities and the potential to be employed in hydrogen fuel cell vehicles. However, many of these
materials remain limited by slow kinetics in their cycling reactions between hydrogenated and dehydrogenated states. In addition, mechanisms for hydrogen formation on the surface have been postulated for several hydrides but not directly investigated during desorption. Using both operando and ex situ measurements, on several length scales, combined with ab initio simulations, we show an unambiguous view of the surface chemistry evolution in dehydrentgenating NaAlH4 and Mg(BH4)2. Shifts in speciation are observed in real time during desorption using ambient pressure X-ray photoelectron spectroscopy and low-energy ion scattering, and detailed computational models provide atomistic descriptions and energetics of the observed surface processes. While adventitious oxidized species on the surface are often assumed to be inert or inhibitory for metal hydrides, we show that, instead, they participate in the release of hydrogen, in some cases with lower computed barriers than pristine, unoxidized surfaces. Hydrogen enrichment near the surface indicates that dehydrenation in NaAlH4 is limited by surface processes, which have the potential to be improved through optimization of the extent surface processes described here.

CM01.03.33
Galvanic Simulation of Photoelectron Spectra Adam J. Jackson1, 2, Alex M. Ganose1, 2, Anna Regoutz4 and David O. Scanlon1, 2, 3; 1 Dept of Chemistry, University College London, London, United Kingdom; 2 Thomas Young Centre, University College London, London, United Kingdom; 3 Diamond Light Source Ltd, Didcot, United Kingdom; 4 Dept of Materials, Imperial College London, London, United Kingdom.

Photoelectron spectroscopy (PES) is a powerful tool for the characterization of materials by probing their electronic structure; indeed, experiments with x-ray sources in the early part of the 20th century contributed to the modern understanding of electronic structure.[1, 2] In the later part of the 20th century, computational methods become available for ab initio predictions and analysis of electronic band structure. With the widespread use of density-functional theory, it is now a routine procedure to compute an accurate density of states (DOS) for a hypothetical structure. The occupied energy levels in the DOS should map directly to the first-order transition energies observed in photoelectron spectroscopy, providing insight into valence band phenomena.[3, 4]

However, additional processing is required to form a realistic simulated spectrum. There are several mechanisms causing broadening, typically modelled with Gaussian and Lorentzian functions.[5, 6] In addition, relative peak intensities generally match the DOS poorly until corrected. The Gelius model assumes that the contributions of bands will be dominated by their behaviour close to atom centers.[7] This allows free-atom photoionization data to be used with a DOS which is decomposed into atomic contributions (e.g.[3]). Although the data for this process is widely available, the analysis is not performed routinely, partly because it is tedious. We have automated this process and present an open-source package to assist the community in the implementation of this analysis.[8] Free-atom data has been parametrised to enable the selection of optimal HAXPES energies and exploration of the system sensitivity before expensive synchrotron measurements are performed.

CM01.03.34
Synthesis, Structural and Magnetotransport Properties of Antiferromagnet-Fe3O4: Epitaxial Thin Films Obtained by Polymer Assisted Deposition Myriam H. Aguierre1, 2, Engienio Otal1, Manuela Kim1, Rafael Ramos3 and Francisco Rivasdulla1; 1 Institute of Nanoscience of Aragón-Laboratory of Advanced Microscopy, Zaragoza, Spain; 2 Dept. of Physics Condensed Matter, University of Zaragoza, Zaragoza, Spain; 3 U.T.N.-CONICET, Buenos Aires, Argentina; 4 Ciquus-University of Santiago de Compostela, Santiago de Compostela, Spain; 5 AIMR-Tohoku University, Sendai, Japan.

Bismuth ferrite (BiFeO3, BFO) has been widely studied for its unique magnetoelectric properties at room temperature, such as antiferromagnetism coupled with ferroelectricity. It has also been shown to display various novel phenomena, e.g., an increased conductivity at specific ferroelectric domain walls, photovoltaic properties, and new structural phases in thin films. Understanding microstructure and phase evolution in multiferroic BFO thin films is an important issue, because interesting physical properties with practical applications are related to the microstructure and 2D nanostructures. This manuscript is also related with the synthesis/fabrication of the thin film. In this study, we address the polymer assisted deposition synthesis (PAD), a chemical technique of deposition with high control of thickness, stoichiometry and epitaxial crystallinity. This method allows to produce a high quality epitaxial thin films of BiFeO3 on SrTiO3. We present a detailed investigation on the atomic structure, morphology and microstructure of BFO/STO thin films based on studied by various transmission and scanning transmission electron microscopy techniques (in particular, with a probe Cs -corrector for atomic resolution in the latter case). Correlation with magnetotransport and thermal properties of the epitaxial films are also addressed.

CM01.03.35
Influence of Surface Chemistry on the Electrocatalytic Activity of Oxygen Electrodes for Solid Oxide Fuel Cells Clement Nicollot, Dmitri Kalaev, Chang Sub Kim, Thomas Deffevere and Harry L. Tuller; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Solid oxide fuel cells (SOFCs) offer direct conversion of hydrogen or hydrocarbon fuels to electricity with high energy conversion efficiency (>50%). In reverse electrolysis operation, powered by wind or solar generated electricity, the same devices produce H2 for later consumption, thus serving as a valuable means of energy storage. The electrode polarization related to electrochemical reactions at the gas/solid interface of the cathode is often the dominant flux limiting mechanism. Accumulating surface impurities (e.g. Si, Na, Al, Cr, and Sr) leads to reduction of long term durability. Identifying means for overcoming the detrimental impact of surface impurity accumulation on oxygen surface exchange kinetics can be expected to result in high payoffs in both improved performance and extended operating life. Pr-doped ceria (PCO), a mixed ionic and electronic conductor with a high electrocatalytic activity toward the oxygen reduction reaction, has a strong advantage over state-of-the-art materials such as La0.6Sr0.4CoO3-δ and La0.6Sr0.4Co0.2Fe0.8O3-δ by not containing strontium, known to readily segregate to the solid gas interface, thereby limiting catalytic activity. Silicon contamination, however, remains a problem even with Sr-free materials, given external sources such as glass sealants, or as an impurity in precursor materials used to fabricate the devices. This work focuses on Si contamination of PCO cathodes, observed to reduce electrode kinetics by as much as several orders of magnitude. By controlling the levels of Si contaminant applied to PCO thin films by wet chemical methods, it becomes possible to systematically study its impact on the oxygen reduction reaction by an in-situ optical transmission relaxation method. We also further investigate the feasibility of using lanthanum as an efficient Si getter [1], and extend this strategy to study the effect of various single valence oxides on the oxygen surface exchange rates of PCO.

CM01.03.36
Probing the origin of multicolor emission in La$_2$Zr$_2$O$_7$ nanoparticles (NPs) is crucial for its applications as tunable phosphors and assessing the effects of doping, varying particle size and other factors on its optical properties. In this work, the effect of doping has been explored by making size tunable La$_2$Zr$_2$O$_7$:Eu$^{3+}$ (LZOE) NPs by varying the concentration of precipitating agent in molten salt synthesis. The effect of such changes has been explored on structure, surface area, photoluminescence, radioluminescence, lifetime and quantum yield of LZOE NPs. Furthermore, the effect of changing B site ions by replacing Zr$^{4+}$ with Hf$^{4+}$ on optical properties of undoped NPs and europium ion doped NPs is investigated to find suitable pyrochlore host for phosphor and scintillator applications. Photoluminescence spectroscopy on undoped La$_2$Zr$_2$O$_7$ (LZO) and La$_2$Hf$_2$O$_7$ (LHO) NPs shows violet-blue emission from the LHO NPs whereas the LZO NPs display both violet-blue and red emission upon UV irradiation. Such differences has been explained based on density functional theory (DFT) calculated density of state (DOS), which presented different energetics of ionized oxygen vacancies in LHO and LZO. The differences in luminescence spectroscopy of the La$_4$Zr$_2$O$_7$:Eu$^{3+}$ (LZOE) and La$_4$Hf$_2$O$_7$:Eu$^{3+}$ (LHOE) NPs highlighted higher quantum yield, emission output, radioluminescent intensity and luminescence lifetime from the LHOE NPs which could be highly beneficial in newer pyrochlore materials for red phosphors, scintillators and fluorimmunoassays.

**Lateral Size Control of Multiple Anions in Oxyhydrides and Oxychalcogenides**

Hiroshi Kageyama, Kyoto Univ, Kyoto, Japan.

We show how difference in anion compressibility in mixed-anion compounds gives rise to drastic changes in structures and resultant chemical and physical properties. For example, we recently found from the high-pressure XRD of SrV$_2$H that H$^+$ is extraordinary compressible, as compared with oxide, providing an interesting platform to tune crystal field stabilization energy and thus physical properties [1]. Such flexible nature of hydride is useful to drive a structural phase transition in oxyhydrides [2]. The presence of chalcogenides anions (e.g., Se$_2^-$) with greater compressibility than oxide anions leads to extensive control of metal–oxide distance, leading to unusual spin state [3].

**Learning Solid State Chemistry from Atomic Fluctuations—A Statistical Physics and Machine Learning Approach**

Rama K. Vasudevan, Lukas Vlcek and Sergei V. Kalinin; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

A key aspect of statistical physics is that the fluctuations of a system encode information about the response of the system to changing thermodynamic variables. However in most studies, structural and chemical fluctuations in materials characterization are seen as a hindrance, that complicates analysis. Here, we present a method to take advantage of atomic-scale observations of chemical and structural fluctuations and use them to build a generative model that can be used to predict the phase diagram of the system in a finite temperature and composition space. We show the example for understanding cationic segregation in a manganese thin film (La$_{0.8}$Ca$_{0.2}$MnO$_3$), where a combination of in-situ atomic imaging via scanning tunneling microscopy as well as bulk measurements of composition as a function of layer (via angle-resolved x-ray photoemission spectroscopy) enables constraining the generative model. Through use of a recently developed statistical distance framework, the fluctuations in the system are inherently captured (as opposed to averaged out). The model leads to the prediction of weak segregation forces in bulk (attributable to elastic effects) and weak de-segregation forces in the surface (attributable to electrostatic interactions), which agree with recent quantum-chemical calculations (J. Am. Chem. Soc. 135, 7909 (2013)), but which are derived entirely from experiment. We further extend this approach to mapping atomic dynamics observed with scanning transmission electron microscope, providing insight into solid state chemistry on a single-defect level. This approach can be applied to a large array of systems, wherein the observed fluctuations can be exploited to understand the interactions between the constituent components of the system.

The work was supported by the U.S. Department of Energy, Office of Science, Materials Sciences and Engineering Division (R. K. V., S. V. K., L.V). Research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

8:45 AM *CM01.04.03*

**A Structural Characterization Challenge Using Atomic Pair Distribution Function Based on Electron Diffraction**

Iamara C. Nogueira, Edson R. Leite, Jefferson Bettini and Gustavo Azevedo; 1Physics Department, Federal University of Amazonas (UFAM), Manaus, Brazil; 2LNNano-CNPEM, Campinas, Brazil; 3Chemistry Department, Federal University of São Carlos, São Carlos, Brazil; 4LNLS-CNPEM, Campinas, Brazil.

In this work, we intend to investigate the extent of information about the size-dependent structure of nanoparticles from the atomic pair distribution function (PDF) method. However, we intend to use the PDF method in an innovative way. Instead of using x-ray and neutron powder diffraction data, we will use electron diffraction data acquired from a conventional transmission electron microscope (TEM), that we will call PDFe. We will show results regarding the characterization of reference materials (amorphous Carbon and gold nanoparticle) in order to establish a protocol of characterization and to confront the results obtained by electron diffraction with results (from the literature) obtained by other scattering techniques. Another important point of our work is to use the PDFe to characterize nanoparticles, more specifically, we performed the accurate determination of atomic-scale structure and structural defects of Zirconium Oxide (ZrO$_2$) nanoparticles synthesized by different sol-gel routes, considering the tetragonal and monoclinic phases. The advantages and disadvantages of using electron diffraction (using a transmission electron microscope) will also be presented to obtain the PDF.

9:00 AM *CM01.04.04*

**Expanding the Toolset for Colloidal Synthesis and Integration of Functional Inorganic Nanomaterials**

Dmitri V. Talapin; Department of Chemistry and James Franck Institute, University of Chicago, Chicago, Illinois, United States.
The synthesis of inorganic nanomaterials has seen impressive developments, both in the fundamental understanding of nucleation, growth and surface chemistry of inorganic phases, and in the ability to prepare functional materials with precisely engineered optical and electronic properties. However, the lack of atomic precision in nanomaterial synthesis restricts our ability to harness all the power of this broad and diverse class of matter. Heterogeneity introduces broadening of the absorption and emission spectra, reduces charge carrier mobility in nanocrystal solids, and generally restricts our ability to engineer nanomaterials. I will discuss new approach for colloidal synthesis of nanomaterials with minimal, ideally no, size distribution. The concept is inspired by gas-phase atomic layer deposition (ALD) widely used in microelectronics. Our studies show that the ALD concept can be successfully implemented in solution and, when applied to nanomaterials, enables layer-by-layer growth of crystalline lattices with close-to-atomic precision.

I will also discuss recent advances in the surface chemistry of semiconductor nanostructures. Molecular inorganic species can be designed to electronically couple individual nanostructures into nanocomposite materials with high electron mobility. By making surface ligands photochemically active, we introduce a general approach for photosensitiser-free, direct optical lithography of functional inorganic nanomaterials (DOLFIN). Examples of patterned materials include metals, semiconductors, oxides, and magnetic and rare earth compositions. No organic impurities are present in the patterned layers, which helps achieve good electronic and optical properties. The ability to directly pattern all-inorganic layers using a light exposure dose comparable to that of organic photoresists opens up a host of new opportunities for additive nanomanufacturing.

9:30 AM BREAK

10:00 AM - CM01.04.05
Structures, Magnetism and Soft Chemistry of Layered Oxide Chalcogenides and Oxide Pnictides
Simon Clarke; University of Oxford, Oxford, United Kingdom.

Oxide chalcogenides and oxide pnictides have become of increasing interest following the discovery of the iron-based pnictide and chalcogenide superconductors. In this talk, I will present the synthesis (using high-temperature and soft techniques), crystal structures and physical properties of a series of layered oxide arsenides and oxide chalcogenides will be described and the changes in magnetic ordering and other physical properties will be described as functions of temperature and composition, and related to changes in crystal structure. Examples will include the complex magnetic ordering in Sr2Fe3Se2O3, the changes in magnetic structure of A2Cr2O5Sr2xLa(1−x)O3 (A = Sr, Ba) as a function of temperature and the changes in magnetic structure in the series Sr2CoO2Cu2−xSe2, Sr2CoO2Ag2−xSe, Sr2MnO2Cu1.5−xSe and Sr2MnO2Ag1.5−xSe and the homologous series Sr2Mo2O2Cu2m+ySm1−x+y which serves as a function of coinage metal content, and hence transition metal oxidation state, and which will be correlated with composition and structure.

10:30 AM - CM01.04.06
A Soft Chemistry Route to Control the Oxidation States of Dopants in Inorganic Phosphors
Romain Gautier; Centre National de la Recherche Scientifique, Nantes, France.

Photoluminescence properties are important for different applications such as solid-state lighting, sensors, and display devices. Among the materials exhibiting such properties, doped phosphors are of particular interest owing to high thermal stability and potentially high quantum efficiency. Interestingly, the photoemission of such doped materials differs according to the oxidation states of their dopants. The reduction under controlled atmosphere or the co-doping with other cations enable to target dopants in specific oxidation states but this control is usually poor.

In this context, we carry out a soft chemistry route to reduce the dopants of inorganic phosphors by heating the solid-state compounds at low temperature with oxygen getters in glass tubes sealed under vacuum. This soft reduction enables to control the ratio Ni3+/Ni2+ in SrTiO3:Ni and Eu3+/Eu2+ in SrAl2O4:Eu or (CaMg)x(NaSc)1−xSi2O6:Eu [1-3]. The optical properties could also be tuned according to these ratio. The control of the ratio Ni3+/Ni2+ in SrTiO3:Ni allowed the tuning of IR photoluminescence vs. optical absorption which could have potential applications in biomedicine. For SrAl2O4:Eu or (CaMg)x(NaSc)1−xSi2O6:Eu, the photoluminescence corresponding to the 4f-4f transition of Eu3+ dopant vs. the photoemission corresponding to the 4f-5d transition of Eu2+ dopant can be tuned to control the photoluminescence color of these compounds. In the specific case of (CaMg)x(NaSc)1−xSi2O6:Eu, the additional modification of the solid-solution composition enables to design a white phosphor for potential applications in solid-state lighting.

1:00 PM - CM01.04.07
Preparation and Characterization of Graphite Terinary Intercalation Compounds Containing Alkaline Earth Metal Cations and Ethyleneimine
Wei Xu and Michael Lerner; Department of Chemistry, Oregon State University, Corvallis, Oregon, United States.

A series of new ternary graphite intercalation compounds (GICs) containing alkaline earth metal cations (M=Mg, Ca, Sr, Ba) and ethyleneimine (en) are reported. These GICs are deep blue to green in color and can be prepared as phase pure compounds by the direct reaction of graphite powder and the metal in liquid en at mild temperatures (25-100 °C) under an inert atmosphere. X-rays diffraction and thermal analyses were employed to determine the structural and composition. [M(en)2]C60 and [Ba(en)2]C60 can be obtained as stage-1 GICs with gallery expansions of 0.55 and 0.46 nm, respectively, indicating the presence of intercalate monolayers with the en co intercalates oriented perpendicular to the encasing graphene layers. Reactions with Ca and Sr metals form [Ca(en)]3C60 and [Sr(en)]3C60, which are stage-1 GICs with intercalate bilayers and expansion heights of 0.76 nm. The effect of reaction temperature, stoichiometries, and time on product phases will be described. The complexes formed by the cationic intercalates within GICs are highly unusual, with low oxidation states exhibited by some of the cations and M-M bonding to form intercalate clusters.

11:00 AM - CM01.04.08
Understanding and Designing Novel H⁺ Ionic Conductors Based on First Principles Calculations—Toward Facile Anion Conduction in Oxide-Based Materials
Qiang Bai, Xingfeng He, Yizhou Zhu and Yifei Mo; 1University of Maryland, College Park, Maryland, United States; 2Maryland Energy Innovation Institute, College Park, Maryland, United States.

H⁺ ion conductor materials have the great potential to enable high-energy density electrochemical storage based on hydrogen. Fast H⁺ conduction has been recently demonstrated in the (CaMg)1−xSr2xLi2(H2O)x−yO3 (0 ≤ x ≤ 1, 0 ≤ y ≤ 1) oxide materials. However, little is known about the H⁺ diffusion mechanism in this new material and its unique structure. The origin of such exceptional H⁺ conduction in the oxide-based materials is of great interest. Using first-principles calculations, we studied the energetics and diffusion mechanisms of H⁺ ions as a function of structures and compositions in this oxyhydride system. Our study identified that fast H⁺ diffusion is mediated by H⁺ vacancies and that the fast two-dimensional or three-dimensional H⁺ diffusion is activated by different anion sublattices in different compositions. In addition, novel doping was predicted from ab initio computation to increase H⁺ conductivity in these materials. The unique two-anion-site feature in this structural framework enables highly tunable lattice and minimizes the blocking of anion diffusion by oxygen sublattice, allowing high mobile-carrier concentration and good diffusion network. This conclusion offers general guidance
Electrides are compounds in which electrons serve as anions. First electride material was synthesized by James Dye in 1983 (JACS 1983) who obtained the crystal by dissolving alkali metal into an ether solution of crown-ether solution. We reported the first RT stable electride, C12A7:e, in 2003 (Science 2003) using insulating 12CaO7Al2O3(C12A7) with nano-cage structure. Resulting C12A7:e- is metallic conducting and exhibits BCS-type superconductivity (JACS 2007, PRB 2008, Phil.Trans A 2014). A unique property of C12A7:e- has low work function (2.4eV) comparable to alkali metals but chemically and thermally stable (Adv.Mat.2007). Electride materials had been restricted to crystal to 2011. We obtained amorphous C12A7:e- by rapid quenching (Science 2011) molten C12A7:e- or sputtering. Amorphous electride, characterized by anionic electron at interstitial position, is a novel class of amorphous semiconductors (PNAS 2016).

We have examined to apply C12A7:e to electronic devices(Adv.Mat.2004, JPCC 2007), and chemistry such reducing regent (Org Lett 2007) usable in aqueous media. The representative examples are: Ru-loaded C12A7:e- works an effective catalyst for ammonia synthesis at mild conditions(Nat.Chem.2012) and is free from hydrogen poisoning which is known as a common drawback of Ru-catalysts (Nat.Comm.2015). Amorphous C12A7:e- thin film with low work function and high optical transparency is promising as an electron injection layer, an obstacle, in organic light emitting diodes(PNAS 2017).

C12A7:e may be regarded as 0D-electride viewed from dimensionality of anionic electrons. The concept of electride was extended to 1D and 2D materials. Several 1D/2D electride materials such as Y5Si3 (JACS 2016) and LaScSi (Adv.Mat. 2017) were found by extending the system to intermetallics. Sr5P3 is a 1D electride material with low work function (2.4eV) comparable to alkali metals but chemically and thermally stable (Adv.Mat.2007). We obtained amorphous C12A7:e- by rapid quenching (Science 2011) molten C12A7:e- or sputtering. Amorphous electride, characterized by anionic electron at interstitial position, is a novel class of amorphous semiconductors (PNAS 2016).

Electrides are rare ionic compounds in which an electron does not occupy an atomic orbital but rather acts as an anion. This electron is expected to behave differently to those occupying the valence state of standard materials, making electrides desirable as electron emitters,[1] nonlinear optical switches,[2] superconductors,[3] battery anodes,[4] and catalysts for applications ranging from compound synthesis to CO2 splitting.[5]

We use high-throughput screening and advanced calculations to identify undiscovered electrides among all known materials. Our method recovers the compounds Ba3ScN3 and Sr3CaN3 as electrides. These ternary nitrides are the first known case of electrides containing a transition metal element, which is surprising as one would expect a redox active transition metal to accept the anionic electron rather than allowing its existence in the lattice. We confirm these results with self-consistent GW theory, one of the most accurate methods available for charge density prediction. Besides these compounds we find more than 60 previously unknown electrides along with 4 already known, significantly expanding this class of industry-relevant materials.

Harnessing Chemical Frustration Toward the Creation of Modular Intermetallic Phases

Recent years have witnessed growing interest in the research of thermoelectric materials. Intermetallics offer immense opportunities for the creation of new materials, with their crystal structures ranging from simple packings to complex arrangements that lead one to invoke cells containing thousands of atoms or higher-dimensional axes. However, navigating this structural diversity is made challenging by the need for predictive principles relating composition, structure, and properties. In this presentation, we will derive lessons from some of the most complicated intermetallic structures toward the development of one such principle: chemical frustration. A common theme that can be perceived in complex intermetallics structures is microscopic segregation between competing interactions. Using the results of theoretical calculations, we will develop mechanisms that will be derived by which competition between segregation and attraction between incompatible structural motifs can emerge in these phases. For example, in the epitaxial stabilization mechanism, structures with strains of opposite signs in the interactions between the majority elements have to opportunity for the cancellation of these strains at interfaces between them. Similarly, in the electron-hole pairing scheme the potential for electron transfer across interfaces is viewed means of stabilizing multi-domain character. Based on these mechanisms, the chemical pressure schemes and non-optimal electron counts of simple but geometrically distinct compounds are used as measures of their potential reactivity toward intergrowth. New crystal structures that have been encountered in our synthetic attempts to induce frustration in intermetallic systems following these and other approaches will also be presented and analyzed.
properties, including Fermi surface, electron localization and charge transfer, will be discussed, thus enabling an in-depth understanding of the fundamental properties of these new materials.

3:45 PM CM01.05.06
FeSi as New Conductive Layer for Fe-Based Superconductors Sophie Tence1 and Andres Cano1; 1Institut Néel, Grenoble, France; 2Institut de Chimie de la Matière Condensée de Bordeaux, Bordeaux, France.

Since the discovery of unconventional superconductivity in Fe-based materials in 20081, Fe-based superconductors (Fe-SC) have attracted much attention and have been the subject of intense and systematic investigations. To date, in high-Tc Fe-SC, iron is invariably associated to toxic pnictogen or chalcogen elements (P, As and S, Se, Te respectively) in the conductive layer. This circumstance raises the important fundamental question about the link between Fe-based superconductivity and the apparent need of these pnictogens and chalcogens. Besides, Fe-SC are usually obtained by solid state reaction with possibly the use of high pressure.

In this context, we have recently synthesized the new silicide hydride LaFeSiH by solid-gas hydrogenation of the precursor LaFeSi. Preliminary results show that this hydride is stoichiometric to the 111 Fe-SC compounds (e.g. Pr4V(213)). Interestingly, LaFeSiH displays onset of superconductivity at 11 K as evidenced notably on the resistivity measurement on single-crystal2. This hydride also presents other structural, magnetic and electronic similarities with the previously reported Fe-SC compounds, similarities that will be presented in this talk. Therefore, LaFeSiH can be considered as the first Fe-SC obtained by solid-gas hydrogenation and free from toxic pnictogen and chalcogen elements. This is the first member of a new class of materials with which we have surpassed traditional pnictide and chalcogenide compounds and promoted, for the first time, original Fe-based silicides to unconventional high-temperature superconductors.

Exploiting Controlled Nanoarchitecture to Study Structure-Property Relationships in [(SnSe)1+δ][TiSe2]. Thin-Film Heterostructures Danielle M. Hamann1, Sage Bauers2 and David C. Johnson1; 1Chemistry, University of Oregon, Eugene, Oregon, United States; 2National Renewable Energy Laboratory, Golden, Colorado, United States.

Recent research on monolayers and their heterostructures has led to the discovery of numerous emergent properties. These can be markedly different from those of the respective bulk materials and are not always additive, making the properties of heterostructures difficult to predict. Self-assembly of designed precursors with composition profiles that mimic the desired product allows for the synthesis of superlattice heterostructures with controllable stacking sequences between the layers, or “nanoarchitecture”. Using this unique control, homologous series of compounds are prepared where the layer thickness of a single constituent is changed with unit-cell precision, allowing the study of properties as a function of material thickness or stacking order. One family of compounds with properties dependent on nanoarchitecture is [(SnSe)1+δ][TiSe2], where n and m can be individually varied. These compounds exhibit thickness-dependent structural distortions, degree of interlayer templating, and transport properties. Interestingly, distortions in the SnSe constituent are a result of a surface area to volume competition and are influenced by interfaces with TiSe2. When single layers of TiSe2 and SnSe are interleaved there is an unexpected lattice match between constituents that results in regions of alignment in an otherwise rotationally disorder system. Coupled with the structural distortions are changes in resistivity, Hall, and Seebeck coefficients. Measurements suggest competition between n-type TiSe2 and p-type SnSe, with the specific properties dependent both on the constituent ratios as well as their dimensionality. The ability to study the properties in these heterostructures is a result of precise layer control through synthesis of systematically varied compounds. Using this technique to gain advanced knowledge about the source of emergent properties in heterostructures will facilitate future “materials by design” approaches to target and optimize a desired property for a specific application.

From Quasicrystals to Crystals and Superconductors in Ca–Y–Au–Al Joyce Pham1,2; 1Walter Schnelle1, Gudrun Auffhammer1, Claudia Fels1 and Gordon J. Miller1,2; 1Max-Planck Institute for Chemical Physics of Solids, Dresden, Germany; 2Department of Chemistry, Iowa State University of Science and Technology, Ames, Iowa, United States; 3U.S. Department of Energy, Ames Laboratory, Ames, Iowa, United States.

In the Au-rich region of the Ca–Au–Al system, an icosahedral quasicrystal (i-QC) CaAu4.5–xAl2.5+x, was discovered and shown to irreversibly transform into the cubic 2/1 crystalline approximant (CA) Ca21Al20(205) (space group (no. 205); Pearson symbol: cP722; a = 23.8918(2) Å) via in-situ X-ray diffraction, thereby providing direct experimental evidence for the relationship between QCs and their associated CAs. The 2/1 CA crystallizes in a Tais-type structure and, following the polar intermetallic depiction, the atoms of different electronegativities, viz., electronegative Au vs. formally electronegative Ca, are arranged in concentric shells. As part of an overarching chemical pressure and valence electron count investigation, the cubic 1/1 CA Y3Au14(0.082)Al4.49(1) (space group (no. 204); Pearson symbol: cP122; a = 14.462(2) Å) was discovered and shown to also crystallize in the Tais-type, and in which preliminary magnetization data show potential surface superconductivity behavior below Tc around 3.7 K. The QC-CA transformation, crystallographic structure, and atomic site preference analysis of Ca–Au–Al, along with the crystal and electronic structures, chemical analysis, and preliminary transport properties, including resistivity and specific heat, of the 1/1 CA Y3Au14(0.082)Al4.49(1) will be presented for discussion.

4:30 PM CM01.05.09
Complex Intermetallic Alloys Anja V. Mudring; Stockholm University, Ames, Iowa, United States.

The design of new materials with desired chemical and physical characteristics requires thorough understanding of the underlying composition–structure–property relationships and the experimental possibility of their modification through the controlled involvement of new components. From this point of view intermetallic phases, a class of compounds formed by two or more metals, present an endless field of combinations that produce several chemical compounds and classes ranging from simple alloys to true ionic compounds. Polar intermetallics (PICs) belong to the class that is electronically situated in the middle, between Hume-Rothery phases and Zintl compounds and possessing an a/b (valence electron per atom) values around two. In contrast to the latter, where logical rules of formation and classification systems have been developed decades ago, polar intermetallics remain a dark horse with a huge diversity of crystal structures, but unclear mechanisms of their formation. Partial incorporation of structural and bonding features from both nonpolar and Zintl compounds is commonly observed here. A recent number of PICs can be described in terms of complex metallic alloys (CMAs) following the Hume-Rothery electron counting schemes, but, exhibit electronic structure changes that cannot be explained by the latter. For that reason, research efforts are aiming at the discovery and synthesis of new polar intermetallic compounds, their structural characterization and properties' investigation in line with the
analysis of the principles connecting all these components. Understanding of the basic structural tendencies is one of the most anticipated outcomes of this analysis and systematization of the available knowledge is the initial and the most important step. The occurrence of different structure types for PICs ranging from commonly encountered AlB2 or BaAl4 types in line with the recently discovered diamond-like homometallic networks, formation of local five-fold symmetry, different types of tunneled structures and more complex intergrown multicomponent structures will be discussed.

CM01.06.01
Novel Heteroleptic Tin Precursors for Atomic Layer Deposition of Tin Oxide Thin Films Applications Seong Ho Han1, 2, Ho Keun Park1, 2, Chang Gyoum Kim1, 2, Seung Uk Son1 and Taek-Mo Chung1, 2; 1Thin Film Materials Research Center, Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2Department of Chemistry, Sungkyunkwan University, Suwon, Korea (the Republic of); 3Advanced Materials and Chemical Engineering, University of Science and Technology, Daejeon, Korea (the Republic of).

Over the past decade, oxide semiconductor materials have attracted significant interest as important materials for various applications, including thin film transistors (TFTs), gas sensors, lithium batteries, and solar cells. Particularly, p-type tin(II) monoxide (SnO) has generated considerable research attention owing to its wide optical band gap energy (2.7-3.0 eV), which can translate into the possibility of completely transparent electronic devices. Moreover SnO based TFT recently showed a record field effect mobility of ~6.75 cm2/Vs and Hall mobility of ~17.6 cm2/Vs. On the other hand, tin(IV) dioxide (SnO2) which is an n-type material, with a wide band gap energy of ~3.6 eV and excellent optical, electrical, and chemical properties is also constantly under investigation to improve upon its properties for various applications. SnO2 is transparent under visible light and has a resistivity that can extend over a wide range depending on the deposition process and the growth conditions. Doped SnO films have also demonstrated good performance as transparent conducting oxides for solar cells.

Generally, chemical vapor deposition (CVD) and atomic layer deposition (ALD) are the preferred growth methods for uniform and conform thin films. Moreover, SnO and SnO2 can be selectively deposited by controlling the oxidation state of the Sn(II) precursor and the oxygen source. In the case of ALD, several attempts have been made to grow SnO or SnO2 films using different Sn precursor/reactant combinations. Unfortunately, most of the attempts have only resulted in n-type SnO films. Only few reports have shown the successful deposition of SnO films including a recent publication from our lab.

Recently, the importance of heteroleptic precursors with improved properties have been highlighted by a number of reports. Most common precursors exist as homoletic type in nature, where identical ligands are bonded to a metal center. In contrast, a heteroleptic precursor is a metal complex with two or more distinct ligands attached to the metal center. Reports have shown that heteroleptic precursor design through suitable ligand selection could result in several improved properties in comparison to the homoletic precursors. Even though the selection of suitable ligands for heteroleptic metal precursors is as challenging as designing a new ligand for homoletic precursors, the heteroleptic precursors are advantageous because of the availability of several ligands and their complexes with well-known properties to choose from.

To develop novel tin(II) precursors for thin film applications, we have synthesized new tin complexes using tin(II) chloride as starting material. The resulted complexes were characterized by various analysis equipments such as nuclear magnetic resonance (NMR), elemental analyses (EA), thermogravimetric analysis (TGA), and single crystal X-ray diffraction. The detailed applications of thin films by ALD will be shown in the presentation.

CM01.06.02

Transparent conducting oxides (TCOs) have been a very hot topic over the past few decades due to their great importance in electronic industries including touch screen display, organic light emitting diodes (OLED) and liquid crystal displays (LCD). However, the majority of TCOs used currently all belong to N-type TCOs. The lack of high performance P-type transparent conducting oxides (TCOs) presents a huge problem in many optoelectronic applications ranging from organic light emitting diodes (OLED) to transparent electronics. Oxychalcogenide based P-type TCOs are very promising due to the recent outstanding results in terms of P-type conductivity and transparency. Oxychalcogenides with the basic form of LnCuOCh have layered structure consisting of alternating [LnO] layers and [CuCh] layers, which allows more degrees of variation. LaCuOSe with the band gap 2.85eV has lower conductivity than LaCuOSe of band gap 2.85eV. In this work, LaCuOSe has been firstly prepared via our novel solid state reaction without using commonly used toxic gas H2S. The LaCuOSe prepared in this shows high conductivity due to the absence of hydrogen atoms in the process. Then LaCuOSe was doped with Se via solid state reaction to prepare LaCuOSe1-xSex without any impurities. The optical properties of the polycrystalline samples were studied by UV-Vis spectroscopy, and the chemical states of the aforementioned five elements in films with varying concentration of Se were examined by using X-ray photoelectron spectroscopy (XPS). The electrical properties were measured by four point probe method. The detailed atomic structures and doping sites of the LaCuOSe1-xSex samples were analyzed by scanning transmission electron microscopy (STEM).

CM01.06.04
Brownmillerite Type SrCoOz (z = 2 for Oxygen Enrichment—Optimization of Absorption Parameters Aswathy M. N and Arun M. Umarji; Materials Research Centre, Indian Institute of Science, Bengaluru, India.

Ternary oxides are known for many applications like solid oxide fuel cells, catalysis and gas sensing. These oxides can be oxygen non-stoichiometric if transition metals with variable oxidation states are present. This can be regarded as a functionality when the extent of oxygen vacancies inside the lattice is very high. They can transport oxygen through the lattice if a partial pressure gradient of oxygen is applied. This is normally exploited in case of oxygen separation membranes and solid oxide fuel cells. Perovskite oxides (general formula ABO3) are promising candidates as they can exist in a variety of oxygen non-stoichiometric forms by varying temperatures and oxygen partial pressures. SrCoO2 (Perovskite, Pm-3m) is one such material which reversibly transforms to SrCoO2 (Brownmillerite, Ima2) phase at 623 K. Here in we report the application of Brownmillerite SrCoO2 for oxygen enrichment. Brownmillerite (BM) SrCoO2 phase has been stabilized to date only by liquid nitrogen quenching. We report a cost-effective method of quenching for the stabilization of the BM SrCoO2. The solution combustion synthesized powder was calcined and sintered at 1223 K in pellet form. This pellet was quenched to 473 K using Al foil pads to stabilize the intact ceramic with Brownmillerite phase. A simple home-built volumetric setup has been fabricated for studying the oxygen storage property of the material. The sample was pre-treated with a higher partial pressure of oxygen at 673 K to form the oxygen-rich perovskite phase and this phase was heated at lower pressure to study the desorption characteristics. The pressure change observed when sample
energy dispersive X-ray spectroscopy (EDX). The chemical environment of the doped Ag atom was studied by Extended X-ray Absorptance Fine Structure synthesized via a hydrothermal reaction. The products were identified using X-ray powder diffraction (XRD), scanning electron microscopy (SEM) and K4Nb6O17.nH2O structure, the radial distribution functions (RDF) measurement suggest that the Ag atoms are incorporated in the interlayers. The XANES (EXAFS) measurement. The photocatalytic activity was evaluated by analyzing the kinetics of the decomposition of a 20 ppm phenol solution under UV light irradiation. The development of non-Pt based electrocatalysts for the hydrogen evolution reaction (HER) is a pre-requisite for the generation of hydrogen, a feasible and cost-effective source of hydrogen. Structural transitions and generating metal deficiency are the effective ways of manipulating the d-band centre of a metal surface which enhances the catalytic activity of metal nanoparticles towards the HER. Charge-transfer from in situ generated oxide species to the metal centre also leads to an enhancement in catalytic activity towards the HER. In the present work, we report a facile colloidal synthesis of PdBi nanoparticles using sodium borohydride as the reducing agent. Upon annealing the as-synthesized nanoparticles, a phase transition from the lower symmetry monoclinic phase to the higher symmetry tetragonal phase has been observed, and hence a change in morphology from agglomerated to core–shell nanoparticles. Potential electrochemical cycling of both monoclinic and tetragonal PdBi leads to the formation of a Pd-rich PdBi2 alloy with enhanced catalytic activity (onset potential: ∼11 mV and ∼18 mV vs. the RHE, 20 mA cm−2 current density at an overpotential of ∼140 mV and ∼207 mV for monoclinic and tetragonal phases, respectively). The low co-ordination number of Pd active sites formed by the dissolution of Bi alters the d-band centre of Pd, and hence the optimal energy required for hydrogen adsorption leading to enhanced activity. Although the obtained composition after potential cycling is almost similar for both phases it is seen that the dealloyed monoclinic phase shows higher activity as compared to the dealloyed tetragonal one. Cyclic voltammometry of the monoclinic PdBi2 shows the formation of Bi–O species after potential cycling. Electron transfer from the Bi–O species to the Pd centre enhances the charge-transfer kinetics of the HER on the catalyst surface and hence an increased catalytic activity of the monoclinic phase as compared to the tetragonal one. Thus, in situ generated oxide species facilitate charge-transfer from oxide to the metal surface which in turn enhances catalytic activity towards the HER.

The K2O-Nb2O5-H2O hydrothermal system produces potassium niobates with various crystal structures such as layered-, pyrochlore-, perovskite-, or tunnel-type structures depending on the reaction conditions. This system is a promising candidate for lead-free piezomaterials, optical devices, and hydrogen storage. Structural transitions and generating metal deficiency are the effective ways of manipulating the d-band center of a metal surface which enhances the catalytic activity of metal nanoparticles towards the HER. In the present work, we report a facile colloidal synthesis of Ag-incorporated potassium niobates; a layered K4Nb6O17.nH2O, a pyrochlore-type (K,H)NbO3.nH2O, and a perovskite-type KNbO3, were also observed. Defined and sharp Raman modes as well as characteristic luminescence peaks for all the samples due to f–f transitions. The morphology was confirmed by FE-SEM showing structures in the nanosized range. These results show possible application of these materials to suppress the demand for conventional luminescent biomarkers as well as new optical devices.

The K2O-Nb2O5-H2O hydrothermal system produces potassium niobates with various crystal structures such as layered-, pyrochlore-, perovskite-, or tunnel-type structures depending on the reaction conditions. This system is a promising candidate for lead-free piezomaterials, optical devices, photocatalysts, ion-exchangers etc. So far, there have been several investigations on photocatalysis, including water splitting and degradation of organic contaminants in water. Here we investigate Ag incorporation into the K2O-Nb2O5-H2O system under hydrothermal conditions and the photocatalytic activities of these as synthesized potassium niobates. Three types of Ag-incorporated potassium niobates; a layered KNbO3:nH2O, a pyrochlore-type (K,H)NbO3:nH2O, and a perovskite-type KNbO3, were synthesized via a hydrothermal reaction. The products were identified using X-ray powder diffraction (XRD), scanning electron microscopy (SEM) and energy dispersive X-ray spectroscopy (EDX). The chemical environment of the doped Ag atom was studied by Extended X-ray Absorbance Fine Structure (EXAFS) measurement. The photocatalytic activity was evaluated by analyzing the kinetics of the decomposition of a 20 ppm phenol solution under UV light irradiation.

Low crystalline layered type, and highly crystalline pyrochlore and perovskite-type compounds were obtained by the hydrothermal reaction. In the layered KNbO3:nH2O structure, the radial distribution functions (RDF) measurement suggest that the Ag atoms are incorporated in the interlayers. The XANES spectra and RDF for pyrochlore-type, (K,H)NbO3:nH2O, Ag, indicate that Ag atoms exist as Ag+ ions, in the tunnels of the pyrochlore-type structure. On the other hand, the XANES spectra and RDF for perovskite-type KNbO3:Ag show an environment similar to Ag metal. The optical band gap energies for layered-, pyrochlore-, and perovskite-type compounds incorporated with Ag are estimated to be 3.1, 3.0, and 3.1 eV respectively. The photocatalytic activity of the layered-type Ag-doped compound is comparable with that of the perovskite-type compound and superior to that of the pyrochlore-type compound without Ag. Nevertheless, the degradation rate of phenol on the layered-type compound is lower than that of the undoped compound. These results can be explained by the difference in local environments of the Ag atoms in these structures. The higher photocatalytic activity of the perovskite-
Novel Copper Precursor Based-Deposition of Cu₂O and CuO Thin Films Using Atomic Layer Deposition

Seungmin Yeo1, 2, Jeong Hwan Han1, Gun Hwan Kim1, Bo Keun Park1, Chang Gyuon Kim1 and Taek-Mo Chang1, 4; 1 Korea Research Institute of Chemical Technology, Daejeon, Korea (the Republic of); 2 Yonsei University, Seoul, Korea (the Republic of); 3 Seoul National University of Science and Technology, Seoul, Korea (the Republic of); 4 University of California, San Diego, California, United States.

Copper oxide has been attracted considerable attention because of its favorable intrinsic characteristics such as environmental-friendly, low-cost and reconfigurable electronic structure. Among various copper oxides, cuprous oxide (Cu₂O) and cupric oxide (CuO) are well known for many kinds of applications due to their attractive electrical characteristics. For example, Cu₂O and CuO show the n- and p-type characteristic when they have crystalline structure of cubic and monoclinic, respectively, and their combination can be utilized in various applications such as gas sensor, photodiode, anode materials in batteries, thin film transistors (TFTs), solar cells, and photo-catalysts. Until now, however, atomic layer deposition (ALD) based thin film fabrication of Cu₂O and CuO have not been seriously studied yet.

In this research, Cu₂O and CuO thin films were successfully deposited by ALD technique using novel copper precursor, (bis(1-dimethylamino-2-methyl-2-butoxy)copper) (Cudmbnmb) for copper source, and H₂O and O₃ for oxygen source, respectively. To clarify the structural and electrical characteristics of individual thin films, X-ray diffractometry (XRD), X-ray photoelectron spectroscopy (XPS), and X-ray fluorescence (XRF) analyses were performed. All the analyses results demonstrated that Cu₂O and CuO thin films have cubic and monoclinic structure with low C-impurity in it. The XPS measurement also showed consistent result with XRD analysis. The electrical characteristic was investigated using UV-Visible (ultraviolet-visible) spectroscopy, and it revealed that each thin film has favorable optical band-gap. The more detailed experimental procedures and physical/chemical characterization results of thin films will be discussed in presentation.

CM01.06.09
Thermodynamic, Crystal Structural, Electric and Magnetic Studies on (K₂SrₓCu₃₋ₓSeO₇)₄ and (K₂SrₓCu₃₋ₓSeO₇)₄, (Bi, Pb)₀.₀₂₋₀.₂₀ flux the formation was at low temperature. Then it is formed in air at atmospheric pressure, K₂CuSe₂O₇ compound at 400 °C. With N₂ flux the formation was at low temperature. Then it is formed in air at atmospheric pressure, K₂CuSe₂O₇ at 300 °C/12 h and K₂CuSe₂O₇ at 400 °C/12 h, faster and low T process, that the ones reported. TB reaches a maximum at 150 K.

CM01.06.10
Substitutional Solute Atom Effect on Dislocation Motion in FCC Iron Alloys—An Atomistically Informed Kinetic Monte Carlo Study Shuhei Shinzato1, Masato Wakeda1 and Shigenobu Ogata1, 2; 1 Osaka University, Osaka, Japan; 2 National Institute for Materials Science, Tsukuba, Japan; 3 Kyoto University, Kyoto, Japan.

Solute atom changes the mechanical properties of alloys, which is known as solid solution strengthening and softening. This solute atom effect is widely used to control the mechanical strength of alloys. In this work, we analyze the solute effect on screw dislocation motion in FCC iron, which dominates plastic deformation of BCC iron, using an atomistically informed kinetic Monte Carlo (kMC) model. The kMC model represents dislocation motion via kink-pair nucleation and migration, and all of the necessary kMC parameters, such as activation energies of kink-pair nucleation and migration and its stress dependency, are computed using atomistic methods based on developed interatomic potential. We successfully predicted the solute effects on dislocation velocity, temperature dependent yield strength, and activation volume of dislocation motion.

CM01.06.11
A Comparative Study on Ca-Doped and Sr-Doped Gd₂Ti₃O₁₀ for Microwave Absorption Applications Qinlong Wen1, 2, Wancheng Zhou1, Fa Luo1, Dongmei Zhu1 and Yongmin Liu2, 3; 1 State Key Laboratory of Solidification Processing, School of Materials Science and Engineering, Northwestern Polytechnical University, Xi’an, China; 2 Department of Mechanical & Industrial Engineering, Northeastern University, Boston, Massachusetts, United States; 3 Department of Electrical and Computer Engineering, Northeastern University, Boston, Massachusetts, United States.

With the development of communications industry, unexpected and harmful electromagnetic waves have raised concerns about the impact on communication devices, aircraft, and human beings. A wide variety of microwave absorption materials (MAMs) have been investigated based on magnetic, dielectric, semiconducting and conductive materials. Most of the conventional absorbers are 1-5 mm thick, which degrades their practical applications. In order to reduce the thickness of MAMs, we need to judiciously engineer the complex permittivity of the absorber. Towards this goal, we have doped...
Gd$_2$Ti$_5$O$_{15}$ with Ca and Sr, and systematically investigated their dielectric and microwave absorption properties in the frequency range of 8.2-12.4 GHz (X-band). The samples were prepared by hot press method according to the chemical formulas Gd$_2$M$_x$Ti$_2$O$_7$ (M = Ca, Sr; x = 0.03, 0.06, 0.09 and 0.12). The XRD patterns of Gd$_2$M$_x$Ti$_2$O$_7$ show typical pyrochlore-type crystal structure. There exist oxygen vacancies in all the samples according to the thermogravimetric analysis, which have significant effects on the electric conductivity and dielectric properties. When the Ca doping concentration is less than 9wt%, there are no big influences on the dielectric properties. When it reaches 12wt%, the real part of permittivity increase from 66 to 114 at 8.2 GHz as the Sr doping concentration rises. At the same doping concentration, the Sr-doped Gd$_2$Ti$_5$O$_{15}$ has higher complex permittivity. The calculated reflection loss shows that the Sr-doped Gd$_2$Ti$_5$O$_{15}$ absorber is thinner than the Ca-doped counterpart. The optimal thickness of the Sr-doped Gd$_2$Ti$_5$O$_{15}$ is 0.74 mm with an effective absorption bandwidth of 2.7 GHz, surpassing the existing MAMs. In the next stage, we will plan to modify the frequency dispersion characteristics to broaden the effective absorption bandwidth and further reduce the thickness by adjusting doping concentration and combining with other ceramics. These doped Gd$_2$Ti$_5$O$_{15}$ and related composite ceramics would be very good candidates for microwave absorption applications in the future.

CM01.06.12
Superstructures Driven Through Ordered Chemical Bonding in Unconventional Clathrates—Cs$_8$Zn$_{18}$Sb$_{28}$ and Cs$_9$Cd$_{12}$Sb$_{28}$ Bryan Owens-Baird$^1$,$^2$, Shannon J. Lee$^1$,$^2$, Oleq Lebedev$^3$ and Kirill Kovnir$^1$,$^2$; $^1$Iowa State University, Ames, Iowa, United States; $^2$Amer National Laboratory, Ames, Iowa, United States; $^3$Laboratoire CRISMAT, Caen, France.

Unconventional clathrates, whose frameworks are composed of late row transition metals and pnictide elements (e.g. M = Ni, Cu, Zn, Au; Pn = P, As, Sb), are a promising class of materials for thermoelectric applications. Previous studies have shown that many unconventional clathrates show a disposition to order their frameworks into larger supercells due to the difference in chemical bonding between framework elements. This framework ordering often minimizes bonding interactions within the framework, e.g. M-M interactions. The previously reported clathrates, Cs$_8$Zn$_{18}$Sb$_{28}$ and Cs$_9$Cd$_{12}$Sb$_{28}$, were described to have the arystotpe cubic clathrate-I structure in which all framework sites were mixed occupied by metal and antimony. In our study of these clathrates, we show that the frameworks order into discrete metal and antimony sites, reducing Cd-Cd and Zn-Zn interactions. Cs$_9$Cd$_{12}$Sb$_{28}$ adopts an 8-fold volume increase into a centered cubic superstructure, space group (No. 206), doubling the unit cell length to 24.3027(7) Å. The structure of Cs$_8$Zn$_{18}$Sb$_{28}$ has proven to be more complex and not easily solved through single-crystal X-ray diffraction experiments due to extensive twinning. Electron diffraction of Cs$_8$Zn$_{18}$Sb$_{28}$ has shown intrinsic twinning down to a nanoscale, and still a source of findings, hexagonal MoO$_3$ (h-MoO$_3$) is a metastable material with, as yet, poorly known structure and physicochemical properties. In addition, this work, undoped and Ag-doped h-MoO$_3$ microrods have been synthesized by a scalable soft chemistry method based on the precipitation of ammonium heptamolybdate, while composites of h-MoO$_3$ microrods and graphene or graphene oxide (GO) were synthesized by a slightly different route. In addition, highly crystalline h-MoO$_3$ nanoparticles were obtained by ball-milling of the as-grown microstructures. All the obtained samples were thoroughly characterized by a wide set of complementary techniques including monochromatic X-ray diffraction (XRD), scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM), UV-Vis spectroscopy, micro-Raman, micro-photoluminescence, X-ray photoemission spectroscopy (XPS) and X-ray absorption (XAS) with synchrotron radiation.

CM01.06.14
Sintering Behavior of Zinc Oxide Under DC Field by EDXRD Hulya Bicec$^2$, Berra Beyoğlu$^1$, Tevfik Ozdemir$^1$, John Okasinski$^1$ and Thomas Tsakalakos$^1$; $^1$Rutgers Univ, Piscataway, New Jersey, United States; $^2$Dumlupınar University, Kutahya, Turkey; $^3$Argonne National Laboratory, Lemont, Illinois, United States.

In this study, the sintering behavior of zinc oxide (ZnO) under dc field was analyzed. The performed method is called as flash sintering where the assistance of electric field reduces sintering temperature much lower than traditional sintering temperatures. Non-isothermal condition runs under 50V/mm electric field and 250°C/min heating rate led us to the rapid increase in power absorption by specimen between 580°C to 834°C in less than a minute and densification of the specimen increased to >95%. No appreciable grain growth was observed in ex situ SEM analyses. While flash-sintering has been demonstrated in a variety of oxide material systems including ZnO, the mechanism behind this technique is not still fully understood. Here, we report on the results of an in situ time-resolved EDXRD study as a function of electric field and temperature. The densification phenomena of ZnO particulate system has been analyzed at the unit cell level over times scales by using polychromatic x-rays with photon energies up to 200 keV.

CM01.06.15
Hexagonal Molybdenum Trioxide (h-MoO$_3$) as a Multi-Functional Material for Energy Storage, Optoelectronics and Photocatalytic Applications Paloma Almódvar$^1$, María Luisa López$^2$, Carlos Díaz-Guerrero$^1$, Julio Ramírez Castellanos$^2$, José María González Calbert$^1$, Marco Perez$^1$,$^4$, Katharina Lorenz$^4$,$^5$, Silvia Suarez$^3$ and Benigno Sánchez$^2$; $^1$Departamento de Física de Materiales, Facultad de Ciencias Físicas, Universidad Complutense de Madrid, Madrid, Spain; $^2$Departamento de Química Inorgánica, Facultad de Ciencias Químicas, Universidad Complutense de Madrid, Madrid, Spain; $^3$IFFN, Instituto Superior Técnico, Universidade de Lisboa, Bobadela, Portugal; $^4$Instituto de Engenharia de Sistemas de Computadores-Microsystems and Nanotechnology (INESC-MN), Lisboa, Portugal; $^5$FOTOAIR-Ciemat, Unit of Analysis and Photocatalytic Treatment of Pollutants in Air, Avida, Madrid, Spain.

Molybdenum oxides are considered exceptionally functional and adaptable optical and electronic oxides due to their unique physical properties. In particular, molybdenum trioxide (MoO$_3$) is a polymeric material. The thermodynamically stable orthorhombic o-phase is a well-known semiconductor with a widegap of 5.7 eV. However, there is still a source of findings, hexagonal MoO$_3$ (h-MoO$_3$) is a metastable material with, as yet, poorly known structure and physicochemical properties. In this work, undoped and Ag-doped h-MoO$_3$ microrods have been synthesized by a scalable soft chemistry method based on the precipitation of ammonium heptamolybdate, while composites of h-MoO$_3$ microrods and graphene or graphene oxide (GO) were synthesized by a slightly different route. In addition, highly crystalline h-MoO$_3$ nanoparticles were obtained by ball-milling of the as-grown microstructures. All the obtained samples were thoroughly characterized by a wide set of complementary techniques including monochromatic X-ray diffraction (XRD), scanning electron microscopy (SEM), high resolution transmission electron microscopy (HRTEM), UV-Vis spectroscopy, micro-Raman, micro-photoluminescence, X-ray photoemission spectroscopy (XPS) and X-ray absorption (XAS) with synchrotron radiation.

CM01.06.16
Electrochemical Li-Ion Intercalation for Control of Electronic Phases in Transition-Metal Oxide Epitaxial Films Takuto Somi$^1$, Kohei Yoshimitsu$^2$ and Akira Ohtomo$^{1,3}$; $^1$Department of Chemical Science and Engineering, Tokyo Institute of Technology, Tokyo, Japan; $^2$Materials Research Center for Element Strategy (MCES), Tokyo Institute of Technology, Yokohama, Japan.
Electrochemical Li-ion intercalation is widely utilized as Li-ion battery operation. Apart from the battery application, it can be applied for reversible modulation of physical properties in materials, where content of Li-ion is largely controlled while keeping their host structures. Meanwhile, the large amount of carrier as high as $10^{22}$ cm$^{-3}$ can be modulated, which is enough to control the exotic properties of transition-metal oxides (e.g., metal-insulator transition and superconductivity). Nevertheless, due to a hurdle for homogeneous intercalation to bulk materials, it is limited to apply electrochemical intercalation for control of physical properties.

In this study, we have focused on epitaxial films as host materials, which are advantageous to Li-ion intercalation owing to well-defined structural properties and vast specific surface area. Using pulsed-laser deposition technique, high-quality epitaxial films were grown. A compact three-terminal electrochemical cell was implemented for the electrochemical Li-ion intercalation to the epitaxial films, and successive in-situ resistivity measurements were performed.

First, we have applied this experimental technique to tungsten oxide (WO$_3$), which is a typical band insulator owing to empty W 5d band. When Li ions were intercalated to WO$_3$ epitaxial films, systematic modulation of the electronic properties was verified: resistivity systematically decreased with increasing the amount of intercalated Li-ions (i.e., carrier density), and an insulator-to-metal transition occurred at Li-ion content of 0.24 \cite{1}. Next, we have applied this technique to layered lithium niobate (LiNbO$_3$), which is known to show superconductivity in the Li-deficient phase \cite{2}. As-grown LiNbO$_3$ epitaxial films showed metallic conductivity and no superconductivity appeared above 2 K. On the other hand, after Li-ion deintercalation, Li$_{1-x}$NbO$_3$ films showed superconductivity below 5 K. We also demonstrated that the superconducting transition induced by Li-ion electrochemical reaction was reversible just like the Li-ion battery operation, suggesting that electrochemical Li-ion intercalation was useful for both exploration of electronic phases and operation of next-generation devices utilizing electronic phase transitions of transition-metal oxides.

CM01.06.17
Grain and Grain Boundary Properties of ZnO-Zn$_2$Bi$_{2}$O$_5$-CoO$_{2}$-Cr$_2$O$_3$-CaCO$_3$ Ceramics Using Dielectric Functions Youn-Woo Hong, Man-Jin Ha, Jong-Hoo Paik, Jeong-Ho Cho, Young-Hun Jeong and Ji-Sun Yun; KICET, Jinju, Korea (the Republic of).

ZnO has been applied to various electrical and optical applications such as gas sensors, piezoelectric transducers, phosphors, transparent conducting films, and varistors. To control the figure of merits of these devices it is essential to understand the behavior of defects and interface states in doped ZnO, especially in ZnO varistor. All of these applications are either affected by, or depend on, defects and grain boundary properties according to various dopants (Bi, V, Pr, Co, Mn, Cr…oxides). It is known that cobalt oxide doped to ZnO improves the nonlinear current-voltage characteristics, which is presumably due to the formation of the Schottky-type double barriers at the grain boundaries. Also it is found that the presence of a large Bi, V or Pr ions induces the concentration of native defects of acceptor type in the grain boundary of doped ZnO. However, it is not known about the relationship between the defects and grain boundary properties in the simple five component system ZnO-Zn$_2$Bi$_{2}$O$_5$-CoO$_{2}$-Cr$_2$O$_3$-CaCO$_3$ (ZZCCCa) revealed good nonlinear current-voltage characteristics. In this study, we investigated the effects of CaCO$_3$ and Zn$_2$Bi$_{2}$O$_5$ (newly synthesized liquid phase sintering aid by us for varistor application) additives in ZnO-Cr$_2$O$_3$ (it’s a new varistor system developed by us) on the defects and grain boundary properties using dielectric functions ($\varepsilon_\infty$, $\varepsilon_*$, $\gamma$, $\tan\delta$). It will provide information about the relationship between the formations of donor or acceptor defects at the grain or grain boundary for the double Schottky barrier. Experimentally ZZCCCa sintered at several temperatures in air have two kinds of defects (Zn interstitial and O vacancy) according to its sintering temperature, a single grain boundary (apparent activation energy Ea=0.90–1.2 eV), and a good varistor properties (nonlinear coefficient $\alpha$$>$80). The origin of varistor behavior in this system has been discussed in relation to grain boundary traps and defect chemistry based on the experimental results.

CM01.06.18
Materials Discovery by Chemical Analogy—Role of Oxidation States in Structure Prediction Daniel W. Davies, Keith Butler, Alexandra Iasyev and Aron Walsh; 1University of Bath, Bath, United Kingdom; 2Materials, Imperial College London, London, United Kingdom; 3ISIS Facility, Oxford, United Kingdom; 4UNC Eshelman School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

The concept of oxidation states has, for many decades, been integral to the way in which chemists think about the coming together of elements to form molecules and extended solids. Oxidation states continue to be a useful heuristic tool across all areas of the chemical sciences. By treating elements in given oxidation states as species in their own right, it is possible to use these as building blocks to create chemically feasible compositions\cite{1}. Oxidation states also play a crucial role in approaches to structure prediction: Tabulated sources like Shannon’s radii and coordination environments as well as recent data-mined probabilistic models\cite{2} can predict the likelihood of a given crystal structure occurring.

The likelihood of an element to adopt a certain oxidation state in a solid, given a certain set of neighbours in a given coordination environment, might often be obvious to the well trained eye of a chemist, backed up by their intuition. However, encoding this information for use in high-throughput searches presents a significant challenge.

In this work, we carry out a statistical analysis of the occurrence of oxidation states in 25,000 ordered, inorganic compounds. These results demonstrate that a large number of elements are only likely exhibit certain oxidation states when other, particular elements are present.

We use the information gleaned from this analysis to construct a screening process that ascribes a likelihood score to suggested element compositions. This screening procedure is implemented in this work to efficiently explore the enormous search space for new ternary transition metal halide compositions. We show how a large number of otherwise sensible looking compositions can be discounted from such a search using our method.

Structure prediction is then carried out for some candidate compositions using a probabilistic model as implemented in the Pymatgen code,\cite{3} in which the energies of the structures found with those suggested by the probabilistic model, in order to assess its performance. Overall, we show how careful consideration of the occurrence of oxidation states can be used as part of a materials design methodology. Our methodology can be applied in a range of contexts and is an important tool in the quest for accelerated materials discovery.

CM01.06.19
Perovskite Electron Emitters—Computational Prediction and Preliminary Experimental Assessment of Novel Low Work Function Cathodes Tianyu Ma, Lin Lin, Ryan Jacobs, Dane Morgan and John Booske; University of Wisconsin--Madison, Madison, Wisconsin, United States.
Commercial W-based thermionic electron emission cathodes have been used in high frequency, high power vacuum electronic devices for decades. However, there is an ongoing need for the development of new thermionic cathode materials that don’t suffer from the shortcomings of traditional W-based cathodes, such as limited emission lifetime due to the continual evaporation of volatile Ba during high temperature operation and non-uniform emission throughout the cathode surface.[1]

Our recent work explored a representative set of 20 perovskite oxides as potential new electron emitting materials by conducting Density Functional Theory (DFT) calculations of the surface work function using accurate hybrid HSE functionals, where we discovered that pure and Ba-doped SrVO$_3$ could exhibit low work functions of about 1.9 and 1.1 eV, respectively.[2] Given the well-known compositional flexibility of perovskites, the question naturally becomes the following: What other perovskites exist that could also have a low work function?

In this work, we have used high-throughput DFT calculations enabled by the MAterials Simulation Toolkit (MAST)[3] to computationally screen over 3100 perovskite oxides in search of new thermionic electron emitters. We screened materials in search of candidates with (1) low predicted work function of less than 2 eV, obtained using the bulk O p-hc band center as a descriptor as informed from previous work[2], (2) high bulk stability in a typical thermionic cathode operating environment of $T = 1273 \text{ K}$ and $p_{(O_2)} = 10^{-8} \text{ Torr}$, (3) metallic electronic structure to allow for facile electronic transport, and (4) low work function surfaces that are also stable and are thus expected to be present on the surface of a real cathode. From this computational search, we have identified 6 new perovskite compounds that are promising new thermionic cathode materials.

In addition to our high-throughput computational search for low work function perovskites, it is crucial to experimentally synthesize and test these promising materials. We successfully synthesized >95% phase pure polycrystalline SrVO$_3$ powders using solution-based precursor salts and high temperature heat treatment in a reducing atmosphere. Additionally, we pressed and sintered the SrVO$_3$ powders into cathode test pellets and obtained work function values using high temperature electron emission measurements and X-ray photoelectron spectroscopy (XPS). These experimental results demonstrate the promise of SrVO$_3$ as a low work function thermionic emission cathode.

Fracture Damage of Ceramic Substrates Utilizing an Acoustic Emission Method and Frequency Analysis of the Elastic Wave Takuya Ono, Yusuke Daiko, Sawao Honda and Yuji Iwamoto; Nagoya Institute of Technology, Nagoya, Japan.

From the strong demand of both higher efficiency and energy saving of the power semiconductor, material shift from conventional silicon (Si) to silicon carbide (SiC) was gradually seen since the late 1980’s. SiC-based power devices have various advantages including high frequency operation, high thermal conductivity, high breakdown voltage and temperature operating capability higher than 200 °C owing to its wide bandgap compared with silicon.[3] High temperature operation leads to decrease the volume of heat sink (cooling system). Ceramics with high thermal conductivity such as AlN and Si$_3$N$_4$ have been used for the insulating substrate. Because of their high power/current densities and wider range of the operating temperature, thermal fracture at those insulating ceramic substrates during prolonged operation is a serious problem. In addition, since the power module consists of various components including a ceramic insulating substrate, Cu electrode and polymer molding, understanding of the start-point of the thermal fracture, e.g. whether at the ceramic substrate itself or at Cu electrode/ceramic interface etc. also becomes a significant issue. Acoustic emission (AE) has been widely used to detect fractures, and frequency of the elastic wave can be obtained by Fourier analysis. Here we show the relationship between the frequency of the acoustic wave and elastic modulus of various substrates.

Four substrates of a silicate glass (70 GPa), Y$_2$O$_3$-stabilized ZrO$_2$ (231 GPa), Si$_3$N$_4$ (300 GPa) and Al$_2$O$_3$ (390 GPa) were used for the AE measurement, the numbers of brackets are its Young’s modulus. Thermal shock fractures induced using an infrared radiation heating (IRH) method[4,5] were recorded, followed by Fourier transform of the acoustic wave decay in order to estimate the wave frequency. In the case of a three-point bending method for crack generation, serious noise due to the friction between substrate and AE sensor was also detected. On the other hand, characteristic frequencies for each substrate were observed using the IRH method with a good reproducibility especially in the frequency ranging from 200 to 300 kHz. A good linear relationship between the Young’s modulus of substrates and corresponding frequency was successfully obtained. We also confirmed the start-point of the fractures at both AlN substrate AlN/Cu interface from the AE frequency shift. These results will be discussed together with a heating/cooling cycle test.

CM01.06.21

The Influence of Crystal Structure in the Development of Complex Nanosized Mixed Iron Oxides by Cation Exchange Alberto Casu¹, Sergio Lentijo Mozol², Davide Deiana² and Andrea Falqui¹, ¹Biological and Environmental Sciences and Engineering (BESE), King Abdullah University of Science and Technology (KAUST), Thuwal, Saudi Arabia; ²Centre Interdisciplinaire de Microscoop Electronique, Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

The extensive field of application of magnetic nanoparticles (NPs) makes them a wide, popular and attractive class of materials that receives an ongoing development, with different compositions and morphologies being proposed to improve the NPs’ magnetic features. In regards to this, cation exchange (CE) could represent a promising approach to obtain complex, modulated magnetic nanostructures, but its application to this class of materials has been sporadic and not always consistent.

To this aim we studied the effect of a post-synthetic CE approach on same-sized magnetite and wüstite NPs by performing in-depth morphological, structural, thermally resolved chemical and magnetic behavior analysis, finally obtaining bi-concave core/shell NPs with mixed Fe/Mn and Fe/Co ferrite shells that still maintained the initial shape and size. The combination of such diverse techniques evidenced unanimously this unexpected result, while also shedding light on the role of the NPs’ crystal structure for CE reactions: given the common size and shape of the initial NPs, the crystal structure of the two phases (non-defective for magnetite, defective for wüstite) was the only variable among the NPs populations that affected the CE and was responsible for the higher percentage of doping cation (Co or Mn) present in the post-CE wüstite NPs. Then, the experimental evidence provided what needed to clarify the mechanisms that drive CE processes in this class of materials, while also offering a solid basis for the interpretation of the dramatic variations observed in the magnetic features of the post-CE NPs. In particular, the evolution of the magnetic features could be attributed to the combination of three separate
The first factor was the main cause of exchange-bias effects, while the introduction of Mn or Co in the shell modulated the net magnetic hardness of the core/shell NPs, leading to magnetically softer or harder NPs, respectively, with respect to the initial NPs. Finally, the presence of ferrimagnetic (magnetcite) or antiferromagnetic (wüstite) cores in the core/shell NPs has a major influence in the net magnetic hardness and saturation magnetization of the final NPs. These results give a new insight on the mechanisms that command CE of nanosized magnetic oxides, while providing a clearer picture over the possible capabilities of CE approach to develop novel, complex magnetic nanostructures.

CM01.06.22  
Rational Design of Semiconductor Heterostructures for Energy Conversion  
Junsang Cho1,2, Erick Braham1,2 and Sarbajit Banerjee1,2; 1Department of Chemistry, Texas A&M University, College Station, Texas, United States; 2Department of Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

Lead halide perovskites have rapidly emerged as promising next-generation materials for photovoltaics, light-emitting displays, and other optoelectronic applications owing to their desirable optical and electronic properties. Dimensional control provides a means to tune the optical, electronic, and magnetic properties of semiconducting materials as a result of quantum confinement effects. Ligand-mediated colloidal synthesis methods allow for control over nucleation/growth kinetics and enable precise modulation of nanocrystal dimensions through variation of reaction parameters such as the precursor concentration, reaction temperature, and the electronic and steric parameters of passivating ligands. I will focus on synthetic efforts at establishing dimensional control of semiconductor nanostructures with a particular emphasis on the ligand-mediated synthesis of two dimensional (2D) lead halide perovskite nanocrystals guided by elucidation of crystal growth mechanisms. I will further discuss the design of semiconductor heterostructures for photocatalytic water oxidation that couple multiple polymorphs of vanadium oxide (V2O3) nanowires with semiconductor nanocrystals. The alkyl chain length, branching, ligand concentration, and temperature greatly influence the dimensional modulation of 2D perovskite nanoplanelates (MAPbBr3 and CsPbBr3). Our recent work demonstrates that the crystalline order of the ligand-shell assembly, as dictated by the length of the alkyl chains, the degree of branching, the reaction temperature, and ligand concentration, strongly influences the extent of dimensional confinement attainable for the perovskite nanoplanelates. The denticity, steric bulk, and concentration of the added alkylamine ligands further provide a means of modulating structural dimensionality from 3D CsPbBr3 to 0D CsPbBr3 structures. Machine learning approaches for navigating synthetic landscapes have further been developed and provide control over layer thickness down to a single layer.

The rational design and interfacing of semiconductor heterostructures comprising light harvesting (charge donor) and wide-bandgap semiconductor (charge acceptor) elements is imperative for solar energy conversion within PEC cells wherein incident solar radiation is converted and stored as a chemical fuel. Such heterostructures need to be carefully designed to efficiently harvest a large portion of the incident solar radiation, which requires precise control of energetic offsets (governing the thermodynamic driving forces for charge separation) and the kinetics of charge transfer (determined in large measure by interfacial properties). I will discuss the design of V2O3/quantum-dot heterostructures that simultaneously optimize thermodynamics and kinetics. The ability to tune the V—O connectivity across multiple polymorphs of V2O3, and the specific composition of QDs allows for a broad palette of heterostructures to be systematically developed.

CM01.06.23  
Re Segregation at Interfacial Dislocation Network in a Nickel-Based Superalloy  
Jixue Li, Qingqing Ding, Qian Yu and Ze Zhang; Zhejiang University, Hangzhou, Alabama, United States.

The distribution of Rhenium (Re) in a Ni-based single-crystal superalloy is studied by sub-angstrom resolution transmission electron microscopy (TEM) and energy dispersive X-ray spectroscopy. It is found that Re atoms segregate at the tensile stress regions near the interfacial dislocation cores, and the segregation process is facilitated by dislocation pipe diffusion. In situ TEM and scanning electron microscopy (SEM) straining studies reveal that the Re-decorated dislocation networks along the phase boundaries act as mechanical walls that effectively block dislocation motion and crack propagation. Furthermore, the degree of Re segregation can be regulated by thermal treatment; the slower the cooling rate, the higher the concentration of Re at the interfacial properties. I will discuss the design of V2O3/quantum-dot heterostructures that simultaneously optimize thermodynamics and kinetics. The ability to tune the V—O connectivity across multiple polymorphs of V2O3, and the specific composition of QDs allows for a broad palette of heterostructures to be systematically developed.

CM01.06.24  
Sequential Charge Transitions in Ca0.5Bi3+0.5Fe3+O3 and the Electronic Consequences of B-Site Substitution  
Fabio Denis Romero1,2, Takashi Saito1, J. Paul Attfield3 and Yuichi Shimakawa1; 1Institute for Chemical Research, Kyoto University, Kyoto, Japan; 2Hakubi Center for Advanced Research, Kyoto University, Kyoto, Japan; 3University of Edinburgh, United Kingdom.

Transition metal oxides with unusually high-valent cations often show unusual structural, magnetic, and transport behavior as a result of their inherent charge instabilities. Additionally, the charge transitions via which these instabilities are relieved often lead to coupling of several fundamental properties. For example, CaFeO3 shows charge disproportionation of the unstable Fe3+ cations (2Fe3+ → Fe3+ + Fe5+) which leads to a structural phase transition due to ordering of the disproportionate cations and a metal-insulator transition.[1] In addition, competing magnetic interactions in the charge disproportionated phase lead to the emergence of incommensurate magnetic order.[2] In BiNiO3, there is an intersite charge transfer transition (Bi3+3Ni3+O3 → Bi5+3Ni5+O3) which is accompanied by significant structural modifications due to the columnar ordering of the Bi5+ and Bi3+ cations.[3]

Recently, we reported the synthesis of Ca0.5Bi3+0.5Fe3+O3, which shows sequential charge transitions of the unusually high valent Fe3+5: first at 250 K there is charge disproportionation from Ca0.5Bi3+0.5Fe3+O3 to Ca0.5Bi3+0.5Fe3+5+3Ni5+O3 with accompanying charge and magnetic ordering and then at 200 K there is intersite charge transfer between Bi and Fe to form Ca0.5Bi3+0.5Fe3+5+3Ni5+O3.[4] These charge transitions are accompanied by significant changes to the structural, magnetic and transport properties of this material.[5] This material is tolerant to substitution of the iron for cobalt enabling the formation of the full Ca0.5Bi3+0.5Fe3+Co3O3 solid solution. This results in an initial sharp suppression of the charge disproportionation transition at x = 0.03 due to the broadening of the oxygen hole peak while the interstitial charge transition remains up to approximately x = 0.67.

Influence of Nanoparticle on Microstructure and Magnetic Properties of Bi-Substituted LiZnTi Ferrites with Low Sintering Temperature Fang Xu and Huaiwu Zhang; University of Electronic Science and Technology, Chengdu, China.

Microstructural changes including grain growth and densification in ceramic materials, either through liquid phase sintering or by lowering reaction energy, have a profound effect on the material properties. In this work, Li$_{0.43}$Zn$_{0.27}$Ti$_{0.13}$Fe$_{2.17}$O$_4$ nanoparticles (LZNs) with were prepared by sol-gel method. HRTEM image of the LZNs showed that the spinel structure nanoparticles with ~26 nm average particle size were obtained. As a reaction additive, the LZNs were introduced into a Bi-substituted Li$_{0.43}$Zn$_{0.27}$Ti$_{0.13}$Fe$_{2.17}$O$_4$ (LiZnTiBi) ferrite ceramic to control abnormal grain growth and enhance magnetic properties (sintering temperature is ~920 °C). XRD patterns demonstrated that a pure spinel phase structure composite ceramics were synthesized. This indicated the LZNs can further react with LiZnTiBi ferrite ceramics. Also, SEM images showed that adding LZNs can obviously control abnormal grain growth and reduce pores between grains. More importantly, results of ferromagnetic resonance (FMR) linewidth (ΔH) showed that optimized LZNs additives can reduce ΔH of the LiZnTiBi ceramics. Meanwhile, saturation magnetization (4mM) of the ceramics can be improved by adding moderate LZNs. The doping method reported in this study also provides a referential experience for other low temperature sintering ceramics.

CM01.06.26
Magnetcocaloric Materials Based on Binary and Ternary Mn Compounds—Screening and Testing Joya Cooley1, Joshua D. Bocarsly1,2, Matthew Horton1, Kristin A. Persson1 and Ram Seshadri1,2,5; 1Materials Research Laboratory, University of California, Santa Barbara, Santa Barbara, California, United States; 2Materials Department, University of California, Santa Barbara, Santa Barbara, California, United States; 3Energy Storage and Distributed Resources Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 4Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 5Department of Chemistry and Biochemistry, University of California, Santa Barbara, Santa Barbara, California, United States.

Magnetic refrigeration is accomplished through the magnetocaloric effect (MCE) associated with a reversible temperature change upon application of a magnetic field. The effect originates from cycling materials between two different magnetic states with high and low entropies. In recent decades, this technology has been proposed as an environmentally friendly alternative to traditional vapor-compression technology, obviating the need for chlorofluorocarbon or hydrochlorofluorocarbon refrigerants, and potentially capable of greater efficiency.1,2 The figure of merit for magnetocalorics is the magnetic entropy change (ΔS_M), and it has been recently proposed that compounds with high ΔS_M can be screened using a density functional theory (DFT) based proxy called the magnetic deformation (Σ_M) – a measure of the deformation between relaxed structures with and without spin polarization.3 Several useful Mn-containing binary and ternary compounds have been identified as potential magnetocalorics. We will discuss the synthesis, characterization, and magnetic property measurement of some of these candidate materials.

This research was supported by the National Science Foundation under Grant DMR-1710638. CM01.06.27

Refractory ceramics, such as metal carbides, metal nitrides, and metal borides offer superior thermal, electrical, and mechanical properties that significantly outpace metal alloys, oxide-based ceramics, and other comparable materials. The outstanding temperature stabilities (over 3,000 °C) and high hardness (over 30 GPa) of these ceramics and ceramic matrix composites (CMCs), therefore, offer significant promise for ballistic protective armor, industrial tools, and hypersonic engine applications. However, conventional synthesis and composite fabrication methods involve expensive and energy-intensive carbothermal synthesis or sintering that is neither safe nor industrially scalable for mass production. Furthermore, since intrinsic ceramics are brittle and require incorporated reinforcements in order to adequately perform, their processing adds significant engineering complexity and remains poorly optimized for refractory carbides.

We rely on blends of metals and phenolic resins to synthesize near net shape refractory ceramics using a single-step in situ reactive melt infiltration/reaction bonding method in which no pressure is required to compact and densify the composites. The polymer source, which is an inexpensive thermoset with a high char yield and zero oxygen-containing groups, reacts with metals at low temperatures (700 – 1,400 °C) under flowing Ar in a tube furnace and requires 75% less energy input than conventional ceramics synthesis methods. A similar method employs a melamine-rich resin and requires on flowing N₂ to synthesize metal nitride monoliths. To date, our approach has successfully yielded TiC, SiC, Si₃N₄, B₄C, ZrC, ZrN, ZrB₂, and TiB₂ composites in preformed shapes (discs, cones, spheres, etc.). The resulting structures exhibit nanocrystalline grains and high density, and the ceramic monoliths demonstrate high toughness and durability in harsh environments. We reinforce these composites with metals, carbon allotropes, and secondary ceramics in a bottom-up approach in order to enhance their oxidation stability, thermal stress mitigation, and fracture toughness. The resulting customizable and inexpensive refractory composites offer a number of solutions for vital applications in the aerospace, military, transportation, and tooling industries.

SESSION CM01.07: Solid-State Catalysis
Session Chairs: Amy Prieto and Dmitri Talapin
Wednesday Morning, November 28, 2018
Hynes, Level 2, Room 203
Water splitting involves the synergistic operation of water oxidation and hydrogen evolution half-reactions and remains a considerable challenge since it requires the concerted transfer of four electrons and four protons. Catalysts that can facilitate both of the half-reactions at low overpotentials are imperative to avoid squandering free energy harvested using a semiconductor in a photoelectrochemical cell, or provided directly in the form of current in a water electrolyzer. Photocatalytic water splitting requires the operation of light harvesting, charge separation, charge transport, and redox catalytic steps that must operate in concert. As such, it is necessary to tune the energetic offsets to establish optimal thermodynamic driving forces for charge transfer. Design and control of interfaces to mediate kinetics of charge transfer. I will discuss the design of compounds with the composition \( \text{M}_n \text{V}_n \text{O}_x \), where \( \text{M} \) is a post-transition metal cation with lone-pairs characterized by intercalative mid-gap states that can accept holes from photoexcited semiconductor quantum dots. Such compounds, accessible through topochemical intercalation of metastable polyoxymetals of \( \text{V}_n \text{O}_x \), have facilitated the design of semiconductor heterostructures with energetic offsets primed to facilitate effective hole transfer upon photoexcitation of the heterostructures, thereby mitigating the longstanding challenge of the anodic photocorrosion of quantum dots. Interfacial design further provides a means of modulating the dynamics of hole transfer, which occurs at \( <1 \) ps timescales. The second half of my talk will focus on discussing the specific electronic structure characteristics of edge sites of MoS\(_2\), that enable them to function as catalysts for the hydrogen evolution reaction. Interfacial hybridization of MoS\(_2\) with n-cistrans provides a means to modulate the electronic structure and enhance catalytic activity. Finally, I will discuss ternary heterostructures that are capable of catalyzing both reactions.

This work was supported by the National Science Foundation under NSF 1627197.

8:30 AM CM01.07.02
Disordered MoTe\(_2\) with Self-Enhanced Catalytic Activity for Hydrogen Evolution
Alexey Ganin and Jessica Meglynn; University of Glasgow, Glasgow, United Kingdom.

Sunlight is widely distributed geographically and provides enough energy in one hour to supply the world’s energy demands for a full year. However, this form of renewable energy is intermittent; thus, current solar energy technologies must be fed into the grid or are otherwise wasted. Recent efforts have therefore been focused on the conversion of excess solar energy into a fuel in the form of hydrogen via water electrolysis. Subsequent oxidation of this hydrogen would allow for the release of energy (and water) without the need for fossil fuels. Due to the diffusivity of solar power, a relatively modest current density of 10 mA cm\(^{-2}\) has been proposed as a benchmark for the comparison of hydrogen evolution reaction (HER) electrocatalysts, which roughly equates to a 10% efficient solar-to-fuels device. \[1\] Layered transition metal dichalcogenides (TMDs) can offer a viable solution for achieving appreciable conversion rates in low currents due to intrinsic and useful feature of any layered material, namely two-dimensionality. \[2\] The 2D nature of TMDs enables a maximum output from the entire surface of a catalyst and allows a simplistic and cheap design of future devices, for example, in form of atomically thin films. A semimetallic 1T\(^-\)-MoTe\(_2\) with the monoclinic structure stands out among chalcogenides of molybdenum due to its remarkable ability to accommodate excess of electrons and thus, presenting an excellent prototype for studies of the role of electrochemical activation on catalytic properties of a 2D material. \[3, 4\] Herein, we report the synthesis, structure and properties of a new disordered MoTe\(_2\) material with self-enhanced catalytic activity for HER that reaches the overpotential value of –187 mV at \( j = 10 \) mA cm\(^{-2}\) after short potential cycling in 1 M H\(_2\)SO\(_4\). The optimisation is coupled with a five-fold increase in turnover frequency and reduced charge transfer resistance as the HER progresses, all while preserving the electrochemically active surface area. By applying a solid state approach to the synthesis of the disordered MoTe\(_2\), we can exclude stoichiometry defects as the cause of the enhanced activity and conclude, in conjunction with electron microscopy, spectroscopy and X-ray diffraction experiments that the improved electrochemical performance is due to the intrinsic activation of the basal plane. The outcome of the studies on optimisation of MoTe\(_2\) thin films using the in operando cycling protocol is discussed as well in connection with how appreciable gains in future energy conversion and storage via HER may be achieved.

Faceted Oxide Nanoparticles as Catalyst Supports
Kenneth R. Poeppelmeier\(^1, 2\), Ryan J. Paulf\(^3\), Zachary R. Mansley\(^2\) and Laurence D. Marks\(^2\); Chemistry, Northwestern Univ, Evanston, Illinois, United States; \(^2\)Materials Science & Engineering, Northwestern University, Evanston, Illinois, United States.

Our focus has been on understanding how the metal/oxide interface can modify the activity and selectivity of supported noble metal catalysts. To this end, metal/support interfaces on faceted oxide perovskites have been examined. Specifically, we use the variable strength of interaction between different perovskite oxide supports and noble metal catalysts. Support particles can be produced through sol-gel or hydrothermal methods. Lanthanide scandates (LnScO\(_3\)) were produced through a low-temperature heat treatment of a stoichiometric hydroxide gel in a humid environment.\(^4\) Water vapor was necessary to preserve the higher diffusivity of the gel, but an excess of water vapor led to the formation of secondary phases. The temperature of the reaction was used to tune the Gibb's free energy of reaction and kinetics of particle growth to produce faceted nanoparticles. The lattice parameters of LnScO\(_3\) match well with several noble metals, which allows for a systematic study of how certain support properties (lattice parameter, acidity, etc.) can affect the catalytic performance of these supports. This study synthesizes the way for different surface structures or morphologies to be obtained, which further influence the metal/support interface. Hydrothermal synthesis of SrTiO\(_3\), for example, may produce materials that are controllably terminated with either SrO-rich \(100\),\(^5\) \(\text{TiO}_2\)-rich \(100\), or \(\text{TiO}_2\)-rich \(110\) surfaces.\(^6\) Pt nanoparticles showed a higher selectivity in acrolein hydrogenation towards allyl alcohol when the Winterton shape had a higher ratio of facets to edges or corners, as was the case when supported on SrTiO\(_3\) rather than BaTiO\(_3\), and exploiting the Strong Metal-Support Interaction further improves the selectivity.\(^7\) This library of the different support oxides with controlled surface structure and morphology allows for better control of specific active sites of several noble metals.

9:15 AM CM01.07.04
Electrochemically Driven Non-Congruent Phase Transitions in Ordered Intermetallic Pd-Bi Electro catalysts
Shoji Hall, Du Sun and Yunfei Wang; Johns Hopkins University, Baltimore, Maryland, United States.
The conversion of $\text{O}_2$ to $\text{H}_2\text{O}$ is an important fuel cell reaction for the recovery of renewable electricity from chemical fuels. Alloys of Pt-group metals (PGMs) with transition metals have emerged as catalysts with enhanced activity and durability for the oxygen reduction reaction (ORR). To date, most studies focus exclusively on alloys that adopt a Face-centered cubic (FCC) or Face-centered tetragonal (FCT) crystal lattice. Under ORR operating conditions, these materials evolve from alloys to Pt core-alloy shell materials, in these systems both the alloy core and Pt shell retains the FCC or FCT type crystal structure. Generally, PGM alloys belonging to the lower symmetry FCT structure usually exhibit higher activity than FCC-type alloys of the same composition. However, materials with lower symmetry than FCT crystal structures are not often explored as catalysts, hence there is wide open opportunity to explore new materials.

Here we present the synthesis and interrogation of low-symmetry Pd-Bi based ordered intermetallics for ORR. We found that under ORR operation conditions, $\beta$-Pd$_2$Bi$_3$ (I4/mmm space group) which adopts a tetragonal lattice, transforms to $\alpha$-Pd$_2$Bi (Pnma space group) which adopts an orthorhombic crystal structure; this transformation is mediated by oxidative Bi corrosion under potential cycling. To the best of our knowledge, this is the first report of a material that exhibits an electrochemically driven, non-congruent phase transition among materials with different crystal structures. The resulting phase-converted Pd$_2$Bi is stable and exhibits high performance for ORR. Phase-converted Pd$_2$Bi outperform Pt and Pd metal, reaching mass activities of 2.6 A/mg$_{\text{Pd}}$, which is nearly 10X higher than Pt/C ($-0.3$ A/mg$_{\text{Pt}}$) and Pd/C ($-0.2$ A/mg$_{\text{Pd}}$) at 0.9 V vs the Real Hydrogen Electrode (RHE). The mass activity of Pd$_2$Bi decreases by $-38\%$ after 10,000 cycles, indicating that it is stable. Activation energy ($E_a$) determined by temperature dependent electro-kinetic measurements indicates that the activity enhancement on phase-converted Pd$_2$Bi originates from anion-poisoning resistant behavior. These results establish that PGMs-based ordered intermetallics with low-symmetry crystal structures can be highly active and durable electrocatalysts.
In contrast to oxides, polyoxometalate compounds adopting sophisticated polyhedral structures with a variety of connectivity types and topologies provide a large playground for searching new cathode materials and tuning their electrochemical properties. [1, 2, 3]

We recently designed and synthesized a novel series of vanadium-based AVPO₄F (A = Li, Na, K, Rb) cathode materials adopting the unique KTiOPO₄ (KTP)-type structure using different soft-chemistry approaches including hydrothermal and freeze-drying techniques. The peculiarities of the KTP-type “VPO₄F” framework enabled excellent rate capability particularly demonstrated in Li cells [4]. The material exhibited remarkable capacity retention maintaining more than 75% of the initial specific capacity in Li-ion cells at 40C and an average potential of 4.0 V vs Li/Li⁺. The structural evolution during Li de/intercalation was studied using in-situ synchrotron diffraction and ex-situ electron tomography. The material was found to undergo a sequence of phase transformations with the change of a non-centrosymmetric space group to a centrosymmetric one.

The materials also support reversible intercalation of Na⁺, K⁺ and even Rb⁺ ions maintaining the host structure. The observed electrochemical behaviour and ion transport properties were quite different for Li⁺, Na⁺, K⁺ and Rb⁺ ions. Alkali ion diffusion coefficients measured by PITT were found the lowest for Li⁺ (10⁻¹⁵ – 10⁻¹⁶ cm²/s) and highest for K⁺ (10⁻¹⁴ – 10⁻¹⁴ cm²/s). [5] Moreover, the full de/intercalation of K⁺ in KVOPO₄F occurs at the highest potentials comparing to Li⁺, Na⁺ and Rb⁺ exceeding 4.6 V vs K/K⁺, which states KVOPO₄F as the most high-voltage cathode material for K-ion batteries studied so far. DFT studies revealed extremely low energy barriers for K⁺ and Rb⁺ migration of less than 0.2 eV along the c-axis, which are in accordance with experimentally observed fast ion transport properties.

Thus, the KTP-type “VPO₄F” framework that exhibits an ability to de/intercalate four types of alkali ions opens up new opportunities in designing polyoxometalate cathodes for metal-ion batteries. We will focus on our recent activities on KTP-type fluoride-phosphates considered as promising cathode materials for metal-ion rechargeable batteries.

Structural and Physical Properties of Novel Double Perovskites, BaLaBO₆O₅
Andrew Bowser and Corey Thompson; Purdue University, West Lafayette, Indiana, United States.

Double perovskite oxides, A₂BB’O₆ and AA’BB’O₆, are a well-studied set of compounds in solid state chemistry. Their importance in both fundamental and technological research is mainly due to the wide variety of properties they exhibit, and the ability to incorporate nearly any element into their structure. The Ba₂BO₆O₅ compounds have been underexplored until recently, with only limited structural data reported. Interestingly, according to current literature, several of these compounds have been reported to adopt either a hexagonal (P₆₃/mmc or P-3m1) or cubic (Pm-3m) structure, dependent on reaction conditions. Recently, magnetic and physical property studies upon hexagonal-Ba₂Fe₁₋ₓOsₓO₅, synthesized under ambient solid-state conditions have revealed ferrimagnetic behavior with a magnetic ordering temperature of ca. 370 K. Whereas, cubic-Ba₂NiO₅, synthesized under high-pressure show properties of a Dirac–Mott insulator with a magnetic ordering temperature at 100 K. In both these cases, the properties observed can be traced to 3d/5d interactions within the B-site sublattice. We have recently synthesized several novel double perovskite compounds, and their structure and physical properties will be presented.

Local Atomic Rearrangement Around the Superconducting CuO₅ Planes Upon Oxidation in the M-1212 Cuprates (M <-> Fe, Mo & W)
Miguel Angel Alario-Franco, Sara Lopez Paz, Xabier Martinez de Irujo and Emilio Moran-Miguelez; Facultad de Quimica, Universidad Complutense, Madrid, Spain.

Superconductivity in cuprates is achieved when holes are doped to an antiferromagnetic Mott insulating parent compound [1]. However, not only a high concentration of holes is required but also an effective charge transfer process from the Charge Reservoir Layer to the superconducting planes [2]. As a result, the critical temperature (Tc) is very sensitive to subtle changes in both local structure and charge distribution between the planes and the charge reservoir block [3].

The M-1212 phases, resulting from total or partial substitution of copper in the chains in the YBCO model compound by other transition metals, are suitable candidates in studying this charge transfer process [4, 5]. In this communication we will present the effect of iron, molybdenum and tungsten substitutions, resulting in Fe-1212, Mo-1212 & W-1212 phases with FeSr₂YCu₂O₇, Mo₀.₃Cu₀.₇Sr₂RECu₂O₇ and W₀.₂Cu₀.₈Sr₂YCu₂O₇ compositions. We have studied the subtle influence of charge balance and compositional order/disorder in both the anion and cation sub-lattices. Besides, we have explored the local atomic rearrangement around the superconducting CuO₅ planes as a function of the oxidation treatment. The ensemble of these results will be presented and discussed.

Improving Charge Transport Properties of Oxide-Based Photoelectrodes for Use in Solar Water Splitting

Among various semiconductor electrodes (photoelectrodes) that have been investigated for solar fuel production, oxide-based photoelectrodes have the possibility of significantly lowering the materials processing costs while also being more stable in aqueous media. However, oxide-based photoelectrodes...
Understanding Metallicity and Magnetism in theories based only on nearest-neighbor interlayer coupling, they compel a closer look at effective second-nearest-neighbor interactions, mediated by

The structural versatility of the tetrahedral vanadate (VO4)3− bridging group provides the opportunity to systematically examine a wide range of low-dimensional magnetic systems with a broad assortment of spin values. The structural and magnetic properties of several novel layered magnetically frustrated manganese vanadate systems will be discussed. Magnetic lattices with mixed corner-sharing and edge-sharing triangular units have recently been found in K2Mn3(VO4)2(OH)2, Mn5(VO4)2(OH)4 and Mn5VO8. The arrangement of triangular [MnO13] building blocks in K2Mn3(VO4)2(OH)2 create a Kagome strip lattice. Mn5(VO4)2(OH)4 contains two unique triangular [MnO13] units formed by the presence of the additional Mn atom, such that every other row of hexagons has an additional Mn atom in the center of each hexagon creating two-dimensional striped triangular lattices. The structure of Mn5VO8 differs from the other two structures, by containing Mn in two valence states 2+ and 3+ distributed over two types of magnetic layers that are alternately stacked in the crystal structure. One layer contains Mn2+ in a Kagome strip lattice and the other contained a mixture of Mn2+ and Mn3+ that form a triangular lattice. For all these systems, neutron diffraction measurements revealed the onset of very complex antiferromagnetic orderings, while inelastic measurements, and density functional theory calculations of structural, electronic, and magnetic ground states. We examine the interplay between electronic properties. Some materials in this family undergo metal-insulator transitions and others host exotic magnetic spin textures such as skyrmions. These properties can be related to clustering of the magnetic moments in the honeycomb sublattice, that become crucial at finite-temperatures and intermediate fields.

The family of ABQn compounds, where A is Al, Ga, or Ge, B is an early transition metal like V, Mo, or Ta, and Q is a chalcogen like S or Se have been studied since the 1970s. They crystallize at room temperature in the F–4m defect spinel structure and display a fascinating array of magnetic and electronic properties. Some materials in this family undergo metal-insulator transitions and others host exotic magnetic spin textures such as skyrmions. These properties can be related to clustering of the B-site atom, crystalline anisotropy, and the electronic correlations present. We study two of these materials, GaVS4 and GaMoS4Se6, using a combination of experimental techniques including high-resolution X-ray diffraction and magnetic measurements, and density functional theory calculations of structural, electronic, and magnetic ground states. We examine the interplay between electronic structure, crystal structure, and magnetic/electronic properties in these systems and develop insights into chemical tuning to optimize functionality.

Rebrodo, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; Department of Physics and Astronomy, Vanderbilt University, Nashville, Tennessee, United States; Department of Chemistry, University of Puerto Rico at Cayey, Cayey, Puerto Rico, United States; Department of Mechanical Engineering and Materials Science, Washington University in St. Louis, Missouri, United States.

Strong electronic correlations, interfaces, defects, and disorder can individually challenge the theoretical methods for predictions of materials properties.
These challenges are all simultaneously present in complex transition-metal-oxides (TMOs). TMO’s interfaces and superlattices are known to exhibit unique electronic properties caused by multiple coupled degrees of freedom and strong electronic correlations. The computational treatment of TMOs remains an outstanding challenge due to the multivalent character of the metal components and the predominant role played by many-body effects (electronic correlations). This challenge is increased at TMO interfaces and superlattices, where the transition-metal ion valence varies sharply. Computational costs drive TMOs out of reach of conventional quantum chemistry methods. On the other hand, the commonly used Density Functional Theory (DFT) approximations, e.g., Local Density (LDA) and semilocal Generalized Gradient (GGA), are not sufficiently accurate and transferable to account for all experimental observations without adjustable parameters. We show [1] that a fundamentally different approach, ab initio diffusion Monte Carlo (DMC), is now a practical solution of the many-electron problem for the full complexity of these systems. Within a single nonempirical theoretical approach, we unambiguously establish the site-specific stability of oxygen vacancies in the (LaFeO3)2/(SrFeO3) superlattice, accounting for experimental data, and predict their migration pathways. In addition, we will describe a number DMC calculations which are currently capable of playing a major role in the elucidation of many-body phenomena complex oxides previously out of reach of theories without adjustable parameters.

Nitride Tuning of Transition Metal Perovskites

Amparo Fuertes; Institute of Materials Science of Barcelona (ICMAB-CSIC), Bellaterra, Spain.

Substitution of nitride for oxide anions is an important method for tuning materials properties in transition metal perovskites, for example, Ca$_x$La$_{1-x}$TaO$_3$, Ca$_x$Ni$_{1-x}$Fe$_2$O$_4$, Ca$_x$F$_{30-x}$Ti$_{42}$O$_{120}$, Sr$_2$FeWO$_6$, Sr$_2$FeWO$_5$N, Eu$_x$Bi$_{2-x}$O$_3$, and Eu$_x$Bi$_{2-x}$O$_3$N. Colossal magnetoresistance (CMR) is one of the main characteristics of CMR materials. However, CMR is not always observed in materials containing metal-oxide nitride substitutions. This paper presents recent research of selected perovskite oxynitrides focusing on the relationships between the synthesis conditions, the oxidation states of the metals, the nitrogen content, the ordering of anions, and the physical properties.

Growth Mechanisms of α-Fe$_2$O$_3$ Nanocubes and Their Influence on Magnetic Properties

Gabriel D. Rocha$^1$, Marcello A. Martínho$^2$, Marco A. Cordeiro$^3$ and Edson R. Leite$^4$; 1Materials Engineering Department, UFSCar, São Carlos, Brazil; 2Chemistry Departament, UFSCar, São Carlos, Brazil; 3LNANO, Campinas, Brazil.

One of the main branches of nanoscience deals with the tailoring of nanoparticles (NPs) shape (e.g., spheres, octahedra, cuboctahedra, cubic structures) due to the possibility of tuning several properties as electrical, optical and magnetic. Likewise, hematite (α-Fe$_2$O$_3$) NPs have a series of fascinating polyhedral structures, which magnetic properties are ruled by NP shape and size, finding fundamental applications in many fields including ferrofluid technology, biomedicine, catalysis and magnetic storage. Accordingly, in this study we provide some insights into the growth process of hematite NCs in the colloidal state, as well as the parameters that affect crystal growth and morphology, which are essential for designing new hematite-based nanostructured functional materials. Many shape and size oleate-capped α-Fe$_2$O$_3$ NPs were synthesized by hydrothermal route under microwave heating. By fine-tuning the amount of surfactant (sodium oleate) and reaction time (450 min), three main structures: spheres, polyhedral, and cubic-like shapes were identified by high-resolution transmission electron microscopy (HRTEM). According to HRTEM observations, the proposed mechanism for the formation of cube-like NPs from spheres is based on a three-step growth process, with the initial formation of a seed or nucleus, and then sphere particles (~7 nm). With the progress of the synthesis, those spheres grow under the oleate groups action and polyhedral NPs are obtained (~12 nm). The second part of the growth mechanism is the oriented attachment of polyhedral NPs, mainly by the coupling of graphite exposed facets, resulting in diamond-like shapes (25-30 nm). Although it was possible to identify many oriented attachments in progress by HRTEM, these structures were only found in a small-time gap (20-25 min of synthesis). Finally, the diamond-like NPs reshape, resulting in the formation of a cubic shape, with small size increasing from monomers in solution. According to the particle shape evolution, we also investigated the dependence of magnetic properties by using a superconducting quantum interference device (SQUID) that revealed the role of NPs shape and size in the magnetic properties of the α-Fe$_2$O$_3$NPs. This knowledge provides fundamental improvements in chemical preparation protocols for the reproducible production of NCs with specific properties and high yields.
until 1% w/w. A secondary phase of FeSbO$_4$ (PDF#74-4588) was indexed from 2% w/w on. For the samples sintered at 1300 °C, the solubility was reached until 4% w/w, and the 5% w/w concentration shows that the secondary phase was also indexed as FeSbO$_4$. SEM analysis show that average grain sizes are 2 µm for 1100 °C and 30 µm for 1300 °C. Electrical measurements were performed after the electroceramics were heat treated in N$_2$ atmosphere at 850 °C by 20 minutes. The results show that for 1100 °C, resistivity reaches $10^5$ Ω cm, while for the higher temperature, it lowers by 2 orders of magnitude. These results suggest that possibly the reaction between the precursor oxides is facilitated at higher temperatures, which favor the electrical properties of hematite. The resistivity values found are comparable with those obtained with Sn-doped hematite, therefore showing the potential of Sb as a dopant.

CM01.09.03
Solventless Synthesis of Copper Antimony Sulfide Materials from Reactive Melts of Metal Xanthate Precursors Tahani Alqahtani, David J. Lewis and Paul O'Brien; University of Manchester, Manchester, United Kingdom.

In recent years, ternary copper antimony sulfides show considerable promise as alternative absorber materials for cost-efficient and scalable photovoltaics due to their high absorption coefficients, optimum band gap and consist of cheap, low-toxicity and earth-abundant elements. The Cu-Sb-S system exist in four ternary phases, which are Cu$_2$Sb$_3$ (chalcostibite), C$_3$Sb$_4$S$_3$ (tetrathedrite), Cu$_3$Sb$_5$S$_7$ (skinnerite) and Cu$_5$Sb$_5$S$_7$ (fematinite). Chalcostibite has been considered as an alternative absorber to the CuInS$_2$ because of the comparable optical properties required for solar absorber materials, with the advantage that antimony is earth-abundant element and less expensive than indium.

Tetrathedrite has been recently attracted a huge amount of attention due to its potential for energy conversion applications. It is highly suitable for thermoelectric materials because of its unique feature in its crystal structure as it has naturally low lattice thermal conductivity. Furthermore, it is an attractive candidate for solar absorber materials as it displays strong absorption in wide spectral range. Partially substituting on the copper, antimony and chalcogen sites has been an active area of research to optimize the thermoelectric properties. These dopants could lead to additional and interesting optical and magnetic properties.

This work, we report a facile simple solvent-less route for the preparation of chalcostibite and tetrathedrite nanostructure phases using metal xanthates. One feature of this approach is the absence of a solvent, which gives the melt route a potential/environmental and economic advantage as compared to other solution-phase routes. The use of metal xanthates is advantageous because they already contain the sulfur required for the preparation of the metal sulfide. Another important advantage of metal xanthates is that they have low decomposition temperature and the by-products of the decomposition are volatile, allowing the clean formation of Cu-Sb-S materials using mild temperature without impurities. The compositions of the obtained materials were adjusted by varying the molar ratio of the copper and antimony xanthate precursors. In addition, zinc and bismuth xanthates were also used for the preparation of the Zn and Bi-v-doped tetrathedrite.

The results obtained from XRD indicate that the solventless pyrolysis of the metal xanthates is advantageous in that it has demonstrated successful formation of the single-phase chalcostibite and tetrathedrite of high purity in short time of amount. Furthermore, incorporation of dopants into the tetrathedrite crystal structure has shown to form the pure phase of tetrathedrite. As the dopant content increase in the samples, the diffraction peaks gradually shifted toward lower angle. The lattice parameter increases linearly with increasing the dopants content in the samples. In addition, the morphology, composition and optical properties of the obtained Cu-Sb-S nanomaterials were also investigated.

Multimodal Chemical and Functional Imaging of Materials via Combined AFM/ToF-SIMS Platform Anton V. Ievlev, Matthias Lorenz and Olga Ovchinnikova; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Polarization switching in ferroelectric materials underpins a broad gamut of applications ranging from random access memory, tunneling barriers, data storage, and ferroelectric ceramics. Classically, the polarization switches due to a co-existence of energetically equivalent crystallographic states, that can be altered with an external electric field. To stabilize polarization, charge discontinuity at surfaces and interfaces requires compensation, or screening, to avoid long-range electrostatic fields that destabilize the ferroelectric phase. Most studies consider polarization screening to be chemically inert; leaving the composition of the ferroelectric intact. However, analysis of extant ferroelectric phenomena suggests higher complexity. It is well known that multiple polarization switching cycles can accumulate damage at interfaces, dubbed “ferroelectric fatigue.” Typically, tens or hundreds of thousands switching events are required, and the exact mechanisms remain controversial. Furthermore, polarization-dependent photovoltaic effects in perovskites suggest that even under optimal screening conditions a considerable electric field remains in the material. Thus, switching is associated with high fields, which can chemically alter material composition.

Here we utilize multimodal approach combining time of flight secondary ion mass spectrometry (ToF-SIMS) with atomic force microscopy (AFM) to explore the structure property interplay of ferroelectrics during polarization switching in lead zirconate titanate (PZT, Pb$_2$TiO$_3$) thin films. Using this multimodal imaging platform, we demonstrated that chemical phenomena plays significant role in ferroelectric switching process. Specifically, we found that local ferroelectric switching by the AFM tip, significantly alters the chemical composition in the 3-nm-thick surface layer of the sample, forming reversible concentration wave, of Pb$^+$ ions. Furthermore, investigations of the polarization cycling in the PZT sample with copper electrodes, showed penetration of the copper cations into the structure of PZT. This explains ferroelectric fatigue phenomenon, leading to decrease in spontaneous polarization with sample cycling.

Altogether, explored chemical phenomena associated with ferroelectric switching will enhance fundamental understanding of ferroelectric phenomena and aid in the practical application of ferroelectrics in devices.

This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility, and using instrumentation within ORNL’s Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

CM01.09.05
Magnetic Properties of Novel Tellurides, Tl$_{1-x}$A$_x$Fe$_3$Te$_3$ Robert Compton and Corey Thompson; Purdue University, West Lafayette, Indiana, United States.

Materials with a pronounced magnetocaloric effect (MCE) are promising candidates for magnetic refrigeration technology. The intermetallic TlFe$_2$Te$_3$ phase has several characteristics that make it an ideal system to study. These include a moderate MCE at near room transition temperature (T$_m$ = 220 K), low thermal and magnetic hysteresis, and a low dimensional structure consisting of pseudo-1D chains composed of iron telluride clusters. To become commercially feasible, replacement of thallium with non-toxic elements and a higher magnetic ordering temperature (>300 K) are desirable. Partial substitutions of earth-abundant alkali metals for thallium have been successful. These substitutions have a substantial effect on the magnetic properties, which can be tuned based on the choice of alkali metal. Their interesting structural and magnetic properties will be presented.

CM01.09.06
Study the Synthesis, Crystalline Structure, Morphology and Magnetic Properties in the Ba$_x$Bi$_{1-x}$O$_3$-$V_2$O$_5$ and SnO$_2$-$MgO$-$Sb_2$O$_3$ Systems Elizabeth Chavira$^1$, Jose Hurtado$^{1,2}$, Jorge Barreto$^3$, Jesús Aenas$^3$, Roberto Sato$^3$, Adriana Tejeda$^2$, Joséh Esaú Romero-Ibarra$^2$, Omar Novelo$^2$ and Karla Eriseth$^2$.
Our interest is to study the thermodynamic properties on two systems of oxide materials to reproduce the $\text{Sn}_x\text{SbTe}_5\text{Ba}_2\text{Y}_2\text{Mg}_2\text{O}_{26}$ and $\text{Sn}_x\text{SbTe}_5\text{Ba}_2\text{Y}_2\text{Mg}_2\text{O}_{26}$ superconductors reported in the web site www.superconductors.org.

The two systems $\text{Ba}_2\text{Mg}_2\text{O}_3$ and $\text{Sn}_2\text{O}_3\text{Mg}_2\text{O}_3$, were synthesized, by solid-state reaction at 880°C. It is observed the formation of ternary and binary phases after reaction. Powder X-ray diffraction (XRD) was used to identify those phases.

Thermal Analysis characterization was used to know on what range of temperatures the reaction could occur.

One way to study the thermodynamic properties was the comparison of reaction into a high-alumina (A1O3) crucible, because implies a slow cooling, with the reaction into a Platinum crucible cooled into an ice bath. When the cooling of the products is made into an ice bath (4°C media), a different effect from the air (for the alumina crucible) in the formation of crystalline phases is observed, having a wider range of different crystalline phases in the case a high alumina crucible. The cooling velocity effect was observed in the x-ray diffractograms; for the products cooled in ice bath, some displacements of the experimental x-ray patterns related to the powder diffraction files (PDF) were observed, and in the case of the alumina crucibles, results were aligned with PDF files. For the case of the platinum crucible, an isostructural compound related with $\text{Ba}_2\text{Mg}_2\text{O}_3$ structure was obtained; also, the formation of an isostructural solid solution (Sc:SbO3) in the planes: (110), (101), (200), (111), (210), (211), (220), (002) and (112), with rutile type structure. Due to the size of the ionic radii of $\text{Sc}^{3+}$ and $\text{Sb}^{3+}$ a cationic substitution of $\text{Sc}$ by $\text{Sb}$ forms the solid solution. Cooling rate had a great effect in the stability of the solid solution since when the samples were cooled into the high alumina crucibles this phase disappeared by the lack of conditions to its stability.

A magnetic characterization helped to know the behavior of the system, so the reaction products cooled into the ice bath were studied with an SQUID.

The samples cooled into the ice bath were analyzed by Raman spectroscopy to know the oxidation states and the coordination number of the atoms involved in the solid solution.

A variation of composition for the system $\text{Sn}_x\text{Mg}_2\text{O}_3\text{Sb}_2\text{O}_3$ was studied too, $\text{Sn}_x\text{Mg}_2\text{Sb}_2\text{O}_5$. Two compositions were used, x = 0.15 and x = 0.20. XRD was performed to characterize the products and a thermal analysis.

Changes in weight were found during the reaction period. After XRD, a change in the oxidation state of $\text{Sb}$. An oxide phase formed between $\text{Sb}$ and $\text{Mg}$ ions was found, $\text{MgSb}_2\text{O}_5$, with other antimony oxide ($\text{Sb}_2\text{O}_3$), in both cases. The increase in weight is due to the change in the oxidation state of $\text{Sb}$ and to an amount of oxygen entered to the system. Thermal analysis detected the total change in weight.

CM01.09.08
Temperature Dependence of the Ionic Conduction in the Dy$_{3-x}$Sc$_x$TaO$_7$ (0 < x < 0.2) Solid Solution Jesús E. Ortega, Jesús Arenas, Gustavo Tavízón and José Francisco Gómez; Universidad Nacional Autónoma de Mexico, Ciudad de Mexico, Mexico.

The defect fluorite related crystal structures poses a very wide variety of interesting properties, like structural and electronic [1], some compounds with this crystal structure are ionic conductors. The recent interest in novel ionic conductor materials has been increased in recent years due the development of new devices for some applications like gas sensors or in electronic industry. The novel polycrystalline solid solution Dy$_{3-x}$Sc$_x$TaO$_7$ (0 ≤ x ≤ 0.15) was obtained by standard solid state reaction technique and single-phase compositions formation were confirmed by X-ray diffraction studies. Structural characterization of compounds was made using Rietveld refinements. The electrical measurements were carried out using complex impedance spectroscopy in a wide range of frequencies (102 – 107 Hz) in the 250 °C – 650 °C temperature range, also the electrical measurements were carried out in dc experiments to compare the data. The impedance spectra were modeled using equivalent circuits and the dc conductivity shows an Arrhenius-type behavior. The frequency dependence of the ac conductivity obeys the Jonscher universal power law[2]. The results of the activation energy values obtained for the ac measurements and the behavior of the critical exponent show that the mechanism of electrical conduction is ionic and the charge carrier is the (O2-) oxygen ion. Also, we have found two temperature regions of ionic conduction, the intrinsic and the extrinsic region, differentiate by a change in the activation energy and the critical exponent value.

Effect of Cl on the Hydroxylated CrO$_{3}$ Protective Layer of Stainless Steel Kofi Oware Sarfo1, Pratik V. Murkute1, Julie D. Tucker1, Linsey Arnadottir1, Burkan Isgor1 and Yongfeng Zhang2; 1Oregon State University, Corvallis, Oregon, United States; 2Idaho National Lab, Idaho falls, Idaho, United States.

The stainless steel is important materials for nuclear industry applications and is extensively used in light water reactor systems (LWR). The corrosion resistance of stainless steel is attributed to presence of chromium which segregates to the surface to form Cr$_{2}$O$_3$, a strong passive layer that provides corrosion protection for the material. Understanding the surface chemistries of these oxide layers in different conditions provides an essential insight into the stability of these protective layers. Chlorides and other aggressive ions are often part of the water chemistry surrounding stainless steel, but these ions can lead to a breakdown and loss of passivity. In this work, we used density functional theory (DFT) to examine the interactions of chlorine (Cl) and adsorbed water on Cr$_{2}$O$_3$. The work is intended to provide models of the Cr$_{2}$O$_3$ surface in the presence of Cl. Structural and electronic properties of the Cr$_{2}$O$_3$ terminated surfaces but do not affect the order of the most to least stable configurations. However, the inclusion of implicit water decreases the Cl-interactions with the O-terminated surface. This is because the O-terminated surface is slightly more stabilized by the implicit solvent than the Cr and Cr-O terminations. Theoretical and experimental studies suggest this can be modeled using equivalent circuits and the dc conductivity shows an Arrhenius-type behavior. The frequency dependence of the ac conductivity obeys the Jonscher universal power law[2]. The results of the activation energy values obtained for the de measurements and the behavior of the critical exponent show that the mechanism of electrical conduction is ionic and the charge carrier is the (O2-) oxygen ion. Also, we have found two temperature regions of ionic conduction, the intrinsic and the extrinsic region, differentiate by a change in the activation energy and the critical exponent value.

Sintering Behavior, Microstructure and Microwave Dielectric Properties of Novel Temperature Stable Li$_3$Mg$_2$NbO$_8$-TiO$_2$ Composite Ceramics Gang Wang and Huaiwu Zhang; State Key Laboratory of Electronic Thin Films and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China.

A novel series of temperature stable Li$_3$Mg$_2$NbO$_8$-xTiO$_2$ ceramics were prepared by the conventional solid-state route. The effects of TiO$_2$ addition on the sintering behavior, phase composition, microstructure and microwave dielectric properties were investigated systematically. The dense microstructure could be obtained in low TiO$_2$ content (x=0.1) samples sintered at 1100 °C. The dielectric constant $\varepsilon_r$ was attributed to the bulk density and TiO$_2$ content.
The variation in $Q \times f$ values is related to the bulk density, and improved $Q \times f$ values could be obtained for Li$_3$Mg$_2$NbO$_6$–0.1TiO$_2$ ceramics. The quality factor $Q$ had a maximum for $x = 0.1$ and the resonant frequency ($f$) value shifted towards positive direction with the increase of TiO$_2$ addition. Notably, Li$_3$Mg$_2$NbO$_6$–0.1TiO$_2$ ceramics sintered at 1100 °C possessed excellent microwave dielectric properties: $Q \times f = 74,000$ GHz, $T_e = -3.4$ ppm/°C, which made the ceramics as promising low loss and temperature stable candidates for millimeter-wave applications.

CM01.09.11

Ternary Vanadium Oxide Bronzes as a Palette for Imagining Metastable Cathode Materials with Improved Multivalent-Ion Storage Capacities

Justin L. Andrews and Sarbajit Banerjee; Texas A&M University, College Station, Texas, United States.

The discovery and investigation of metastable materials has only sparsely sampled the available design space. In this contribution, we explore a systematic approach to identifying metastable phases of interest in the vanadium-oxygen system. In particular, we report on the successful stabilization of several novel polymorphs and discuss their subsequent utilization as cathode materials in Li- and multivalent-ion batteries. A detailed elucidation of structure-function relationships that underpin their much-improved performance over the thermodynamically stable sink of the system, $\alpha$-V$_2$O$_5$, has been performed based on structural characterization, elucidation of electronic structure, and first-principles calculations of diffusion pathways. The first example, $\zeta$-V$_2$O$_5$, can be topochromically stabilized from the ternary quasi-1D $\beta$-M$_n$V$_2$O$_6$ tunnel bronze and has been demonstrated to be far superior to its thermodynamically stable counterpart as a cathode material in both Li- and Mg-ion batteries. In particular, metastable $\zeta$-V$_2$O$_5$ overcomes several challenges associated with $\alpha$-V$_2$O$_5$, mitigating irreversible structural transitions and polaronic confinement effects that are a severe constraint on electrode applications of the thermodynamically stable phase. Mitigating these challenges allows for the unprecedented, fully reversible insertion of up to 3 Li$^+$ per V$_2$O$_5$ as well as the highly reversible insertion of 0.33 Mg per V$_2$O$_5$ at moderately high operating voltages. In a second example, metastable $\gamma$-V$_2$O$_5$ can be stabilized from the ternary $\gamma$-Li$_2$V$_2$O$_6$ phase and shows promising initial results as a cathode in both aqueous and non-aqueous Mg- and Ca-ion batteries. The role of metastability is central to explaining the improved performance of these metastable polymorphs and thereby insight gleaned from a fundamental evaluation of the origins of this behavior provides a glimpse into the importance of structure-function relationships and crystal structure motifs as they relate to metastability, further establishing the potential use of metastable materials as synths for accessing undereexplored compositional space.

CM01.09.12

Interfacial Oxidation and the Photoluminescence of InP-Based Core/Shell Quantum Dots

Michaël Tessier2, Edwin Baquero1, Dorian Dupont1, Valeria Grigel1, Yannick Coppél1, Zeger Hens2, Céline Naryal1 and Fabien Delpech1; 1Laboratory of Physics and Chemistry of Nano-Objects, INSA Toulouse, Toulouse, France; 2Ghent University, Ghent, Belgium; 3Laboratoire de Chimie de Coordination, Toulouse, France.

CdSe based QDs have been intensively studied, however, due to their toxicity Cd-based materials are not acceptable for real-life applications. Indium phosphide (InP) based QDs represent the most advanced alternative without toxic heavy metals. Nevertheless, for industrial applications, the photoluminescence quantum yield (PLQY) and the emission linewidth (FWHM) of InP QDs have to be significantly improved. The analysis of InP specificities shows that in contrast to their CdSe analogues, the InP QDs suffers from a high oxophilicity. This leads a strong tendency to oxidize and results in the formation of an amorphous phosphate layer at the surface of the InP QDs either during the synthesis or the shelling (often with ZnS). The role and the influence of this oxidation on the optical properties (PLQY and FWHM) is still a matter of controversy and the definitive answer has so far been precluded because of the lack synthesis method allowing the access to comparable oxide-free samples. In this presentation, we will describe our new approach to prepare oxide-free InP core and InP/ZnS core/shell QDs. Then, we will compare the structural (using XRD, TEM, MAS NMR) and the optical properties (UV-Vis and PL) of oxidized vs. oxide-free samples. The use of the same InP QDs core for the preparation of the samples provides fully comparable data and will thus allow unraveling for the first time the influence of phosphate at the core/shell interface.

CM01.09.13

Characterization of Crystalline Defects Studied by STEM-in-SEM

Chunyang Zhang1, Jean-Claude Menard2, Julien Guyon1, Jean-Jacques Fundenberger1, Yudong Zhang1, Emmanuel Bouzy1, Cécile Hébert4 and Antoine Guitton1; 1Université de Lorraine, CNRS, Arts et Métiers ParisTech, Metz, France; 2AHEAD Microscopy, Bois d’Arcy, France; 3Labex Damas, Université de Lorraine, Metz, France; 4EPFL-LSME, Lausanne, Switzerland.

Mechanical tests followed by microstructural investigations provide engineers information to computationally predict the mechanical performance of components. Electron microscopy is one of the most well-known techniques for analyzing deformation features of materials allowing understanding their response to exterior solicitations [1]. Two kinds of electron microscopes are generally used and bring complementary information: at macro/meso-scopic scale, Scanning Electron Microscopy (SEM) and at micro/nano-scale, Transmission Electron Microscopy (TEM) [2,3]. Weak Beam Dark Field (WDBF) is a TEM techniques allowing fine characterization of dislocations [4]. Such comprehensive dislocation studies at microscopic scale bring valuable information for understanding macroscopic mechanical response of materials [5]. Full characterization of dislocations is not only synonym of TEM experiments. SEM can access diffraction contrast with Scanning Transmission Electron Microscopy in a SEM (STEM-in-SEM). Briefly, this technique is based on the classical STEM (in a TEM) [6]; the electron beam is scanned and diffraction contrast allows observing defects. Diffraction patterns are acquired from domains below 10 nm in diameter [7]. In this framework, we report here technological challenges such as detector development and sample holder design will be presented. Moreover, first dislocation analyses, which clearly show the full potentialities of this new characterization technique will be discussed.

Computationally Aided Discovery of Layered Quinarian Oxyselenoginide P-Type Transparent Conductors

Benjamin A. Williamson3, 2, Gregory J. Limburn1, Geoffrey Hyett1 and David O. Scanlon1, 2, 4; 1Department of Chemistry, University College London, London, United Kingdom; 2Thomas Young University College London, London, United Kingdom; 3Department of Chemistry, University of Southampton, Southampton, United Kingdom; 4Diamond Light Source Ltd., Diamond House, Didcot, United Kingdom.

Despite the major advances in n-type transparent conducting oxides (TCOs), the scarcity and performance of an equivalent p-type TCO has been a stumbling block for the opto-electronics industry for decades. Solid design principles such as the ‘chemical modulation of the valence band’, where the Cu
Composite materials usually exhibit the combined physical properties of their constituents. The result is a material that is superior to conventional monolithic materials. Advanced composites are used in a variety of industrial applications and therefore attract much scientific interest. Here we report on the formation of novel carbon-based nanocomposites via incorporation of graphene oxide (GO) into the crystal lattice of single crystals of calcite (1). Incorporation of a 2D organic material into single-crystal lattices has never before been reported. The resulting nanocomposites were characterized utilizing state-of-the-art characterization techniques such as high-resolution synchrotron powder X-ray diffraction, electron microscopy, aberration corrected high resolution transmission electron microscopy, fluorescence microscopy and nanoindentation tests. Our results show that GO sheets can indeed become incorporated into calcite single crystalline hosts, allowing for the fabrication of graphene-based composite materials with enhanced properties. A detailed analysis reveals a layered distribution of GO sheets entrapped within the calcite host. Moreover, the optical and mechanical properties of the calcite host are altered when a carbon-based nanomaterial is introduced into its lattice. Carbon-based calcite single crystals exhibit new optical properties: in contrast to pure calcite, the hybrid crystals become fluorescent and are spectroscopically characterized by the presence of three lifetimes, one of which is considerably longer than that observed for bare GO in solution. Nanoindentation tests demonstrated that relative to pure calcite the composite GO/calcite crystals exhibit lower elastic modulus and higher hardness.

The results of this study demonstrate that the incorporation of a 2D material within a 3D crystalline lattice is not only feasible but can also lead to the formation of hybrid crystals exhibiting novel properties.

Cationic Impurities Modifications of Mayenite Nanocages—Interpretations from DFT Calculations Jian Huang1,1, Loredana Valenzano2 and Gaurav Sant3, 1Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China; 2Department of Chemistry, Michigan Technological University, Houghton, Michigan, United States; 3Department of Civil and Environmental Engineering, University of California, Los Angeles, Los Angeles, California, United States.

Mayenite (i.e., Ca12Al4O33, C12A7), and more specifically its electrode form (C12A7-e-) has attracted attention as a functional material which shows high ionic conductivity, and for its potential in oxidation catalysts, fuel cells, and hydrogen storage. In contrast to anionic substitutions into C12A7, less is known about the effects of cationic substitutions on the properties of C12A7. This study applies DFT methods to rigorously understand the influences of Mg2+, Cu2+, Sr2+, Fe3+, Ir4+, P5+ and V5+ impurities on the structural and electronic features of C12A7 and its electrode variant. Broadly, the presence of impurities and their relation to their ionic radii are noted to influence the lattice parameters and altering charge localization. Impurities also effect mayenite’s cage framework with a major influence in the ‘window’ connecting two adjacent cages. Since the cage conduction band (CCB) depends are related to the presence of framework’s electrons changes into the ‘window’ is considered as a critical factor able to influence conductivity. Different dopants can differently influence the behavior of the trapped anionic electrons. While Mg2+, Sr2+, P5+ and V5+ impurities can still maintain their F+-like attractors nature, Cu2+, Fe3+ and Ir4+ neutralize such a tendency in the cages of electrode. This corresponds to change the conduction mechanism of electrode mayenite from that of hopping electrons to that of band conduction electrons. In other words, the s-electrons are now diffuse over the cages. Interestingly, the insertion of Cu-impurities results in the ‘window’ between two cages to collapse and inducing the formation of a transport channel between two neighboring (Ca-Al-O) cages across the localized interstitial electrons. Such an observation is confirmed by the analysis of electron-localization functions (ELF), procrystal, and non-covalent interactions (NCI) indices. This suggests new means to induce electron coupling between nearest neighbor cages. This last aspect is of particular interest for the engineering of electronic transport properties of mayenite-like electrodes.

CM01.09.17

Synthesis, Characterization and Magnetic Behavior of α-Fe2O3 and α-Cr2O3 Nanoparticles and Their Composites with Graphite, Graphene and Graphene Oxide—Memory and Exchange Bias Effects Paloma Almodovar1, Carlos Diaz-Guerra1, Julio Ramirez Castellanos2 and José María González Calbet2, 1Departamento de Física de Materiales, Facultad de Ciencias Físicas, Universidad Complutense de Madrid, Ciudad Universitaria, Madrid, Spain; 2Departamento de Química Inorgánica, Facultad de Ciencias Químicas, Universidad Complutense de Madrid, Ciudad Universitaria, Madrid, Spain.

Nanocomposites of transition metal oxides with graphene or graphene oxide (GO) have recently received much attention for applications in Li ion batteries (LIBs), supercapacitors, solar cells and photocatalysis. The development of such applications requires new strategies to synthesize these nanocomposites and a detailed characterization of their physicochemical properties. Hematite (α-Fe2O3) is a widely studied semiconductor because of its availability, low environmental impact and corrosion resistance. Cr2O3 is a wide band gap (~3.2 eV) semiconductor with potential uses in LIBs, optical, electronic and magnetic devices. Due to its high specific surface area and electrical conductivity, graphene appears to be an ideal adjuvant for α-Fe2O3 and Cr2O3 to improve their capacity and cycling stability in LIBs anodes.

In this work, α-Fe2O3 and Cr2O3 nanoparticles and their composites with graphite, graphene and GO, were synthesized by a wet chemistry method of hydroxide precipitation at low temperature. The morphology, structure, composition and electronic properties of the samples were investigated by X-ray
Effects of Excess Electrons on the Structure of BiVO₄

As-grown α-Fe₂O₃ nanoparticles show a good crystallinity and an average size of 5 nm, as revealed by HRTEM. Raman and XRD measurements indicate that the synthesis route critically determines the crystallinity and phase composition of the final products. A homogeneous distribution of the nanoparticles on the graphene/GO/graphite sheets was revealed by SEM, EDS and TEM observations. Oxygen 1s core level XPS spectra reveal the existence of oxygen vacancies in the nanocomposites. DC and AC magnetization measurements reveal a superparamagnetic behavior with strong dipolar interactions between the hematite particles in all the samples investigated. Moreover, zero field cooled memory experiments of the thermal variation of the magnetization allowed us to confirm that both the hematite nanoparticles and their composites with graphene and graphite show superspin-glass behavior. The as-grown Cr₂O₃ nanoparticles show dimensions between 15 and 30 nm. Raman measurements indicate that the synthesis route determines the crystallinity of the Cr₂O₃-based nanocomposites, which show superparamagnetic behavior and exchange bias effects according to SQUID magnetometry results. The exchange bias field is as high as 3200 Oe in graphite nanocomposites. Correlation of the obtained results with XAS measurements of the C 1s edge suggests orbital hybridization and electron sharing at the C-Cr₂O₃ interface.

CM01.09.18
The Role of Hydrogen in the Persistent Photoconductivity in Strontium Titanate Zhisong Zhan¹ and Anderson Janotti²; ¹Department of Physics and Astronomy, University of Delaware, Newark, Delaware, United States; ²Department of Materials Science and Engineering, University of Delaware, Newark, Delaware, United States.

Strontium titanate (SrTiO₃ or STO) is a wide band-gap material (3.25 eV at room temperature) with potential applications in oxide-based electronic devices, such as resistive switching memory. Extremely long persistent photoconductivity (PPC) at room temperature has been observed in annealed strontium titanate single crystals under sub band gap light excitation [M. C. Tarun, F. A. Selim, and M. D. McCluskey, Phys. Rev. Letters, 111, 187403 (2013)]. Annealing studies indicate that hydrogen impurities as well oxygen and strontium vacancies are involved in this effect. Using electronic structure calculations based on density functional theory (DFT) we investigate possible mechanisms behind the PPC effect. We consider both interstitial and substitutional configurations in different charge states, as well as the possible participation of oxygen and strontium vacancies. We present results for formation energies, migration energy and optical absorption peak position due to defects. The results are then used to explain the experimental observations.

CM01.09.19
Effects of Excess Electrons on the Structure of BiVO₄ Iflah Larabi¹, Marciano A. Carneiro² ¹ and Anderson Janotti²; ¹University of Delaware, Newark, Delaware, United States; ²Universidade Federal Fluminense, Rio de Janeiro, Brazil.

Among the available photoelectrochemical materials, BiVO₄ has huge potential to be utilized as a cheap and efficient material. Precisely knowing its band gap and understanding of electron transport in BiVO₄ are crucial for improving its performance, but both aspects of the material are debated, mainly due to its two extant different phases which have similar structures and are close in energy. We use density functional calculations with the PBE, meta-GGA SCAN, and hybrid functionals to study the stability of the different phases of BiVO₄, the effects of excess electrons in its conduction band, changes in local structure with excess electrons, and the possibility of carrier localization through electron-small polaron formation. The obtained results are compared to previous calculations and available experimental data.

CM01.09.20
Synthesis and Characterization of Mayenite Electride - Ti Composites for Thermionic Electron Emission Applications Adam Kuehster¹, Bao Nguyen¹, Luke Uribarri², Gautham Ramachandran¹, John Williams¹ and Kaka Ma¹; ¹Colorado State University, Fort Collins, Colorado, Colorado, United States; ²Lockheed Martin Corporation, Bethesda, Maryland, United States; ³Lockheed Martin Space Systems Company, Palo Alto, California, United States.

Mayenite (12CaO·7Al₂O₃ or C12A7), a typical electrical insulator, can be converted into an electro-active functional material, i.e., mayenite electride (C12A7:2e⁻), with a low work function, chemical inertness, and superconductivity at low temperatures. Mayenite electride has attracted extensive interests due to its application as inexpensive thermionic emission sources. However, pure mayenite electride exhibits brittleness, low fracture strength, and poor machinability. Thus, it is in demand to explore composite materials, such as a mayenite electride-titanium (Ti) composite, that will overcome these drawbacks while retaining the low work function characteristic of the mayenite electride. In the present work, C12A7:2e⁻ - Ti composites (50:50 wt%) were synthesized in a single step via electric field assisted sintering (EFAS). The microstructures of the composite consist of some other calcium aluminate phases (e.g., Ca₅Al₂O₇) in addition to C12A7:2e⁻ and Ti phases. The work function of the composite is approximated 2.5 eV evaluated by thermionic emission current measurement.

CM01.09.21
Structural and Magnetic Behavior in Rhenium-Based Double Perovskites Fang Yuan and Corey Thompson; Purdue University, West Lafayette, Indiana, United States.

Double perovskites, A₂B'B''O₆, have been intensely studied due to their interesting chemical and physical properties. The different B-site cations combination allows for a wide range of novel materials with unique magnetic behavior, from ferromagnets to spin glasses. Our current work is focused on the synthesis, structure, and magnetic properties of Re-based double perovskites, La₂B'ReO₆ (B' = Mg, Co, and Ni). All phases adopt the monoclinic P2₁/c crystal structure and are paramagnetic above room temperature. The Co-and Ni-analogs are ordered below 250 K, while the Mg-analog shows no magnetic phase transition down to 2 K. These results and a comparison to their ruthenium and osmium analogs will be presented.

CM01.09.22

The quantification of atomic transport processes such as solid-state diffusion is important for controlling the processing, properties, and stability of solids in general. Measurements on bulk solids have provided a wealth of information on the nature of diffusing species (vacancies, interstitials, etc.) and their mobility, but it is uncertain to what extent these properties may be extrapolated to the nanoscale. The relative dearth of experimental methods for determining these properties in nanostructures complicates this question.

In this work we use the Pb₅Sb₃Cs cation exchange reaction to quantify the kinetics of ion diffusion in core-shell nanoparticles. Pb₅Sb₃Cs-poor nanocrystals (NCs) provide an ideal model system due to their well-established synthetic chemistry and their relatively simple structure, which facilitates structural
interrogation. Using in-situ x-ray diffraction of 7 nm-diameter PbS NCs as they undergo cation exchange to CdS, we have identified that three processes are important in the conversion of the NCs: an initial surface reaction (chemisorption of Cd) which imposes significant inhomogeneous strains on the underlying PbS; the exchange of the first underlying atomic layer(s) of the NC; and a diffusion-controlled growth of a thick zincblende-phase CdS shell. Quantification of the kinetics of shell growth based on a shrinking-core model show that the activation energy for chemical diffusion of the rate-limiting species lies in the range of 110 kJ mol$^{-1}$, which is in good agreement with prior measurements of the energy of interstitial self-diffusion in bulk CdS. This suggests that, at least for diffusion lengths longer than 1-2 nm, energies of point defects in these simple ionic solids may not be greatly perturbed by the presence of a nearby surface, even under large chemical potential gradients.

Finally, we also discuss some structural peculiarities of these NCs. Previous suggestions of the existence of a metastable rocksalt CdS phase during shell formation are not supported by our experimental results, as we observe a monotonic change in the relative diffraction intensities to those consistent with zinblende CdS, a trend opposite to that expected in rocksalt phase formation. Additionally, an apparent symmetry breaking of the structure of the PbS/CdS NCs (loss of cubic structure) is evidenced by anomalous peak shifts in the diffraction patterns. We show this phenomenon does not indicate a true distortion of the unit cells, and account for it in terms of the kinematical diffraction theory supported by Debye scattering equation simulations. The interfered, of diffracted waves from octahedral Pb and tetrahedral Cd sublattices, which are displaced relative to each other by a non-integer multiple of the unit cell along key directions, is sufficient to give rise to substantial apparent peak shifts. This diffraction effect will be important in reflecting on previous observations of “symmetry breaking” in nanoparticles in general.

**Dynamic Structural Changes upon Hydrogenation and Dehydrogenation of Mg-Nanoparticles by In Situ Transmission Electron Microscopy and Electron Tomography**

Jochen A. Kammerer$^1$, Xiaoyang Duani$^2$, Frank Neubrech$^2$, Rasmus Schroeder$^1$, 4, Laura Na Liu$^2$, 3 and Martin Pfannmüller$^1$.$^1$Department of General Studies, Tangntional University, Heidelberg, Germany; $^2$Kirchhoff-Institute for Physics, Heidelberg University, Heidelberg, Germany; $^3$Max Planck Institute for Intelligent Systems, Stuttgart, Germany; $^4$Cryo Electron Microscopy, Heidelberg University Hospital, Heidelberg, Germany.

A theoretical capacity of 7.6 wt% hydrogen and favorable hydrogen desorption kinetics turn Mg-based nanomaterials into promising candidates for solid state hydrogen storage$^1$. Furthermore, the excellent plasmonic properties of Mg and the transition to dielectric MgH$_2$ enable dynamic photonic applications$^2$. Hydrogenation and dehydrogenation are accompanied by large volumetric expansion and shrinkage leading to drastic structural changes and thus alter (de)hydrogenation kinetics and plasmonic properties. To be able to steer Mg behavior it is of utmost importance to understand these changes at nanoscale and below. Here, we use Mg nanoparticles (NPs) preparation by electron lithography, which are reproducible in size and shape. This allows a meaningful comparison of pristine and dehydrogenated NPs depending on size. We demonstrate that radiation induced dehydrogenation process and accompanied structural alterations lead to long-term reorganization of the Mg nanostructure. Time resolved electron energy loss spectroscopy and electron diffraction in the transmission electron microscope were used together with time and spatially resolved electron spectroscopic imaging to visualize the dynamic changes of MgH$_2$ and Mg from characteristic bulk and surface plasmon excitations. Furthermore, three-dimensional analysis by electron tomography enables the detailed observation of voids that are formed during dehydrogenation. We investigated Mg NPs with diameters from 100 nm to 350 nm and 40 nm in thickness, covered by 2 nm Ti and 3 nm of catalytic Pd. Volume expansion during hydrogenation and mechanical constrains in $x$-$y$-direction frequently cause twinning in the hydridate, especially in large NPs. Interestingly, the size of the twins clearly exceeds the grain size of pristine NPs. Shrinkage during dehydrogenation is accompanied by the formation of faceted cavities, visualized through the excitation of surface plasmons within the NPs. Surface energy reduction driven coarsening of the initially fine cavity network continues for several days at room temperature after complete dehydrogenation. Thereby, ripening of the network slows down in small NPs faster than in large ones. The transformation to Mg is observed to be rather governed by a large number of small nuclei with a low growth rate than a small number of fast growing nuclei. Our results contribute to understanding the influence of defect structures and orientation relationship between Mg and MgH$_2$ on the structure of the corresponding NPs. The presented methodology and results will enable defined experimental designs to reveal the dynamic processes in MgH$_2$ particles and related structures. Such insights will crucially influence the optimization of materials parameters that determine applications in nanophotonics and hydrogen storage.

**CM01.09.24**

**DFT+DMFT Study on the LaTiO$_3$/LaAlO$_3$ Superlattice—Magnetic Properties near Metal-Insulator Transition**

Jae-Hoon Sim$^1$, Hunpyo Lee$^2$ and Myung Joon Han$^1$; $^1$Department of Physics, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); $^2$School of General Studies, Kangwon National University, Samcheok-si, Korea (the Republic of).

The strongly correlated electron system is of central importance in the condensed matter physics. Among the correlated materials, transition-metal oxide superlattices are extensively studied, due to their novel characteristics and potential applications. The electronic and magnetic properties can be significantly different from their bulk counterpart, showing unexpected interface phenomena, e.g., magnetism, high-temperature superconductivity, correlation induced metal-insulator transition. Importantly, due to the strong couplings in TMO between the charge, spin, orbital, and lattice degrees of freedom, the material properties can be controlled by external perturbations, e.g., pressure, electric/magnetic field, or strain.

Motivated by the previous experiment and density functional theory+U (DFT+U) results$^1$, 2, we have studied LaTiO$_3$/LaAlO$_3$ superlattice. From the previous theoretical study, it was found that the magnetic transition from the ferromagnetic-spin/antiferro-ortorial order to the antiferromagnetic-spin/ferro-orbital phase induced by epitaxial strain. This magnetic transition is not observed in the bulk LaTiO$_3$ compound. While the standard DFT and DFT+U are successful methods to describe real materials, correlated materials are not properly treated with this method, especially near the transition point. To overcome the technical limitation, we performed dynamical mean-field theory calculations combined with the density functional theory, which is one of the successful approaches to study these systems. Under epitaxial tensile strain, we observed unexpected insulator-to-metal transition, followed by magnetic transition$^3$. Our findings demonstrate that not only magnetic but transport properties can be controlled by strain.

We also present the implemented DFT+DMFT method based on the non-orthogonal pseudo-atomic orbitals (PAOs) basis DFT code, OpenMX$^4$. Newly developed methods for analytic continuation, so-called maximum quantum entropy method$^5$, is applied to obtain resulting spectral functions.

Highly-Ordered Hollow Nanochanneled-Silica Nanospheres Prepared Using Sacrificial Copolymer Nanospheres

Yong Ku Kwon, Hyun Jun Lim, Seho Kwon, Minkee Lee and Tae-Yang Jeong; Inha Univ, Incheon, Korea (the Republic of).

Monodisperse hollow mesoporous silica nanospheres were synthesized based on the cationic colloidal polymeric nanospheres. The nanospheres were prepared by the surfactant-free emulsion copolymerization of styrene and butyl acrylate in the presence of a cationic monomer, methacryloyloxyethyl trimethyl ammonium chloride using azobisisobutyramidine hydrochloride as an initiator. The charged polystyrene nanospheres were dispersed in water and mixed with cetyltrimethylammonium bromide and ammonium hydroxide in ethanol. Tetraethylorthosilicate as a negatively charged silica precursor was then added dropwise to achieve rapid hydrolysis onto the cationic surfaces of colloidal particles and allow mesoscopic ordering of the co-self-assembly of tetraethylorthosilicate and cetyltrimethylammonium bromide on the shell phase. The samples were then heated to 600°C to remove the colloidal template, resulting in monodisperse hollow mesoporous nanospheres. These nanospheres were characterized by transmission electron microscopy, scanning electron microscopy, X-ray diffraction.

CM01.09.26

Synthesis, Optical and Structural Properties of Copper Sulfide, Cadmium Sulfide and Lead Sulfide Nanocrystals for Use in Quantum Dot Sensitized Solar Cells

Peter A. Ajibade; University of KwaZulu-Natal, Pietermaritzburg, South Africa.

Quantum dot sensitized solar cells (QDSSC’s) have attracted numerous research interest in the past decades as alternative to silicon based photovoltaic devices. It has emerged as promising agent in solar energy conversion due to its size-dependent optoelectronic characteristics, facile and low cost fabrication techniques.\(^1\). Their tunable bandgaps, high extinction coefficients, multiple exciton generation effect and large intrinsic makes QDSSC’s distinctive solar cells\(^2\). In this paper, copper(II), cadmium(II) and lead(II) dithiocarbamate complexes were synthesized and characterized by elemental analysis, thermal gravimetric analysis, mass spectrometry, \(^1\)H and \(^13\)C-NMR spectroscopy. The complexes were used as single source precursors to prepare oleyamine, TOPO and HDA capped quantum dots at three different temperatures. The structural properties of the quantum dots were established using FeSEM, HRTEM, FTIR, EDS and XRD. Absorption and photoluminescence spectroscopy was used to study the optical properties of the as prepared quantum dots. HRTEM images shows quantum dots with particle size in the range 4 - 9 nm. The potential of the quantum dots as sensitizers in solar cell fabrication are being evaluated.

Computational Discovery of Novel Structural and Functional Heusler Compounds

Christopher Wolverton; Northwestern University, Evanston, Illinois, United States.

Heusler compounds are being widely studied for their potential usage in spintronics, shape-memory devices, superconductors, thermoelectrics, topological insulators, etc. The crystal structure and its variants are ubiquitous, with more than 1000 Heusler compounds being reported. However, the phase space for possible Heusler compounds is orders of magnitude larger, raising the real possibility that many new, stable Heusler compounds are still awaiting discovery. We demonstrate a high-throughput computational DFT screening approach for ~200,000 potential Heusler compounds, and use this method to predict hundreds of new stable and metastable Heusler compounds, which we further examine for interesting functional properties. We highlight three distinct examples of computational discovery of Heusler compounds, demonstrating the extraordinary diversity of properties possible with this single structure type: efficient thermoelectrics, off-stoichiometric semiconducting Heuslers, and strengthening precipitates in bcc metals.

8:30 AM CM01.10.02

Predicting the Thermodynamic Stability of Perovskite Oxides Using Machine Learning Models

Wei Li, Ryan Jacobs and Dane Morgan; University of Wisconsin-Madison, Madison, Wisconsin, United States.

The thermodynamic phase stability of a perovskite is a key materials property, the value of which may determine the utility of the perovskite in the given application of interest. The stability typically correlates at least loosely with whether a perovskite is synthesizable, as well as whether it may be expected to degrade (or remain stable) over time under some operational environment, such as a specific working temperature or partial pressure of oxygen. Of the numerous materials families investigated with high throughput DFT methods,\(^1\)\(^2\) perovskite materials stand out as a particularly challenging class of materials for computational screening and property evaluation.\(^3\) When one accounts for the large number of different A- and B-site elements, as well as different typical dopant ratios and combinations, the potential number of unique perovskite compositions may be easily greater than \(10^5\) materials, the full space of which cannot be currently assessed experimentally or with DFT. Accurate machine learning model predictions for a material can be orders of magnitude faster than the corresponding DFT simulations or experiments, allowing them to be used to quickly understand trends in materials properties and inform materials discovery.\(^4\)

In this work, we used machine learning models to predict the stability of a set of nearly 2000 perovskite oxides from the work of Jacobs, et al.\(^3\) We first constructed a set of features based on the properties of the constituent elements of each perovskite composition and well-known empirical perovskite structural descriptors, and performed feature selection routines to select the set of features which produced the best predictions of material stability without significant overfitting. We performed both binary classification (to determine whether material is expected to be stable or unstable) and regression (to predict a numerical value for stability as an energy above the convex hull), and found that an extra trees classifier and kernel ridge regression model performed the best for classification and regression, respectively. The best F1 score for classification was 0.881 (+/- 0.032) and RMSE score for regression
Energetic Upper Bound for Synthesis of New Materials

Muratbahan Aykol, Shyam Dwaraknath, Wenhao Sun and Kristin A. Persson; Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Laboratory synthesis of new functional inorganic materials, in particular the metastable ones, designed or discovered on the computer or suggested by theorists is a significant hurdle in materials science. To bridge this gap between computational and experimental worlds, we introduce a new thermodynamic upper bound on the energy scale for the creation of metastable crystalline polymorphs that is based on the entropic dominance of amorphous form of materials. This “amorphous limit” can be computed from first-principles and is found to be remarkably accurate and very sensitive to chemistry and composition in classifying hundreds of inorganic materials in the Materials Project database, from oxides to nitrides to sulfides, as synthesizable or not. The limit is expected to replace constant common, heuristic energetic limits or intuition often used as guidelines in filtering computed materials in materials screening for functional applications.

Structural and Thermodynamic Effects in High Entropy Oxides

Colin Freeman1; Gautam Anand2; Christopher M. Handley1; John H. Harding1 and Derek Sinclair1;
1University of Sheffield, Sheffield, United Kingdom; 2University of Warwick, Coventry, United Kingdom.

The functional ceramics community is increasingly exploring complex solid solutions containing multiple cations [1,2] to generate the desired properties and to avoid the need for rare or expensive dopants. These multi-component systems no longer possess regular, periodic lattices with occasional point defects but show variable stoichiometry over nanometre scales, regions of disorder and cluster formation. These features are likely to be key to the properties. Because of the heterogeneous nature of these systems their characterisation can be very challenging as the bulk response must be an average of the different configurations present. Fabrication is also hindered as we move away from conventional processing where enthalpy is the dominant factor and must contend with entropic contributions.

We have performed a range of classical atomic scale simulations to study these systems. These are ideal tools as the atomic level detail explores the local relaxations that can occur around particular atomic configurations and identify issues of clustering. The relatively low cost of the simulations also means it is possible to look at multiple large cells providing the opportunity to actually sample the configurational variation that is present.

Our simulations examine the recently reported high entropy oxide system (Mg,Co,Ni,Cu,Zn)O [3]. We demonstrate that these phase is entropically stabilised over the enthalpy penalty of mixing. By sampling an ensemble of configurations we are able to consider some the average structural and property features the material exhibits and comment on how mixing influences the local atomic behaviour. We also explore the formation of defects and how these might disrupt the material.

Theoretical and Experimental Studies on the Mixed Chalcogenide Phases Sb2Se-xTe-x and GeSe-xTe-x

Ralf P. Stoffel and Richard Drönskowski; RWTH Aachen Univ, Aachen, Germany.

Chalcogenide phases, in particular tellurides, are of enormous technological importance nowadays because they serve as, for instance, phase-change [1] and thermoelectric materials [2]. The substitution of tellurium by selenium seems a promising pathway to obtain chalcogenide compounds with new electronic properties. Here we present the results of density-functional theory-based investigations regarding the structural, lattice dynamical and thermodynamic properties of mixed chalcogenide materials in the Sb2Se-x – Sb2Te-x and GeSe-x – GeTe pseudo-binary systems compared with experimental measurements carried out by us.

Crystal structures in the system GeSe-xTe-x have been studied up to pressures above 20 GPa using synchrotron radiation at DESY, Hamburg. The results are supported by theoretical investigations, including lattice dynamical and bonding properties [3]. We found a new orthorhombic structure type forming under pressure which has not yet been reported.

In the Sb2Se-xTe-x system we investigated the crystal structure as dependent from the selenium content x [4]. We focused on the preferred incorporation of selenium into one of the two possible chalcogenide sites of the Bi2Te3 structure type which is the ambient pressure structure up to a selenium content of x = 1.8. This incorporation was investigated additionally by DFT calculation as regards its energetic landscape and the bonding properties by making use of the COHP method as implemented in the LOBSTER code [5]. Additionally, low-temperature heat capacities were measured experimentally and compared to theoretically calculated data [6] using lattice dynamical calculations and the quasi-harmonic approximation [7].

Since the 1960s, the National Aeronautics and Space Administration (NASA) has successfully utilized radiisotope thermoelectric generators (RTGs) as the primary power source for many deep space probes, landers and orbiters for many missions including Voyagers 1 and 2, Cassini and Curiosity. RTGs are commonly used when other forms of on board power are not practical due to low solar flux, day/night cycles and settling of dust, or when they would significantly enable or enhance a mission’s ability to meet its objectives. RTGs are a proven technology and have been demonstrated to have high reliability, redundancy and long life. Historically, the thermoelectric (TE) materials used in the RTGs by NASA have either been based upon Si-Ge alloys or PCTe/TAGS (tellurium, silver, germanium, antimony), with system level conversion efficiencies of −6.5%. The goal of the Advanced Thermoelectric Materials (ATOM) project in the Thermoelectric Technology Development Project at the Jet Propulsion Laboratory (JPL) is to develop TE materials that are capable of providing 20% conversion efficiency across a wide temperature range 400-1275 K. In this paper we’ll highlight the technical progress of the program and pathways to 20% efficiency. Specifically we will discuss the investigation of f-orbital chemistry on the electronic properties of La$_{3-x}$Te$_4$ and their impact on the thermoelectric figure of merit.

Antisite Pairs Suppress the Thermal Conductivity of Boron Arsenide (BAs) Qiang Zheng1, Carlos A. Polanco2, Mao-hua Du1, Lucas R. Lindsay1, Miaofang Chi3, Jiqaing Yan1,4 and Brian C. Sales1; 1Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3Department of Materials Science and Engineering, University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

As microelectronic devices become faster and smaller, materials with ultrahigh thermal conductivities (κ) are becoming important for new generation electronic devices. Recently, based on first-principles calculations, boron arsenide (BAs) with a zinc blende cubic structure was predicted to possess an unusually high κ at room temperature of over 2000 Wm$^{-1}$K$^{-1}$, comparable to that of diamond [1]. However, the experimentally measured κ of BAs single crystals was only 200–350 Wm$^{-1}$K$^{-1}$, an order of magnitude lower than the predicted value [2-4]. While theoretical calculations revealed that As vacancies even with very low concentration could significantly suppress κ [5] and X-ray photoelectron spectroscopy (XPS) studies suggested possible As-deciency in BAs single crystals [2,3], there has been no direct observation of As vacancies (V$_{As}$) in BAs crystals. Therefore, direct observation and identification of the defect types in BAs that suppress κ become quite urgent for growth of high-quality BAs crystals or films with significantly improved κ.

In this work, we use aberration-corrected scanning transmission electron microscopy (STEM) to investigate the lattice structure and possible defects in BAs single crystals at atomic scale [6]. Rather than finding V$_{As}$, as widely thought to suppress κ of BAs crystals, STEM results showed the enhanced intensity of some B columns and reduced intensity of their neighboring As columns, suggesting the presence of As$_{B}$-B$_{As}$ antisite pairs with significant concentrations. Additional calculations on formation energies confirm that such antisite pair is preferred energetically among the different types of point defects investigated. Using a concentration of 1.88(8)% (6.6±3.0×10$^{17}$ cm$^{-3}$ in density) for the antisite pairs estimated from STEM images, κ of BAs is estimated to be 65–100 Wm$^{-1}$K$^{-1}$, in reasonable agreement with the measured value. Finally, we also propose possible approaches, such as flux growth out of alkali metal-based or Ni-based melts and MBE, to achieve high-quality BAs single crystals or films with high thermal conductivity.

Overall, this combination of computational and experimental methodology offers a more rational and systematic paradigm for targeted synthesis of metal oxides. The future outlook for this “synthesis by design” approach is promising for other binary and ternary oxides with high polymorphism.

The zinc blende cubic BAs and BP, due to their potential ultra-high thermal conductivity calculated through first principle approach, have attracted significant research efforts in the past few years. The crystal growth of these materials, on the other hand, remains a challenge due to incongruent melting/peritectic decomposition nature of BAs/BP, and the low solubility of B in the common metal fluxes. Here, we reported our synthetic efforts to grow the high quality of BAs/BP crystals through chemical vapor transport/metal flux method. We obtained the single domain, and defect-free crystals of BAs and BP up to mm size, evidenced by both single crystal diffraction and scanning transmission electron microscopy (STEM) studies. More importantly, ultrahigh thermal conductivities, ~1000W/mK for BAs and ~500W/mK for BP respectively, have been achieved through time-domain thermoreflectance (TDTR) measurement. The measured experimental thermal conductivity values are also compared with theoretical calculations based on both three phonon (3ph) scattering and three+four phonon (3ph+4ph) scattering process.

Computational driven design of materials has provided guidelines for designing novel materials with desired properties. However, the current computational approaches are not able to predict reaction pathways that pass through intermediate or metastable phases. As a consequence, repeated iteration is usually required to find the reaction conditions needed for realizing targeted materials with desired properties. To address this challenge, we combine theory, computation, and experiments to establish a theoretical framework that guides the synthesis of intermediate/metastable phases [1,2].

This framework has the ability to predict the multistage crystallization, as well as the influence of particle size and solution composition on polymorph stability along reaction pathways. To validate this framework, hydrothermal synthesis of manganese oxide is utilized as a demonstration case. In the experiment, we track the evolution of manganese oxide polymorphs occurring during the synthesis by using in-situ X-ray wide-angle scattering and X-ray absorption spectroscopy. Three synthesis pathways with varying potassium ion concentrations ([K+] = 0, 0.2, and 0.33 M) in the solution were studied. By combining the experimental and computational results together, we find that our computed size-dependent phase diagrams capture which metastable/intermediate polymorphs appear, the order of their appearance, and their relative lifetimes [3]. Furthermore, we demonstrated that the intermediate phases can be isolated from reaction pathways by quenching the reaction to stabilize the phases at room temperature.

Overall, this combination of computational and experimental methodology offers a more rational and systematic paradigm for targeted synthesis of metal oxides. The future outlook for this “synthesis by design” approach is promising for other binary and ternary oxides with high polymorphism.

Structure and Properties of Pnictide Zintl Phases with Rare Earth Cations Susan M. Kauzlarich; University of California, Davis, Davis, California, United States.

Zintl phases have generated a great deal of interest because their structures can be understood using simple electron counting rules allowing for strategic compositional tuning to enable and enhance useful properties for applications in energy conversion and information technologies. We have employed the Zintl concept to introduce new compounds with unique structures to the thermoelectric community. In addition, many of these new compounds also show complex magnetic ordering and colossal magnetoresistance. I will outline our motivation for employing rare earths in pnictide containing Zintl phases and discuss their structures and properties.
K₂SnO₃ and Related New Oxide Structure Types

Rebecca D. McAuliffe, Christopher A. Miller, Shuai Li and Daniel P. Shoemaker; Univ of Illinois-Urbana. Urbana, Illinois, United States.

Our exploratory forays into the K-Sn-O phase space are motivated by the search for Sn²⁺-containing transparent conducting oxides, and have revealed a surprisingly diverse phase space, with many previously-unreported stable and metastable phases. We present techniques for combatting experimental challenges in this system, including deliquescence of certain precursors and a proclivity for beam damage in some products. Among them is K₂SnO₃, a Sn⁴⁺-containing oxide with a unique structure type among oxides. The compound is orthorhombic and reminiscent of an offset hollandite, where open channels hold a row of four K⁺ per channel per cell. The continued discovery of new structure types in ternary tin oxides should remain a priority for the identification of prospective ion conductors and transparent conducting oxides.

Structures and Properties of Kesterite-Type Quaternary Chalcogenides
Anthony V. Powell, Panagiotis Mangelas, Alex Aziz, Ricardo Grau Crespo and Paz Vaqueiro; University of Reading, Reading, United Kingdom.

Quaternary chalcogenides of general formula A₂BCO₄, where A, B and C are elements from groups 11, 12 and 14 respectively and Q = S, Se, have applications in solar cells, thermoelectric devices and photocatalysts for water splitting. Thin-film solar cells containing Cu₂ZnSnO₄ have attracted considerable interest, as they have efficiencies of 12.6%. Although this is lower than that of CIGS (CuInGaSe₂) based devices, Cu₂ZnSnO₄ confers the advantage of being composed of Earth-abundant elements, affording significant reductions in materials costs. An emerging body of work suggests the detailed structure of these materials plays a key role in their functionality. Band–gap fluctuations, which reduce solar cell efficiencies, are strongly correlated with the degree of cation disorder, while phase transitions have a marked impact on the transport properties that underlie thermoelectric performance.

The presence of cations with similar atomic numbers hampers analysis by X-ray methods and has led to ambiguity over the detailed structures of members of this family of materials. Using neutron diffraction, we have established that the room-temperature structures of all A₂ZnCoO₄ (A = Cu, Ag; C = Sn, Ge and Q = S, Se) phases are best described in the kesterite (I-4) derivative of zinc blende, which DFT calculations indicate is energetically favoured over the stannite (I-42m) form. However, the detailed structures show a marked dependence on composition. Cu₂ZnGeO₄ phases exhibit partial disorder of Cu and Zn cations within cation planes at z= ¼ and ¾. Disorder is greatly reduced in the tin analogues and the silver-containing phases Ag₂ZnSnO₄ are fully ordered at room temperature. DFT suggests the disordered structure may be considered as a probability-weighted average of two ordered configurations, differing in the stacking sequence of the Cu-Zn planes. Ordering of silver cations is driven by minimization of the inter-plane Zn²⁺-Zn²⁺ repulsions in one of these configurations. The magnitude of this stabilization is reduced with increasing c/a value, and both configurations have a similar probability in the Cu-containing phases, leading to a disordered structure.

On heating, Cu₂ZnSnO₄ transforms at 1123 K, to a wurtzite-stannite-type structure with complete ordering of cations over the tetrahedral sites. The analogous selenide (Cu₂ZnSnSe₄) remains in I-4 at all temperatures to 973 K, despite the signature in thermal analysis data of a phase transition in the region 437 ≤ T/K ≤ 512. These observations are reconciled by Rietveld analysis, which reveals an order-disorder transition to a fully disordered kesterite structure at 450 K. Simultaneously, copper-ions become mobile, conferring phonon-liquid-electron-crystal characteristics, and copper-ion vacancies are created. This leads to marked changes in electron-transport properties: both ρ(T)and S(T) indicate the order-disorder transition is accompanied by a semiconductor to metal transition.

Improved Synthesis of Two-Dimensional Covalent Organic Frameworks
William Dichtel; Northwestern University, Evanston, Illinois, United States.

Polymerizing monomers into periodic two-dimensional (2D) networks provides structurally precise, layered macromolecular sheets that exhibit desirable mechanical, optoelectronic, and molecular transport properties. 2D covalent organic frameworks (COFs) offer broad monomer scope but are generally isolated as powders comprised of aggregated nanometer-scale crystallites. Here we control 2D COF formation using a two-step procedure, in which monomers are added slowly to pre-formed nanoparticle seeds. The resulting 2D COFs are isolated as single-crystalline, micron-sized particles. Transient absorption spectroscopy of the dispersed COF nanoparticles provides two or three orders of magnitude improvement in signal quality relative to polycrystalline powder samples and suggests exciton diffusion over longer length scales than those obtained through previous approaches. These findings will enable a broad exploration of synthetic 2D polymer structures and properties.

Microstructure—Properties Relationships in MOFs
Rifan Hardian, Marie-Vanessa Coulet and Philip Llewellyn; CNRS-Aix Marseille Univ, Marseille, France.

Metal-Organic Frameworks (MOFs) are a class of porous materials that combine metal oxide clusters with organic linkers. The wide variety of metal precursors and organic ligands allows tuning the properties of this class of materials to be used for gas storage and separation, catalysis, mechanical energy storage, etc. It has been recently proposed that the presence of defects and disorder in MOFs can have an impact on many of their properties [1,2]. In this contribution, the microstructure-properties relationships are studied in two kinds of defective MOFs.

The first example concerns the generation of defects by ball-milling in ZIF-8. It is shown that this kind of post-synthesis modification allows the control of the microstructure and the reactivity. Microstructure is analysed using X-ray diffraction while reactivity toward polar and non-polar molecules is studied using gas and vapour sorption experiments. Although the maximum uptake at high pressure is decreasing with increasing number of defects, the reactivity at low pressure is higher. This indicates that defects induced by ball-milling improve the reactivity which can be of interest for catalytic reactions.

The second example focuses on the influence of the microstructure on the structural flexibility in functionalized MIL-53(Cr) compounds. This MOF family presents the remarkable property of being flexible. This means that one compound exists in at least two crystalline states with distinct pore size and shape: a narrow pore (NP) structure and a large pore structure (LP). The NP/LP transition is reversible and can occur under gas adsorption and desorption or without any guest, that is to say under mechanical pressure or temperature. Functionalization of this compound allows tuning the NP/LP transition temperature. Various functionalized samples that possess different microstructures in terms of crystallite size and strain are studied using differential scanning calorimetry combined with X-ray absorption spectroscopy and X-ray diffraction. It is shown that the microstructure strongly modifies the energies associated with the transition as well as the temperature or pressure at which it occurs. It is thus proposed that microstructure may be used to
Metal-organic framework (MOF) materials containing oxometalate cluster-based nodes, such as oxozirconium or oxocerium nodes, can provide the basis for single-site heterogeneous catalysts, for example, if all nodes are uniformly modified with suitable metal species. However, the application of MOFs for catalysis at high temperatures, particularly in oxidizing environments, is limited, because the instability of the organic linkers under these conditions leads to loss of the MOF structure and aggregation/sintering of the catalytic clusters. Under those conditions, it may be necessary to stabilize the cluster sites. We will discuss methods of stabilizing MOF-derived functionalized and non-functionalized oxometalate clusters by nanocasting with silica, titania, or carbon scaffolds. A silica scaffold, for example, can prevent the oxozirconium clusters in the MOFs NU-1000 or UiO-66 or oxocerium clusters in related cerium-based MOFs from aggregating after the linkers are removed at temperatures between 500 and 600 degrees C. This is in contrast with bare NU-1000 or UiO-66, which shows sintering of the clusters after undergoing the same thermal treatment. The clusters in the nanocast material remain accessible to probe molecules and their Lewis acidity is maintained, keeping them active as catalysts in certain acid-catalyzed reactions. This nanocasting method can also be extended to other scaffolds to support cluster nodes in large-pore MOFs. We will consider synthesis parameters that permit uniform infiltration of the MOF with the scaffold precursors and correlate these to nanocast products that maintain discrete clusters after thermal treatment at 500 degrees C or higher, without formation of extended zirconia or ceria aggregates. Accessibility of the stabilized clusters in the scaffolds is probed by spectroscopic and catalytic reaction methods. Nanocasting, combined with the exceptional tunability of the composition and structure of MOFs, provides a starting point for designing a new generation of highly active and stable heterogeneous catalysts.

Wurtzite (WZ)-derived ternary nitrides are an interesting class of materials promising enhanced optoelectronic functionalities. Peculiar to this category of materials is their capability of accommodating large off-stoichiometries, as we recently demonstrated for the Zn3MoN4-ZnMoN2 system. In the latter case, cation off-stoichiometry enables a continuous tuning of the composition between the two end points, while retaining the WZ structure, through a process that we defined as redox-mediated stabilization. Most of the cations in the periodic table have been reported to form nitrides as either a monometallic or bimetallic compound. To date, an exception to this rule is represented by antimony: M-Sb-N ternary compounds where Sb is acting as an anion are known, however crystalline nitrides where Sb is acting as a cation have not been reported to date. In this contribution, we theoretically predicted and experimentally realized the first ternary antimony nitride where antimony is a cation. A data-mined structure prediction (DMSP) algorithm was used to identify the compound and evaluate the stability of the candidate crystal structures by comparing their density functional theory (DFT) formation energies to the competing phases. Combinatorial RF magnetron sputtering was used as growth technique, to enable access to high nitrogen chemical potential (AQc) and fast screening of deposition conditions. It was found that this metastable compound could be synthesized over a wide range of deposition conditions, showing tunable optical and electrical properties as a function of the Sb content in the cation sub-lattice and growth conditions. The low native n-type conductivity and moderate carrier concentration, coupled with an almost ideal direct band gap (1.7 eV theoretical, ~1.4 eV experimental) make it a promising candidate as a photoactive material. Based on measured values of the ionization potential and the electron affinity, the applicability of this material as a photoactive absorber will be discussed.

References:

Colloidal inorganic nanocrystals offer many advantages for use in photovoltaic devices: controllable synthesis, processability, and tunable band gap energies. Ideal materials for photovoltaics would contain earth abundant, nontoxic elements and would possess ideal band gaps. Copper and iron chalcogenides exhibit these properties. However, many of these compounds are ternary compounds, with interesting bonding between transition metals, main group elements, and chalcogenides, so developing synthetic routes toward nanocrystals of these materials is a significant challenge. We are exploring how the interactions between precursors, surfactants, organic solvents, and temperature in injection-type reactions can affect the reaction pathways toward the ultimate products.

**CM01.12.01**

**Lattice Dynamics of Layered AMg2Pn2: Zintl Compounds**

Wanyue Peng1, Guido Petretto2, Gian-Marc Rignanese3, Geoffrey Hautier4 and Alexandra Zevalkink5

1: Michigan State University, East Lansing, Michigan, United States; 2: Université catholique de Louvain, Louvain-la-Neuve, Belgium.

AMg2Pn2 compounds with the layered CaAl2S3 structure type have received a great deal of attention recently due to their excellent thermoelectric properties. The binary member of this structure type, Mg2Sb2, exhibits the highest peak z ≤ 1.6, due in part to its surprisingly low lattice thermal conductivity. Here, we explore trends in the thermal properties of AMg2Pn2 compounds (Pn = Sb or Bi and A = Mg, Ca, Sr, Ba, Yb, Eu) to elucidate the role that the cation radius and electronegativity in determining the elastic moduli and anharmonicity in this structure type. Temperature-dependent resonant ultrasound spectroscopy and inelastic neutron scattering are used to investigate the elastic moduli and speed of sound, while phonon calculations within the quasi-harmonic reveal mode Grüneisen parameters. The binary compounds Mg2Sb2 and Mg2Bi2 are found to have anomalously soft shear moduli and large mode Grüneisen parameters. We attribute this primarily to the undersized Mg cations, which are too small for the 6-fold octahedral coordination with Sb or Bi, leading to weak interlayer bonds, highly anharmonic transverse acoustic phonon modes, and high rates of phonon-phonon scattering. The consequence is that those compounds with the lowest density in the AMg2Pn2 series are also those with the lowest lattice thermal conductivity.

**CM01.12.02**

**Oxidation-Resistive Two-Dimensional Dihafnium Sulfide Electride with Efficient Electrocatalytic Activities in Water-Based Solution**

SeHyang Kang, Ye Ji Kim and Sung Wng Kim; Sungkyunkwan Univ, Suwon, Korea (the Republic of).

Electrides are exotic ionic crystals where excess electrons are located in cavities as anions. Because of the loosely bound anionic electrons, electrides have been received much attention, exhibiting intriguing physical and chemical phenomena, such as low work function, high electron mobility and excellent catalytic reactivity1,2. However, the electro-active functionalities of electrides have been degraded once oxygen and/or moisture is absorbed, preventing the novel applications for an industry. It is thus highly demanded to discover a thermally or chemically stable electride in ambient or moisture condition. Here, we report the highly oxidation-resistive dihafnium sulfide ([Hf2S]2+2e−) electride with efficient hydrogen evolution electrolysis (HEE) activities over 5,000 cycles in water. We have grown single-crystals [Hf2S]2+2e− electride with floating zone (FZ) melting method. X-ray photoelectron spectroscopy (XPS) and electron energy loss spectroscopy (EELS) combined with density functional theory (DFT) calculations clarify that [Hf2S]2+2e− electride has two excess electrons per formula unit, which are confined in the Hf-Hf interlayer with dumbbell-like shape. [Hf2S]2+2e− electride shows a state-of-the-art durability against air and water among the existing electrides, retaining the crystal structure and physical/chemical properties over 1 month. Furthermore, Cu-loaded [Hf2S]2+2e− electride shows highly effective HEE performances comparable to the defect-rich MoS2, which is one of the most effective catalyst except Pt for water splitting. Transmission electron microscopy (TEM) observation indicates that the formation of thin native amorphous HfO2 layer, known as oxidation-resistive passivation layer, is responsible for the electro-catalytic activity in water. It is verified that the anionic electrons of [Hf2S]2+2e− electride can migrate to the Cu nanoparticle through the amorphous HfO2. Our findings provide an important insight into the design strategy of new oxidation-resistive electrides and their active functionality in electro-catalysis.

**Effect of Crystal Structure on Hole Carrier Generation in Wide-Gap P-Type Tin-Niobate**

Akane Samizo1, 2; Naoto Kikuchi3; Yoshihiro Aiura2 and Keishi Nishio1

1: Tokyo University of Science, Tokyo, Japan; 2:National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan.

Transparent conducting oxides (TCOs) are widely used as transparent electrodes in displays and solar cells. However, most of existing TCOs are n-type semiconductors such as ITO (In2O3:Sn) and ZnO. In order to fabricate transparent devices based on p-n junctions, the development of p-type TCOs are required. The reason of the difficulty in development of p-type TCOs is low hole mobility. Since the wide band-gap of TCOs comes from significant contribution of ionistic character to chemical bonds between metal cations and oxygen anions, positive holes at valence band maximum (VBM) are strongly localized around O 2p orbitals. Thus, delocalization of VBM is essential for material design for realizing p-type TCOs. The oxidation of metal cations with ns2 electronic configurations (n: the principal quantum number) such as Pb5+; Sn4+ (hereafter s-orbital-based oxides) have been recently attracted as new candidates for p-type TCOs. The large spatial spreading and isotropic nature of metal s orbitals delocalize the VBM, then low effective mass of holes is expected. However, only a few reports on electrical properties of these oxides exist because of difficulties in hole carrier generation. The s-orbital-based oxides require to anneal in reduced atmosphere in order to prevent oxidative decomposition (eg. SnO changes to SnO2),
which results in a charge compensation of holes by electrons generated by the formation of oxygen vacancies ($V_{o}^{**}$). Therefore, controlling of structural defects, e.g., oxygen vacancies is indispensable for introduction of hole carriers. We focus on Sn$^2+$ oxides, which is more environmental-friendly compared to Pb$^2+$, and succeeded in preparation of p-type Sn$_2$Nb$_2$O$_7$ and SnNb$_2$O$_6$ by sample annealing. The crystal structure of both oxides has a substructure of Nb$_6$O$_{12}$ octahedral, and there are considerable three kinds of native point defects, $V_{o}^{**}$, Sn$^{4+}$-on- Nb$^{5+}$ substitutional defects (Sn$'$Nb), and tin vacancies ($V_{Sn}''$). We found that the hole carriers were generated by Sn$'$Nb in Nb$_6$O$_{12}$ octahedra in both p-type tin-niobates. Although same hole carrier source was found, the carrier generation efficiency of Sn$_2$Nb$_2$O$_7$ was in two orders higher than that of SnNb$_2$O$_6$. In this paper, the amount of each defects and distortion of the crystal structure was discussed by the Rietveld analysis in order to clarify the origin of difference in the carrier generation efficiency. We summarize characteristics of hole carrier generation related to structural defects of two tin-niobates. The findings obtained in this study may bring us detailed mechanisms of carrier generation in Sn$^2+$ oxides, leading to future transparent device applications.

CM01.12.04

Grain Boundary and Discontinuous Precipitation Phenomena in a Multicomponent Alloy Julio C. Spadotto$^2$, Grace Burke$^1$ and Guillermo Solórzano$^2$; $^1$University of Manchester, Manchester, United Kingdom; $^2$PUC-Rio, Rio de Janeiro, Brazil.

Discontinuous precipitation (DP) reaction is a grain-boundary (GB) diffusion-controlled phenomenon driven by migrating GB, acting as fast reaction path under the action of chemical and capillary forces, leaving behind a regularly-spaced array of lamellar precipitates growing cooperatively from the supersaturated matrix. In multicomponent alloy systems containing both substitutional and interstitial solutes normally the DP colonies are constituted of either Cr-rich M$_2$C$_6$ or Cr$_7$N lamellae. However, DP colonies in superaustenitic stainless steel have been observed in which the lamellar σ phase has precipitated at the migrating GB and the additional precipitation of Cr$_7$N has occurred within the colony with increasing ageing time [1]. The present investigation deals with the DP reaction in Alloy 33, with nominal composition (wt.%) 33Cr-32Fe-31Ni-1.6Mo-0.6Cu-0.4N, upon aging at 800 °C. In order to understand the complex DP phenomenon in this alloy, both analytical scanning (SEM) and analytical transmission electron microscopy (TEM) have been used extensively for detailed microstructural characterization. The DP phenomenon in Alloy 33 displays different characteristics from those reported in the literature. After aging at 800 °C for 1 hour heterogeneous precipitation occurred at the GBs, where, in some cases, the initial stages of development of DP colonies were observed. At this stage, dislocations walls marking the original grain boundary position had been observed. Upon aging for 2 hours its verified in some regions of DP colony that the precipitates are connected to migrating GB, but in other regions of the same GB the boundary appears disconnected from the precipitate in a similar fashion as diffusion-induced grain boundary migration (DIBM) topologies. The intergranular precipitates were identified using selected area electron diffraction (SAED) and EDX microanalysis as Cr-rich M$_2$C$_6$ carbide with FCC structure. Based on DP theory, it is expected that the precipitate initially formed at GB grows together with the GB migration. After aging at 800 °C for 5 hours, energy dispersive X-ray spectrum imaging and SAED analyses confirmed that the original GB position is M$_2$C$_6$ in the DP colony, as expected. However, in the same DP colony, a platelet-type precipitate, identified as α-Cr phase with BCC structure, was also observed at the GB. Similar behavior was also observed in a different DP colony: M$_2$C$_6$ precipitation did not occur at the original GB position. In this DP colony, α-Cr phase was also observed along with a phase rich in Cr, Mo, and Fe at reaction front. These results showing different types of precipitates occurring at the early stages of the DP reaction show the complexity of this phenomenon in Alloy 33, and suggest a high entropy system behavior [2].

CM01.12.06

Unveiling the Nature and Structure of ZnO-Bi$_2$O$_3$ Grain Boundaries Marcelo A. Martinho, Gabriel D. Rocha, Marco A. Cordeiro and Edison R. Leite; UFSCar, São Carlos, Brazil.

Owing to the structural and chemical nature of polycrystalline materials, grain and phase boundaries play a fundamental role in these materials properties by tailoring desired material features. For example, grain boundaries have a tremendous implication in plastic deformation in materials, especially in failure mechanisms such as fatigue, fracture and creep, which are fundamental for the development of new materials, as superplastic ceramics. In spite of the evident importance, the basic understanding of interfaces is still in its beginning, and lacks an essential correlation of its structure and materials properties. In order to provide fundamental insights into the structure and chemical nature of the grain boundary in oxides, Bi$_2$O$_3$-doped ZnO$_2$ system was used. Due to its ample physical and chemical properties (e.g., chemical stability, broad range of radiation absorption and high photostability), ZnO$_2$ materials find place in a myriad of applications (e.g., varistors, photocatalysts, solar cells.). Besides, Bi$_2$O$_3$-doped ZnO$_2$ has been studied as a model for liquid-phase/activated sintering due to the lower temperature in the eutectic (~740 °C). Despite the important studies over the years, the knowledge of the sintering and grain boundary development is based on ex situ studies, which approach could hide fundamental aspects of sintering and grain boundary formation phenomena. In this study, ex situ and in situ studies of sintering and grain boundary formation were performed. Ex situ studies were carried out by using samples produced by oxide mixture (Bi$_2$O$_3$ and ZnO$_2$) followed by conventional sintering. The resulted pellets were polished and the grains revealed by temperature, and then studied by scanning electron microscopy (SEM). On the other hand, in situ studies were carried out by using ZnO$_2$ and Bi$_2$O$_3$ nanoparticles (NP) (10-20 nm), both synthesized by non-hydrolytic route (thermodecomposition of the acetate precursors) under the action of organic ligands (oleylamine and/or oleyl alcohol). Self-organization of ZnO$_2$ and Bi$_2$O$_3$ NPs on amorphous carbon film supported on nickel grids were submitted to in situ heating experiments in a Gatan 628 single-tilt heating holder (with an Inconel-based furnace) in a FEI Tecnai F20 field emission TEM operating at 200 kV. By real-time tracking the NPs sintering and grain boundary holder, it was possible to analyze the structure formation and further grain restructuration and correlation with the ex situ experiments. Moreover, the evolution of grain boundary formation and the final structure were correlated to the complex structures, providing a promising avenue toward the construction of grain boundary phase diagrams.

CM01.12.07

Control of Size Distribution of Surface Nanoparticle Formed by Selective Phase Transition in Sr$_{0.98}$Ti$_{0.95}$Me$_{0.05}$O$_{3-\delta}$ (Me = Mn, Fe, Co, Ni, and Cu) Jun Kyu Kim, Bonjae Koo and WoOchul Jung; Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Supported metal nanoparticles (NPs) are of significant importance in heterogeneous catalysis owing to their excellent dispersion and many undercoordinated surface sites. Recently, the in-situ growth phenomenon of metal NPs directly from an oxide support, known as ‘ex-solution,’ has been reported as a new method of decorating oxide surfaces with uniformly dispersed metal NPs. Here, a catalytically active metal is embedded in the crystal lattice of a backbone in oxidizing conditions, forming a solid solution, and then is released (ex-solved) on the surface of the structure as metallic nanoparticles upon exposure to a reducing atmosphere. Compared to conventional nanoparticle synthesis and dispersion techniques, this process is faster, more cost-effective and allows finer and better particle distribution. Furthermore, the sintering of nanoparticles can be prevented by re-oxidation, enhancing the life-time of the supported nanoparticles. Despite extensive research efforts, however, the fundamental mechanisms of the processes remain largely unknown. Accordingly, how to control particle size and distribution precisely are also unknown, despite the fact that these processes are crucial to
render this phenomenon technologically attractive.

In this study, we prepared dense thin-films of 3d-transition metal (Mn, Fe, Co, Ni and Cu) doped and A-site deficient SrTiO3 with highly flat surfaces and observed the ex-solved particles on their surfaces depending on the annealing temperature, oxygen partial pressure, and kind of dopants. SrTiO3 was selected as a model perovskite host due to its superior phase stability in a wide range of temperatures and gas atmospheres, and the thin-film samples were used for reliable and reproducible surface analysis. We found that the nucleation and growth of ex-solved particles took place extremely fast, and their rate gradually increased as the pO2 decreases. Significantly, the lower the pO2 at the same temperature, or the higher the temperature at the same pO2, the greater the number of nuclei, which forms metal NPs with higher density and smaller size. These observations were explained through the classic nucleation theory, suggesting a novel technique to control the size and dispersion of supported metal NPs, which can be readily applied to various applications.

CM01.12.08
Rapid Discovery of Ternary Transition Metal Chalcogenides Ankit Bhutani¹, Julia Zuo¹, Thrivongadam Ranagarajan¹, Piush Behera¹, Awadhesh Narayan¹, Joshua Schliller¹, James N. Eckerstein¹, Santanu Chaudhuri², Lucas K. Wagner¹ and Daniel Shoemaker¹; ¹University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; ²University of California, Santa Barbara, Santa Barbara, California, United States; ³ETH Zurich, Zurich, Switzerland; ⁴Illinois Applied Research Institute, Urbana, Illinois, United States.

In order to capitalize on computational modeling and predictions, fast and accurate experimental synthesis and characterization techniques must evolve. In this study, we investigate transition metal chalcogenides using high-throughput experimental techniques, such as temperature and time-resolved in-situ x-ray diffraction, powered by computational predictions. High-temperature in-situ x-ray diffraction accelerates materials discovery by allowing us to watch a chemical reaction in real time and identify new stable/metastable phases. It provides useful insights into the thermodynamics and kinetics of reactions. Transition metal chalcogenides are particularly interesting because of their understudied d-electron correlations which lead to various interesting properties including superconductivity, meta-magnetic metallic behavior, and quantum phase transitions.

I applied such a tandem approach to explore the Ba–Ru–S phase space using a combination of evolutionary algorithms and density functional theory (DFT) to inform traditional and in situ diffraction methods. My work identified a high-temperature polymorph of BaS2, that would have been otherwise missed in ex-situ reactions and did not reveal formation of the predicted candidates BaRu2S2 or BaRuS3 (Bhutani, A. et al. Chem. Mater. 29 (14), 5841–5849 (2017)). I then used this methodology to study several other ternary systems to screen for novel phases. I screened 31 ternary chalcogenide phase diagrams of the form XYZ (X = K, Na, Ba, Ca, Sr, La, K, Bi, Pb; Y is a 3d transition metal; and Z = S or Se), where DFT predicted new compositions (Wagner Research Group, Physics, UIUC). I discovered 9 new phases belonging to the K/Na-Zn/S/Se systems with potential uses as wide band gap semiconductors and found 27 phase diagrams to be “empty” in the case of bulk synthesis (Narayan, A., Bhutani, A. et al. Phys. Rev. B. 94, 045105 (2016)). I complete my study with detailed characterization of new phases using XRD, UV-Vis Spectroscopy, SEM and magnetic and transport measurements.

CM01.12.09
Exceptionally Enhanced Electrode Activity of (Pr,Ce)O2-δ-Based Cathodes for Thin-Film Solid Oxide Fuel Cells Han Gil Seo, Yoonsok Choi and WooChul Jung; Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

We show that an electrochemically-driven oxide overcoating substantially improves the performance of metal electrodes in high-temperature electrochemical applications. As a case study, we overcoat Pt thin films with (Pr,Ce)O2-δ (PCO) by means of cathodic electrochemical deposition process that produced nanostructured oxide layers with a high specific surface area and uniform metal coverage and then examine the coated films as an O₂-electrode for thin-film-based solid oxide fuel cells (TF-SOFCs). The resulting structures were examined by SEM, XRF and ICP-MS. The electrode activity of symmetric cells (cathode|electrolyte|cathode) was analyzed by the AC impedance spectroscopy (ACIS) measurements. The combination of excellent conductivity, reactivity and durability of PCO dramatically improves the oxygen reduction reaction rate while maintaining the nanoscale architecture of PCO layers and thus the performance of the PCO-coated Pt thin-film electrodes at high temperatures. As a result, with an oxide coating step lasting only 5 min, the electrode resistance is successfully reduced by more than 1000 times at 500 °C in air. Based on these observations, furthermore, we successfully designed and fabricated nano-columar PCO films with an enhanced specific surface area and succeeded in achieving high electrode performances. These findings provide useful guidance for design and fabrication of high-performance TF-SOFCs.

CM01.12.10
Oxygen Interstitial Migration in Solids from First Principles—Apatites and Mellitides Steffen P. Grieshammer¹, ¹Institute of Physical Chemistry, RWTH Aachen University, Aachen, Germany; ²Helmholtz-Institut Münster, Forschungszentrum Jülich GmbH, Münster, Germany.

Solid state oxygen ion conductors play a crucial role as electrolytes in solid oxide fuel cells (SOFC), solid oxide electrolyzer cells (SOEC) and rechargeable oxide batteries (ROB). In common oxygen ion conductors, like yttria-stabilized zirconia, oxygen transport is enabled by oxygen vacancies, while in recent years oxygen ion conductors where transport is enabled by interstitial ions have gained increasing attention.

In the present study, two examples of oxygen batteries (ROB). In common oxygen ion conductors, like yttria-stabilized zirconia, oxygen transport is enabled by oxygen vacancies, while in recent years oxygen ion conductors where transport is enabled by interstitial ions have gained increasing attention.

In the present study, two examples of oxygen ion conductors with an interstitial mechanism are investigated using density functional theory. Lanthanum apatites with the general formula La₃(BO₃)₂X₃X₆O₁₄ form a hexagonal structure with oxygen ion channels enabling transport along the crystallographic c-direction. Mellitides with the composition Al₂Ga₄O₉ crystallize in a tetragonal layered structure with oxygen interstitials migrating in a layer composed of GaO₆-units. The energies of defect formation and migration of oxygen ions via vacancy and interstitial mechanism are calculated for different compositions. In both types of materials the transport of oxygen ions by a cooperative interstitiality mechanism is favorable compared to vacancy migration. However, the migration energies clearly depend on the ordering of the cations around the migration oxygen ion. For apatites, compositions with X = Mg, Ca, Sr and Ba as well as B-deficient variations are considered. The migration energies are in a range of 0.1 eV to 0.4 eV for interstitialcy migration and more than 1 eV for vacancy migration. In mellitides with the composition La₂₋₅Sr₅Ga₄O₉₋₂ the migration barriers vary in a wide range of about 1 eV depending on the migration direction and the occupation of the surrounding cation positions.

The energies of intrinsic defect disorder for both materials are several eV suggesting that the fraction of ionic charge carriers is determined by the adjusted composition or by impurities in experiments. Experimental results from impedance spectroscopy measurements are used to complement the ab initio results.

CM01.12.12
Light Absorption Coefficient of CsPbBr3 Perovskite Nanocrystals Jerick Maco¹, ², Lieve Balcaen¹, Émile Drieyvers², Qiăng Zhao³, Jonathan De Roo⁴, ¹, André Vertommen¹, Frank Vanhaecke¹, Pieter Getregat¹, ² and Zeger Hens¹, ²; ¹Department of Chemistry, Ghent University, Ghent, Belgium; ²Center for Nano and Biophotonics, Ghent University, Ghent, Belgium; ³Instituut voor Kern- en Stralingsfysica, KU Leuven, Leuven, Belgium; ⁴Department of Chemistry, Columbia University, New York, Belgium.

The concentration of colloidal nanocrystals (NCs) is a key characteristic for any quantitative study on nanocrystals. At present, the concentration of CsPbBr3 NCs is typically quantified by means of an absorption coefficient or cross section obtained from photoluminescence saturation or by
thermogravimetric analysis; two methods that are not accurate and need benchmarking by direct quantification methods. We combined inductively coupled plasma mass spectrometry (ICP-MS), UV−vis absorption spectroscopy and transmission electron microscopy to determine the size, composition, and intrinsic absorption coefficient $\mu_i$ of 4 to 11 nm sized colloidal CsPbBr$_3$ NCs. The ICP-MS measurements demonstrate the nonstoichiometric nature of the NCs, with a systematic excess of lead for all samples studied. Rutherford backscattering measurements indicate that this enrichment in lead cores with a relative increase in the bromide content. At high photon energies, $\mu_i$ is independent of the nanocrystal size. This allows the nanocrystal concentration in CsPbBr$_3$ nanocolloids to be readily obtained by a combination of absorption spectroscopy and the CsPbBr$_3$ sizing curve.

Nanoparticle temperature monitoring using a complete thermodynamic cycle, including detailed molecular dynamics simulations of vacancy migration through the growing nanocrystals, has been combined with a comprehensive analysis of the properties that are determined by the vacancy formation process. This approach has been used to gain insights into the properties of nanocrystals that are relevant to their potential applications in a wide range of fields, including catalysis, electronics, and energy storage.

The use of magnetic nanoparticles (NPs) to convert electromagnetic energy into heat is known to be a key strategy for numerous biomedical applications but is also an approach of growing interest in the field of catalysis. We have shown that, associated to catalytic metals (Ni, Ru), iron carbide NPs submitted to magnetic excitation very efficiently catalyze CO$_2$ hydrogenation in a dedicated continuous-flow reactor. Since a huge gradient of temperature between the self-heated particles and the “cold” environment is expected, nanoscale measurements need developments to correlate the result of catalysis reaction to NPs temperatures, but also to control the process to keep constant the heating power or the NP surface temperature. Thermometric probes have been described at low temperatures with different luminescent species. However, using phosphors to determine high temperatures under harsh experimental conditions remains largely unexplored and highly challenging. At the nanoscale, QDs optical properties offer a rare opportunity to build an innovative complex nano-object integrating heating capacities, catalytic ability and thermal reporting property. The temperature-dependent emission of different QDs (InP@ZnS and CdSe@CdS) have been investigated in this purpose. Peak emission wavelength, intensity, and full width at half maximum were completely described as a function of temperature. We will present here the use of QDs as local temperature probes during the magnetic heating of iron carbides NPs in catalysis conditions. We evidence that the global temperature (measured by a thermal camera) of the catalytic solid is drastically lower than the local temperatures measured by the QDs at the nanoscale.

Quantitative understanding of high temperature oxidation of alloys at the atomic scale to the microscale has remained a challenge and can guide in rational materials design. We employed accurate interatomic potentials and available experimental data to analyze the oxidation mechanism of Ni at high temperature using a complete thermodynamic cycle, including detailed molecular dynamics simulations of vacancy migration through the growing

*Control of Transition Metal---Oxygen Bond Length Boosts the Redox Ex-Solution in Perovskite Oxide Surface*  
Bongsoo Koo, Kyeoung academia, Yong-Ryun Joo, Siwon Lee, Jun Kyu Kim, Min Ji Seo, Bong-Joong Kim, Jeong Woo Han and Woochul Jung; 2; Korea Advanced Institute of Science and Technology (KAIST), Daejeon, Korea (the Republic of); 3Pohang University of Science and Technology (POSTECH), Pohang, Korea (the Republic of); 4Gwangju Institute of Science and Technology (GIST), Gwangju, Korea (the Republic of).

Nano-sized metal particles have been widely used as heterogeneous catalysts for various reactions due to their high surface-to-volume ratios and possibly unique catalytic properties. Particularly when dispersed on oxide supports, their catalytic activities are often greatly enhanced compared to those in pure metal particles. Recently, in-situ growth via metal nanoparticles (NPs) directly from an oxide support, known as ‘ex-solution’, has been reported by multiple researchers in the fields of high-temperature catalysis and renewable energy. When perovskite oxides (ABO$_3$) are used as a hosting framework, transition or precious metals can be dissolved as cations in the B-sites of the perovskite lattice under oxidizing conditions; they can also be ex-solved partially upon subsequent reduction as nano-sized metallic phases decorating the oxide surface. Compared to traditional nanoparticle synthesis and dispersion techniques, this process is faster, more cost-effective and allows finer and better particle distribution. Furthermore, the exsolved metal NPs are deeply soaked into the parent perovskite with a wide particle-substrate interface, leading to enhanced sintering and hydrocarbon cracking resistance. More importantly, its reversibility indicates that catalyst agglomeration can be avoided through re-oxidation, significantly enhancing the lifetime of the supported catalysts. Since the key to this phenomenon is how stable certain cations are in a perovskite lattice, it is obvious that the bond strength between neighboring cations and oxygen ions determines the outcome of ex-solution. To the best of our knowledge, however, there is no atomic-level consideration of the intrinsic stability of a reducible cation surrounded by six oxygen ions in a lattice, and thus a solution that effectively controls the amount or distribution of the exsolved particles is not yet known.

Here, we investigate the influence of the bond length between the B-site transition metal and the neighboring oxygen in a perovskite lattice on surface transition metal ex-solution. Considering dense epitaxial thin films of Sr$_{1-x}$Co$_x$O$_3$ (STC) as a model system, we control the average Co-O bond length through the misfit strain of STC films, and monitor how the surface composition and catalytic reactivity for CO oxidation changes accordingly. Combined theoretical and experimental analyses show that the relatively weak bond strength induced by the elongated Co-O bond in STC drives the Co ex-solution significantly and thus activates the CO oxidation. Based on the observations, we conclusively demonstrated that the tensile strain could be sufficiently increased by introducing a large-sized isovalent dopant, offering a new strategy for activating the ex-solution phenomenon.

**A Novel Class of Oxynitrides Stabilized by Nitrogen Dimer Formation**  
Sanjae Kim, Seung-Hyub Back and Chong-Yung Kang; 1; 2; 3Korea Institute of Science and Technology, Seoul, Korea (the Republic of); 2KU-KIST Graduate School of Converging Science and Technology, Seoul, Korea (the Republic of).

Despite the wide applicability of oxynitrides from photocatalysis to refractory coatings, our understanding of the materials has been limited in terms of their thermodynamics. The configurational entropy via randomly mixed O/N or via cation vacancies are known to stabilize oxynitrides, despite the positive formation enthalpies. Here, using tin oxynitrides as a model system, we show by ab initio computations and experimental characterization that oxynitrides in seemingly charge-unbalanced composition stabilize by forming nitrogen dimers among metal-(O,N)$_6$ octahedra. The nitrogen dimer, (N-N)=, reduces formation enthalpies. Here, using tin oxynitrides as a model system, we show by computationally and experimentally that oxynitrides in seemingly charge-unbalanced composition stabilize by forming nitrogen dimers among metal-(O,N)$_6$ octahedra. The nitrogen dimer, (N-N)=, reduces formation enthalpies.

**CM01.12.15**

**Magnetic Heating Monitoring with Quantum Dots Nanothermometers**  
Celine Navral, Gaelle Muraille, Robert Swain, Benjamin McVey, Bruno Chaudret and Fabien Delpech; Univ of Toulouse, Toulouse, France.

The use of magnetic nanoparticles (NPs) to convert electromagnetic energy into heat is known to be a key strategy for numerous biomedical applications but is also an approach of growing interest in the field of catalysis. We have shown that, associated to catalytic metals (Ni, Ru), iron carbide NPs submitted to magnetic excitation very efficiently catalyze CO$_2$ hydrogenation in a dedicated continuous-flow reactor. Since a huge gradient of temperature between the self-heated particles and the “cold” environment is expected, nanoscale measurements need developments to correlate the result of catalysis reaction to NPs temperatures, but also to control the process to keep constant the heating power or the NP surface temperature. Thermometric probes have been described at low temperatures with different luminescent species. However, using phosphors to determine high temperatures under harsh experimental conditions remains largely unexplored and highly challenging. At the nanoscale, QDs optical properties offer a rare opportunity to build an innovative complex nano-object integrating heating capacities, catalytic ability and thermal reporting property. The temperature-dependent emission of different QDs (InP@ZnS and CdSe@CdS) have been investigated in this purpose. Peak emission wavelength, intensity, and full width at half maximum were completely characterized as a function of temperature. We will present here the use of QDs as local temperature probes during the magnetic heating of iron carbides NPs in catalysis conditions. We evidence that the global temperature (measured by a thermal camera) of the catalytic solid is drastically lower than the local temperature measured by the QDs at the nanoscale.

Quantitative understanding of high temperature oxidation of alloys at the atomic scale to the microscale has remained a challenge and can guide in rational materials design. We employed accurate interatomic potentials and available experimental data to analyze the oxidation mechanism of Ni at high temperature using a complete thermodynamic cycle, including detailed molecular dynamics simulations of vacancy migration through the growing
nanometer-thick NiO oxide layer. The energy profile of all steps including oxygen adsorption, bond dissociation, charge transfer from metal to oxygen, cation vacancy-diffusion, and growth of the oxide interfacial layer are discussed and quantified. Cation vacancy migration in the NiO films becomes the critical process determining the overall oxidation rate. The effect of oxide film thickness, a step-edge, and a crescent on the Ni cation diffusion barrier was predicted which is consistent with experimental observations, and the methods can be applied to models up to several 100 nm size. The atomistic model of NiO used a nonbonded-only potential that involves Coulomb and Lennard-Jones terms. Care is taken that the atomic charges remain close to verifiable internal dipole moments even though covalent bonding contributions are disregarded. The non-bond model of NiO is inherently reactive, enabling changes in morphology and defects. It achieves quantitative agreement with experiment in lattice parameters (-1% deviation) and in bulk modulus (+10% deviation). It is fully compatible with existing parameters for other oxides, metals, solvents, and polymers following the IFF protocol. The parameters are available using both 12-6 and 9-6 Lennard-Jones potentials to achieve compatibility with CHARMM, CVFF and AMBER.

CM01.12.17
Understanding Processing-Property Relationships in Pulsed Laser Deposition of Complex Oxides via Crowd-sourced Database Generation and Machine Learning
Rama K. Vasudevan, Steven R. Young, Robert Patton and Sergei V. Kalinin; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Current methods of material design and synthesis relies largely on researcher intuition and large numbers of iterations in a vast parameter space. Much of the data that can aid in this process is scattered throughout the extant literature, but is scattered, uncollated and unindexed. We present a method to employ text mining through the form of regular expressions in combination with crowd-sourcing, to yield a database of growth condition-functional property information for select oxides grown via pulsed laser deposition. Open source tools facilitate the text mining, automatically annotating the relevant information, while user-led efforts in the form of crowd-sourcing sift through annotated data as well as figures, to compile database entries in an efficient manner. We have produced a database with hundreds of entries, which show growth windows, trends and outliers, and which can serve as a template for analyzing the distribution of growth conditions and provide starting points for related compounds. Basic visualization and machine learning enables correlations to be determined, with an example shown for the narrow growth window of BiFeO3, and a decision tree-based classifier that can predict whether a Tc for a manganite thin film will be in a certain range. These tools and methods will be useful to assisting in mining processing-property relationships, aiding both materials synthesis and materials design, and their integration with first-principles modeling will be critical in completing the materials feedback loop.

The Laboratory Directed Research and Development fund at ORNL is acknowledged. Research was conducted at the Center for Nanophase Materials Sciences, which is a US DOE Office of Science User Facility.  

CM01.12.18
New “ZN” Model for Zero Poisson’s Ratio Structures
Alexandre F. Fonseca1, Socrates O. Dantas2-1 and Douglas S. Galvao1; 1State University of Campinas, Campinas SP, Brazil; 2Universidade Federal de Juiz de Fora, Juiz de Fora, Brazil.

Poisson’s ratio (PR) is a measure of a material’s change along its transversal dimensions under the application of an axial strain. Most materials present positive PR, i.e., they laterally shrink (expand) under the application of a tensile (compression) strain. Other materials and structures present, on the other hand, negative PR and are called “auxetic”. Re-entrant polymeric crystals and/or foams are examples of auxetic materials [1]. Even more rare are the materials and structures presenting zero Poisson’s ratio (ZPR) [2]. i.e., materials that neither contract nor expand laterally under the application of an axial strain. Gases and semi-re-entrant honeycomb structures are known examples of ZPR materials [2,3]. Motivated by recent attempts to produce new ZPR structures [4,5], we propose a new type of ZPR structure that is not based on re-entrant honeycomb or hexagonal structures. The proposed structural model is composed of planar structures formed by the junctions/fusions, side by side, of several blocks in the shape of letters “Z” or “N”, which are two parallel bars connected by a diagonal bar, so the name “ZN” model. These diagonal bars are formed by soft, low bending stiffness materials, while rigid, high stiffness materials form the other two parallel bars. We show that such a kind of structure presents ZPR along both orthogonal directions. We discuss the challenges involving the production of these models, how to build a tri-dimensional ZPR structure from our two-dimensional “ZN” model, and the feasibility of having such a ZPR structure at nanoscale.

CM01.12.19
Thermal Properties of 2:1 Bismuth Borate Ceramics—Microscopic Contribution of Lone Electron Pairs for Lattice Expansion Tensors
Mangir Mushref1,2, Hilke Petersen1, Michael Fischer1-2, Mariano Curti2, Cecilia B. Mendive1, Volodymyr Baran1, Anatoly Sensyshyn2 and Thorsten M. Gesing1-2; 1Institute of Inorganic Chemistry and Crystallography, University of Bremen, Bremen, Germany; 2MAPEX Center for Materials and Processes, University of Bremen, Bremen, Germany; 3Crystallography, University of Bremen, Bremen, Germany; 4Departamento de Química, Facultad de Ciencias Exactas y Naturales, Universidad Nacional de Mar del Plata, Mar del Plata, Argentina; 5Research neutron reactor ZWE FRM-II, Munich University of Technology, Munich, Germany.

The applications of bismuth-borates require knowledge of thermal expansion coefficients for optical, mechanical and electronic properties. However, to understand the microscopic features leading to macroscopic thermal expansion of bismuth borates is not straightforward as borates mostly show high anharmonic thermal expansion even with negative expansion tensors. Herein we report the thermal expansion of Bi2B6O11 between 4 K and 900 K using temperature-dependent neutron and X-ray powder diffractions and Raman spectroscopy. Thermal expansion was modeled using the Debye-Einstein-Anharmonicity [1,2] fit. The calculated phonon density of states (PDOS) shows two broad continua with a sharp feature at 890(1) cm⁻¹. Comparing the highest frequency of the PDOS the model simulation results in a Debye frequency that represents only the acoustic lower frequency parabolic spectrum. The model also follows six independent thermal expansion tensors of the monoclinic system. The ¹¹B-enriched sample showed a mean B-O bond distance of 138(1) pm within the whole investigated temperature range. Due to stereochemical activity of the 6x⁶ lone electron pair (LEP) of Bi³⁺, four distinctive BiO₆ polyhedra showed different distortions: (i) the Wang-Liebau eccentricity (WLE) parameter [3] for each Bi-atom decreases with increasing temperature, indicating the electron deformation density associated with LEP is a function of temperature as well as the thermal expansion tensors. These phenomena are of fundamental interest to understand temperature-dependent non-linear optical and ferroelectric behaviors of relevant centrosymmetric systems.

Temperature-Dependent Structural and Spectroscopic Investigations of \( (\text{Bi}_{0.83}\text{Fe}_{0.17})\text{FeO}_3 \) Using Neutron Elastic and Light Inelastic Scattering

Andrea Kirsch\(^1\), Manjir Murshed\(^1\),  Ashfaq Haq\(^2\), and Thorsten M. Gessing\(^1\)

\(^1\)University of Bremen; \(^2\)Institute of Inorganic Chemistry and Crystallography, Bremen, Germany; \(^3\)Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; \(^4\)University of Bremen; \(^5\)MAPEX Center for Materials and Processes, Bremen, Germany.

\( \text{BiFeO}_3 \) is one of the widely studied multiferroic materials for interesting properties \([1]\) depending on crystal chemistry \([2]\) and crystalline/particle dimensionality \([3]\). Recently, a \(^{57}\text{Fe} \) Mössbauer spectroscopy and X-ray powder diffraction (XRPD) study revealed a series of \((\text{Bi}_{x}\text{Fe}_{1-x})\text{FeO}_3\) perovskite-type structures, where the Bi-site is partially shared by Fe \([4]\). To further tune the multiferroic property either from electric or magnetic approaches, or simultaneously both directions, the present study reports two compositions \((\text{Bi}_{0.83}\text{Fe}_{0.17})\text{FeO}_3\) and \((\text{Bi}_{0.67}\text{Fe}_{0.33})\text{FeO}_3\). Samples were synthesized by a sol-gel route at 873 K. Starting from X-ray amorphous nano-crystallites heating time and temperature exclusively determine the iron occupancy on the perovskite site \([4]\). The materials were investigated by temperature-dependent neutron time-of-flight powder diffraction at POWGEN (SNS, Oak Ridge, USA) from 10 K to 650 K. A deep minimum has been observed at about 240 K for the change of coordination of Fe-site and O-sites in \((\text{Bi}_{0.67}\text{Fe}_{0.33})\text{FeO}_3\) system, which has been shifted to 260 K for \((\text{Bi}_{0.83}\text{Fe}_{0.17})\text{FeO}_3\). Any anomaly was not observed for the temperature-dependent atomic displacement parameters (ADPs) and thermal expansion. Fitting the ADPs using Debye approach, all three atom-sites showed usual harmonic behavior, leading to a Debye temperature of 288(10) K and 368(13) K for \((\text{Bi}_{0.83}\text{Fe}_{0.17})\text{FeO}_3\) and \((\text{Bi}_{0.67}\text{Fe}_{0.33})\text{FeO}_3\), respectively. Notably, the Bi/Fe and O-sites show significantly a higher frequency shift of two selective modes than those of the stoichiometric \(\text{BiFeO}_3\) perovskite. The damping factors obtained from the simplified Klemens phonon decay model distinguishes between the phonon and magnon contributions to the microscopic heat capacity of the modes.

Investigation of Structural and Magnetic Properties of RT\(_2\)Ga Compounds

George Ahegworovri and Corey Thompson; Chemistry, Purdue University, West Lafayette, Indiana, United States.

Ternary \( \text{RT}_2\text{X} \) compounds \((\text{R} = \text{rare earth, T} = \text{transition metal, X} = \text{Al, Ga, Si, Ge}) \) and their derivatives have been the subject of intense research during recent years. These compounds crystallize in three structure-types, cubic \( \text{MnCu}_2\text{Al} \), orthorhombic \( \text{YPd}_2\text{Si} \), and hexagonal \( \text{GdP}_2\text{Sn} \). In this system, the silicides, germicides, and aluminides are the most studied and little is known about their gallium congeners. \( \text{RPd}_2\text{Ga} \left( \text{R} = \text{La} - \text{Dy} \right) \) is the only gallium compounds that have been studied thus far. These compounds exhibit both ferromagnetic \((\text{R} = \text{Tb})\) and antiferromagnetic \((\text{R} = \text{La} - \text{Gd, Dy})\) properties with an ordering temperature ranging from 2 to 24 K. We have synthesized several new \( \text{RT}_2\text{Ga} \) phases \((\text{T} = \text{Fe, Co, R} = \text{Gd, Tb, Dy})\), with ferromagnetic transitions greater than those exhibited by the \( \text{Pd}-\text{analogs} \). The structural and physical properties of these new ternary compounds will be highlighted in this talk.

Structural Transitions, Jahn-Teller Distortion, Cyclability and Specific Energy in \( \text{PZ}-\text{Type Na}_2\text{MnO}_2 \) (M=Transition Metals) Materials as Candidates for Sodium-Ion Battery Cathode Applications

Uma Garg\(^1\), William C. Rexhausen\(^2\), Nathaniel P. Smith\(^1\), Joshua Harris\(^2\), Deyang Qu\(^2\) and Prasenjit Guptasarma\(^1\); \(^1\)Department of Physics, University of Wisconsin Milwaukee, Milwaukee, Wisconsin, United States; \(^2\)Department of Mechanical Engineering, University of Wisconsin Milwaukee, Milwaukee, Wisconsin, United States.

Development of reliable, high-performance solid state materials for advanced energy conversion and storage is of technological importance for the US economy as well as for a secure, sustainable energy future for humankind. The design of present-day Li and Li-ion batteries have relied on previous studies of composition, crystal structure-property characterization, and device performance. Na-ion cathode materials are potential alternatives to Li-ion materials due to the natural abundance, and low cost, of sodium resources. Recent developments in suitable electrolyte and anode materials have revived interests in the use of newer Na-based compositions and structures as potential battery electrode materials. Here, we report our results on different compositions of layered oxides of the type \( \text{Na}_2\text{MO}_2 \) (where \( \text{M} = \text{a transition element, or a combination of transition elements} \)) as cathodes in coin cells built using a Na anode, \( \text{NaClO}_4 \) electrolyte and Celgard separator in a CR 2032 coin cell assembly. Specifically, we discuss the effect of \( \text{in-situ} \) battery voltage cycling on crystal structure, and on structural transitions, in \( \text{PZ}-\text{type Na}_2\text{MnO}_2 \) (NMFO). We find NMFO to have a reversible capacity of 185 mAh/g, but relatively low cyclability. Our results confirm that NMFO undergoes a structural transition from \( \text{P6}_3\text{mmc} \) to \( \text{P6}_3 \) at 4.3 V while charging, and to a \( \text{Cmcm} \) at 1.5 V while discharging. It is currently believed that the presence of \( \text{Mn(III)} \), a Jahn-Teller active ion leads to a cooperative distortion and structural instability, resulting in a transition from \( \text{hexagonal P2} \) to \( \text{orthorhombic P2'} \) during cycling. We have studied the effect of substitution of additional transition metals in NMFO in an effort to suppress this distortion and structural instability and to increase cyclability. We performed crystal structure refinement on \( \text{ex-situ} \) x-ray diffraction under controlled atmospheric conditions, as well as studies of battery capacity, specific energy, and cyclability at different battery voltage values during cycling. The substitution of additional transition metals is found to lead to an absence of structural transitions during charging and discharging to 4.3 V and 1.5 V, respectively. However, charging at 4.3 V affects the crystallinity of the material as observed by the broadening of x-ray diffraction (XRD) peaks. The cyclability and capacity was found to improve when the cells are cycled in the voltage range 1.5–4.0 V and 2.0 – 4.0 V, with an increase in specific energy from 325 Wh/g to 375 Wh/g when cycled in the 1.5 – 4 V range. Specific energy remains steady up to 100 cycles, pointing to the possibility of higher cyclability. We believe that additional detailed work on the effect of the Mn(III) Jahn-Teller distortion on properties of Na-ion cathode phases can lead to battery materials with improved capacity and cyclability.
CrFeO₃ is a spinel inverse spinel structured crystal with potentially interesting magnetic, electronic, and photophysical properties. The parent materials Fe₂O₃ (magnetite) and Fe₃O₄ (chromite) are naturally occurring minerals each with their own interesting and industrially useful properties. Despite the general interest in the parent compounds, CrFeO₃ is among the least studied of the transition metal spinels. Part of this gap in research lies in the lack of availability of high quality single crystals to study on top of being an unnatural compound. To get around the latter part we can use molecular beam epitaxial (MBE) growth techniques to control the precise stoichiometry and orientation to allow for synthesis of meta-stable or unnaturally layered materials. However, there still remains a lack of suitable single crystal substrates for epitaxial growth of CrFeO₃. MgO (magnesia) has a favorable lattice mismatch of just ~0.34% compressive, but Mg diffusion from the substrate into the overlying film can become significant at deposition temperatures as low as 250°C, creating a tradeoff between crystallization kinetics and intermixing. MgAlO₃ (spinel) is isostructural with CrFeO₃ and more stable against intermixing, but it also has a much smaller lattice constant, and lattice mismatch >5% compressive. Here we report on novel MBE synthesis of CrFeO₃ on spinel and with a variety of similar systems, previously studied. A novel method for estimating cation concentration is presented and scrutinized.

Transmission electron microscopy (TEM) (1) has been used to analyze the material structure in detail and correlated to bulk techniques like x-ray diffraction (XRD). Surface chemistry, surface structure, optical absorption, magnetic properties, out-of-plane lattice constants, and other material properties are examined as a function of reversible cation valence, cation stoichiometry, and growth conditions.

Keywords: Molecular beam epitaxy (MBE), ellipsometry, reflected high energy electron diffraction (RHEED), low energy electron diffraction (LEED), X-ray photoemission (XPS), thin film, stoichiometry, magnetite, Fe₃O₄, chromium, iron, oxygen, Fe₃O₄, magnesite, hematite, semiconductor, optical, X-ray diffraction (XRD), extended x-ray absorption fine structure (EXAFS), x-ray absorption near edge spectroscopy (XANES), Rutherford backscattering spectrometry (RBS)

CM01.12.24
Heterointerface Effects on the Peculiar Growth Characteristics of Brownmillerite SrFeO₂.₅ Thin Film Grown on Perovskite SrRuO₃ and SrTiO₃

The rich properties and broad utilities of transition metal oxides are enabled by the strong coupling among the lattice, charge, spin, and orbital degree of freedom, which basically originates from the strong hybridization between transition metal d and oxygen 2p orbitals. Engineering such complex correlations has thus been recognized as a route for tailoring functional properties of transition metal oxides. In recent years, unprecedented physical phenomena further emerged by manipulating the heterointerface of transition metal oxides, such as two-dimensional free electron gases, which have never been accessed in their bulk equilibrium phases. These new phenomena were born through the interface controls which essentially modify the degree of the orbital hybridization. Basically, such interface structure and/or chemistry could also exert a profound influence on the growth dynamics of oxide thin films on foreign substrates. In addition to controlling the growth process of the thin films by a conventional method, i.e. imposing an epitaxial strain, various interface effects can extend the range of choice for manipulating the growth behavior of oxide thin films. The resulting growth behavior significantly affect the microstructures and physical properties of the thin films correspondingly. Therefore, accurate determination of oxide heterointerface structure is essential for understanding the growth characteristics of oxide thin films and for fabricating the functional devices having desired physical properties.

The interface effect can play a crucial role in controlling the growth behavior of oxide thin films by overcoming the simple epitaxial strain energy. For that purpose, brownmillerite SrFeO₂.₅ (BM-SFO) thin films were grown on SrTiO₃ (STO)(001) and SrRuO₃ (SRO)(001) substrates as a model system, and their microstructures were investigated using first principles calculations and transmission electron microscopy. The BM-SFO thin films grown on both the STO(001) and SRO/STO(001) substrates showed b-axis oriented growth at the interface, as opposed to the a-axis oriented growth predicted simply by the epitaxial strain effect from lattice mismatch with the substrates. They even revealed distinct heterointerface structures and growth processes on the two substrates having the same in-plane lattice parameters, which indicates the presence of additional key factors controlling growth characteristics of the thin films. We found that these discrepancies in the growth processes of the thin films originated from the interface effects governed by the heterointerface structures such as the ‘peculiar transition layer’ as well as the different chemical species and ‘octahedral connectivity’.

CM01.12.25
Diamond-Clad Semiconductor Optical Fibers

Optical fibers are a cornerstone of modern communications and research. The simplest of these fibers, made of silica, guide light with exceptionally low losses, while more complex microstructured or doped silica fibers are capable of advanced photonics. Such structures are immensely useful but have one clear limitation: optical fiber technology has historically been limited to glass. Materials such as semiconductor materials can expand the optical and electronic functionality of fiber technology, but have proven difficult to manufacture because their properties are not compatible with conventional glass drawing processes. High pressure chemical vapor deposition (HPCVD) circumvents this issue by enabling the direct deposition of semiconductor materials into glass capillaries via the thermal decomposition of gaseous precursors. With HPCVD, optical fibers composed of highly pure semiconductor cores, including silicon and zinc selenide, have been synthesized. These fibers possess low optical losses due to their atomically smooth surfaces and infrared transparency and exhibit a range of tunable material properties, opening the way for new functional fibers. Despite broadening the materials base for optical fibers, HPCVD continues to operate with the constraint that materials are deposited into glass templates. Current efforts are underway to replace this glass cladding with materials such as diamond. Diamond possesses a range of extraordinary properties, including high thermal conductivity and wide optical transparency in the IR, making it an ideal cladding for materials such as silicon or zinc selenide fiber. To synthesize diamond claddings, silicon wires are first deposited using HPCVD. Following deposition, the silicon glass is removed by etching in hydrofluoric acid, leaving a bare silicon wire that may be used as a substrate for microwave plasma CVD. Dip-coating and sputtering are then used to seed...
such fibers and enable the deposition of diamond claddings tens of microns thick around the entire fiber structure. Scanning electron microscopy and Raman spectroscopy are used to characterize the diamond, revealing excellent crystallinity. In addition, waveguiding of infrared light has been demonstrated in such fibers.

CM01.12.26 Synthesis and Structural Characterization of Non-Stoichiometric Ferrite Nanopowders Keri A. Ledford1, Kenneth Allen1, Jason H. Nadler1, Rick Moore1, David Reid2 and Sarah Lombardo2; 1Georgia Tech Research Institute, Atlanta, Georgia, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States.

Sol-gel processes, followed by an auto-combustion reactions to synthesize ferrites with tailorable stoichiometry have been investigated. Different compositions were produced by this method, substituting the iron in some of the crystal structure with other metals, including nickel, zinc, copper, manganese, and cobalt. A parametric study was conducted on the different compositions to determine the effects of calcining and leaching on the structure of the material. The as-synthesized, calcined, and leached nanopowders were characterized by x-ray diffraction and transmission electron microscopy.

CM01.12.27 Visible Absorbance Variation in Bismuth-Containing Dion-Jacobson Perovskites Luis J. Smith, Wendy Nason and Raistlin Bittues; Carlson School of Chemistry and Biochemistry, Clark University, Worcester, Massachusetts, United States.

Dion-Jacobson perovskites with the general formula A’A-nBnO3n+1 are of interest due to their photocatalytic, piezoelectric, ferroelectric properties as well as their ability to exfoliate into nanosheets and restack into new heterogeneous materials. Insertion of lead or bismuth into the interstitial sites of the layered niobates can shift the band gap of the material from the UV into the visible region. Incorporation of bismuth is desired to produce an alternative to the known APb2Nb2O7 (A = Cs, Rb) due to toxicity concerns with lead containing materials. However, the band gap energies of the double and triple perovskite layer version appear to depend on the A’ cation and A cation identities and the synthesis and ion exchange pathways when bismuth is part of A’ interstitial site population. The double-perovskite layer version, RbBiNb2O7, is reported to display ferroelectric and piezoelectric properties as well as possess a moderate indirect band gap (2.5 eV). However, when RbBiNb2O7 is acid-exchanged to remove rubidium under typical conditions (6M HNO3 at 60 °C) in preparation for the exfoliation process, the observed band gap of the material is no longer in the visible region, yet acid-exchange at low temperatures preserves the visible region band gap. A new Dion-Jacobson perovskite RbBiKnO3 has been synthesized via high temperature solid state methods using RbBiNb2O7 and KNbO3. The triple-perovskite layer version, RbBiKnO3, maintains an indirect band gap in the visible region (2.5 eV) before and after acid-exchange over a wide temperature range. However, replacement of the interstitial site potassium atoms with sodium results in a band gap in the ultra-violet region even in the rubidium-containing parent form. Results from x-ray diffraction, diffuse reflectance spectroscopy, and 93Nb solid-state NMR spectroscopy will be presented to discuss the evident changes in local structure due the site population variations that drive the band gap changes.

CM01.12.28 Comparative Study on Structural and Optical Properties of InGaN/GaN MQWs Grown by Pulsed MOVPE Mantas Dmukauskas1,2, Tadas Malinauskas3, Rolandas Tornasiunas1, Juras Mickevicius1, Darius Dobrovolskis1, Martynas Skapas4, Sandra Stanionyte5 and Arunas Kadys5; 1Institute of Photonics and Nanotechnology, Faculty of Physics, Vilnius University, Vilnius, Lithuania; 2Department of Characterization of Materials Structure, Institute of Chemistry, Center for Physical Sciences and Technology, Vilnius, Lithuania.

InGaN alloys continue to experience problems of incorporating indium (In) when grown by metalorganic vapor phase epitaxy (MOVPE) [1]. On a theoretical level it should be possible to incorporate higher In concentrations into InGaN alloys, however, current attempts to do so lead to In clustering or even segregation into metallic In, ultimately leading to the deterioration of crystal quality. One of the possible solutions to overcome In segregation is to use growth with metallic (MO) flow interruptions [2]. This method gives extra time for adsorbed atoms to migrate on the surface and either be incorporated to crystal or to desorb. In this work we present a detailed analysis of InGaN multiple quantum wells (MQWs) grown by MOVPE using interruptions of MO flow into the reactor chamber. All samples were grown using Aixtron CCS 3×2 reactor keeping all growth parameters constant except timing of MO flow interruptions from 0s (conventional growth) up to 15s.

X-ray diffraction (XRD) measurements were conducted to evaluate the In mole fraction, composition, homogeneity and crystalline structure of the InGaN QWs. Structure morphology and layers thicknesses of MQWs were studied using transmission electron microscopy (TEM). XRD measurements revealed that In concentration in InGaN MQWs was 9.5 ± 0.5% for all samples and so the desorption of In during the interruptions was found to be minor. TEM measurements showed that the QW, barriers, as well as super-lattice (SL) structure are easily distinguishable by the In fluctuation, which confirms a well-formed crystalline structure. A systematic study of the photoluminescence (PL) intensity on interruption duration was carried out at different temperatures from 10 K up to 300 K. PL intensity increases up to 2 times with blue shift of 54 meV at room temperature with interruption time increase. The FWHM value increase is minor and can be neglected. To determine the extent of the carrier localization effect in MQWs the Gaussian broadening parameter of carrier localization states was evaluated from S-shape temperature dependence of the PL peak. Though, the value of s parameter does not change significantly (21÷24 meV) with increase of interruption duration. To get a better understanding of MO flow interruption influence on In fluctuation in InGaN layers spatially-resolved sub-micrometer scale PL (µPL) measurements were carried out. Extracted areas (grains) having the average values of PL peak position with ± 3 nm deviation represent the carrier localization centers. It was found that increasing the duration of interruption resulted in reduction of the average grain area. Meanwhile, the number of individual grains increased and resulted in a total grain area increase. This leads to a higher density of states and an increase in PL intensity.

CM01.12.29 Atomistic Origins of Shear Strength in 2D Materials Adam R. Hinkle, John F. Curry, Tommas Babuska, Brandon Keick, Michael T. Dugger, Michael Chandross and Nicholas Argibay; Sandia National Laboratories, Albuquerque, New Mexico, United States.
The low-friction behavior of two-dimensional lamellar materials has been reported in dry, inert environments and is known to depend upon the diffusive motion of the lamella and their relative degree of commensurate stacking, as well as temperature. However, no encompassing theoretical framework presently exists to predict macroscopic friction-related properties such as shear strength. We present a simplified, yet unifying model where the frictional behavior of lamellar materials is described entirely in terms of rotational and translational energy barriers, whose values are determined directly from chemically reactive molecular dynamics (MD) calculations. In the specific case of molybdenum disulfide (MoS2), the barrier heights are shown to converge with increasing lamellar flake size, and reveal the most probable activation mechanisms to interlamellar sliding. We evaluate the model's prediction of interfacial shear strength by comparing to related MD shear simulations and thin-film sliding experiments of MoS2, and find strong agreement over a wide range of temperatures.

CM01.12.30
Defect Architecture for Decoupling Carrier Mobility and Lattice Thermal Conductivity in N-Type PbSe Thermoelectric Materials [Chongjian Zhou] and In Chung; 2Center for Nanoparticle Research, Institute for Basic Science (IBS), Seoul, Korea (the Republic of); 3School of Chemical and Biological Engineering, Seoul National University, Seoul, Korea (the Republic of).

Structural defects including vacancies, nanoprecipitates, and dislocations can reduce lattice thermal conductivity. However, they also tend to be deleterious to carrier mobility. As a result, the overall effects for improving ZT are often compromised. In fact, developing strategies allowing for strong phonon scattering and high carrier mobility at the same time is a primary task in thermoelectric. In this presentation, we report a high performance thermoelectric system of Pb0.95Sr0.05Sn0.5Si0.5Te3 that includes unique defect architecture. Considering the mean free paths of phonons and electrons, we integrate multiple defects that include point defects, vacancy-driven dense dislocations, and Te-induced nanoprecipitates with different sizes and mass fluctuations. They scatter thermal phonons collectively in a wide range of frequency to give ultralow lattice thermal conductivity of ~0.4 W m⁻¹ K⁻¹, which approaches to the theoretical lower limit. Remarkably, Te alloying increases a density of nanoprecipitates that affect mobility negligibly and disrupt phonons significantly, and it also reduces a density of dislocations that scatter both electrons and phonons heavily, As x is raised to 0.4, electron mobility is increased and lattice thermal conductivity is decreased concurrently. As a consequence, Pb0.95Sr0.05Sn0.5Si0.5Te3 exhibits the highest ZT ~1.5 at 823 K, which is attributed to the significantly enhanced power factor and depressed lattice thermal conductivity, compared with a ZT ~0.9 for Pb0.95Sr0.05Sn0.5Te3 that contains heavy dislocations only. These results highlight the potential of defect engineering to control electrical and thermal transport properties independently.

CM01.12.31
Enhanced Energy Storage Properties of Ba(Zr0.2Ti0.8)O3-0.15(Ba0.7Ca0.3)TiO3 Ceramics with BaO-SrO-TiO2-Al2O3-SiO2-BaF2 Glass [Addition Weiwei Ping1, Wenfeng Liu2 and Shengtao Li; 1Electrical Engineering, Xi’an Jiaotong University, Xi’an, China; 2Department of Electrical Engineering, Xi’an Jiaotong University, Xi’an, China.]

Glass addition BaO-SrO-TiO2-Al2O3-SiO2-BaF2 was employed to improve the microstructures and energy storage properties of the Ba(Zr0.2Ti0.8)O3-0.15(Ba0.7Ca0.3)TiO3 ceramics, which exhibited a large dielectric constant of 3458 at 25 °C under 1 kHz, slim hysteresis loop with the maximum polarization of 12.53 μC/cm² and a remnant polarization of 4.05 μC/cm². Microstructural observation indicated that the average grain size reduced significantly with increasing the glass concentration. Macroscopically the glass ceramics exhibited diffusion phase transition with reduced peak dielectric constant but broad peak with relatively large dielectric constant of around 1000 within the room temperature region. Meanwhile the electrical breakdown strength (BDS) of the glass modified ceramics was nearly quadruple to the pure ceramics form. Energy storage performance of the glass modified ceramics, both 419.4 kJ/m³ calculated from the product of dielectric constant and square of BDS and 192.8 kJ/m³ from the integration of the hysteresis loop strength (BDS) of the glass modified ceramics was nearly quadruple to the pure ceramics form. Energy storage performance of the glass modified ceramics, both 419.4 kJ/m³ calculated from the product of dielectric constant and square of BDS and 192.8 kJ/m³ from the integration of the hysteresis loop strength under the electric field of 9.6 kV/mm, showed significant superiority to that of the pure ceramic form.

CM01.12.32
Building Optical Anisotropy via Polarizability Engineering in Quasi-1D Crystal Structures [Shuyuan Ni; 1Huan Zhao; 2Graham Joe; 1Yucheng Zhou, 1Thomas Orvis1, Huaxiong Huang1, Jad Salman1, Krishnamurthy Mahalingam3, Brittany Urwin3, Jiangbin Wu2, Yang Liu1, Tom E. Tiwald1, Stephen B. Cronin2, Brandon M. Howe2, Matthew Mecklenburg2, Ralf Haiges2, David Singh1, Han Wang2, 1Mikhail A. Kats1 and Jayakanth Ravichandran1, 3Mork Family Department of Chemical Engineering and Materials Science, University of Southern California, Los Angeles, California, United States; 2Ming Hsieh Department of Electrical Engineering, University of Southern California, Los Angeles, California, United States; 3Department of Electrical and Computer Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States; 4Materials and Manufacturing Directorate, Air Force Research Laboratory, Dayton, Ohio, United States; 1A. Woollam Co. Inc., Lincoln, Nebraska, United States; 5Center for Electron Microscopy and Microanalysis, University of Southern California, Los Angeles, California, United States; 6Loker Hydrocarbon Research Institute and Department of Chemistry, University of Southern California, Los Angeles, California, United States; 7Department of Physics and Astronomy, University of Missouri, Columbia, Missouri, United States.]

Rational design or discovery of new materials or innovative functionalities in underexplored materials, has been a key contributor to several electronic, photon, and energy technologies. We report the realization of strong optical anisotropy via chemically tuning the polarizability tensor in quasi-one-dimensional (quasi-1D) crystal structures. Optically anisotropic materials are of great scientific and technological importance in photonic and optoelectronic applications. Quasi-1D structures feature long parallel chains with strong intra-chain bonding and weak inter-chain interaction. In contrast to other low-dimensional materials, they offer robust cleavage planes with easily accessible in-plane anisotropy, which is critical for practical application of optical anisotropy. The optical anisotropy is enhanced by considering the constituent ions’ polarizability to maximize the polarizability difference along different axes in the system. We demonstrate two model systems, BaTiS3 and Sr0.7Ti0.3S0.7T0.3, both with hexagonally aligned chains of face sharing TIs6 octahedra. Large single crystals were grown using chemical vapor transport method with iodine as a transporting agent, allowing extensive spectroscopic studies of their inherent anisotropic properties. We report the observation of strong and broadband infrared birefringence, as well as linear dichroism with distinct polarization-dependent optical absorption edges in the mid-infrared spectrum. Notably, the unprecedented birefringence of up to 0.76 in the transparent region of BaTiS6 more than doubles that in any other bulk crystal.

CM01.12.33
Memristor Behavior and Novel Structural Properties in (Ph3As)3(BiI3)3 Mixtures [Graff C. Alexander1, 2Hue Joon Jung2, Patrick Krantz2, Giancarlo Tormen3, 4Mannes van den Waals5, 6K. Jayme McCall7, 8Bruce Wessels7, 8Vinayak P. Dravid7, 8Venkat Chandrasekhar7, 8Chemistry, Northwestern University, Evanston, Illinois, United States; 4Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; 5Physics and Astronomy, Northwestern University, Evanston, Illinois, United States; 6Physics and Astronomy, Northwestern University, Evanston, Illinois, United States.]

Heavy metal halide semiconductors have been widely investigated for their optoelectronic properties for photovoltaic and high energy radiation detection applications. Ph3As (Eg = 2.3 eV) and BiI3 (Eg = 1.7 eV) are highly resistive semiconductors that have been exhaustively characterized for device applications but suffer structurally due to their 2D van der Waals structure. Ph3As crystallizes in the CdI2 structure type with layers of fully edge-sharing...
octahedral PbI4 and BiI3 displays an analogous structure with ordered vacancies to compensate for Bi being trivalent. This work focuses on the preparation of (PbI2)(BiI3)
and characterizes the material chemically, electronically, and structurally. Our work predominantly features (PbI2)(BiI3)1.8 which is prepared by the direct reaction of PbI2 and BiI3 to yield dark black crystalline ingots. (PbI2)(BiI3)1.8 displays an absorption edge at 1.7 eV and tuning cooling rate can be used to induce low energy absorption beginning at 1.0 eV. Density Functional Theory calculations demonstrate that this low energy absorption arises as Bi is incorporated into the PbI2 non-vacancy lattice leading to strong mid-gap states. Single crystal X-ray diffraction is deceptive to the true structure as by X-ray (PbI2)(BiI3) appears as a single structural phase. However, transmission electron microscopy (TEM) reveals that while the material has a new structure, it partially phase separates yielding Pb and Bi rich regions while still retaining an overall contiguous structure. (PbI2)(BiI3)1.8 displays consistent and reproducible memristor behavior. As bias is swept perpendicular to the layers (PbI2)(BiI3) behaves as an ohmic resistor and is activated. As bias is reversed a significant current spike is observed as the sample is “switched” on and activated in the opposite direction. This observed “switch” current decays on the time scale of seconds when the bias is held constant, contrasting with other memristor materials that remain in their low resistive states once induced. We propose that this effect is due to observed lattice mismatch between Pb and Bi rich regions as observed by TEM. At these regions some layers terminate abruptly leading to undercoordinated iodine atoms which can be liberated with the appropriate field applied across the material and moved in within their narrow defect regions. These results expose a new class of robust memristor materials with novel optical and structural properties that are ready for further development.

CM01.12.34
Non-Equilibrium Crystallization Pathways of Manganese Oxides in Aqueous Solution
Wenhao Sung1, Daniil Kitchaes2, Denis Kramer3 and Gerbrand Ceder1; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Drexel University, Philadelphia, Pennsylvania, United States; 3Argonne National Laboratory, Argonne, Illinois, United States.

Aqueous precipitation of transition metal oxides often proceeds through non-equilibrium phases, whose appearance cannot be anticipated from traditional phase diagrams. Without a precise understanding of which metastable phases form, or their lifetimes, targeted synthesis of specific metal oxides can become a trial-and-error process. Here, we construct a theoretical framework to reveal the nanoscale and metastable energy landscapes of Pourbaix (E-pH) diagrams, providing quantitative insights into the size-dependent thermodynamics of metastable oxide nucleation and growth in water. By combining this framework with classical nucleation theory, we interrogate how solution conditions influence the multistage oxidation pathways of manganese oxides. We calculate that subtle variations in pH and redox potential can redirect a crystallization pathway through different metastable phases, even when the final equilibrium product remains unchanged. Our theoretical framework offers a predictive platform to navigate through the thermodynamic and kinetic energy landscape towards the rational synthesis of target oxide transition pairs.

CM01.12.35
A Map of the Inorganic Ternary Metal Nitrides
Wenhao Sung1, Christopher Bartel2, Elisabetta Arca3, Sage Bauers3, Bethany Matthews4, Bor-Rong Chen5, Michael F. Toney3, Laura Schelhas4, William Tumas3, Janet Tate3, Andrij Zakutayev2, Stephan Lany4, Aaron Holder1 and Gerbrand Ceder1; 1Lawrence Berkeley National Laboratories, Berkeley, CA, CA, California, United States; 2University of Colorado Boulder, Boulder, Colorado, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States; 4SLAC National Accelerator Laboratory, Menlo Park, California, United States; 5Oregon State University, Corvallis, Oregon, United States.

Exploratory synthesis in novel chemical spaces is the essence of solid-state chemistry. However, uncharted chemical spaces can be difficult to navigate, especially when materials synthesis is challenging. Nitrides represent one such space—where stringent synthesis constraints have limited the exploration of this important class of functional materials. Here, we employ a suite of computational materials discovery and informatics tools to construct a large stability map of the inorganic ternary metal nitrides. Our map connects the ternary nitride clusters into chemical spaces with distinct stability and metastability; and highlights hundreds of promising new ternary nitride spaces for experimental investigation, from which we synthesized 7 novel Zn- and Mg-based ternary nitrides. By extracting the mixed metallicity, ionicity, and covalency of solid-state bonding from the DFT-computed electron density, we reveal the complex interplay between chemistry, composition, and electronic structure in governing large-scale stability trends in the ternary metal nitrides.

CM01.12.36
Revealing the Atomic Kinetics of Phase Transition from 2D Layers to 1D Tunnels in Transitional Metal Oxides
Yifei Yuan1, Bryan W. Byles2, Kun He3, Cong Liu4, Jun Lu5, Khalil Amine6, Ekaterina Pomerantseva7 and Reza Shahbazian-Yassar1; 1University of Illinois at Chicago, Chicago, Illinois, United States; 2Drexel University, Philadelphia, Pennsylvania, United States; 3Argonne National Laboratory, Argonne, Illinois, United States.

MnO2 abundantly exists in the earth’s crust and marine sediment. Based on how its structural units ([MnO6] octahedra) are linked, polymorphic MnO2 is categorized into two types: two-dimensional (2D) layered and one-dimensional (1D) tunnel phases. In general, layered MnO2 can transform into tunnel structures, such as the well known σ-MnO2-α-MnO2 and buserite-todorokite phase evolution. Therefore, layer-to-tunnel (L-T) transition, typical for manganese oxide (MnO2) polymorphs, is the ubiquitous reaction leading to the formation of one-dimensional angstrom-scale tunnels that are extensively applied in catalysis, energy storage and material separation. This transition is also fundamental in the natural formation of Mn-rich marine sediment on the Earth. Current mechanisms explaining the L-T transition are debating, particularly in the critical role of Jahn-Teller distortion of [Mn3+O6] in guiding the behavior of the layered precursors. The lack of fundamental and atomic level understanding of this phase transition leads to poorly controlled synthesis of size-specific tunnels, and also results in difficulty to clarify the role of marine sediments in global trace element cycles.

Herein, we report the first atomic-scale visualization of two novel L-T transition pathways via aberration-corrected scanning transmission electron microscopy, electron energy loss spectroscopy and density function theory calculations. 10 Å-spaced layered buserite is used as the precursor subjected to hydrothermal treatment to enable the L-T transition. By characterizing the atomic structure of the products at different reaction stages, we found that the L-T transition requires multiple steps via formation of intermediate tunnels with large openings, and this stepwise process obeys the numeric rule: one 3+ (2N-1) tunnel → two 3+ N tunnels. The important role of Jahn-Teller Mn3+O6 octahedra in driving the microscopic layer distortion, causing strain concentration and triggering the L-T transition is also demonstrated. We expect these atomic-level discoveries to guide the synthesis of MnO2 nanostructures with controllable and uniform tunnel sizes, and also results in difficulty to clarify the role of marine sediments in global trace element cycles.

CM01.12.37
Extremely Low Thermal Conductivity and High Thermoelectric Performance in Polycrystalline SnSe
YongKyu Lee1, 2 and In Chung1, 2; 1Seoul National University, Seoul, Korea (the Republic of); 2Center of Nanoparticle Research, Institute for Basic Science, Seoul, Korea (the Republic of).

SnSe have emerged as a promising thermoelectric material due to the recent discovery of an ultralow thermal conductivity and ultrahigh thermoelectric figure of merit in its single crystalline form. Since then polycrystalline counterparts have been extensively investigated because of their machinability and probability of large scale applications. However, polycrystalline SnSe samples show much higher thermal conductivity and consequently poor thermoelectric performance. Our work here explores the influence of hydrothermal treatment to enable the L-T transition. By characterizing the atomic structure of the products at different reaction stages, we found that the L-T transition requires multiple steps via formation of intermediate tunnels with large openings, and this stepwise process obeys the numeric rule: one 3+ (2N-1) tunnel → two 3+ N tunnels. The important role of Jahn-Teller Mn3+O6 octahedra in driving the microscopic layer distortion, causing strain concentration and triggering the L-T transition is also demonstrated. We expect these atomic-level discoveries to guide the synthesis of MnO2 nanostructures with controllable and uniform tunnel sizes ideal for specific nanoengineering applications, as well as clarify the geochemical interpretation of marine sediment discoveries for the geological evolution of the Earth.
thermoelectric performance than single crystals. It is in contrary to the general understanding that the polycrystalline specimens show suppressed thermal conductivity due to phonon scattering at the grain boundary. Several reports suggested that higher thermal conductivity of polycrystalline SnSe originates from impurities as induced by powder processing. In this work, we discuss that our synthesis process successfully impurities that can increase thermal conductivity. As a result, we can obtain extremely low lattice thermal conductivity and remarkably enhanced thermoelectric figure of merit in polycrystalline SnSe samples.

CM01.12.38
Multi-Steps Sintering Synthesis Process of Ferrite for Enhancing Magnetic Property
Ning Jia and Huaiwu Zhang; State Key Laboratory of Electronic Thin Film and Integrated Devices, University of Electronic Science and Technology of China, Chengdu, China.

The criteria of the synthesis of high-performance bulk ferrite might be very rigor especially for the temperature. Most of the ceramic and ferrite should be sintered at hundreds degree centigrade and for YIG (yttrium iron garnet, original), the sintering temperature should be 1450 °C. The high level of sintering conditions limits the applications of ferrite for instance of co-sintering with silver. In decades, many researchers launched the research in ions doping, adulteration, adding sintering aids, changing the method of sintering. But rare of them considered on optimizing the synthesis process. Therefore, it is highly desirable to design a new synthesis process that allows us to improve it. Here, we study doped Bi-YIG simples synthesized by multi-steps including different sintering tempales and variable steps. The results showed an obvious improvement on soft magnetic properties and low linewidth. Then the multi-steps sintering enables enhancing the carrier mobility and the fusion of grain boundary which makes main effect on the homogenization of grains.

CM01.12.39
Pulsed Laser Deposition of Ti3AlC2 of the New Class of Layered Mn+1AXn Phase Solids
Arundhati Sengupta, Abhijit Biswas and Satishchandra Ogale; Department of Physics and Centre for Energy Science, Indian Institute of Science Education and Research (IISER), Pune, Pune, India.

Mn+1AXn phases (where n = 1–3, M is an early transition metal, A is mostly a group 13 or 14 element and X is carbon/nitrogen) are a new class of layered solids with intriguing chemical, physical, electrical, and mechanical properties arising from basal dislocations. These materials combine metallic and ceramic characteristics exhibiting oxidation/ corrosion resistance, elastic stiffness and low friction coefficient together with high thermal and electrical conductivities and machinability. These features lead to diverse applications such as structural, microelectromechanical, protective coatings, sensors, and electrical contacts. Although very large volume of outstanding work has been done on these systems in bulk by Gogotsi and coworkers as well as others, there is hardly any work on high quality Mn+1AXn and MXene films. Here we report oriented growth of films (~100 nm thickness) of Ti3AlC2, a well-recognized Mn+1AXn phase comprising earth-abundant elements, on substrates such as sapphire, silicon and quartz by pulsed laser deposition (PLD) at moderate temperatures (550–600°C) under vacuum (~10−6 mbar). These deposits were carried out by ablating a Ti3AlC2 target using the 248 nm radiation from a KrF* excimer laser (10 Hz frequency and fluence ~2 J/cm²). PLD technique was chosen for depositing the films because its hyperthermal particle energies enable low-temperature processing which is advantageous over conventional techniques such as chemical vapor deposition. Deposition of Ti3AlC2 films was confirmed by X-ray diffraction, Raman and energy dispersive X-ray spectroscopy (EDS). Preferred orientation of hexagonal Ti3AlC2 film grown on c-cut (006) sapphire was found to be along (103) plane while that on p-type (100) Si and quartz substrates was along (105) plane. Most intense Raman band ~270 cm−1 exhibited by the deposited films corresponds to longitudinal displacements of Ti and Al atoms of A1g symmetry. High energy band around 680 cm−1 corresponds to vibrations in C sublattice. Observed atomic % of Ti, Al and C were 30.8, 20.1 and 49.1, respectively, as per EDS elemental analysis (on films deposited on Si), fairly in accordance with 3:1:2 atomic ratio of Ti:Al:C in Ti3AlC2. Scanning electron microscopic images of the films showed homogeneous deposition. Thickness of films was tuned by varying the number of laser shots in optimizing the electrical conductivity for pertinent device applications.

Highly Ordered and Nanostructured Hexagonal Boron Nitride Synthesized through Molten Salt Synthesis Method
Kaiflin Wang1, Metin Örnek1, Sisi Xiang2, Chawon Hwang1, Kelvin Xue2 and Richard A. Haber1; 1Materials Science and Engineering, Rutgers, The State University Of New Jersey, Piscataway, New Jersey, United States; 2Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

Hexagonal boron nitride (h-BN) is one of the materials of choice for applications such as electronic insulators, heat sinks, and coatings due to its unique properties of high thermal conductivity, low thermal expansion, high thermal shock resistance, high electrical resistance, and a low dielectric constant. These properties, along with chemical inertness and resistance to wetting by metallic or non-metallic melts, make h-BN a viable material for metallurgical applications of high pressure. However, commercial highly ordered h-BN is synthesized at temperatures of 1800°C or higher, while lower synthesis temperatures through conventional methods result in unstable and less ordered (turbostratic) BN. Molten salt synthesis (MSS) allows precursor reactions to occur in a liquid media, allowing for improved diffusion and reaction kinetics, and therefore reduces synthesis temperatures. Through MSS, highly ordered h-BN was formed at 1000°C, and confirmed through X-ray diffraction (XRD). Fourier transform infrared spectroscopy (FTIR), and high-resolution transmission electron microscopy (HR-TEM). In this presentation, we will address the effect of synthesis conditions including heating temperature, dwelling time, and precursor composition on the formation of BN and its structural ordering. We will also propose a possible reaction mechanism to describe BN formation in molten salt based on thermodynamic considerations.

CM01.12.41
Precursor Dependent Synthesis of Aluminum Oxide Thin Films
Yvonne Afriyie; Washington Univ-St. Louis, Saint Louis, Missouri, United States.

Abstract
Aluminum is an ideal metal for solution-processed oxide dielectrics because it can form polymerized hydroxide networks in aqueous solution and dense amorphous oxide dielectrics by vacuum methods. Atomic layer deposition (ALD) is the traditional vacuum method for thin film deposition, however, ALD is not the most economically feasible method for fabrication due to the high operational cost and limitations in large surface-area applications.1 Solution deposition is a more economical deposition method which is more cost-saving and ideal for large surface area thin film fabrication.2 The behavior of the solution-solid conversion remains an enigma thus the project seeks to understand the thin film transformation from solution to solid in order to fabricate films with optimal properties.3

1. Aluminum oxide (Al2O3) thin films prepared from aqueous solution-deposited cluster precursors have been proposed for use in devices such as high-k dielectrics in solar cell materials.4 The films are fabricated with different Al precursors, spin-coated on a substrate and annealed to high temperatures. The low-temperature range of these films are amorphous and lack long-range order which complicates the analysis by traditional means; however, solid-state nuclear magnetic resonance (ssNMR) can be used to determine the structure of these materials. Herein, a combination of x-ray diffraction (XRD), and NMR techniques are used to elucidate the phase transformation of these thin films as they are annealed to high temperatures.

References
Indium phosphide is the leading Cd-free quantum dot material for application in photoluminescence downconversion display and lighting technologies. To date the performance of InP quantum dots has lagged behind cadmium selenide in terms of both luminescence line width and quantum yield. Extensive studies in our lab have implicated kinetically persistent magic-sized cluster intermediates as a leading contributor to polydispersity in these samples, providing new opportunities for achieving high color purity. Now, using a combination of X-ray emission and solid-state NMR spectroscopy we have studied the evolution of oxidized phosphorus species during both synthesis and shell growth. Correlations of this data with observed ensemble and single particle luminescence will be used to reveal the role of interfacial oxidation on the luminescence properties of InP QDs.

Ultrasmall Inorganic Cages Directed by Surfactant Micelles

Tangi Aubert\(^1,4\), Kai Ma\(^1\), Yunye Gong\(^2\), Melik Z. Turker\(^1\), Teresa Kao\(^1\), Peter C. Doerschuk\(^2,3\) and Ulrich Wiesner\(^1\);
\(^1\)Department of Materials Science and Engineering, Cornell University, Ithaca, New York, United States; \(^2\)School of Electrical and Computer Engineering, Cornell University, Ithaca, New York, United States; \(^3\)Nancy E. and Peter C. Meinig School of Biomedical Engineering, Cornell University, Ithaca, New York, United States; \(^4\)Department of Chemistry, Ghent University, Ghent, Belgium.

Functional silica nanoparticles have become highly relevant materials in the fields of biology and medicine. Ultrasmall fluorescent silica nanoparticles developed in our group (Cdots) have now reached phase 2 of clinical trials for cancer diagnostics. Nevertheless, modern nanomedicine techniques and their increasing complexity today are still in demand for more efficient and multifunctional tools for advanced applications such as theranostics. To this end, new alternative particle geometries have been investigated for targeted drug delivery applications.

In this contribution, we will review some of the recent progress made in our group that ultimately led to the discovery of highly symmetrical dodecahedral silica nanocages, or ‘silicages’ \(^[1]\). Ultrasmall (< 10 nm) silica nanoparticles with tunable geometries can be obtained through their templating with surfactant micelles. The self-assembly of silica clusters on these micelles gives rise to unique and well defined structures. The dodecahedral cage structure in particular is of great fundamental importance. It is the simplest of a set of Voronoi polyhedra suggested to form the smallest structural units of multiple forms of mesoporous silica, yet such highly symmetrical silica cages had never been isolated before. In order to resolve the actual structure of these ultrasmall objects, single-particle 3D reconstruction from tens of thousands of cryo-electron microscopy images was performed using a custom-built ‘Hetero’ machine learning algorithm. We will finally show that cage formation is not limited to silica, but has been observed for other materials including metals and transition metal oxides.

The chemical and practical value of this polyhedral structure may prove immense. Given the versatility of silica surface chemistry one can readily conceive of cage derivatives of many kinds, which may exhibit unusual properties and be useful in applications ranging from catalysis to drug delivery. For example, given recent success in the clinical translation of ultrasmall fluorescent silica nanoparticles with similar particle sizes and surface properties to these cages, one can envisage a range of new diagnostic and therapeutic probes with drugs hidden inside the cages.

Ultrasonic Melting Synthesis Method for Nanomaterials

Yuanbing Mao; The University of Texas at Rio Grande Valley, Edinburg, Texas, United States.

Bottom-up synthesis of nanomaterials with controllable crystallite size, shape, and composition often enhances the materials performance and provides model systems to aid in understanding nanoscale phenomena. Such benefits are evident in the application of nanomaterials towards heterogeneous catalysis, energy conversion, and environmental remediation, just name a few. Given the intimacy between the structural features and functions of nanomaterials, the development of facile synthetic methods with controllable growth of nanomaterials, especially for those with complex chemical compositions/morphologies, becomes an urgent necessity. Molten-salt synthesis (MSS) method is one of those as a simple, versatile, and cost-effective approach available for obtaining crystalline, chemically purified, single phase powders at lower temperatures and often in overall shorter reaction times with little residual impurities as compared with conventional solid-state reactions. While bulk materials have long been prepared using the flux method, the preparation of uniform nanostructures using the similar MSS technique has only arisen relatively recently, that is, within the current century. Over the years, our laboratory has applied this method to make various nanomaterials, especially those of transition-metal oxides. In this presentation, various examples will be demonstrated, including materials with perovskite, fluorite, pyrochlore and spinel structures, along with relevant growth mechanism studies and the property measurements of these synthesized nanomaterials. Therefore, it is expected that the MSS method will be widely disseminated and broadly adopted as a facile, reliable, scalable and cost-effective approach in synthetic nanochemistry.
understand MXene's properties, the precursor MAX phases have to be studied more in depth, specifically how starting MAX properties affect the consequent MXene properties.

Ti3AlC2 MAX was synthesized using three carbon sources: graphite, carbon lampblack, and titanium carbide. The synthesis was carried out using two routes: an equilibrium and non-equilibrium route. The equilibrium route was conventional high-temperature annealing, while the non-equilibrium route was via self-propagating high-temperature synthesis (SHS). By doing this, optimized synthesis conditions were determined for production of highly pure (>95 at.%) MAX phase materials. The reaction conditions were further varied, including heating rate, holding time, and pre- and post-ball milling treatment. Furthermore, the reaction mechanisms were studied, showing that the initial carbon source and heating rates change the reaction pathway. These additional parameters led to further refinement over the produced MAX phase. The effect of these changes was studied on the final MXene product, showing that there are significant changes in the resultant MXene quality, and consequently the electromagnetic interference shielding, electrical and electrochemical properties. Finally, these findings were applied to a wider variety of different MAX and MXenes, including V, Cr, Hf, and Nb-containing materials in 211, 312, and 413 phases.

9:15 AM CM01.13.05

Transition metal chalcogenide nanoparticles (NPs) have been proposed for applications in batteries, solar cells, and supercapacitors. Many methods have been established for synthesizing Ni NPs and the conversion chemistry to form Ni oxide and phosphides from template Ni NPs is well understood. The sulfidation and selenidation of Ni NPs have been much less explored, however. We report a method for the conversion of Ni template NPs into sulfide and selenide product NPs using elemental sulfur, l-hexadecanethiol, thiourea, trioctylphosphine sulfide, trioctylphosphine selenide, and selenourea. While maintaining molar ratios of 1.6 mmol S/Se precursor : mmol Ni in the Ni NPs, products with phases of NiS2, NiSe2, NiS, NiSe, Ni0.6H2O, NiSn, Ni3Se8, and Ni3S6 were obtained. Trends relating the chemical properties of the precursors to the phases of the products have been identified. While some precursors contained P, incorporation of P was not observed in the products. An increase of the NP size during sulfidation and selenidation is consistent with ripening. The products also can have voids that can be attributed to the Kirkendall effect, which also commonly occurs during oxidation and phosphidation of Ni NPs.

9:30 AM CM01.13.06
Colloidal Semiconductor CdS Magic-Size Clusters—Thermally-Induced Reversible Structural Isomerization Kui Yu; Sichuan University, Chengdu, China.

Here, we report the first pair of structural isomers identified for colloidal nanocrystals which exhibit thermally-induced reversible transformations. The two isomers are CdS magic-size clusters exhibiting sharp absorption peaks at 311 nm and 322 nm. We show that their thermally-induced interconversions follow first-order unimolecular reaction kinetics. We anticipate that our findings on structural isomerism should stimulate attention towards solid-solid transformations and advanced design and synthesis of functional nanomaterials for a diversity of applications enabled by structural transformations.

Solution-Grown Sodium Bismuth Dichalcogenides—Toward Earth-Abundant, Biocompatible Semiconductors Javier Vela, Bryan Rosales and Miles White; Iowa State University of Science and Technology, Ames, Iowa, United States.

Many technologically relevant semiconductors contain toxic, heavily regulated (Cd, Pb, As), or relatively scarce (Li, In) elements and often require high manufacturing costs. We report a facile, general, low-temperature, and size tunable (4–28 nm) solution phase synthesis of ternary APM2 semiconductors based on Earth-abundant and biocompatible elements (A = Na, Pn = Bi, E = S or Se). The observed experimental band gaps (1.20–1.45 eV) fall within the ideal range for solar cells. Computational investigation of the lowest energy superstructures that result from “coloring”, caused by mixed cation sites present in their rock salt lattice, agrees with other better-known members of this family of materials. Our synthesis unlocks a new class of low cost and environmentally friendly ternary semiconductors that show properties of interest for applications in energy conversion.

10:30 AM CM01.13.08
A New Perovskite-Type Sulfide Semiconductor, SrHfS3, Exhibiting Intense Green Emission at Room Temperature Kota Hanzawa1; Soshi Limura1,2; Hidenori Hiramatsu1,2; and Hideo Hosono1,2; 1Laboratory for Materials and Structures, Tokyo Institute of Technology, Yokohama, Japan; 2Materials Research Center for element Strategy, Tokyo Institute of Technology, Yokohama, Japan.

Semiconductors that are capable to dope into both of p- and n-types are key components in practical devices such as light-emitting diodes and CMOS transistors. Currently we have critical issues on next-generation device applications such as higher resolution display. To overcome such issues, the most difficult challenge is to develop bright green-emitting sources (λ ≈ 550 nm), which has not been realized even in GaN-based systems. Thus it has strongly been required to explore novel semiconductors with a bandgap of ~2.3 eV exhibiting efficient green emission at room temperature (RT). We focus on exciton in semiconductors due to its highly efficient emission. High ionicity of the chemical bonding is a key factor to obtain high exciton binding energy (BE); for SrF2, with high ionicity, the exciton has a large BE (0.9 eV), while for covalent compounds such as Ge and GaAs the BE is quite small (4 meV for Ge and GaAs). On the other hand, deep CBM and shallow VBM are also required to achieve n- and p-type dopings, respectively. However, the orbitals of low electron-negativity elements such as alkaline earth (AE) and early transition metals (eTM) usually form a shallow CBM level, while energy level of oxygen or halogen-p-orbital is too deep to dope hole. Hence, ionic compounds composed of AE and eTM have not attracted interest as a constituent of semiconductors so far.

Recently, our research group proposed a design concept for eTM-based semiconductors [1]. Our idea is to create non-bonding state at a specific k-point in high symmetry crystal structure. Since the non-bonding d-orbitals of cation form a deeper energy level than that of anti-bonding state between cation d- and anion p-orbitals, the deep CBM is realized in high symmetry crystals. In the same manner, shallow VBM is also obtained due to the formation of the non-bonding p-orbital of anion.

Based on the above consideration, we selected SrHfS3 with a high symmetry perovskite-type structure. The DFT calculations indicate that the CBM and VBM consist of nearly non-bonding state of Hf 5d and S 3p orbitals, respectively. As a result, the deep CBM and shallow VBM as well as the resultant bandgap of 2.2 eV meet our research target. We successfully synthesized polycrystalline SrHfS3 by a solid-state reaction. The optical bandgap was 2.3 eV and photoluminescence (PL) exhibited intense green emission peaking at ~521 nm, which are all consistent with the DFT results and meet all our requirements. It should be noted that the emitting light can be seen by human eyes even at RT. PL arising from defects was not observed, suggesting that concentration of deep defects is quite low.
Controlling the Surface Chemistry of Metal Phosphide Quantum Dots

B. A. Glassy, B. M. Cossairt

unlocking the true potential of these emerging materials.

Metal phosphides, Zn$_2$P$_2$, Cd$_3$P$_2$, InP, are an important class of semiconductor quantum dots (QDs) with applications ranging from light emitting diodes to biomedical imaging.\[1\] The extreme sensitivity of metal phosphide quantum dots to air and moisture require the development of robust surface passivation strategies to truly harness their potential in the above applications. To create such robust surface passivation strategies, a thorough understanding of metal phosphide surface chemistry and interfaces is required.\[2\]

In particular, we have previously demonstrated that the use of classical high-temperature procedures with indium carboxylate precursors induces an indium oxide surface layer that readily forms as a result of decarboxylation processes leading to water-based, in-situ – formed impurities.\[3\] We present here a comprehensive study that elucidates this oxidation mechanism utilizing a novel indium precursor, In(amidinate)$_3$, more reactive than traditional carboxylate or halide indium sources.\[4\] Indeed, while several reports utilizing different phosphorus sources can be found,\[5\] the variation of the indium source has been much less described. Our research has granted insight into the mechanism of oxide formation, including the sources of oxidants arising from previously unconsidered side-reactions. This increased knowledge of ligand and surfactant chemistry is valuable to the further efforts of precise surface control. The possibility to avoid oxidation of the QD surface under the correct conditions will be exposed and we demonstrate the ability to successively grow multiple layers of oxide-free InP surfaces. With lessons in hand, we could go on to create oxide-free InP nanocrystals, allowing us to study surface passivation strategies via a clean, native interface.\[6\] The role of Zn$_2^+$ and Zn precursors played in i) producing robust surface passivation, ii) enhancing key optical properties (emission linewidth, quantum yield) for InP QDs will also be discussed, highlighting the importance that surface chemistry and interfaces play in unlocking the true potential of these emerging materials.

References

Iron germanides (FeGeₓ) is a fascinating class of material that provides several phases with attractive and, in some cases, exotic properties including ferromagnetism (FeGeₓ, Fe₅Ge₃, Fe₃Ge₂…), antiferromagnetism (FeGe₂…), or helimagnetism (B20-FeGe). This latter phase has become the focus of intense interest due to the chiral magnetic ordering at RT which makes them highly relevant for the next generation of magnetic information storage.[1] Despite the attractiveness of nanoscale FeGeₓ structures, there exist only two synthetic approaches for their preparation: chemical vapor transport process to Fe₅Ge₃ at 650°C,[2] and solution phase thermolysis of precursors at high T (>260°C).[3] This latter example provides a proof-of-concept of the relevancy of solution-based strategies. However, the size, the shape or the phase purity are poorly controlled.

We will present herein a novel approach for the preparation of iron-germanium nanocrystals, which relies on the design of single source organometallic precursors that display special features: i) a preformed iron germanium bond, ii) labile substituents to facilitate their removal and iii) low coordinate metal to provide an easy access to FeGeₓ NCSs. We will show how the design of novel organometallic single source precursors allows the synthesis of nanocrystals at the lower temperature ever reported using thermolytic approach, ii) the dramatic influence of the substitution on the germanium atom to control the NCs formation and their magnetic properties.

Nano-Grained Hexagonal LaMgAl₁₁O₁₉ Doped with Ce for Optical Applications Ladislav Nadberny, Vaclav Dolezel, Vit Jakes and Katerina Rubesova, University of Chemistry and Technology, Prague, Prague, Czechia.

Due to their isotropic properties, high chemical stability and radiation resistance, aluminates (such as Y₃Al₅O₁₂, MgAl₂O₄, LaAlO₃, LaMgAl₁₁O₁₉) are suitable for use in optical applications for the detection of high-energy sources. One of the main advantages of lanthanum-magnesium hexaaluminate (LMA) is its ability to be doped with high concentrations of transition metals or rare-earth elements (REE) without the need for quenching. Hence, LaMgAl₁₁O₁₉ doped with REE has been investigated for many applications such as solid-state lasers, thermal barriers, w-LEDs, solar panels and non-contact thermometers.

Cerium is frequently used as an optical activator; for example, in mixed oxides, halides or glasses [1]. However, it has rarely been studied as a dopant for LMA, largely because of technological demands involved in preparing such a material by a solid-state method at 1600 °C [2, 3]. Recently, though, sol-gel methods have emerged as a new approach for preparing perfectly homogenous materials at a lower sintering temperature and in a shorter reaction time. We prepared La₆₋ₓCeₓMgAl₁₁O₁₉ with four different non-hydrolytic sol-gel methods La⁺, Ce³⁺, Mg²⁺ and Al³⁺ cations in the form of oxides, carbonates, chlorides and acetates. Two of the methods were based on active polymerization while water-soluble polymers were applied in the others. All these sol-gel methods produced stable solutions, from which white-to-brown fine amorphous and nanocrystalline precursor powders were prepared. These precursors were then pressed into pellets and annealed for 0.1–16 h at 1150–1300 °C in an Ar–H₂ flow. The annealing temperature was several hundred degrees lower than that of a solid-state method.

The phase compositions of the precursor powders and final polycrystalline materials were analyzed by RT-XRD, using Cu-Kα₁,₂ radiations in the range of 5–120° 2θ. The XRD data were matched with the PDF-4 reference database and refined by Pawley and Rietveld analysis. XRD full profile, TEM image analysis and dynamic light scattering were used to describe the relationships between precursor properties (particle size, morphology, crystallinity) and the final phase composition. In addition, we outline the mechanism of LMA phase formation. Finally, the optical activity of cerium in the prepared LMA matrices is shown in UV-Vis photocatalytic excitation and emission spectra.

The Continuous Random Network—A Review
Franz Spaepen, School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

The continuous random network (CRN), introduced by Zachariasen for oxide glasses, became the paradigm for the structure of covalent, directionally bonded amorphous materials. Elemental amorphous Si and Ge, which form one of the simplest CRNs, have been studied for more than fifty years. We will review their structure, thermodynamic properties, phase transformations, flow and structural relaxation. We will revisit some striking features, such as their density being higher than that of the diamond cubic crystal, their negative activation volumes for crystallization, and the bimolecular kinetics of their structural relaxation.

Understanding Indentation Behavior of Oxide Glass from Molecular Dynamics Simulation
Liping Huang, Rensselaer Polytechnic Institute, Troy, New York, United States.

To evaluate the damage resistance of glasses, instrumented indentation using sharp indenters is the method of choice, as it can mimic real-life damage incidents under controlled conditions. Furthermore, indentation provides a useful system to study crack initiation, as unstable crack propagation is prevented by the highly localized stress state. However, unravelling the nature of structural change under indentation is a formidable task in experiment because of the complexity that originates from the atomic-scale disorder of glass, and the experimental difficulties associated with the in-situ investigation at a local scale (tens of microns) under very high stresses. To this end, computer simulations can provide an important complement to experimental approaches. In this work, we carried out large scale molecular dynamics (MD) simulations to investigate the effect of quench pressure during hot compression and chemical composition variation on the response of glass to nanoindentation. A rigid hollow Vickers indenter made of carbon atoms is used to indent the glass sample with a fixed loading rate, during which atoms in the indenter interact with the glass via a repulsive force field. To minimize the boundary condition effects in simulated nanoindentation tests, large samples of several hundred nm in lateral dimensions are used. The indenter angle is varied to study the effect of the indenter sharpness on the deformation of glasses, as what has been done in experiments. Short- and medium-range order of glass structure evolve with the deformation underneath the indenter, which in turn shed light on the degree of densification and pile-up in different glasses.

Connecting Mechanical Properties of Amorphous Polymers to Chain Alignment and Entanglements
Marco A. Galvani Cunha and Mark O. Robbins; Johns Hopkins Univ, Baltimore, Maryland, United States.

Polymer glasses are frequently used in a form of additive manufacturing called fused filament fabrication (FFF). Melts are extruded onto previous layers and form a weld before the temperature drops below the glass transition temperature. Extrusion is typically fast enough to produce significant chain alignment that affects the welds formed by diffusion between layers and leads to a strongly anisotropic amorphous structure. Improved understanding of the structure property relations in printed parts is essential to optimizing FFF for structure-critical parts and FFF offers unique opportunities to create non-crystalline materials with continuously tunable local alignment and entanglement densities.

We have used molecular dynamics simulations of a generic polymer model to examine the relaxation of aligned melts, including the evolution of alignment and the entanglement density in bulk regions and at the interfacial weld. The mechanical properties of the resulting structures are then studied under tensile and shear loading. Local structure determines the initial yield stress while entanglements lead to strain hardening and crazing that strongly affects the total fracture energy. Alignment of chains along the deposition direction means that there are more weak van der Waals bonds in the perpendicular directions. This reduces the yield strength for shear and tensile failure perpendicular to the deposition axis. Alignment and changes in entanglement density also produce profound changes in the strain to failure and ultimate fracture energy. Welded regions are most affected by diffusion during cooling and may be stronger than adjacent bulk material which has higher entanglement density than the weld but is also strongly aligned.

Modeling Slip Statistics and Dynamics in Bulk Metallic Glasses, Granular Materials and Other Systems
Karim Dahmen, Wendelin J. Wright, Dmitry Denisov, Todd Hufnagel, Peter K. Liaw, Peter Schall; John Hopkins University, Baltimore, Maryland, United States.

Slowly strained solids deform via intermittent slips that exhibit a material-independent statistics and dynamics. We compare predictions of a simple model for the plastic deformation, the slip statistics and dynamics, and time series properties to experiments on slowly deformed bulk metallic glasses and granular materials. We highlight measures that can be used to differentiate between different systems and explain connections to other systems with avalanches. Predictions for future experiments will be discussed. The results are important for transferring results across scales and material structures.
Tailoring Glass Structure to Break the Speed Record of Phase-Change Memory

This talk describes our recent success (F. Rao et al., Science 2017) in controlling the amorphous structure of chalcogenide Sc-Sb-Te glass to accelerate its crystallization, reaching an unprecedented operation speed for memory and switch applications. Specifically, we have designed a new phase-change memory alloy with drastically reduced crystal nucleation stochasticity from the parent amorphous phase. The ultrafast transition between the two metastable states accomplishes sub-nanosecond switching for cache-type phase-change random-access memory (PCRAM) technology. This is a milestone in memory materials, because operation speed is currently a key challenge in the amorphous Ge2Sb2Te5 glass. Here we use alloying into the parent glass to speed up the crystallization kinetics by orders of magnitude. The newly designed chalcogenide Sc-Sb-Te alloy enables a record-setting writing speed (as short as ~700 picoseconds) in a conventional PCRAM device, with no requirement for pre-programming or additional device design. This ultrafast crystallization stems from the reduced stochasticity of nucleation via geometrically matched and robust chemical bonds that stabilize crystal precursors in the amorphous state, which are found via ab initio simulations to exhibit long life-times, shortening the incubation time for crystallization. This discovery is an example of physical metallurgy principles in action, using atomic-scale insight into glass structures (bonding configurations and sub-critical nuclei) to control properties. For details, see F. Rao et al., Science 358 (6369), 1423 (2017).

The Interaction Between Stress, Light and Chemistry in Glass

Application of mechanical stress to glass causes interesting changes in how it transmits light. This interplay is summarized by the elasto-optic tensor, the key metric for technological applications including zero stress-optic glass, and reduced stimulated Brillouin scattering glass. Fundamentally, these effects are controlled by the glass chemistry, and in particular the nature of the chemical bonds that make up the glass. We will summarize our approach to this problem, which is focused on both an empirical and ab initio approach to the structure-property relations governing the elasto-optic tensor. We will describe the control of the stress-optic response through judicious choice of glass chemistry, and also describe our current progress in understanding and developing glass with reduced stimulated Brillouin scattering. We will include discussion of both average properties and energy-dispersive effects. We will show how these effects may be computed ab initio, with a reasonable trade-off between accuracy and speed, and illustrate a bond-based model we are developing that attempts to put in simple terms the empirical relations we have discovered.

Ductility and Residual Liquidity in Metallic Glasses

**Takeshi Egami**1, 2 and Wojciech Dmowski1; 1Univ of Tennessee, Knoxville, Tennessee, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Lack of ductility is one of the major shortcomings of bulk metallic glasses which hamper their wide application as structural material. Ductility is a complex mechanical property which is difficult to characterize precisely. In a sense metallic glass is always microscopically ductile, because applied shear stress can locally liquify glass. But it has no work-hardening, thus often local yielding results in catastrophic shear failure. In order to achieve macroscopic ductility glass must be able to relax local stress concentration before it starts macroscopic shear band or crack. In our view the key is the residual liquidity in glass. The structure of supercooled liquid is heterogeneous, and the frozen-in structure at the glass transition contains weak liquid-like and solid-like regions. It is difficult to assess such heterogeneity directly from the structure itself, but it is possible to characterize it through the structural response to applied stress. We determined the anisotropic pair-density function (PDF) of various metallic glass samples under uniaxial stress by high-energy x-ray diffraction using the spherical harmonics expansion of the structure function $S(Q)$ and the PDF. The measured anisotropic PDF at large distances agrees with the one expected for affine (uniform) deformation which determines the long-range strain $e_{\infty}$. However, at short distances it deviates from the affine deformation, and at the first neighbour the local strain, $e_c$, is smaller than $e_{\infty}$. The deviation from the affine deformation occurs because of local liquid-like regions, so that the ratio $G = e_{\infty}/e_c$, or $\Delta G = 1 - G$, characterizes the strength of residual liquidity in glass. We found that the ratio $e_{\infty}/e_c$ is closely related to ductility. In particular, $G = 0.77$ is the threshold which separates brittle and ductile behaviors. If $G > G$, the samples are brittle, whereas if $G < G$, the samples are ductile. Thus we suggest that the percolation of the liquid-like regions results in ductile behaviour. This new parameter is compared to other criteria for ductility.

Network Structures and Dissolution Behavior of Specialty Oxide Glasses

**Richard K. Brow**, Department of Materials Science and Engineering, Missouri University of Science and Technology, Rolla, Missouri, United States.

Borate, phosphate, and borophosphate glasses have been developed for a variety of technological applications, including fast ion conductors, optical substrates, and biomedical devices. For the latter, compositions are often tailored to control the rate at which physiologically significant ions are released to induce the desired biomedical response. These reaction rates depend on the hydrolysis of bonds that link neighboring glass forming polyhedra as well as the hydration of bonds associated with other metal cations that modify the glass forming network, and so detailed understanding of the glass structure connect composition to design performance. For borate and borophosphate glasses, the network hydrolysis rates decrease with increasing fractions of tetrahedral borate. For phosphate glasses, hydrolysis is not significant in neutral pH physiological conditions, but the hydration rates of metal cations are faster when they are linked to chain-forming P-tetrahedra than when they are linked to a chain-terminating pentahedron. Quantitative and qualitative structural information about Na-Ca-borate, phosphate, and borophosphate glasses, obtained by techniques like nuclear magnetic resonance spectroscopy, Raman spectroscopy, and ion chromatography, will be described and used to explain their bio-functionalit.

Progress in Scattering with the Neutron Electrostatic Levitator (NESL) at the Spallation Neutron Source

**Dante Quirinale**, Neutron Technologies Division, Spallation Neutron Source, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Progress in Scattering with the Neutron Electrostatic Levitator (NESL) at the Spallation Neutron Source (SNS) is described. The NESL is described as an approach to the scattering of neutrons from condensed matter systems. The NESL measures the dependence of the neutron scattering cross-section on momentum transfer by placing a sample into a strong electrostatic field and recording the scattered neutrons as a function of time and energy. This approach is highly efficient and allows for the rapid measurement of the scattering cross-section for a wide variety of materials. The NESL is useful for studying a wide range of materials, including liquids, glasses, and amorphous solids. The NESL is also useful for studying the dynamics of materials, such as the motion of molecules in liquids and glasses. The NESL is also useful for studying the structural properties of materials, such as the distribution of atoms in a crystal. The NESL is also useful for studying the response of materials to external stimuli, such as temperature and pressure. The NESL is also useful for studying the evolution of materials over time, such as the aging of glasses and the crystallization of glasses and liquids. The NESL is also useful for studying the response of materials to external stimuli, such as temperature and pressure. The NESL is also useful for studying the evolution of materials over time, such as the aging of glasses and the crystallization of glasses and liquids.
There is great interest in a developing understanding of the relationships between structures and dynamics in liquid and glassy systems. Metallic liquids, which exhibit a degree of short and medium range ordering, are well suited to scattering probes, but there are many difficulties associated with selecting the proper furnaces for such studies. The Neutron Electrostatic Levitator (NEL) [1] at the Spallation Neutron Source is a containerless environment developed for challenging systems, including high temperature alloys and undercooled liquids. It provides a high vacuum, high purity, non-contact environment for fundamental studies of materials at wide temperature ranges. Combined with x-ray scattering data and isotopic substitution, the system is well suited to structural characterization of liquids via pair distribution function analysis, as has been successfully demonstrated at the Nanoscale Ordered Materials Diffractometer (NOMAD) [2,3].

A series of upgrades has improved the stability of the levitator and enabled new avenues of exploration. Recently, the system has been operated at the Wide Angular Range Chopper Spectrometer (ARCS) [4] and is currently being commissioned at the Cold Neutron Chopper Spectrometer (CNCS) [5] for high resolution inelastic and quasi-elastic scattering, enabling non-contact probes of excitations in glass forming liquids as well as high temperature self-diffusion measurements. The current capabilities and characteristics of the levitator furnace, progress in inelastic scattering measurements, and early results from the commissioning at CNCS will be discussed.

2:15 PM CM02.02.03

Modern drug delivery increasingly relies on micro- and nano-structures to achieve specific release rate and therapeutic target. The delivery systems modulate drug release via engineering control of the API and drug domains. Recent advances involve the use of functional coating or performance-enabling excipients. The small-scale nature of pores, drug domains, and delivery vehicles demands higher resolution technique to characterize. High-resolution image-based characterization has been broadly utilized in drug product development for fundamental understanding on the process-property-performance interplay and optimizing formulation process and design. It finds applications in various novel drug release systems such as tailoring rate-limiting film coat thickness where the pore formation is critical to control drug release and interrogating the underlying mechanism of in-situ drug nanoparticle formation from amorphous solid dispersions in dissolution media for solubility enhancement. 3D micro-imaging can qualitatively visualize micro-structures, quantify their spatial and chemical distribution, and predict release behavior. In recent years, the emerging image-based numerical simulation has received significant traction and plays an important role in predicting drug release performance. Information-rich 3D images can be converted to characteristic drug transport parameters through intelligent analysis and applied to numerical simulation models to predict release performance. This image-based simulation approach represents a potential paradigm shift in drug design and evaluation, with significantly reduced evaluation time, improved release performance, and lowered in-vitro and in-vivo experiment cost.

Nanoscale Imaging of Bulk Bottlebrush Polymers Using Helium-Ion Microscope Nikolay Borodinov; Alex Belianinov; Dongsook Chang; Jan-Michael Carrillo; Matthew J. Burch; Yuewen Xu; Anton V. Levchuk; Bobby G. Sumpter and Olga Ovchinnikova; Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; Institute for Functional Imaging of Materials, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; Kimberly-Clark Corporation, Irving, Texas, United States.

Recently, bottlebrush polymers have attracted significant interest due to their potential applications in drug delivery and electronics. The tunability of their properties, stemming from the diversity of sidechains and their spatial arrangement, have emphasized their industrial potential as compared to the linear macromolecules. In this context, the structural information and organization of these systems play a major role in the rational design of functional bottlebrush polymers. Specifically, direct observation of the molecular organization can reveal inter-chain interaction phenomena and explain the fundamental physical properties of these systems. Here, we report a new method to analyze bulk macromolecular chain arrangement of bottlebrush polymers based on Helium Ion Microscopy ( HIM ). By using the HIM we were able to quantify structural nematic-type ordering in an amorphous polymer bottlebrush system. High-resolution imaging coupled with data analytics has proven to highlight the location and distribution of the polymer backbones, after oxygen plasma-generated height contrast; as well as map changes in the backbone spatial arrangement as a function of thermal annealing. Our experimental findings are corroborated by the coarse-grained molecular dynamics simulations. Overall, this approach can generate clear insights on the internal structure of amorphous materials and provides a complimentary information channel to scattering techniques and theoretical modeling.

This work was performed at the Center for Nanophase Materials Sciences, a US Department of Energy Office of Science User Facility. This research used resources of the Oak Ridge Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC05-00OR22725. The authors acknowledge Scott Retterer at the Center for Nanophase Materials Science at Oak Ridge National Laboratory for helpful input and discussion.

Correlating Nanoscale Structural Heterogeneity to Glass Forming Ability and Mechanical Properties of Metallic Glasses Soobyun Im; Jared Johnson; Gabriel Calderon Ortiz; Menglin Zhu; Pengyang Zhao; Guen Hee Yoo; Eun Soo Park; Yuzhi Wang; and Jinwoo Hwang; Seoul National University, Seoul, Korea (the Republic of); Materials Science and Engineering, The Ohio State University, Columbus, Ohio, United States.

We determine the nano-to-mesoscale structural heterogeneity in metallic glasses (MGs) using 4-dimensional (4D) nanodiffraction in scanning transmission electron microscopy (STEM). Structural heterogeneity in MGs has been suggested by both experiments and simulations previously. The heterogeneity must involve local structural ordering at the nanoscale, commonly known as medium range order (MRO), some of which has been studied using small electron probes in the past. However, the statistically reliable information on how such MRO constitutes the heterogeneity has remained difficult to determine. Our new approach to determine the MRO and structural heterogeneity involves 4D-STEM, which uses a new-generation pixelated fast STEM detector that allows for the continuous collection of the diffraction patterns from a large area of the MG sample. Using angular correlation and intensity
variance analyses, the diffraction patterns can then be converted to real space maps of the local ordering, which we use to precisely determine the type, size distribution, and volume fraction of MRO. We will present two cases of how the heterogeneity affects the important properties of MGs, one is the glass stability in Ti-based MGs, and the other is the ductility of Zr-based MGs. To connect the structural heterogeneity to ductility, we use a new mesoscale simulation that incorporates the exponentially determined heterogeneity, which can simulate realistic shear band formation and overall deformation that match the spatial and temporal scales of the deformation of real MGs.

Structure is the Organization Plan of Glasses—But Dynamics Might Bring Deeper Insight
Bernhard Frick1, Henriette W. Hansen1,2,3 and Kristine Niss4; 1Institut Laue–Langevin, Grenoble, France; 2Roskilde University, Roskilde, Denmark; 3Chalmers, Göteborg, Sweden.

It is well known that for a large number of glass forming liquids the static structure factor, S(Q), shows no or only subtle changes when passing from the liquid into the glass. In contrast the dynamic structure factor S(q,ω) of simple or more complex glass forming liquids evidences in the GHz - THz frequency range and close to the glass transition clear and common signatures which have been addressed by several theories over the last decades. In spite of large experimental and theoretical activity in this field the glass transition is still not fully understood. Quasielastic neutron scattering plays a vital role for the experimental investigation of dynamic properties of disordered materials, glasses and undercooled liquids. We will give a brief overview over typical experimental findings near the glass transition and over recent instrumental progress on neutron spectrometers before presenting some examples. We then focus on our recent investigations on simple organic, hydrogen bonded and ionic liquids for which we have probed the dynamics near the glass transition by simultaneous dielectric and neutron spectroscopy. For these simultaneous experiments we have controlled both temperature and pressure which did allow us to map lines in the (P,T)-diagram along which the dynamics is unchanged and therefore is isochronous over a wide time range.

4:00 PM CM02.02.07
Spatially Heterogeneous Dynamics in Metallic Glass Nanowires Imaged by Electron Correlation Microscopy
Debaditya Chatterjee1, Pei Zhang1, Jittisa Ketkaew2, Jan Schroers2 and Paul M. Voyles1; 1Department of Materials Science and Engineering, University of Wisconsin–Madison, Madison, Wisconsin, United States; 2Department of Mechanical Engineering and Materials Science, Yale University, New Haven, Connecticut, United States.

We have used electron correlation microscopy (ECM) to image the nanometer scale heterogeneities in the relaxation dynamics of the supercooled liquid of a metallic glass forming alloy [1]. The length and time scales of the heterogeneous dynamics are central to the glass transition and influence nucleation and growth of crystals from the liquid. Electron correlation microscopy (ECM) experiments use time-resolved tilted dark field transmission electron microscopy with sub-nanometer resolution for direct measurement of those length and time scales. ECM data on Pt-based metallic glass nanowires above the glass transition temperature (Tg) reveal a relaxation time scale that varies from a few seconds to hundreds of seconds and a length scale that varies from 0.8 to 1.4 nm. They also demonstrate the existence of a ~1 nm thick near-surface layer with an order of magnitude shorter relaxation time than inside the bulk which may influence crystallization of the wires. Additional measurements of the surface layer relaxation time below the bulk Tg and its connection to enhanced surface diffusion in metallic glasses and surface crystallization will be discussed.

4:15 PM CM02.02.08
Kinetic Metallic Glass Evolution Model
Thomas J. Hardin and Christopher A. Schuh; Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Metallic glass is a heterogeneous composite on the scale of a few nanometers; the structure of the glass on this scale governs its macroscopic thermomechanical response. This structure evolves in response to thermal and mechanical loading; this evolution is mediated by discrete kinetic events in which clusters of atoms locally rearrange themselves. We present a model of this structural evolution and mechanical response which consists of a thermodynamic state space, density of states, and models for relaxation and shear transformation events which move the glass through that state space. We implement this model in a homogenized statistical sense and compare to homogeneous relaxation and flow data previously in literature; we also implement it in a discrete mesoscale framework. We conclude with a discussion of gaps in the current understanding of the fundamental structure of metallic glass.

Atomic-Level Insight into Amorphous Aluminum Oxide Structure—Atomic Simulation vs In Situ Experiment
Marcela E. Trybula1,2, Przemyslaw W. Szafranski1, Pavel A. Korzhavyi1, Nikolay A. Vinogradov2 and Edvin Lundgren3; 1Institute of Metallurgy and Materials Science Polish Academy of Sciences, Krakow, Poland; 2Department of Materials Science and Engineering, KTH-Royal Institute of Technology, Stockholm, Sweden; 3Department of Organic Chemistry, Faculty of Pharmacy, Jagiellonian University Medical College, Krakow, Poland; 4Institute of Metal Physics, Ural Branch of RAS, Ekaterinburg, Russian Federation; 5MAX IV Laboratory, Lund University, Lund, Sweden; 6Synchrotron Radiation Research, Lund University, Lund, Sweden.

Structural disorder in amorphous solids may depend on the method of their preparation. An easily-accessible method is electrochemical anodization of metal surface, which may result in formation of periodic voids, or pores, for example in a well-known Al anodization process [1,2]. These voids, or pores, are thought to derive from the morphological instabilities underlying the initial stage of oxidation [1]. Such nanostructuring can have a profound impact on local structural anisotropy or hierarchical ordering of atom clusters build-up in the structure of the amorphous Al oxide film.

In this contribution, we determine the structural and topological descriptors of bulk alumina to compare them with those obtained from in situ synchrotron-based experiment of porous anodic aluminum oxide scale growth. We also discuss the impact of self-assembling ring structure on chemical and topological short- and intermediate-range ordering in bulk alumina in the light of in situ oxide growth. The interpretation of out of in situ X-ray diffraction data is supported by molecular dynamics simulations and DFT-based calculations. These allowed us to capture physical phenomena accompanying in situ anodic aluminum oxide growth. Obtained calculation results agree well with the available experimental [3] and computational data [4].

Hierarchical Machine Learning to Decode Structural Origin of Heterogeneous Deformation in Disordered Materials Qi Wang and Anubhav Jain; Lawrence Berkeley National Lab, Berkeley, California, United States.

When subjected to external stimuli such as mechanical loading, atoms in disordered solids respond heterogeneously. Due to lack of representations to resolve the subtle packing difference around atom sites and approaches to deal with the long-range correlation involved, it is hard to quantitatively predict this heterogeneous, site-specific response solely from the structure. Here, by designing a robust hierarchical machine learning framework, we show that it is possible to predict the mechanical heterogeneity in disordered solids a priori, directly from the quenched structural state itself. We encyclopedically create a large pool of 810+ site descriptors, from 40+ sets of structural measures, spanning topological and chemical short- and medium-range order, and develop a novel hierarchical scheme to further extend the studied scale to an unprecedentedly long-range while still retaining good interpretability and generality. Impressive predictability is achieved in a fairly large strain regime, suggesting a long-lived inheritance of the quenched state until later obstructed by shear banding. The framework is robust over a range of compositions and processing conditions and can well detect the site environments tuned by these conditions. We also identify a bag of promising structural signatures unrevealed previously, with their predictability exhaustively benchmarked and discussed. This hierarchical learning framework is general and could potentially be applied to decode structural origin of any site-specific properties in the family of disordered materials.

Microstructure Design for Ductile Glass Composite Yanming Zhang, Binghui Deng, Liping Huang and Yunfeng Shi; Department of Materials Science and Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.

In this work we use molecular dynamics (MD) simulations to investigate glass composites constituted by two brittle model glasses with different stiffness. We show that tuning the stiffness ratio (SR), shape, volume fraction and distribution of the two brittle glass constituents can trigger a brittle to ductile (BTD) transition. Such composite glasses can exhibit high strength, remarkable toughness and some work hardening. The highest failure strain of 80% can be reached in composite glasses as compared to 7% in monolithic model glasses. We also found that mechanical properties of such glass composites will not be deteriorated by introduction of pre-notch. Excellent load redistribution capability introduced by structural heterogeneity is responsible for high ductility in our composite glasses. Through a systematic analysis, we unveil the design principles that lead to the aforementioned BTD transition. We believe the current approach could enhance ductility and broaden the application of glasses as enabling structural materials.

CM02.03.02
Molecular Modeling of Stress Corrosion Behavior Swastik Basu, Liping Huang and Yunfeng Shi; Department of Materials Science and Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.

Glass is well known to be susceptible to stress corrosion cracking caused by chemicals in the environment, a phenomenon that can cause delayed failure of glasses due to growth of pre-existing surface defects in the presence of humidity. The complex macroscopic effects of stress corrosion, like fracture, occur due to microscopic interactions, which demand a study to replicate the microstructural interactions within a model, which should reproduce the macroscopic behaviors. The purpose of this research is to study the stress corrosion behavior of a model metallic glass system with a view towards representing the underlying atomic level mechanisms using a molecular dynamics approach.

CM02.03.03
Liquid Metal Nanoscale Structures as Novel Platform for Characterization of Structural Relaxation of Metallic Glasses Ziyang He1, Chen Liang2 and Chenhao Qian3; 1Economics Department, Columbia University, New York, New York, United States; 2Engineering Department, University of Liverpool, Liverpool, United Kingdom; 3Department of Mechanical Engineering, Jiangnan University, Wuxi, China.

This poster firstly introduces a new microfluidic method for preparing nanostructures of gallium-indium liquid alloy systems. Due to its smaller nanometer size (50-100nm diameter), good self-healing behavior, strong oxide layer formed by spontaneous oxidation, rich changeable nanomorphology driven by voltage variation and large undercooling range, the alloy system has become a good platform for studying amorphous structure transformation and internal structure of liquids using in-situ characterization technology under current conditions. We have successfully discovered the presence of secondary structures in this liquid metal system through in situ TEM lithiation experiments and subsequent nanomechanical and electrical experiments. By comparing the structural relaxation of the same kinetic fragility liquid with or without the oxide layer structure, we found that the oxide layer structure could guide the dynamic non-uniformity of the nano-amorphous system to some extent. At the same time, we are also actively exploring the future application of this alloy system in liquid metal self-healing electrodes, nano-heat pipes, nanoscale self-propelled robots and other industrial fields.

CM02.03.04
Self-Diffusion Mechanism of Atoms in Forsterite Glass Junya Nishizawa and Tomoko Ikeda-Fukazawa; Department of Applied Chemistry, Meiji University, Kawasaki-shi, Japan.

Forsterite glass exists as dust grains in interstellar molecular clouds and young stellar objects [1]. In interstellar molecular clouds, elements such as hydrogen, oxygen, carbon, and nitrogen deposit on dust grains, and form various molecules (e.g., H2O, CO, CO2, NH3, CH4, H2CO, CH3OH, and so on) [2]. These molecules undergo chemical evolutions to organic molecules through various processes on the surface of dust grains [2]. Dust grains are important materials governing the chemical and thermal evolutions in space. However, the transport coefficients of forsterite glass are less conclusive, because forsterite glass is easily to crystallize. To investigate the mechanism of self-diffusion of atoms in forsterite glass, molecular dynamics (MD) calculations were performed.

The MD calculations were performed using an atom-atom potential model with MDXORTO program [3]. The potential parameters were empirically determined by constraining the model to reproduce the experimental results of density, thermal expansion coefficient, and bulk modulus [4]. The transition
point from glassy state of supercooled liquid state ($T_g$) for our potential model is 1567 K. A fundamental orthorhombic cell consisting of 160 MgSiO$_4$ with three-dimensional periodic boundary conditions was used. The glass structure was prepared by quenching the liquid phase from 3000 K to 10 K with 0.4 K/ps in rate. The quenched glass was warmed to 3000 K with the same rate. The MD code was run with NTP ensemble. The pressure was kept at 0.1 MPa. The self-diffusion coefficients of Mg, Si and O were calculated using mean-square displacement (MSD). To investigate the mechanisms of self-diffusion, the temporal variations of pair correlations functions for Mg were analyzed. The result shows that the jumping probability of Mg, which is located at a position with high Si and low Mg densities is high. Because of the strong Si-O bonds in the tetrahedral SiO$_4$ units, the jump of Mg atom (or MgO$_x$ unit) was induced by structural distortion of the surrounded SiO$_4$ units. From analyses of spatial distribution of MSD, it was found that the MSD values of Mg are inhomogeneous at temperatures just below $T_g$. Because the self-diffusion coefficient of Si is significantly low at $< T_g$, the distribution of Si in forsterite glass is inhomogeneous. Therefore, the diffusivity of Mg depends on surrounded Si distribution.

Methods for Estimating Appearance of Metal-Like Plastic
Sun Chul Jin, Hyungjin Roh, Kiyong Kim and Sunghawn Cho; Samyang, Daejeon, Korea
(the Republic of).

A plastic has a lower specific gravity than glass or metal and has many advantages such as lightweight and good mechanical properties. These thermoplastics are rapidly replacing conventional glass and metal areas in fields such as electronic and automobile parts. Recently, as increasing need for environmentally friendly material, there is an increasing demand for plastic that can feel a metallic appearance similar to a metal without a spray process. For the development of metal-feeling thermoplastics, it is well-known way to use metallic pigment. But because of difference in flowability between metal pigment and plastic, there is an appearance problem such as flow mark and weld-line. This is why metal-feeling plastic can’t be expanded. In order to solve these problems, much research have been studied to control the shape and aspect ratio of metallic pigment and to improve the surface coating of it. However, it is limited to improve the appearance problems such as aggregation and orientation. In addition, there is no effective method for objectively estimating the appearance of the metallic feeling except for flop index. But the flop index can evaluate only the metallic brightness and the degree of defects such as flow mark and weld-line caused by the metallic pigment could not be evaluated. As a result, there is no method of evaluating the appearance that can represent the overall phenomenon caused by the metallic pigment as an objective numerical value. In this research, development of method for estimating appearance of metal-feeling plastic is studied. Through correction of flop index, new index named as ‘T/N. Flop. X’ was developed. Using this index, it is available to objective evaluation and comparison of metal-feeling. And using the CCD camera, it was studied that correlation of sparkle effect, metallic pigment’s orientation and weld-line. Based on these studies, we found out sparkle index that could be explained about orientation and metal-feeling. Additionally we studied about control of metallic pigment for reduce an appearance problem. Orientation is important factor to determine weld-line degree and in a constant direction makes decrease it. We found out factors that could control orientation especially additive having an affinity of polar and non-polar.

CM02.03.07
Amphiphilic Modification of PDMS Surface with PVA/PSBMA Zwitterionic Semi-Interpenetrating Hydrogel for Marine Antifouling
Application
Xingyang Xu, Rongrong Chen and Jun Wang; College of Material Science and Chemical Engineering, Harbin Engineering University, Harbin, China.

Marine biofouling is a highly complex process and a worldwide problem which involve a wide variety of species. The common techniques proposed incude heavy metals (Cu$_2$O), or organic biocide, are bring potential harm to marine environment and ecosystem. Therefore, the nontoxic approaches, particularly silicone-included low-surface-energy Fouling Release Coatings (FRCs) may be the alternatives to chemically active coatings and more environmentally friendly AF strategies. In this research, development of method for estimating appearance of metal-feeling plastic is studied. Through correction of flop index, new index named as ‘T/N. Flop. X’ was developed. Using this index, it is available to objective evaluation and comparison of metal-feeling. And using the CCD camera, it was studied that correlation of sparkle effect, metallic pigment’s orientation and weld-line. Based on these studies, we found out sparkle index that could be explained about orientation and metal-feeling. Additionally we studied about control of metallic pigment for reduce an appearance problem. Orientation is important factor to determine weld-line degree and in a constant direction makes decrease it. We found out factors that could control orientation especially additive having an affinity of polar and non-polar.

CM02.03.08
The Effect of Arm Segment Length on Thermally Induced Self-Healing Behavior of Supramolecular Star Poly(ε-caprolactone)s Network
Woojin Lee,1 Dae-Young Won1, Hye-bin Wi2, Jae Woo Chung2 and Seung-Yeop Kwak1;1 Department of Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of);2 Soongsil University, Seoul, Korea (the Republic of).

Supramolecular polymer is comprised of oligomers or polymers that are held together by reversible non-covalent supramolecular interactions. It is capable of responding to damage or crack and restoring the polymer’s performance without affecting the initial materials properties. The healing property of supramolecular polymer network depends on two factors, that is, the first being the supramolecular interactions, and the second being the chain dynamics of the individual polymer chains. In this study, we synthesize the simple supramolecular network consisted of ureidopyrimidinone (UPl) ends functionalized 6-arm star poly(ε-caprolactone)s and investigate the effect of arm length on thermally induced self-healing behavior of the supramolecular star poly(ε-caprolactone)s network. The resulting materials can be healed several times at 90°C during 10 minutes, and even can be healed at 60°C after 40 minutes. We find the compromise number of tie points by supramolecular force and chain dynamics related to sufficient mobility of network. Both supramolecular end clusetery crystal and main chain crystal might affect the mobility of network. For the efficient healing behavior, the crystalline domain of supramolecular polymer network should be collapsed. Thus, the sufficiently thermally induced healing behavior can be achieved through the enhanced mobility of network.

CM02.03.09
Ab Initio Study of the Amorphous Cu-Bi System
David Hinojosa-Romero1, Isaias Rodriguez2, Alexander Valladares2, Renela M. Valladares2 and Ariel
As a pure element, bismuth is a semimetal which possesses several interesting physical properties, not all of them well understood. The recent discovery of superconductivity [1], as predicted by our group [2], and the increasing superconducting transition temperature as the pressure applied increases, are some examples of its particularities. Also, the fact that the amorphous phase is superconductive with a transition temperature several orders of magnitude larger than the crystalline at ambient pressure is unusual [2]. These phenomena have also motivated our predictions for the transition temperatures of Bi-bilayers [3] and the Bi-IV phase [4]. When mixed with other elements, bismuth seems to contribute to the superconducting character of the resulting material. Here we study the binary copper-bismuth amorphous system which is known to superconduct in diverse compositions [5]. Using \textit{ab initio} molecular dynamics and the undermelt-quench method, we generate an amorphous structure for a 144-atom supercell corresponding to the Cu$_{44}$Bi$_{56}$ system. We shall report the calculated electronic and vibrational densities of states for this system and relate them to the superconducting properties of this alloy.

**CM02.03.10 Structural Commonalities in Different Classes of Non-Crystalline Solids—A Pair Distribution Function Analysis**

Isaias Rodríguez$^1$, David Hinojosa-Romero$^1$, Renela M. Valladares$^2$, Alexander Valladares$^2$ and Ariel A. Valladares$^1$; $^1$IIM-UNAM, Mexico City, Mexico; $^2$Physics, Faculty of Science, UNAM, Ciudad de México, Mexico.

In the past decades the research community has explored diverse structures and new fabrication methods of non-crystalline solids. Glassy materials that belong to the semiconductor realm and to the metallic type are the most studied both experimentally and simulationally. The present work investigates common structural trends whenever they exist and different trends among different classes. Amorphous semiconductors display Pair Distribution Functions (PDF) that are very similar among themselves and this indicates that these network forming materials have properties that are alike [1]. Analogously metallic systems have comparable PDFs but different from the network forming materials, as it should be, since the properties between these two classes are very different [2].

Here we pay attention to the Short-Range Order (SRO) and Intermediate Range Order (IRO) of these two classes. In particular, the first peaks of the structures studied are contrasted, while the second peaks are shown to differ considerably. Whereas the semiconductor structures display a simple first and second peak with a near-zero value between them, the metallic systems have a very well defined non-zero value between the first and second peaks and they also display what we have come to identify as an “elephant” second peak [3]. To manifest the uncommonalities with amorphous semimetals we recall calculations carried out by our group for bismuth where the elephant peak does not appear but the non-zero behavior between the first and the second peak is present [3]. The Plane Angle Distribution (PAD) functions are also reported.

**CM02.03.11 Dependence of Modulus on the Annealing Conditions of Pt$_{57.5}$Cu$_{14.7}$Ni$_{5.3}$P$_{22.5}$ Bulk Metallic Glass**

Zheng Chen$^1$, Amit Datye$^1$, Jittisa Ketkaew$^1$, Sungwoo Sohn$^1$, Jan Schroers$^1$, and Udo Schwarz$^1$; $^1$Department of Mechanical Engineering and Materials Science, Yale University, New Haven, Connecticut, United States; $^2$Department of Chemical Engineering and Environmental Engineering, Yale University, New Haven, Connecticut, United States.

The mechanical properties of bulk metallic glasses are often tuned by annealing, which influences these properties by adjusting the relaxation or crystallization status of the glasses. Here, we studied the modulus of Pt$_{57.5}$Cu$_{14.7}$Ni$_{5.3}$P$_{22.5}$ bulk metallic glass (Pt-BMG) annealed at different temperatures in the metastable regime by nanoindentation, where the annealing generates the BMG different fictive temperature and fractions of crystallization. We find the modulus of the investigated BMG samples exhibits a “V” trend: As the annealing temperature increases, we first observe a decrease that is followed by an increase until saturation is reached. This phenomenon can be explained as a result of the combination of the glasses relaxation and the glasses crystallization: Relaxation caused by higher fictive temperatures lead first to higher free volumes, which leads to lower moduli, while past a specific temperature, crystallization generates new, denser phases with higher moduli. The latter finding is confirmed by nanoindentation measurements at which fully amorphous Pt-BMG samples with different fictive temperatures are compared with partially crystalline samples featuring the same fictive temperature.

**CM02.03.12 Theoretical Support to Hydrogen Elimination Monitoring by Ultraviolet Photodissociation Mass Spectrometry Using Density Functional Theory**

Lindsay Morrison, Wenru Chai, Jake Rosenberg, Graeme Henkelman and Jennifer Brodbelt; The University of Texas at Austin, Austin, Texas, United States.

Mass spectrometry (MS) has became an increasingly popular and useful in analyzing structures of proteins. Initially only information of low resolution and of the whole protein in general can be obtained. Many techniques that utilize property differences between parts of the protein to produce signature

---

fragmentation patterns and products have been developed to gain more information on local geometry, such as collision induced dissociation (CID), electron transfer dissociation (ETD), electron capture dissociation (ECD) and ultraviolet photodissociation (UVPD). A new method called hydrogen elimination monitoring (HEM) was invented by Brodbelt et. al, to overcome disadvantage of other methods. For example, CID disrupts protein structure prior to fragmentation therefore higher order structural information is lost and ECD cannot differentiate highly ordered surface regions with internal buried regions. HEM aims finding out higher order structure anywhere in the protein by using hydrogen elimination information after fragmentation to determine the level of hydrogen binding prior to fragmentation, therefore determining local geometry. Experiments have demonstrated that hydrogen elimination correlates strongly to absence of backbone hydrogen bonding yet the underlying process and reason to this correlation is unknown. DFT studies of model peptides at ground state can help in illustrating the process and in providing theoretical support to HEM method.

In the computational study complementary to experimental findings, we used 3 structures of Ala8 peptide models with increasing amount of hydrogen binding: an unstructured linear peptide, a hairpin turn and a helix, to study the thermodynamics as well as the kinetics of the fragmentation process, by finding out the enthalpy change of the fragmentation reaction and the minimum energy pathways (MEPs) for the processes. The thermodynamics show that fragmentation products without hydrogen elimination are much higher in energy compared to products with hydrogen elimination, and therefore extremely unfavorable. The MEPs revealed reasons why the thermodynamic favorable product may not always form. In the unstructured peptide, hydrogen elimination always take place at the same time as the C-C back bone is cleaved. In the hairpin turn and helix structure, however, the MEP show that C-C cleavage takes place first and produces spatial separation that could prevent hydrogen elimination. This finding shows the underlying principle of the correlation between hydrogen elimination and amount of hydrogen binding prior to fragmentation, and therefore supports HEM as an effective method for analyzing protein structure.

The Molecular Influence on High Strain Rate Microscale Impact Response of Synthetic Polymeric Materials
Yuchen Sun1, 2, 4, David Veysey1, Alex Hsieh1, Steven Kool1, You-Chi M. Wu1, John P. Mikhail1, A. A. Maznev2, Jan W. Andzelm3, Gregory C. Rutledge1, Timmy M. Swager2 and Keith A. Nelson1, 2, 4, 5
1 Institute for Soldier Nanotechnologies, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3U.S. Army Research Laboratory, RDRL-WMM-G, Aberdeen Proving Ground, Maryland, United States; 4Department of Material Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 5Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The deformation of materials in extreme dynamical environments such as high-velocity microparticle impact is a challenge to understand though important for many areas of science and technology from space exploration to sand erosion. While impact dynamics of macroscale projectiles have been studied in real time using high-speed imaging, investigations of microscale impact have been essentially limited to post-mortem analysis of impacted specimens. Here, we present real-time observations of supersonic microparticle impacts using multi-frame imaging. In a laser-induced projectile impact test, a microparticle is accelerated by laser ablation from a sacrificial gold layer on a glass substrate. These particles can be accelerated into free space with controllable speeds up to 1.0 km/s depending on laser pulse energy and particle characteristics. The particles are monitored in flight and during impact with an ultra-high-speed camera that can record up to 16 images with a minimum interframe time of 3 ns. We investigated the high-velocity impact deformation response of elastomers to further the fundamental understanding of the molecular influences on high strain rate elastomeric response. The types of materials that were synthesized and tested are glassy polymers, graft copolymers, and other materials. We show the dynamic stiffening response of various elastomers including poly(urea urethane) upon impact at strain rates of ~10⁸ s⁻¹ and demonstrate the significance of molecular constitution in the response. These results provide an impetus for modeling the molecular influence on high strain rate microscale impact responses in these polymeric materials.

Enhancing the Mechanical Properties of Biodegradable PLA using Ternary Polymer Blends
Xianghao Zuo1, Yuan Xue1, Elena Urquiola2, Ruilin Yin3, Jinhai Tang4 and Miriam Rafailovich1
1 Stony Brook University, Stony Brook, New York, United States; 2Hunter College High School, New York City, New York, United States; 3St. Anthony's High School, South Huntington, New York, United States; 4Hunter College High School, New York City, New York, United States; 5Stony Brook University, Stony Brook, New York, United States.

Acrylonitrile butadiene styrene (ABS) has a similar matrix structure to the styrene acrylonitrile copolymer but has additional distribution of polybutadiene which strengthens it and allows ABS to surpass the properties of traditional commercial polymers. PLA is a 100% biodegradable polymer which can be regarded as a replacement to many current commercial plastics. However, it’s brittleness limited its applications. Commonly, binary blends including PLA and another polymer additives are created to enhance the mechanical properties of PLA, but this has been found to be ineffective due to the poor interfacial reaction between the polymers. Previous studies have determined that a 70:30 PLA: ABS ratio effectively balances the bio-based properties of PLA with the exceptional mechanical properties of ABS. Many have observed that the binary PLA/ABS blend actually has worse mechanical properties than just the PLA alone. Therefore, an efficient compatibilizer with good affinity with both PLA and ABS is a key factor to solve this problem. In our previous work, we have certified that PMMA is miscible with PLA and considering the structure of ABS, we hypothesise PMMA should be an excellent compatibilizer to the blend.

To create the ternary blends, the polymers were added to a C.W. Brabender and then molded into the tensile and impact test shapes using a Carver Hot Press. The blends were also run through an extruder to create filaments for 3D printing. A 286% increase for the molded sample in the impact test was observed when 4% by weight PMMA was used with the 70PLA/30ABS blend. Mechanical tests also showed that this ternary polymer material can maintain high mechanical properties even when 3D printing, as the mechanical properties of the 3D printed surpassed the pure PLA sample and PLA/ABS binary blend by 24.3% and 55.5% respectively. SEM and TEM imaging were used to verify the location of PMMA phase. And contact angle tests show that ABS has a higher affinity with PMMA than PLA.

The ternary blends reached their peak mechanical properties with less than 5% by weight of compatibilizer added, suggesting the economic efficiency of this blend for industrial use. For future study, interfacial properties in the ternary blends could be investigated using secondary ion mass spectrometry (SIMS) analysis to reveal interactions that contribute to mechanical strength.

Enhancing Impact Resistance of Polymer Blends via Self-Assembled Nanoscale Interfacial Structures
Xianghao Zuo, Yuan Xue, Yichen Guo and Miriam Rafailovich
1 Stony Brook University, Stony Brook, New York, United States.

We have designed and engineered ternary polymer blends with the mechanical properties comparable to high impact resistant conventional polymers under the guidance of the lattice self-consistent field model. Tow formulas were used to study the mechanical properties. In one system, poly (methyl methacrylate) (PMMA) was used as the compatibilizer for the widely used biodegradable polymer blend, poly (lactic acid) (PLA)/Poly (butylene
where quantized steps with height of $2g_0$ are found in Labyrinth tiling with periodic order along the applied electric field direction, in contrast to the step a set of independent chains with rescaled Hamiltonians [2]. Such transformation leads to an analytical solution of the direct-current conductance spectra, the best focus on the mechanical analysis. Single-edge-notched-tension (SENT) and double-edge-notched-tension (DENT) samples with pre-notch size of tensile experiments and finite element methods analysis.

60 nm and thickness of 200 nm were fabricated in mushroom like shape with head size of ~2 μm using Focused Ion Beam (FIB) on DLC film of ~1.5 μm present an unwonted roll of cracks at the nanoscale as an activator of a fracture resisting mechanism not as an enemy of brittle ceramics through nanoscale flaws when they shrink below a certain critical size and enables to reach almost theoretical strength of the material [1]. Getting ideas from this, here we usually never been reached before the total failure in bulk scale. However, in some theoretical studies, fracture of nanomaterials becomes insensitive to space renormalization method [3], we can address in a non-perturbative way the electronic transport in macroscopic aperiodic Labyrinth tiling based on height of $g_0$ observed in the corresponding square lattices, being $g_0$ the conductance quantum. When this convolution theorem is combined with the real-exponentially localized eigenstates [1]. Nowadays, the study of electronic transport in artificial structures is of great importance in condensed matter physics, because such structures introduce many new physical properties essential for technological applications of atomic-scale devices. In this work, we revisted a previous convolution theorem developed for the Kubo-Greenwood formula in Labyrinth tiling by transforming the original two-dimensional lattice into a set of independent chains with rescaled Hamiltonians [2]. Such transformation leads to an analytical solution of the direct-current conductance spectra, where quantized steps with height of 2$g_0$ are found in Labyrinth tiling with periodic order along the applied electric field direction, in contrast to the step height of $g_0$ observed in the corresponding square lattices, being $g_0$ the conductance quantum. When this convolution theorem is combined with the real-space renormalization method [3], we can address in a non-perturbative way the electronic transport in macroscopic aperiodic Labyrinth tiling based on generalizad Fibonacci chains [4]. Furthermore, we analytically demonstrate the existence of ballistic transport states in such aperiodic Labyrinth tiling. This finding suggests that the periodicity should not be a necessary condition for the single-electron ballistic transport even in multidimensionally fully non-periodic lattices. This work has been partially supported by UNAM-IN114916, UNAM-IN106317 and CONACyT-252943. Computations were performed at Miztli of DGTF, UNAM.

Electronic Transport in Aperiodic Labyrinth Lattices

Vicenta Sanchez, Fernando Sanchez and Chumin Wang; Universidad Nacional Autonoma de Mexico, Mexico City, Mexico.

The search for a simple and direct relationship between atomic scale arrangement and macroscopic properties of a material constitutes a principal task of the materials science. For example, the Bloch theorem establishes extended electronic wavefunctions and then a ballistic conduction if the atoms of a crystalline material are periodically ordered. At the other extreme, one- and two-dimensional amorphous solids with randomly arranged atoms possess only exponentially localized eigenstates [1]. Nowadays, the study of electronic transport in artificial structures is of great importance in condensed matter physics, because such structures introduce many new physical properties essential for technological applications of atomic-scale devices. In this work, we revisited a convolution theorem developed for the Kubo-Greenwood formula in Labyrinth tiling by transforming the original two-dimensional lattice into a set of independent chains with rescaled Hamiltonians [2]. Such transformation leads to an analytical solution of the direct-current conductance spectra, where quantized steps with height of 2$g_0$ are found in Labyrinth tiling with periodic order along the applied electric field direction, in contrast to the step height of $g_0$ observed in the corresponding square lattices, being $g_0$ the conductance quantum. When this convolution theorem is combined with the real-space renormalization method [3], we can address in a non-perturbative way the electronic transport in macroscopic aperiodic Labyrinth tiling based on generalizad Fibonacci chains [4]. Furthermore, we analytically demonstrate the existence of ballistic transport states in such aperiodic Labyrinth tiling. This finding suggests that the periodicity should not be a necessary condition for the single-electron ballistic transport even in multidimensionally fully non-periodic lattices. This work has been partially supported by UNAM-IN114916, UNAM-IN106317 and CONACyT-252943. Computations were performed at Miztli of DGTF, UNAM.

Fracture Tensile Test for Brittle Diamond-Like-Carbon at the Nanoscale

Dahye Shin and Dongchun Jang; Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of).

Ceramics are well used in various fields as functional materials and their property range is a way more expanded these days by adding new nanoscale properties. Even though a number of studies have been achieved for investigating electronic, magnetic, optic properties etc. at nanoscale, the fracture behavior is not reached to the same level of evaluation. It is in need of investigating the fundamentals of fracture mechanics for nano-sized ceramic materials to guarantee the reliability of the systems adding to enjoy the newly enhanced nano-properties at the same time. Brittle failure of ceramics is usually mediated by a rapid crack propagation due to the lack of intrinsic crack tolerant mechanism which requires extremely high critical stress for its activation, usually never been reached before the total failure in bulk scale. However, in some theoretical studies, fracture of nanomaterials becomes insensitive to flaws when they shrink below a certain critical size and enables to reach almost theoretical strength of the material [1]. Getting ideas from this, here we present an unwonted roll of cracks at the nanoscale as an activator of a fracture resisting mechanism not as an enemy of brittle ceramics through nanoscale tensile experiments and finite element methods analysis. In situ SEM tensile fracture tests with different crack geometries were carried out. Diamond-like-carbon (DLC) was chosen to be conductive for SEM image quality, isotropic, and brittle material to eliminate any complicate material issues and to make the best focus on the mechanical analysis. Single-edge-notched-tension (SENT) and double-edge-notched-tension (DENT) samples with pre-notch size of 60 nm and thickness of 200 nm were fabricated in mushroom like shape with head size of ~2 μm using Focused Ion Beam (FIB) on DLC film of ~1.5 μm coated on Si wafer. The head part was grabbed and pulled by a self-produced claw-like tip. In short, we observed that the DENT samples were deviated from the expectations based on classical linear elastic fracture mechanics showing 150% higher fracture strength even with 60% of total crack length out of thickness. It is explained by the interaction between the two stress fields of each crack that activates additional fracture resisting mechanism in the neck region of the specimen preventing the whole sample from the failure.

CM02.03.18

Studies of Photo-Thermal Dual Curing Behaviors of Acrylate Monomers with FTIR and Photo-DSC

Hyuck Sik Wang, Seung Hyuk Lee, Seok Hyung Bu and Kigook Song; Kyung Hee University, Yongin-si, Korea (the Republic of).

The photo-curing behaviors of acrylate monomers capable of urethane thermal reaction were investigated using time-resolved FTIR spectroscopy and photo-DSC (Differential Scanning Calorimetry). Faster photo-reaction and lower conversion of acrylate reactions were observed in the thermal-photo dual curing process compared to the photo-curing only process. In the case of the acrylate system with long chain oligomers, faster photo-reaction was also observed in the dual curing process although no difference was found in the degree of conversion of acrylates between two photo-curing processes. The photo-curing process of three acrylate monomers was investigated using ATR-FTIR spectroscopy with a deuterated acrylate compound. In the free-radical terpolymerization, the conversion of three acrylate monomers into terpolymer as a function of time was monitored by observing the characteristic FTIR peaks of each component. In order to identify the acrylate components involved in the free-radical terpolymerization, careful peak assignments were made for the acrylate terpolymer such that characteristic FTIR bands from different monomers chosen for quantitative analysis should not overlap with one...
Carbon dots (C-dots) are a class of low-dimensional carbon-based particles which exhibit a signature photoluminescence (PL) consisting of a red-shifted emission when irradiated with UV-visible light. This photoluminescence (PL) has been explained as either the effects of quantum confinement, or of energy traps on the particle surface. Several groups have reported the synthesis of C-dots directly from the thermal treatment of aqueous solutions of simple sugars (e.g., glucose, sucrose) either in a conventional autoclave or in a microwave oven. These studies have looked exclusively a preparation from low concentration (less than 10 wt% sugar) solutions reacted at rather high temperatures (between 160 to 200 °C). We report the synthesis of fluorescent carbon particles produced from viscous glucose solutions of a much higher concentration heated at much lower temperatures. Analysis by photon correlation spectroscopy (PCS) reveals the particles form immediately with a size (approximately 300 nm) that is nearly 100 times larger than the precursor clusters of sugar but which decrease slightly in size with additional heating. Despite their larger size, PL shows emission similar to that of smaller C-dots but with clear indications of fine structure suggesting a set of discrete surface energy levels likely associated with different functional groups attached to the particle's surface.

Crystallization is a key issue in understanding glass and plays a fundamental role in the development of advanced glass-ceramics. In the absence of catalytic agents, most supercooled liquids crystallize heterogeneously from the external surfaces of a few initial nuclei and slowly crystallize homogeneously in the interior. It is essential to follow the formation of the first nuclei. Is the whole local structure around the cations modified well before crystallization is completed? The precise role of nucleating agents in glass-ceramic formation will likely only be understood by investigating the very first stages of crystallization with a strictly local structural probe having atomic selectivity. The X-ray Absorption Fine Structure (XAFS) technique is quite appropriate to characterize the local structure of specific cations present in glassy samples from the earliest stage of crystal nucleation. In this work, partially crystallized and fully crystallized samples were obtained after treatment at temperatures and times defined in previous studies. The XANES and EXAFS spectra of selected cations ions in the BaO-SiO₂, Ba₂Ti₃O₉, CaMgSi₂O₆ − 9 mol% Fe₂O₃, MgO-SiO₂, NaO-2CaO-3SiO₂ and 2NaO-1CaO-3SiO₂ glassy systems were collected at room temperature by using the transmission and total electron yield modes. A preliminary analysis of the data indeed showed modifications in the local order around some cations as the time of crystallization increased. The results will be fully discussed.

Shear Band Nucleation and Propagation in Metallic Glass Matrix Composites Jonathan Gentile1, Douglas Stauffer2 and Jason R. Trelewicz1; 1Stony Brook University, Stony Brook, New York, United States; 2Bruker Nano, Minneapolis, Minnesota, United States.

Metallic glass matrix (MGM) composites combine high-strength amorphous metals with ductile crystalline inclusions to overcome the inherent brittleness of metallic glasses. While the crystalline heterogeneities have been shown to influence the process of shear localization, the underlying mechanisms are not well understood especially since they seemingly operate at disparate length scales. To explore the role of crystalline inclusions in the process of strain delocalization, we employ instrumented nanoindentation, which is particularly suited to study the deformation physics of these composite materials due to its ability to detect individual shear band propagation events and its precise control over plastic zone size. Using nanoindentation, we focus on elucidating three specific phenomena including the onset of plasticity through the formation of shear bands, the propensity for shear localization and its dependence on indentation strain rate, and the nature of shear band propagation. In this presentation, we describe instrumented Hertzian contact experiments that provide additional evidence for enhanced shear band nucleation as the shear band trajectory evolves with indentation depth to encompass the crystalline phase. Additionally, by measuring the fraction of discrete plastic events deriving from shear band plasticity during loading, we outline a transition from discrete to continuous deformation with increasing indentation strain rate, which is consistent with the behavior of monolithic metallic glasses. Through comparison of the propensity for shear localization with microstructural length scales of the MGM composites, we show that the presence of amorphous-crystalline interfaces simultaneously limit shear band propagation and promote a more homogeneous response through the partitioning of shear strain to the crystalline phase.

Revealing β-Relaxation Mechanism Based on Energy Distribution of Flow Units in Metallic Glass Zhen Lu1, Wei Hua Wang2 and Hai Yang Bai1; 1Mathematics for Advanced Materials Open Innovation Laboratory (MathAM-OIL), Sendai, Japan; 2Institute of Physics, Beijing, China.

The β-relaxation, which is the source of the dynamics in glass state and has practical significance to relaxation and mechanical properties of glasses, has been an open question for decades. Here, we performed stress relaxation experiments under isothermal and linear heating modes and molecular dynamics simulations to investigate the different β-relaxation behaviors of various metallic glasses and the correlation between β-relaxation and flow units based on the activation energy distribution of flow units. We show that the β-relaxation originates from the flow units in metallic glasses, and the activation energy distribution of flow units modulates the β-relaxation modes such as excess wing, shoulder and peak in their dynamic spectra. A clear picture on the structural origin of β-relaxation and the correlation between activation energy distribution of flow units and β-relaxation behaviors in metallic glasses is proposed, which might be helpful to understand the nature of glasses and glass dynamics.

CM02.03.25
Diffusion and Avalanches in a Mesoscopic Model of Amorphous Plasticity Botond Tyukodi1, 2, Kareem Khirallah1, Damien Vandembroucq2 and Craig E. Maloney2; 1Northeastern University, Boston, Massachusetts, United States; 2PMMH, ESPCI, Paris, France.

Plastic deformation of amorphous materials around the yielding point shows critical properties such as avalanches, diverging correlation lengths and finite size effects. While this criticality is captured by various models, there is less consensus regarding the degree at which critical exponents are robust to the details of the particular system. Here we focus on the robustness of fluctuations in these properties to the main ingredients of amorphous plasticity: elastic interactions and structural disorder. We find that, at short times, neither the details of the elastic interaction kernel, nor the type of the disorder are important when it comes to the critical properties. We find a short term diffusive behavior in our model and the associated diffusion coefficient shows the same finite size scaling as previous particle simulations. We connect the scaling of the diffusion coefficient to the scaling of avalanche sizes and the correlation between β-relaxation and flow units based on the activation energy distribution of flow units. We show that the β-relaxation originates from the flow units in metallic glasses, and the activation energy distribution of flow units modulates the β-relaxation modes such as excess wing, shoulder and peak in their dynamic spectra. A clear picture on the structural origin of β-relaxation and the correlation between activation energy distribution of flow units and β-relaxation behaviors in metallic glasses is proposed, which might be helpful to understand the nature of glasses and glass dynamics.

Atomistic Simulation of Nearly Defect-Free Models of Amorphous Silicon—An Information-Based Hybrid Approach Dil K. Limbu1, Raymond Atta-Fynn2 and Parthapratim Biswas3; 1Department of Physics and Astronomy, The University of Southern Mississippi, Hattiesburg, Mississippi, United States; 2Department of Physics, The University of Arizona at Tucson, Arizona, Arizona, United States.

We present an information-based total-energy optimization method to produce nearly defect-free structural models of amorphous silicon. Using geometrical, structural and topological information from tetrahedral networks, we have shown that it is possible to generate structural configurations of amorphous silicon, which are superior to the models obtained from conventional reverse Monte Carlo methods involving structural constraints and total-energy optimization. The new static (i.e. relaxation-based) approach presented here is capable of producing atomistic models with structural properties which are on a par with those obtained from the modified Wooten-Winer-Weaire (WWW) models of amorphous silicon. Structural, electronic, and vibrational properties of the hybrid models are compared with the best dynamical models obtained from using machine-intelligence-based algorithms and efficient molecular-dynamics simulations, reported in the recent literature. We have shown that, together with the WWW models, our hybrid models represent one of the best static models so far produced by total-energy-based Monte Carlo methods in conjunction with experimental diffraction data of amorphous silicon.

CM02.03.27
Metastable Hydrogenated Amorphous Silicon (a-Si:H) as Reversible Programmable Photonic Material Mahir A. Mohammed1, 2, Ripalta Stabile1, 3, Jimmy Melskens2, 3, Wilhelms (Erwin) Kessels1, 4 and Oded Raz2, 3; 1Electrical Engineering, Eindhoven University of Technology, Eindhoven, Netherlands; 2Applied Physics, Eindhoven University of Technology, Eindhoven, Netherlands; 3Institute for Photonic Integration, Eindhoven University of Technology, Eindhoven, Netherlands.
Hydrogenated amorphous silicon (a-Si:H) is known to exhibit light-induced metastable properties that are reversible upon annealing. Although these metastable properties suggest the existence of reversible optical properties of a-Si:H as well, very little is known about this effect. If indeed properly identified and characterized, such reversible optical properties may find application in the reversible programmable photonic integrated circuits (PICs) that can enable multiple functionalities on the same chip, similar to field-programmable gate arrays (FPGAs). However, the required reversible effective refractive index change due to light soaking and annealing has not been reported yet nor has it been thoroughly investigated. Therefore, the effects of prolonged high intensity light soaking and annealing on a-Si:H on the near infrared (NIR) optical properties are studied in this work. A thin-film interferometric technique was developed to detect minute changes probed using a NIR laser source (1465-1575 nm). Using this approach, an increase in refractive index resulted in a reduced value of the sharp reflection minimum and a blue shift for the decrease in refractive index. To detect the changes in optical properties more precisely, double-layered thin films were used: a-Si:H was deposited by inductively coupled plasma-enhanced chemical vapour deposition (ICP-PECVD) on SiO2, which was in turn deposited by PECVD on a crystalline silicon substrate. The a-Si:H deposition temperature was set to 80 °C and 300 °C, such that significantly different structural properties, e.g. hydrogen content and density, could be achieved. An irreversible blue shift was observed during the first cycle of annealing and light soaking after the deposition. However, from the second cycle onwards, a red shift of the spectrum due to light soaking, i.e. reversal of the annealed state was observed. It appeared that the initial irreversible changes are inevitable and only after these changes reversibility is observable. The reversibility was sustained after further cycles of annealing and light soaking. The reversibility appears for both a-Si:H deposited at 80 °C and 300 °C. However, the magnitude of the reversibility for a-Si:H deposited at 80 °C is significantly larger when compared to a-Si:H deposited at 300 °C. This suggests a correlation of the metastable properties of a-Si:H on the hydrogen content and density of the material, i.e. porous films (deposited at 80 °C) are more susceptible to light-induced change than dense films (deposited at 300 °C). The magnitude of the reversibility in refractive index for a-Si:H deposited at 80 °C is estimated to be around 0.03%. Although small, this metastable state could be sufficient for an application in reversible programmable optical switch. These results therefore indicate that a-Si:H has potential in enabling reversible programmable PICs and work to implement this material in a photonic device is currently ongoing.

**Ag’ Ion Emission from Sharp-Edged Ag’ Ion Conducting Glasses and Two Emission Mechanisms**

Yusuke Daiko, Hiroki Mori, Sawao Honda and Yuji Iwamoto; Nagoya Institute of Technology, Nagoya, Japan.

Ion implantation is an effective method for surface modification of materials, and that has been used in various fields such as the semiconductor and metal industries, and bio-technology. In general, a discharged plasma (gas) or liquid (e.g., liquid Ga for a focused ion beam) is used as the ion source so far. However, in these cases, side reactions such as generation of radicals or various ions with different mass, e.g. in the case of H’ emission, H2’ and H3’ etc. are also generated) are unavoidable. Also, ion accelerators are huge and expensive. On the other hand, ion emissions from high ion conductors such as alkali-lead electrolytes have also been investigated because in a good solid electrolyte the mobile ions can move almost as freely as those in a liquid. The emission of O’ ions from O’-ion-conducting yttria-stabilized zirconia (YSZ) was first reported in 1997. Similarly, continuous Ag’ ion emissions for a few days were reported using Ag’-ion-conducting (AgI)0.5(AgPO3)0.5 or RbAg4I5, for AgI-7AgClO4(C12A7) pellets. However, side recombination (generation of radicals or various ions with different mass, e.g. in the case of H’ emission, H2’ and H3’ etc. are also generated) are unavoidable. Also, ion accelerators are huge and expensive.

We have studied ion emissions from various types of ion-conducting glasses [1-3]. One advantage of utilizing glass is its formability for tip sharpening because the electric field strength is proportional to the inverse of the curvature radius of the tip. Here we report Ag’ ion emission from a sharpened Ag’ ion conducting glasses. An aluminum phosphosilicate glasses Ag2O-Al2O3-P2O5-SiO2 show Ag’ ion conductivity of 3×10−5 S/cm at 300 °C, and an ionic current of Ag’ ion emission was successfully observed at 300 °C and 1×10−5 Pa. A good linear correlation is obtained between the log(current) and voltage. At the source of the acceleration voltage, the current of Ag’ ion changes from Ag’ ion to Ag’ ion is eliminated by Schottky model similar to a thermionic emission source.

The relationship between the emission current and voltage is expressed by a space-charge limited current model, in which the current is proportional to the inverse of the curvature radius of the tip. Here we report Ag’ ion emission from a sharpened Ag’ ion conducting glasses. An aluminum phosphosilicate glasses Ag2O-Al2O3-P2O5-SiO2 show Ag’ ion conductivity of 3×10−5 S/cm at 300 °C, and an ionic current of Ag’ ion emission was successfully observed at 300 °C and 1×10−5 Pa. A good linear correlation is obtained between the log(current) and voltage. At the source of the acceleration voltage, the current of Ag’ ion changes from Ag’ ion to Ag’ ion is eliminated by Schottky model similar to a thermionic emission source.

Intermediate temperature fuel cells (IT-FCs) operating around 400-500 °C have attracted much attention as next-generation energy source owing to their high conversion efficiency and low fabrication cost. Our group successfully prepared a fast proton conducting phosphosilicate glass using conventional melting method, and we confirmed fuel cell operation using H2 and O2 at the intermediate temperature (~5 mW/cm2) [1,2]. Similar to typical oxide glasses, our glass has quite few H’ (OH groups) just after quenching the melt. However, based on originally developed in-situ FTIR measurement, we found a proton implantation into the phosphosilicate glass occurs under fuel cell operating condition [3]. We anticipated such proton implantation affects mechanical properties of the glass. In this study, creep behavior of proton conducting glass in fuel cell atmosphere is reported.

A new electrochemical indentation apparatus was developed, in which we can control measuring conditions including atmosphere (H2, N2, air and relative humidity), temperature, and electrical field. A spherical Inconel 625 indenter was used as an electrode simultaneously, and we evaluated in-situ creep behavior under the proton implantation. Proton conducting glass was prepared by conventional melting method with composition of 7.5Na2O-7.5K2O-35P2O5-50SiO2 (mol%). After polishing the glass with ~1 mm thickness, Pt ring-electrode was sputtered on a side of the glass plate. Atmosphere was controlled by flowing a humidified H2/gas (4%H2-96% Ar), heating up to 200 °C, and applying DC 5 V between the Pt ring and Inconel electrodes. This condition is similar to the anode reaction of fuel cell (H2 -> 2H++ 2e-), and proton implantation occurs. We conducted an indentation creep experiment under the reaction. We also carried out same experiments in N2 atmosphere as comparison. Humidity effects were also investigated using humid gas (relative humidity ~1%)

The phosphosilicate glass showed typical creep behavior in N2 atmosphere at 200 °C. Interestingly, the creep displacement increases remarkably in H2 atmosphere, and we obtained a longer relaxation time for creep in H2 atmosphere compared with that in N2. These results suggest that proton implantation affects significantly for mechanical properties of glass. Results including Raman spectroscopy will be shown and discussed at the presentation.

Polymer resins are used for numerous applications, for example as matrix materials for high performance fiber-reinforced composites. Such structures operate in humid air and liquid water, which may cause swelling and degradation of the material. Because of imperfections in the chain structure such as chain ends, glassy polymer contain molecular sized voids called “free volume”. In addition, macroscopically sized voids are commonly found in polymers. When polymers absorb water, differential scanning calorimetry (DSC) studies have shown that the absorbed water may be classified as free water and bound water. Free water exist when the water molecules occupy free volume and voids. Bound water state exists when the water molecules interact with the polymer chains and form hydrogen bond. In order to examine the influence of voids on water uptake, and the state of water in epoxy, foaming agents were utilized to produce a controllable amount of voids (void contents from 0 to about 50%).

Epoxy specimens containing voids and void-free were prepared. Water uptake experiments were conducted by immersing specimens with and without voids in distilled water at 40 °C. The moisture content was monitored by gravimetric measurements. To examine the state of absorbed water, DSC analysis of dry and water saturated epoxy specimens without and with voids was conducted over a temperature range from -80 °C to room temperature. DSC data was recorded during both the cooling and heating cycles. The state of water absorbed was determined based on analysis of the appropriate transitions recorded.

The free and bound water phase transitions were absent in the dry void-free specimen. In the water saturated void-free specimen, most the moisture absorbed was non-freezable water. In the water saturated medium and high void content specimens, peaks attributed to free and bound water were observed. The contents of free and bound water were estimated from the exothermic peaks in the DSC curves. The bound water peak was much smaller than the free water peak, and decreased with increasing the void content. The area under the free water peak increased with increasing void content.
The effect of surface disorder, load, and velocity on friction between a single asperity contact and a model surface is explored with one-dimensional and two-dimensional Prandtl-Tomlinson (PT) models [1]. We show that there are fundamental physical differences between the predictions of one-dimensional and two-dimensional models. The one-dimensional model estimates a monotonic increase in friction and energy dissipation with load, velocity, and surface disorder. However, two-dimensional PT model, which is expected to approximate a tip-sample system more realistically, reveals a non-monotonic trend, i.e., friction is inert to surface disorder and roughness in wearless friction regime. The two-dimensional model discloses that the surface disorder starts to dominate the friction and energy dissipation when the tip and the sample interact predominantly deep into the repulsive regime. Our numerical calculations address that tracking the minimum energy path and the slip-stick motion are two competing effects that determine the load, velocity, and surface disorder dependence of friction. In two-dimensional model, the single asperity can follow the minimum energy path in wearless regime; however, with increasing load and sliding velocity, the slip-stick movement dominates the dynamic motion and results in an increase in friction by impeding tracing the minimum energy path. Contrary to two-dimensional model, when one-dimensional PT model is employed, the single asperity cannot escape to minimum energy minimum due to constraint motion and reveals only a trivial dependence of friction on load, velocity, and surface disorder. Our computational analyses clarify the physical differences between the predictions of one-dimensional and two-dimensional models and open new avenues for dispersed surfaces for low energy dissipation applications in wearless friction regime.

Infrared microspectroscopy is a powerful technique for obtaining unique chemical information from a variety of biological systems. In general, spatial resolutions are limited by the Abbe diffraction laws to \( \lambda / 2 \) (3-10 µm). In recent years, the development of the AFM-IR technique has allowed for overcoming these diffraction limitations by using an AFM probe as the detector for IR absorption. Using a quantum cascade IR laser (QCL), the molecular vibrations in a sample are excited, leading to thermal expansion of the surface, which is monitored using an AFM cantilever. This technique reduced the spatial resolution of < 10 nm, however, in certain cases this high resolution is not required and the size of an image in AFM-IR is limited by the piezo stage to sub 100 µm. A new technique has been developed that fills the gap between IR microspectroscopy and AFM-IR. This is an optical based technique that still beaks the diffraction limits associated with conventional IR microspectroscopy, and provides sub-micron spatial resolution. Taking advantage of the same fundamental principles that govern AFM-IR, the thermal expansion of a sample surface induced by a QCL IR laser is monitored using a visible probe laser, instead of an AFM probe. This unique technique provides transmission like IR spectra while operating in a reflective regime. The spatial resolution is limited by the diffraction limit of the visible probe laser, while also being independent of the IR wavelength used. This talk with focus on the use of optical based photothermal IR spectroscopy to characterize a variety of materials.

Non-Contact Sub-Micron Infrared Spectroscopy of Non-Crystalline Materials Using Visible Probe Detection Eoghan Dillon\(^1\), Craig Prater\(^1\) and Curtis Marcolt\(^2\); \(^1\)Photothermal Spectroscopy Corp, Santa Barbara, California, United States; \(^2\)Light Light Solutions, Athens, Georgia, United States.

Nanoscale characterization methods play a key role in the analysis, development and optimization of nanoscopic materials and devices. Often several characterization techniques are required to gain a comprehensive understanding of the various material properties of such complex functional materials. Here we introduce the combined analysis of complex nanoscale material systems by correlating infrared scattering-type Scanning Near-field Optical Microscopy (s-SNOM) [1] and nanoscale Fourier Transform Infrared (nano-FTIR) spectroscopy [2] with information obtained by other Scanning Probe Microscopy (SPM) based techniques. For example, the material-characteristic nano-FTIR absorption spectra of a phase-separated PS/LDPE polymer blend identifies sharp material interfaces between the two materials by measuring a line profile across a ca. 1 µm sized LDPE island inside the PS matrix. Near-field reflection/absorption imaging at 1500 cm\(^{-1}\) of the only 50 nm thin film allows to selectively highlight the distribution of PS in the blend, while selective atomic force microscopy (AFM) modes simultaneously map the mechanical properties like adhesion of the different materials [3,4]. Further, results will be presented that correlate the nanoscale near-field optical response of semiconducting samples like graphene (2D) or functional SRAM devices (3D) in different frequency ranges (mid-IR & THz) to Kelvin Probe Force Microscopy (KPFM) and Electrostatic Force Microscopy (EFM) measurements.

Our goal is to demonstrate novel approaches to extend the performance limits of organic and/or inorganic composites to high-temperature applications of oil and gas applications. Conventional composite technology has fulfilled increasing materials property requirements by using expensive high-end performance polymers and fillers. Our goal is to demonstrate novel approaches to extend the performance limits of organic and/or inorganic composites to high-temperature applications of up to 400°F, without relying on costly high-end raw materials. Commercial low-cost materials were used to develop high-strength performance composites by extensive application of advanced processing techniques. In addition, we studied the potential applications of developed composites for downhole completions applications through prototype testing.
Material properties were assessed within the 300 to 400°F temperature range by using a compressive strength test, Dynamic Mechanical Analysis (DMA), Differential Scanning Calorimetry (DSC), and Thermogravimetric Analysis (TGA). Furthermore, test specimens doped in water and/or downhole fluids to evaluate the effect of prolonged exposure to downhole conditions on mechanical properties. Implementation of out-of-the-box approaches enabled development of low-cost, high-performance systems capable of achieving compressive strengths over 20 ksi at temperatures over 300°F. In-depth processing optimization enabled further improved composite properties. The practical implications of the experiments enabled covering a large number of conventional and unconventional fillers for organic and/or inorganic matrices.

We demonstrated the development of high-strength organic and/or inorganic composites based on low-cost raw materials for high-temperature applications. This novel material-design approach was investigated with advanced material analysis techniques.

Moran Emuna1, Yaron Greenberg1, Eyal Yahel1 and Guy Makov; 1Materials Engineering, Ben-Gurion University of the Negev, Beer Sheva, Israel; 2Physics, NRCN, Beer-Sheva, Israel.

We present a novel experimental design for high sensitivity measurements of the electrical resistance of samples at high pressures (0-6GPa) and high temperatures (0-1000K) in a “Paris-Edinburgh” type large volume press. Uniquely, the electrical measurements are carried out directly on a small sample, thus greatly increasing the sensitivity of the measurement. The sensitivity to even minor changes in electrical resistance can be used to clearly identify phase transitions in similar samples. Electrical resistance measurements are relatively simple and rapid to execute and the efficacy of the present experimental design is demonstrated by measuring the electrical resistance of Pb, Sn and Bi across a wide domain of temperature-pressure phase space and employing it to identify the loci of phase transitions. Based on these results, the phase diagrams of these elements are reconstructed to high accuracy and found to be in excellent agreement with previous studies. In particular, by mapping the locations of several well-studied reference points in the phase diagram of Sn and Bi, it is demonstrated that a standard calibration exists for the temperature and pressure, thus eliminating the need for direct or indirect temperature and pressure measurements. The present technique will allow simple and accurate mapping of phase diagrams under extreme conditions and may be of particular importance in advancing studies of liquid state anomalies.

CM02.03.39
Structure, Curing Dynamics and Performance of Phthalonitrile Resins
Boris Dyatkin1, Stephen M. Deese1, Tristan Butler1, Naresh C. Osti2, Madhusudan Tyagi1 and Matthew Laskoski; 1Chemistry, U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 2Neutron Scattering Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3Center for Neutron Research, National Institute of Standards and Technology, Gaithersburg, Maryland, United States.

High-temperature polymer matrix composites (PMCs) allow great control over various intrinsic properties (e.g. oxidative stability, mechanical toughness, thermal conductivity, etc.) that tailor these lightweights for numerous emerging applications. Despite many available formulations, conventional epoxy and phenolics, which form the matrix backbones of most thermoset composites, require high processing temperatures and cannot adequately withstand fire damage or high temperatures. Our efforts have recently yielded several types of thermosetting polymer resins called phthalonitriles, which are synthesized via a two-step, one-pot nucleophilic displacement reaction between dihaloaromatic compounds and bisphenol, followed by end-capping with 4-nitrophthalonitrile. Several backbone structure variables are available for this resin system, and all of them offer low gelation (150 °C) and final curing temperatures (350 °C). In addition to low processing costs, the resulting thermostats offer high strength and exceptional fire resistance (up to 700 °C). However, existing research efforts have not adequately described the curing process and associated monomer dynamics for these resins; nor have they correlated them with structures and performance of resulting composites. Given that the backbone chemistry of each resin system significantly influences cross-linking and material properties, this information is essential to further optimize materials processing of high-performance phthalonitrile-based PMCs.

We have correlated the microscopic dynamics of three different phthalonitrile resin monomers during different thermal conditions with the morphologies, chemistry, and properties of resulting thermostats. The systems used a resorcilon backbone, a bisphenol A (PEEK-like) backbone, and a reserveratrol backbone. We measured the temperature-dependent monomer dynamics by conducting quasi-elastic neutron scattering measurements of each resin at room temperature, at 135 °C (at the Tg), during the gelation transition, and at 257 °C (fully cured systems), and correlated the extracted mobility and diffusion transformations with rheometry-derived viscosity changes to fundamentally probe the curing process of each system. In turn, these insights provide a proper explanation of the resulting morphology and, in turn, the oxidative stability and tensile strength of each resin system. Our efforts have established greater processing controls over high-performance phthalonitrile thermostats and facilitated their implementation in fiber-reinforced composites, flame-retardant panels, and lightweight airframes.

Porous-Carbon Nanotube Aerogels for Ultrafast Charging Supercapacitors and Potassium-Ion Batteries
Wenqi Zhao1, 1, Yibin Li2 and Anyuan Cao1; 1Peking University, Beijing, China; 2Harbin Institute of Technology, Harbin, China.

Energy storage systems with ultrafast charging properties have become a hot topic in recent years along with the increased life rhythm. Supercapacitors are energy storage systems capable of fast charging and discharging, thus generating superior power density. Potassium ion batteries (PIBs) possess a series of advantages as the next generation energy storage systems, such as low cost, large reserves compared to lithium, and high energy density. Porous carbon with high surface area and tunable pore size represents a promising candidate to construct ultrafast supercapacitors; so far most of porous carbon-based electrodes can only be charged to a moderate current density (100-200 A/g), also with significant capacitance loss at increasing rate. Here, we show that a three-dimensional (3D) aerogel consisting of interconnected 1D porous-carbon nanotubes (PCNs) could serve as a freestanding supercapacitor electrode with excellent rate performance (62% retention at 1000 A/g) and high power density (265 kW/kg). The aerogel is formed through a combination of nitric acid doping and controlled air-etching processes. Mechanism study reveals favorable kinetics including a low and linear IR drop, about 85% contribution from electrical double layer capacitance, a very small time constant (0.057 s) and a metallic feature of 1D PCNs by theoretical calculation. The development of rechargeable batteries using potassium ions has recently attracted considerable attention. Here, we chose carbon nanotube (CNT) sponges as scaffolds to load nitrogen doped porous carbon (NDPC) and form hierarchical structures. The obtained 3D CNT/NDPC sponges can work as freestanding electrodes with significantly increased potassium storage capacity and compressive properties. The hybrid sponges achieve high capacity of 420 mAh/g as PIB electrodes, excellent rate capability and stable cyclic performance.

In conclusion, we demonstrated controlled fabrication of 3D freestanding porous electrode materials with ultrafast charging properties in supercapacitors and PIBs. Our pore-creation method, by combining HNO3-doping and air-etching processes, could be extended to other N-containing precursors to fabricate various porous-carbon structures with tunable hierarchical pores. The highly porous 1D nanotube structure has the potential to develop microelectronic and power-supply devices that require fast charging/discharging capability (e.g. within 0.1 seconds).

Mechanically Strong and Thermally Conductive Ultra-High Molecular Weight Polyethylene Sheets Shengqiang Ren; University at Buffalo, The State University of New York, Amherst, New York, United States.

Ultra-high molecular weight polyethylene (UHMWPE) is of great interest as a next-generation body armor material due to its superior mechanical properties. However, such unique properties depend critically on its microscopic structure characteristics, including the degree of crystallinity, chain alignment and morphology. Here we present a highly aligned UHMWPE and of its composite sheets containing uniformly dispersed boron nitride (BN) nanosheets. The dispersion of BN nanosheets into the UHMWPE matrix increases its mechanical properties over a broad temperature range. Experiments and simulation confirm that the alignment of chain segments in the composite matrix increases with temperature, leading to an improvement in mechanical properties at high temperature. Together with the large thermal conductivity of UHMWPE and BN, our findings serve in expanding the application spectrum of highly aligned polymer nanocomposite materials for ballistic panels and body armor over a broad range of temperatures.

CM02.03.42
Microcellular Materials with Stress-Activated Pores Exhibiting Opto-Mechanical Properties Bilal Abdul Halim, Sheikh Rasel, Reza Rizvi, Navid Namdari and Eranan Hossain; Polymer and Inorganic Composites, Structures and Surfaces Lab, Toledo, Ohio, United States.

Microcellular (1-30µm) and Nanocellular (<1µm) polymers have significantly lower densities relative to the base polymer resulting in improved specific mechanical properties as well as increased impact absorption and thermal insulation. Batch micro- and nano-cellular processes are generally well suited for low volume lab-based studies. The gas sorption within the polymer system tends to swell the polymer, resulting in increased free volume, higher chain mobility and a depressed glass transition temperature (Tg). These porous polymers acquire a static porosity, not quite as applicable or interesting as those with a dynamic porosity. Such a characteristic enables the polymer to mimic several stimuli activated porous systems found in nature, which exist at all length scales. For instance, the regulation of what enters and exits the cell (including oxygen, carbon dioxide, and other molecules and ions) cannot transpire if the cell membrane wasn’t permeable (porous). Another example is the ability of the cuttlefish to use its cuttlebone, which is not exactly a bone, but a calcium carbonate like material that is almost 90% porous. Disjoined from the fish, the cuttlebone floats on water, however, the cuttlefish is able to control the flow of water in and out of the cuttlebone which helps with its buoyancy and structure. Synthetic attempts at systems with dynamic porosity have focused mainly at the molecular-scale and nano-scale. No proven examples of dynamic porosity exist at the micron-scale. This study introduces a fundamental examination of foams composed of the triblock copolymer styrene-ethylene-butylene-styrene (SEBS) which was prepared using batch foaming, where the polymer is put in a pressure chamber using CO2 as the blowing agent, and were then quenched at different temperatures (30°C, 50°C, 70°C, 90°C). These foams exhibit pores that shrink under stress and remain stable with an internal vacuum. Now, the reduced pore size fails to act as a light-scattering site, turning the polymer transparent and recovering back to an almost neat SEBS film. Different characterization techniques were done on foams before and after applying stress, using Scanning Electron Microscopy (SEM), Differential Scanning Calorimetry (DSC), and X-Ray Diffraction (XRD). The opaque to transparent transition (OTT) was studied using an in-situ optomechanical setup comprised of an LED and a photoreistor while under a dynamic load using a universal testing machine. Each foam at different quenching temperature undergoes OTT at different loads and remains transparent. However, collapsed pores can be re-foamed which was demonstrated through saturating the almost-recovered SEBS for many cycles whilst under getting density measurements and electron microscopy images at each cycle. This behavior can be instrumental in making pressure sensitive films.

Unraveling the Solution-State Supramolecular Structures of Donor-Acceptor Polymers and Their Influence on Solid-State Morphology and Charge-Transport Properties Yiqing Zheng1, Jian Pei1, Jie-Yu Wang1 and Lin Zou2; 1Peking University, Beijing, China; 2Institute of Nuclear Physics and Chemistry, China Academy of Engineering Physics, Mianyang, China.

Polymer self-assembly in solution prior to film fabrication makes solution-state structures critical for their solid-state packing and optoelectronic properties. However, unraveling the solution-state supramolecular structures is challenging, not to mention establishing a clear relationship between the solution-state structure and the charge-transport properties in field-effect transistors. Here, for the first time, it is revealed that the thin-film morphology of a conjugated polymer inherits the features of its solution-state supramolecular structures. A “solution-state supramolecular structure control” strategy is proposed to increase the electron mobility of a benzodifurandione-based oligo(phenylene vinylene) (BDOPV)-based polymer. It is shown that the solution-state structures of the BDOPV-based conjugated polymer can be tuned such that it forms a 1D rod-like structure in good solvent and a 2D lamellar structure in poor solvent. By tuning the solution-state structure, films with high crystallinity and good interdomain connectivity are obtained. The electron mobility significantly increases from the original value of 1.8 to 3.2 cm2 V−1 s−1. This work demonstrates that “solution-state supramolecular structure” control is critical for understanding and optimization of the thin-film morphology and charge-transport properties of conjugated polymers.

Toughening PDMS Through Entanglements Deborah Ehrlich, Junpeng Wang and Jeremiah Johnson; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

There is a need for tough PDMS that maintains its optical clarity and high temperature resistance. Fillers increase the modulus, toughness, and tear resistance of PDMS, but diminish optical clarity. Entanglements can be used to improve the mechanical properties of PDMS, without impacting desirable properties. By enhancing entanglements, we can further increase the modulus, toughness, and tear resistance of PDMS elastomers while maintaining optical clarity and high temperature resistance. Here we discuss our efforts to synthesize novel PDMS network architectures with entanglement promoted toughness.

CM02.03.45
Combining Raman Spectroscopy with Rheology to Correlate Physical and Chemical Properties of Polymers Richard A. Larsen1, Frederik Fleissner2, Boris Wezsiha3, Georg Krem2 and Katharina Napp4; 1Anton Paar, Ashland, Virginia, United States; 2Anton Paar OptoTec, Seelze-Lettlert, Germany; 3Anton Paar GmbH, Graz, Austria.

During chemical reactions such as polymerization, the physical as well as chemical properties of a material change. While the viscoelastic properties usually can be characterized with a rheometer, no chemical information is obtained by the mechanical testing. The interpretation of rheometric results often relies on empirical models and a more phenomenological approach. For directly relating the changes in rheological behavior to chemical changes, Raman spectroscopy is employed in-situ with rheology. Raman is a spectroscopic technique based on inelastic light scattering from the sample molecules. By measuring the presence and intensities of molecular vibrations, Raman spectroscopy provides information on the chemical composition and structure of the
The combination of both techniques enables the simultaneous correlation of the mechanical properties and the molecular structure to obtain a better understanding of the sample.

The Anton Paar MCRxx2 (Modular Compact Rheometer) series of rheometers can be easily combined with the Anton Paar Cora Raman spectrometers via an optical fiber probe. For the applications presented here, a high temperature probe with an extended working distance of 10 mm was used to obtain measurements through the lower measurement plate of the rheometer system. To demonstrate the possibilities of a combined Rheo-Raman system, we investigated resin hardening as well as the melting behavior of polyethylene. First, the hardening of an epoxy resin was monitored providing insight into the chemical and physical changes during the reaction. Specifically, the reaction induced changes in the flow characteristics over time were characterized. In the Raman spectrum, the chemical changes can be found in the decrease of vibrational bands belonging to the epoxy group of the reaction component. Secondly, the phase transition from the crystalline to amorphous state in HDPE (High Density Polyethylene) was monitored while the polymer was heated. This resulted in a higher viscosity as well as alteration of vibrational bands in the Raman spectrum reflecting the conversion from a crystalline to an amorphous structure.

Having both viscoelastic and spectroscopic information on a sample provides a more detailed characterization of the observed sample. As a result, sample behavior can be analyzed in all its facets for better quality control as well as optimizing the process properties of materials.

A Compressive-Sensing Pixelated Direct Detector for 4D-STEM

Benjamin Bammes, Robert Bilhorn and Robert Monteverde; Direct Electron, LP, San Diego, California, United States.

Use of a pixelated detector in scanning transmission electron microscopy (STEM) enables the simultaneous acquisition of both the conventional annular dark-field (ADF) signal and the coherent bright-field (BF) diffraction pattern at every probe position. By detecting the scattering angle of nearly all the primary electrons that interact with the specimen, this “4D-STEM” technique promises to provide much more information about the specimen than conventional STEM using only an ADF detector.

An acute challenge for acquisition of 4D-STEM data is the relatively slow speed of pixelated detectors for capturing the coherent BF signal. Slow acquisition of STEM data introduces deleterious artifacts from specimen drift and thus forces users to acquire a severely limited field-of-view—a significant problem for non-crystalline specimens.

One strategy to improve the speed of these detectors, is to reduce the number of pixels in the pixel array. However, this strategy prevents acquisition of the low- and medium-angle DF signal on the pixelated detector and it may also undersample the BF diffraction pattern and reduce its usefulness for differential phase contrast (DPC) or ptychography. This is especially problematic for complex specimens, such as specimens containing light atoms.

To address this challenge, we have implemented a new compressive-sensing readout mode—called Arbitrary Kernel Row Addressing (AKRA)—on our DE-16 direct detection camera. In AKRA readout mode, the user can specify any arbitrary combination of kernel rows from the detector to readout; all other kernel rows are skipped. By reading out fewer pixels, the detector framerate can be increased, enabling STEM imaging of a larger field-of-view. But since the “missing” pixels are scattering across the detector, the pixelated detector still captures a large area of the BF diffraction pattern and surrounding DF signal, with the “missing” pixels reconstructed using compressive-sensing algorithms. Therefore, AKRA enables fast 4D-STEM acquisition with a large pixelated detector so that rich structural information can be collected for large regions-of-interest of complex specimens.

Size-Dependent Properties of Nano-Crystalline Oxides

Siu-Wai Chan; Columbia University, New York, New York, United States.

A number of oxides, when prepared in nano-scale crystallites, exhibit a larger than bulk lattice parameter. A couple of these nano-oxides also show decreasing thermal expansion as well as stiffness constants as crystal-size goes beyond 10nm. We will discuss the physics and the materials science behind such an extraordinary behavior and the implications for solid-state chemistry and physics in nanoscale.

Fluorinated Polyurethane Resin with Fold Shape Structure and the Cavitation Erosion Resistance Performance

Haocheng Yang, Rongrong Chen, Jun Wang, Xuejie Guo and Kazunobu Takahashi; Materials Science and Engineering, College of Materials Science and Chemical Engineering, Harbin Engineering University, Harbin, China.

Cavitation erosion is a common mode of propeller surface damage, which seriously affects the hydrodynamic performance of propeller. In industrial applications, it is a surface treatment technology that effectively improve the cavitation erosion resistance performance by spraying elastomer organic coating on hydraulic components. Fluorinated polyurethane is a good elastomer which not only has excellent mechanical properties, but also has good ability of anti-biofouling. Herein, hydrophobic fluorinated polyurethanes (FPU), which combination of cavitation erosion resistance and biological fouling resistance coating were prepared by using the method of introducing fluorine with perfluoroalkyl ethanol (TEOH-10) for modification of isophorone diisocyanate (IPDI) and controlling the IPDI adding dosage and time. The chemical structure of FPU was investigated by Fourier transform infrared spectroscopy (FT-IR), nuclear magnetic resonance spectrum (NMR) and gel permeation chromatography (GPC). The bonding strength between top coating and metal interlayer is significantly excellent(>4 MPa). Cavitation erosion tests were performed on Ultrasonic bubble generator for 10h. The mass loss of different cavitation time was examined by balance analysis. Surface morphology of the specimens was observed by Contour GTX and scanning electron microscope (SEM), respectively. Six-months marine field test in the Yellow Sea revealed that the FPU coatings exhibited excellent anti fouling/fouling release performance. (This paper is funded by the International Exchange Program of Harbin Engineering University for Innovation-oriented Talents Cultivation.)

Cryo-EM Characterization of Chalcogenide Glass Solution Structure

Nikita Dutta and Craig B. Arnold; Princeton University, Princeton, New Jersey, United States.

The unique optical properties of solution-processed chalcogenide glasses have long been of interest for photonic devices; a common test system is arsenic
The goal of this work is to progress the current understanding of structure-property relationships of amorphous carbons. This presentation will review some surface chemistry, and interfacial capacitance. It will better understand how growth parameters like dopant concentration, substrate etc. affect the electrode properties i.e. electrical conductivity, microstructure, wide potential window, mechanical strength, low-temperature deposition (<100 °C), tunable doping level and surface chemistry. Research is needed to better understand how growth parameters like dopant concentration, substrate etc. affect the electrode properties i.e. electrical conductivity, microstructure, surface chemistry, and interfacial capacitance.

The goal of this work is to progress the current understanding of structure-property relationships of amorphous carbons. This presentation will review some of the basic properties of these advanced carbons, investigated using Raman, X-ray reflectivity, AFM, XPS, and SEM. Structure and dynamics of interface between t-C:N and RTILs will be investigated using cyclic voltammetry and electrochemical impedance spectroscopy. RTILs are solvents composed entirely of ions. They have great potential to replace conventional organic solvent/electrolyte systems in energy storage devices because of their remarkable properties like wide electrochemical potential window (~4V), environmentally-benign characteristics (non-volatility, non-toxicity) and excellent thermal and electrochemical stability. To optimally harness the properties of t-C:N, and RTIL-based devices, a comprehensive fundamental understanding of their electrochemical behavior is critical.

Nitrogen incorporated tetrahedral amorphous carbon (t-C:Nx) is diamond-like carbon composed of a mixture of sp2 (graphite-like) and sp3-bonded carbon. It can be deposited at room temperature and makes a great electrode material because of its remarkable microstructural stability, high inertness, wide potential window, mechanical strength, low-temperature deposition (<100 °C), tunable doping level and surface chemistry. Research is needed to better understand how growth parameters like dopant concentration, substrate etc. affect the electrode properties i.e. electrical conductivity, microstructure, surface chemistry, and interfacial capacitance.

The fracture toughness of eight glasses was measured by the surface crack in flexure (SCF) and single-edged precracked beam (SEPB) methods. These include four soda lime silicas including a common plate glass form, two low iron modern forms, and one ancient Roman glass, a fused silica, a borosilicate crown (BK-7) optical glass, and two other borosilicate glasses for armor applications. The historical soda lime silica glass was made in an ancient Roman glass factory that operated in Palestine until 383 AD. This glass was exposed to the environment for almost sixteen centuries. The two SCF and SEPB methods have different susceptibilities to environmentally-assisted slow crack growth, that can be a major interference in measuring fracture toughness in ambient testing environments. A new definition for fracture toughness of glasses is proposed.

The fracture surface energy (γ) and the fracture toughness (KIc) of glass were estimated from the nominal composition by means of a simple approach to govern the average coordination number, the bond directionality, and the atomic packing density.

Intrinsic Ductility of Glassy Solids

Yunfeng Shi; Materials Science and Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.

8:45 AM

Intrinsic Ductility of Glassy Solids

Yunfeng Shi; Materials Science and Engineering, Rensselaer Polytechnic Institute, Troy, New York, United States.
Glasses are usually brittle, seriously limiting their practical usages. Recently, the intrinsic ductility of glass was found to increase with the Poisson’s ratio (ν), with a sharp brittle-to-ductile (BTD) transition at ν_{cr}=0.31-0.32. Such a correlation between far-from-equilibrium fracture and near-equilibrium elasticity is unexpected and not understood. Via force-field tuning technique, metallic glasses, amorphous silicon, silica glasses, and polymeric glasses have been investigated, showing BTD transition accompanied by an increase in their Poisson’s ratio. Interestingly, beyond monolithic glasses, the Poisson’s ratio of glassy composites embedded with crystallites also correlate to the intrinsic ductility. The Poisson’s ratio, though defined elastically, reflects the bonding covalency and structural disorder, as well as microstructure heterogeneity.

9:00 AM CM02.04.04
Stresses and Strains in Colloidal Glass 1 Zuoqi Terdik1, David Weitz1,2 and Frans Spaepen1; 1SEAS, Harvard University, Cambridge, Massachusetts, United States; 2Department of Physics, Harvard University, Cambridge, Massachusetts, United States.

Micron-sized hard-sphere colloidal particles can be used to form dense amorphous packings. Due to the large size and slow dynamics of colloidal particles, confocal microscopy can be used to investigate the 3D structure and dynamics of these glasses at the particle level. Previous studies have directly visualized both the inhomogeneous particle level strains in deformed colloidal glasses (i.e. STZs), and surrounding continuum strain fields. Measuring the stress in colloidal glasses during deformation, however, is a significant challenge; due to the large size and thermal interaction energies, colloidal solids have very small elastic moduli, on the order of 10-100mPa. We introduce a new technique, traction force rheology, to directly measure the mechanical response of colloidal glasses while simultaneously visualizing the microstructure using a confocal microscope. The method consists of a bilayer of colloidal glass atop a well calibrated soft polymer gel of slightly greater shear modulus. The composite bilayer is sheared and the shear stresses are inferred from the displacement of embedded tracer particles in the calibrated polymer gel. Using these stress measurements, we show that under cyclic applied shear the colloidal glass goes through a sequence of reversible and irreversible microscopic rearrangements which are related to the spatially correlated heterogeneities in the stress field.

9:15 AM CM02.04.05
High Strain Rate Compression Testing of Amorphous Silica Micropillars Rajaprabhak Ramachandramoorthy1, Jakob Schwiedrzik1, Laszlo Petho1, Damian Frey2, Jean-Marc Breguet1 and Johann Michler1; 1EMPA, Thun, Switzerland; 2Alemnis, Thun, Switzerland.

Mechanical testing of bulk materials at high strain rates is a well-established field of research over the past multiple decades. Recently in the past decade, the field of micromechanics has been established and it is now recognized that a reduction in sample dimensions to the micro- and nano-scale leads to enhanced material properties such as strength and ductility. Until now, the micromechanical experiments such as indentation and micropillar compression has been conducted only at quasi-static strain rates. This limitation of low strain rate testing (~0.1/s) at the microscale arises primarily due to the lack of high strain rate testing platforms capable of simultaneous high-speed actuation and high-speed sensing of microscale displacements and millinewton loads. Thus, the micromechanical properties and the deformation mechanisms for almost every material at strain rates above 0.1/s remains largely unknown. This presentation will report, for the first time, a piezo-based experimental methodology for conducting high strain rate in situ micropillar compression testing at rates up to ~1000/s inside a scanning electron microscope. The strain rate achieved in this study is an increase of approximately four orders of magnitude compared to the current state-of-the-art micromechanical testing. The advantages and unique challenges of conducting micromechanical testing at high strain rates, with a particular focus on wave phenomena, inertia and sample recovery capability at particular strain, will be compared against traditional macroscopic high strain rate tests conducted using kolsky bars. Subsequently, a case study on the high strain rate micromechanical characterization of amorphous silica or glass, a commercially relevant classic material, will be presented. The rate dependent mechanical properties of ~1μm diameter amorphous silica micropillars will be presented as a function of strain rate across eight orders of magnitude, from 0.001/s to 1000/s. Remarkably, the amorphous silica micropillars undergo a unique ductile-brittle-ductile transition in failure mechanism as the strain rate is increased from quasi-static to ~1000/s. The stress-strain curves become serrated at strain rates between 0.01 and 10/s, a typical mechanical response of amorphous materials. Using the extracted velocities of the load drops in the serrated stress-strain curves, analytical calculations based on adiabatic heating and atomistic simulations reported in literature, an explanation for the anomalous plasticity behavior of amorphous silica at different strain rates will be presented. Also, it will be shown, for the first time, that the yield stress increases as the strain rate is increased till 10/s and then saturates as the strain rates are increased further till 1000/s. Finally, a comparison between the macro-scale and micro-scale mechanical response of amorphous silica at high strain rates will be used to demonstrate their startling differences.

9:30 AM CM02.04.06
Effect of Aging and Cryogenic Temperatures on the Mechanical Response of Sputtered Zr-Ni-Al Metallic Glass Nano Structures Julia R. Greer1, Rachel Liontas2, Anthony Kwong3 and Yongwei Zhang4; 1California Institute of Technology, Pasadena, California, United States; 2Intel Corporation, Portland, Oregon, United States; 3IHPC, Fusionopolis, Singapore.

Brittleness of metallic glasses (MGs) is a major drawback for their structural use at bulk scale. It has been shown that when reduced to ~100nm, some metallic glasses undergo a brittle-to-ductile transition and become plastically deformable. To harness this ductility emergent only at nano-scale and proliferate it onto materials with macroscale dimensions, we produced hollow-tube octet-truss nanolattices made out of sputtered NiAlZr with median wall thicknesses of ~10 to ~100nm, which results in a relative density of ~5% and renders them to be 20x lighter than their bulk counterparts. In-situ uniaxial compression experiments conducted inside an SEM reveal a transition from brittle, catastrophic failure in thicker-walled nanolattices (~60 nm) to deformable, gradual, layer-by-layer collapse in thinner-walled nanolattices (~40 nm). We explain the brittle-to-deformable transition as wall thickness decreases in terms of the "smaller is more deformable" material size effect that arises in nano-sized MGs. We further irradiated ZrNiAl nano-architectures with 12 MeV Ni+ ions and found that the thickest-walled nanolattices (~88 nm) withstood irradiation; all other substantially shrunk and collapsed. In-situ nanomechanical experiments reveal significant improvement in mechanical response upon irradiation, with a ~36% increase in average yield strength and enhanced deformability. Irradiated nanolattices deformed via a layer-by-layer collapse in contrast to catastrophic failure in equivalent as-fabricated samples. The field of micromechanics has been established and it is now recognized that a reduction in sample dimensions to the micro- and nano-scale leads to enhanced material properties such as strength and ductility. Until now, the micromechanical experiments such as indentation and micropillar compression has been conducted only at quasi-static strain rates. This limitation of low strain rate testing (~0.1/s) at the microscale arises primarily due to the lack of high strain rate testing platforms capable of simultaneous high-speed actuation and high-speed sensing of microscale displacements and millinewton loads. Thus, the micromechanical properties and the deformation mechanisms for almost every material at strain rates above 0.1/s remains largely unknown. This presentation will report, for the first time, a piezo-based experimental methodology for conducting high strain rate in situ micropillar compression testing at rates up to ~1000/s inside a scanning electron microscope. The strain rate achieved in this study is an increase of approximately four orders of magnitude compared to the current state-of-the-art micromechanical testing. The advantages and unique challenges of conducting micromechanical testing at high strain rates, with a particular focus on wave phenomena, inertia and sample recovery capability at particular strain, will be compared against traditional macroscopic high strain rate tests conducted using kolsky bars. Subsequently, a case study on the high strain rate micromechanical characterization of amorphous silica or glass, a commercially relevant classic material, will be presented. The rate dependent mechanical properties of ~1μm diameter amorphous silica micropillars will be presented as a function of strain rate across eight orders of magnitude, from 0.001/s to 1000/s. Remarkably, the amorphous silica micropillars undergo a unique ductile-brittle-ductile transition in failure mechanism as the strain rate is increased from quasi-static to ~1000/s. The stress-strain curves become serrated at strain rates between 0.01 and 10/s, a typical mechanical response of amorphous materials. Finally, a comparison between the macro-scale and micro-scale mechanical response of amorphous silica at high strain rates will be used to demonstrate their startling differences.

Ductility was dependent on specimen size and annealing conditions, with highest ductility of ~150% true strain in ~90 nm wide samples; all annealed.
The fracture toughness of glassy materials, despite its central role in glass science and technology, remains poorly understood. In large part, this is due to the disordered, intrinsically non-equilibrium nature of the glass structure which challenges its theoretical description and experimental determination. By meeting some of these challenges, we show that the notch fracture toughness of metallic glasses exhibits an abrupt toughening transition as a function of a well-controlled fictive temperature $T_f$, which characterizes the glass structure. The ordinary temperature, which has been previously associated with a ductile-to-brittle transition, is shown to play a minimal role. The observed transition is interpreted to result from a competition between the $T_f$-dependent plastic relaxation-rate and an applied strain-rate. Consequently, a similar toughening transition as a function of strain-rate is predicted, which is demonstrated experimentally here. The observed mechanical toughening transition bears strong similarities to the ordinary glass transition and explains previously reported large scatter in fracture toughness data and ductile-to-brittle transitions.

Cyclic Shear in a Mesoscopic Model of Amorphous Plasticity Kareem Khirallah, Botond Tyukodi and Craig E. Maloney; Mechanical and Industrial Engineering, Northeastern University, Boston, Massachusetts, United States.

We present results of a mesoscopic model of amorphous plasticity in which the material is subject to oscillatory shear. We show the existence of a threshold amplitude of the shear. Below this threshold amplitude, eventually all plasticity is exhausted and the material shows a fully elastic response under the periodic shear. The time necessary to reach this fully elastic state diverges as one approaches the critical amplitude. Above the critical amplitude we observe a hysteresis in the stress response. After several cycles the hysteresis reaches a steady state, showing that plasticity never vanishes above the threshold amplitude. Right above the critical amplitude, we observe a strong localization of plastic activity and a diffusive increase of strain and displacement fluctuations. Our results are in good agreement with several recent particle simulation observations.

11:15 AM CM02.04.09

Topological Origin of Strain Induced Damage of Elastomers by Bond Breaking Yikai Yin, Nicolas Bertin, Yanning Wang, Zhenan Bao and Wei Cai; Stanford University, Stanford, California, United States.

Elastomers that can sustain large reversible strain are essential components for stretchable electronics, which enables novel wearable and biological applications. The stretchability and mechanical robustness of unfilled elastomers can be enhanced by adding breakable cross-links, which also causes stress-strain hysteresis indicating strain-induced damage in the elastomer network. However, it remains unclear whether the breaking of the cross-links follows a predictable pattern that can be used to understand the evolution of damage with strain. Through coarse-grained molecular dynamics simulations and topology analyses, we find that bond breaking events are controlled by the evolution of shortest paths between well-separated cross-linkers. We show that the average length of the shortest paths, which is both anisotropic and hysteretic with strain, is the microstructural parameter responsible for damage evolution. These findings provide an explicit connection between the microscopic molecular structures and the macroscopic mechanical behaviors of elastomers, thereby paving the way to the development of physics-based models of elastomers, and providing guidelines for the molecular design of mechanically robust soft materials.

11:30 AM CM02.04.10

Effects of Stress State on Flow and Fracture of Metallic Glasses John Lewandowski; Department of Materials Science and Engineering, Case Western Reserve University, Cleveland, Ohio, United States.

The processing and subsequent mechanical behavior of a variety of commercially important materials are affected by the imposed stress state. An earlier review* has summarised the experimentally documented effects of superimposed pressure on deformation under quasi-static conditions, following the classic work of P.W. Bridgman at Harvard University. This will be used to put the effects of superimposed pressure on metallic glasses into perspective. It will be shown that the pressure response of a variety of materials exhibit distinct differences, including metallic glasses, and the potential reasons for these differences will be presented. If time permits, the relevance of such deformation and fracture studies to deformation processing will be overviewed.

SESSION CM02.05: Deformation of Glasses II

1:30 PM CM02.05.01

A Study of Shear Band Broadening in Simulated Glasses Darius Alix-Williams and Michael L. Falk; Johns Hopkins University, Baltimore, Maryland, United States.

Two models are proposed to predict the evolution of shear band width as a function of applied strain for simulated glasses mechanically deformed in simple shear. The first model arises from dimensional analysis and an assumption that band broadening is controlled by the strain rate inside the shear band. The second model describes the shear band as a pulled front propagating into an unsteady state, the dynamics of which are described using the effective temperature shear transformation zone (ET-STZ) theory. Both models are compared to three simulated systems: a two-dimensional binary Lennard-Jones glass, a Cu64Zr36 glass modeled using an embedded atom method (EAM) potential, and a Si glass modeled using the Stillinger-Weber potential. In systems across a variety of quench rates. Depending on the case these bands either appear to broaden indefinitely or to saturate to a finite width. The shear band strain rate model appears to apply only when band growth is unconstrained, indicating the dominance of a single
time scale in the early stages of band development. The front propagation model, which reduces to the other model in the early stages of band broadening, also applies to cases in which the band width saturates, suggesting that competition between the rate of shear-induced configurational disordering and thermal relaxation set a maximum width for shear bands in a variety of materials systems.

2:00 PM *CM02.05.02
Dynamic of Shear Bands Initiation in Metallic Glasses—Analysis of a Mg-Based Alloy Using Nano-Indentation Yannick Champion; Centre National de la Recherche Scientifique, St Martin d'Heres, France.

Deformation in metallic glasses occurs by initiation and propagation of multiple thin shear bands. This mode is rather difficult to analyse since a single band propagates early and to a large extent in the specimen leading to catastrophic failure. Exception is for example in confined deformation tests. We used instrumented nano-indentations to perform series of independent experiments at room temperature on a Mg65Cu12.5Ni12.5(Ce75La25)10 metallic glass. Loading part of curves shows serrations which size and duration were measured using an automated procedure. To make analyses consistent, data were considered only in the domain with similar strain rates, in the range of 1 to 0.3 s⁻¹. Times between successive serrations follow a normal distribution that suggests a random occurrence of serrations in the glass. It was then conjectured, that (i) serration occurs through activation of appropriate zone in the glass that should naturally scale with a multiple of an elementary domain size characterizing the deformation mechanism. (ii) As activated zones leading to serration are very few in the glass, the process should fit with rare event dynamics. Actually, serration sizes are well fitted by a Poisson distribution. The model predicts an elementary size which scale with that of the activation volume of 3 atoms, measured from nano-indentation creep tests at constant load in the same series of experiments (Thurseau et al. J. Appl. Phys. 2015). Dynamic of shear bands initiation is then analyzed using statistical approach based on the method proposed by Adam and Gibbs (J. Chem. Phys. 1965).

2:30 PM CM02.05.03
Insight into Shear-Band Affected Zone in Metallic Glasses Through the Measurement of Magnetic Domains Lai Quan Shen and Wei Hua Wang; Institute of Physics, Chinese Academy of Sciences, Beijing, China.

Plastic deformation of metallic glasses (MGs) has long been considered to be confined in nanoscale shear band, which usually leads to catastrophic failure and limits their potential applications. Recently, it was found that an affected zone is also involved upon shear banding. Yet, due to technical limitations, the shear-band affected zone (SBAZ), which is critical for understanding shear banding and thus the design of ductile MGs, remains to be precisely identified. Here, by taking magneto-elastic coupling induced magnetic domains as a probe with sufficiently high sensitivity and spatial resolution, we unveil the structure of SBAZ in much more detail. We demonstrate that shear banding is composed of a nanoscale core surrounded by a micron-scale SBAZ with gradient in the strain field, and multiple shear bands interact through the superimposition of the SBAZs. There even exists super-long-range gradual elastic stress field extending hundreds of micrometers away from the shear-band core. Our method and findings enable a visualized insight into SBAZ and provide a comprehensive picture on shear banding, which are important for elucidate the micro-mechanisms for plastic deformation of glasses.

2:45 PM CM02.05.04
Understanding the Mechanisms of Amorphous Plasticity through Molecular Simulation Pemphhi Cao. Michael Short and Sidney Yip; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Using a meta-dynamics method of sampling activated state pathways we study two related plastic responses of a model metallic glass at experimental strain-rate levels beyond the reach of traditional molecular dynamics simulations. The problems are (1) discrete stress relaxation (slip avalanches) in the onset of yielding and subsequent strain evolution, and (2) stress effects on creep rate. In (1) we quantify the yielding response and the role of major and minor avalanches in sustaining serrated plastic deformation. In the case of deformation under a constant stress, problem (2), we demonstrate a nonlinear interplay between non-affine atomic displacement and cooperative shear transformation distortion of local atomic clusters that provides a molecular explanation of the familiar behavior of creep-rate upturn beyond a stress threshold, as well as a mechanism map delineating the effects of stress and temperature. Collectively these findings lead to an understanding of the elementary processes governing deformation and flow of disordered materials and the effects of thermal and stress activations.

Improving the Ductility of Metallic Glasses by Heterogeneous Jurgen H. Eckert1; 2; Erich Schmid Institute of Materials Science, Austrian Academy of Sciences, Leoben, Austria; 3Materials Physics, Montanuniversitaet Leoben, Leoben, Austria.

Significant progress has been made in recent years in how to optimize processing conditions for glass formation, net-shape forming and property rejuvenation. However, the details of the correlation between composition, atomic structure, defects and thermo-mechanical treatments for structure modification and their impact on shear banding behavior and failure mechanisms for achieving macroscopic ductility are still not well-understood. Recent work suggests that the intrinsic properties of metallic glasses and composites are strongly affected by the details of short- and medium-range order arrangements and their response to external fields like mechanical deformation or temperature cycling causing heterogeneous stress and strain variation on different length-scales.

This talk explores the diversity that can be achieved in metallic glasses and composites considering structure changes, recovery and rejuvenation mechanisms when the materials are subjected to different casting conditions or thermo-mechanical cycling. The findings will be discussed with respect to short- and medium-range order modulation, local stress and strain states, defect generation and annihilation, and precipitation of secondary phases. The structure changes will be correlated with plastic deformability and failure mechanisms, and the effectiveness of composition tuning and thermo-mechanical processing for plasticity improvement will be discussed to derive guidelines for property optimization.

4:00 PM *CM02.05.06
Spatial-Temporal Characterization of Shear Band in Bulk Metallic Glasses Xie Xie1, 2; Chieh Lo2, Tong Yang2, Junwei Qiao2, Gongyao Wang1, Shigenobu Ogata2, Hairong Qi1, Karin Dahmen5, Yanfei Gao1, 3 and Peter K. Liaw1; 1University of Tennessee, Knoxville, Tennessee, United States; 2National Chiao Tung University, Hsinchu, Taiwan; 3Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 4Taiyuan University of Technology, Taiyuan, China; 5University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 6Osaka University, Osaka, Japan.

Recent research shows that temperature is an important factor for the shear-band operations in bulk metallic glasses (BMGs). Thus, the characterization of shear bands through thermal imaging provides a way to study BMG deformation. Based on recent reports and research progress, the present work develops a kinetic Monte Carlo (kMC) model to investigate and simulate the initiation and propagation of shear bands, which correlates well with the thermograph-
imaging results. These findings are expected to reveal the hidden structural characteristics during the BMG deformation and advance the basic understanding of the deformation mechanism.

4:30 PM CM02.05.07
Local Yield Stress Analysis in Simulated 3D Glasses Dhiin Raan1, Sylvain Patinet2 and Michael L. Falck3; 1Johns Hopkins University, Baltimore, Maryland, United States; 2ESPCI, Paris, France.

The ‘Local Yield Stress’ (LYS) method is applied to an atomistic model of as-quenched glasses by shearing local regions. By probing the structure in local shear modes, the LYS method measures the local yield stress as the incremental stress at the onset of a plastic instability. This method has been upgraded to a three-dimensional version with variations in orientations, rotations and triaxiality when locally deformed. This analysis is then utilized to identify the population of ‘Shear Transformation Zones’ (STZs), defined as local atomic clusters that rearrange cooperatively when the material is subjected to shear. These STZs are present in the as-quenched material structure. The population of STZs is correlated with the plastic events observed during a molecular dynamics simulation in which the glass is subjected to shear at the boundaries in order to assess the predictive capability and persistence of the derived STZ population while the material undergoes deformation.

4:45 PM CM02.05.08
Atomic-Scale Homogeneous Plastic Flow of Bulk Metallic Glass Jiaxin Yu1,2, Amit Datye2, Zheng Chen3, Chao Zhou3, Omur E. Dagdeviren3, Jan Schroers4 and Udo Schwarz5,6; 1Key Laboratory of Testing Technology for Manufacturing Process, Ministry of Education, Southwest University of Science and Technology, Mianyang, China; 2Department of Mechanical Engineering and Materials Science, Yale University, New Haven, Connecticut, United States; 3Department of Chemical and Environmental Engineering, Yale University, New Haven, Connecticut, United States.

The onset of yielding and the local plastic flow mechanism of bulk metallic glasses (BMGs) at room temperature have not been fully understood at atomic scale. Further reducing the stressed volumes of BMGs during mechanical testing can decrease the amount of activated shear transformation zones (STZs) under shear stress, which is expected to provide direct insight into the onset of plastic deformation and the material’s atomic-scale flow behavior. In this work, we employed thermoplastic forming to produce atomically flat Pt-based BMG surfaces, whose yield stress, the onset of yielding, and plastic flow at the atomic scale were subsequently studied using atomic force microscopy (AFM)-based nanoindentation. The experiments revealed a much higher yield stress compared to the value obtained by conventional nanoindentation testing, which indicates that the yield stress of BMG strongly depends on the stressed volume in the test, with a smaller stressed volume causing a higher yield stress. Differing from control experiments performed on Pt(111), the plastic flow of Pt-BMG is homogeneous, and no pop-in events are observed. Moreover, the plastic response of Pt-BMG does not exhibit any loading rate dependence, but needs a constant stress to sustain flow. These atomic-scale results are contrasted to the larger-scale model that explains plastic deformation of BMG as originating from the finite STZs activation.

Real-Time Observation of Thermally-Induced Structural Changes of Poly(Lactic Acid) Thin Film by Terahertz Spectroscopy Madoka Nakamura, Makoto Okano and Shinichi Watanabe, Keio University, Yokohama, Japan.

PolymERIC materials exhibit intriguing temperature-dependent structural transitions, such as a glass transition at Tg, and a crystallization phase transition at Tc. Since some polymers have relatively low Tg and Tc, the structural change might occur during the productive processes. Since the structure of polymers affects their electrical, mechanical and electrical properties, it is important to characterize the in situ during the productive processes. Recently, it has been demonstrated that the terahertz time-domain spectroscopy (THz-TDS) is a powerful tool to evaluate the structure of polymeric materials[1-5]. In contrast to the conventional methods such as X-ray diffraction, THz-TDS has some clear advantages: (i) Nondestructive and contactless inspection. (ii) Evaluation of Tg[1,3] (iii) Detection of both the amorphous and the crystalline phases[5]. (iv) Prompt measurement within 1 ms. These features allow us to real-time monitor the structural change of the polymeric products. Here, we demonstrate a real-time sensitive monitoring of the thermally-induced structural changes of poly(lactic acid) (PLA) using THz-TDS. PLA is one of the most promising biodegradable polymers for industrial polymer products. Because the PLA has relatively low Tg (~60°C) and Tc (~120°C), its structure easily modified by the heating. Thus, the PLA is a suitable material for investigating the structural changes by the heating with the THz-TDS.

By real-time monitoring the terahertz optical responses of the PLA during the heating, the complicated temperature dependence of the complex dielectric function (ε′) of the PLA was observed. To clarify the structural change of the PLA, we focused on the spectral shape of ε′, especially the absolute value of the slope, |ε′| at 0.5-1.0 THz. We found two characteristic behaviors of |ε′| regarding the structural changes of the PLA: (i) Existence of the inflection point at Tg (ii) Drastic decrease around Tc. Our findings are well explained by the classical Lorentz oscillator model[5]. The former behavior results from the broadening of the vibration mode due to the change in the free volume from the glass to the rubber states[1,3]. The latter one is attributed to the blueshift of the vibration mode accompanied by the phase transition from the amorphous to the crystalline phases[2,5]. Our novel analytical procedure that is based on the Lorentz oscillator model and utilizes |Δε′| as an indicator to evaluate the structure clearly reveals the structural change in the PLA compared with the previous reports [1-5]. Thus, we conclude that our method is promising for proving the structural change of polymeric materials in the productive processes.

CM02.06.02
Beneficial Effects of Oxygen Addition on Glass Formation in a High-Entropy Bulk Metallic Glass Di Cao, Zhaoping Lu and Yuan Wu; University of Science and Technology Beijing, Beijing, China.

Glass-forming ability (GFA) is one of critical scientific problems for the field of bulk metallic glass (BMGs), and how to facilitate glass formation is always a central yet important research theme for this field. Compared with conventional BMGs in the same alloy system, newly developed high-entropy BMGs (HE-BMG) usually show much enhanced thermal stability, but appreciably reduced GFA. In contrast to the conventional wisdom, we found that GFA of the Zr20Cu20Hf20Ti20Ni20 HE-BMG could be enhanced by oxygen microalloying. The underlying mechanism was explored from both thermodynamic and kinetic point of view, and our analysis indicates that the high packing density resulted from addition of small oxygen atoms is responsible for the beneficial effect of oxygen. The current findings not only shed new insights into understanding of glass formation, but also broaden the view for exploring new kinds of HE-BMGs with enhanced properties and low manufacturing costs.

CM02.06.03
ToF SIMS Characterization of Polymer Thin Films—Impact of Molecular Weight Amal Ben Hadi Mabrouk1, 2, 3; 1University Grenoble Alpes, Grenoble, France; 2CEA-LETI, Grenoble, France; 3Sorbonne Universités, Paris, France.

Organic materials have risen to great importance in the world of electronics. Especially polymers have brought new possibilities to the field. With their numerous advantages like thermal stability, etch resistance and flexibility [1], organic compounds are growingly being studied and used for conductive layers, high resolution lithographic and packaging applications. In order to understand the logic behind the development and selection of such materials, it is fundamental to acquire a basic familiarity with the relationships between their structural parameters and physicochemical properties. Chemical depth profiling techniques like time-of-flight secondary ion mass spectrometry (ToF-SIMS) can help identify the relationship between the polymer chemical behavior when being bombarded by primary ions and their structural parameters. ToF-SIMS depth profiling of organic materials has developed rapidly and has been improved by using mainly the “Dual beam” technique which allows the precise tracking of characteristic chemical fragments and the suppression of the accumulated damage during the etching process [2].

In this work we present the characterization of Poly (methyl methacrylate) and Polystyrene thin films with varying molecular weights (2-9.9x10^5 g.mol^-1) by ToF-SIMS measurements. It focuses on the in-depth investigation of the influence of the molecular weight of the mentioned polymers on the efficiency of the sputtering process, at different energies. The characterization was carried out using monoatomic Cesium sources with different energies for sputtering and Bismuth ions sources for analysis. Additionally, roughness measurement using Atomic Force Microscopy (AFM) were performed because the surface topographic change during sputtering is known to be one of the most important factors to affect depth resolution. The experiments show an inversely proportional relationship, with different orders of magnitude, between the sputtering yield volume (nm^3/primary ion) and the molecular weight Mw. This tendency can be related whether to the studied polymers glass transition temperature (Tg) or to the initial solution viscosity.

This work was carried out in the Nano-Characterization Platform (PFNC) at the CEA Grenoble

CM02.06.04
Highly Processable Work-Hardenable Zr-Based Metallic Glass Composites Reinforced by Continuous TiNi Fiber Jie Zhou, Zhaoping Lu and Yuan Wu; University of Science and Technology Beijing, Beijing, China.

Bulk metallic glasses (BMGs) have attracted considerable research activities because of their unique mechanical properties, such as high strength, large elastic limit and high hardness. However, room-temperature brittleness and strain-softening limited their structural applications. Up to now, it has been proved that enhanced plasticity and strong work-hardening ability could be achieved by introducing the concept of transformation-induced plasticity (TRIP) into Zr-based or Ti-based bulk metallic glass composites (BMGCs). Most currently developed TRIP-reinforced BMGCs are fabricated with in-situ formed second phase method, in which homogeneous formation of austenite phase is a big challenge.

To produce work-hardenable BMGCs in a processable way, we designed a series of BMGC reinforced by introducing ex-situ continuous TiNi fibers, which can bring in martensitic transformation (MT) and TRIP effect and eventually leads to the combination of pronounced plasticity and considerable work-hardening ability under both quasi-static and dynamic compressive loading.

In this talk, preparation, microstructure characteristics, mechanical properties and deformation mechanism of BMGCs reinforced by TiNi fibers will be discussed.

CM02.06.05
Combinatorial Temperature Resistance Sensors for the Analysis of Phase Transformations Haitao Zhang1, Yong Xiang1 and Joost J. Vlassak2; 1University of Electronic Science and Technology, Chengdu, China; 2Harvard University, Boston, Massachusetts, United States.

In this work, we describe a sensor array that can effectively measure the resistance of thin films as a function of temperature and composition. The sensor is fabricated in very simple micro fabrication steps. Detailed FEM simulation indicates that the sensor has very high temperature uniformity, which leads to extreme sensitivity and thus the ability to detection of subtle structure change of materials. We have used the sensor to observe structural relaxation, the glass transition, and crystallization of PdCuSi metallic glasses. We also find that the ratio of the resistance of crystallized to as-deposited material is correlated with the glass-forming ability for both PdCuSi and NiZr-based alloys, potentially providing an avenue to the fast screening of good glass formers in complex material systems.

CM02.06.06

Alkali and earth alkaline elements can behave as network modifier or as charge compensator of AlO4- in aluminosilicate glasses and melts. As a function of the role, density, molar volume, viscosity, liquidus and glass transition temperature and more generally, macroscopic properties, can change significantly. But how evaluate or prove this change of role? Recently, Helhen and Neuvillé (2014) have shown by comparing Raman in VV and VH polarization, that a new band appears in the VH Raman spectra when the role of Ca(Na, Mg) changes from charge compensator to network modifier. Furthermore, we have shown in the
XANES spectra at the Ca K-edge, important differences in the Ca pre-edge peaks as a function of this same change of role. Similar behaviour were observed on the Calcium K-edge via XANES spectroscopy (Cicconi et al., 2016) and on the Na, via NMR (Le Losq et al., 2014). During this presentation, we plan to show some new results on XANES, Raman, NMR.

To conclude, by looking at the role of alkaline earth elements in glasses and melts, it is possible to have a better knowledge of the structure of glasses and melts, but also to better understand their influence on redox and nucleation processes.

Short Range Order in Fluorine Containing CaO-SiO2-CaF2 Glasses from NMR, Neutron Diffraction, and X-Ray Absorption Spectroscopy
Laura A. Swansbury1, 2 and Gavin Mountjoy1; 1University of Kent, Canterbury, United Kingdom; 2Morgan Advanced Materials, Bromborough, United Kingdom.

The glass system CaO-SiO2-CaF2 has been studied to help elucidate the structure of more complex CaO-SiO2-P2O5-CaF2 fluorine-containing bioactive glasses. The CaO-SiO2-CaF2 glass series was synthesized and the glass transition temperature decreased linearly with increasing CaF2 concentrations. Compositional analysis revealed that fluorsilicate losses occurred due to fluorsilicate volatilisation during synthesis. The chemical shift positions in the 29F MAS-NMR spectra became more negative with increasing CaF2 concentrations, becoming more similar to that of pure CaF2. By studying the calcium environment using neutron diffraction and x-ray absorption spectroscopy at the Ca K-edge, reasonably consistent values for Ca-F and Ca-O nearest neighbour distances of approximately 2.3Å and 2.4Å (respectively) could be obtained. However, it was challenging to determine the coordination numbers and disorder in distances of such nearest neighbours.

CM02.06.08
Structure-Property Relations in Amorphous Polymer Derived Ceramics for Electronic Applications
Mehrad Abdass1, Soohyun Im1, Jared Johnson1, Gabriel Calderon Ortiz2, Menglin Zhu1, Nathan A. Oyler2, Michelle M. Paquette1, Paul Ruif1, Ridwan Sakidja2 and Jinwoo Hwang1; 1The Ohio State University, Columbus, Ohio, United States; 2University of Missouri – Kansas City, Kansas City, Missouri, United States; 3Missouri State University, Springfield, Missouri, United States.

We develop a novel methodology for accurate design and fabrication of complex disordered solids using a combination of advanced experimental and computational techniques. Complex disordered solids are non-crystalline materials for which the fundamental building blocks are typically molecules or molecule fragments, and therefore they have great potential for tunable structure and properties for various applications. However, the complex nature and large degree of freedom in their structure impose substantial challenges to the design and optimization of these materials. This presentation will focus on the structural characterization of polymer derived amorphous hydrogenated boron carbide thin films using 4-dimensional scanning transmission electron microscopy (4D-STEM). The 4D-STEM utilizes electron nanoprobes and the new-generation fast pixelated STEM detector, which records the diffraction patterns from individual nanoscale volumes of the material. The fluctuation and angular correlation analyses of the diffraction patterns can provide the unprecedented details of the structural heterogeneity, including the size, distribution, connection, and volume fraction of medium range ordering (MRO). We show that the MRO in amorphous hydrogenated boron carbide can be comprised of the connection and networking of the icosahedral short-range clusters, and the MRO can directly affect the important physical and electrical properties of the films. Our finding is promising as it could greatly expand the breadth of materials-by-design approaches by flexibly tuning the structure of disordered materials to achieve desired properties.

CM02.06.09
In Situ Observation of Shear-Driven Amorphization Process in Silicon Crystals
Scott X. Mao1, Yang He1, Chongmin N. Wang2 and Ting Zhu3; 1University of Pittsburgh, Pittsburgh, Pennsylvania, United States; 2Pacific Northwest National Laboratory, Richland, Washington, United States; 3Georgia Institute of Technology, Atlanta, Georgia, United States.

Amorphous materials are used for both structural and functional applications. An amorphous solid usually forms under driven conditions such as melt-quenching, irradiation, shock loading or severe mechanical deformation. Such extreme conditions impose significant challenges on the direct observation of the amorphization process. Various experimental techniques have been used to detect how the amorphous phases form, including synchrotron X-ray diffraction, transmission electron microscopy (TEM) and Raman spectroscopy, but a dynamic, atomistic characterization has remained elusive. Here, by using in-situ high-resolution TEM, we show the dynamic of the amorphization process of silicon nanocrystals during mechanical straining at the atomic scale. We find that shear-driven amorphization occurs in a dominant shear band starting with the diamond-cubic (dc) to diamond-hexagonal(dh) phase transition and then proceeds by dislocation nucleation and accumulation in the newly formed dh-Si phase. The process then leads to the formation of an amorphous Si (a-Si) band, embedded with dh-Si nanodomains. The amorphization of dc-Si via an intermediate dh-Si phase is a previously unknown pathway of solid-state amorphization.

CM02.06.10
Mineralogical Characterization and Quantification of a Complex Natural Mineral Containing Diatomite after Thermal Treatment
Carolina Cárdenas-Ramírez1, 2, Franklin Jaramillo Isaza1 and Maryory Gomez Botero1; 1Universidad de Antioquia, Medellin, Colombia; 2Sumicol S.A.S, Medellin, Colombia.

In the present work, a thermal treatment of a complex natural mineral containing diatomite was carried out to investigate the effect on its phase transitions and, moreover, to properly identify and quantify such phases. Diatomite is a type of hydrated amorphous biogenic siliceous mineral, primarily opal, from geological deposits and possesses unique properties as highly porous structure, excellent absorption capacity and thermal stability. One of the major problems is distinguishing crystalline cristobalite from some forms of opal which have similar diffraction patterns, the opal phases significantly contain water and these phases are not crystalline in the classical sense, therefore as no long-range ordering exists, it is difficult to identify such phases through conventional XRD techniques. The characterization is even more difficult as typical natural minerals are not pure diatomite. The sample studied for this investigation was calcined in a muffle furnace at temperatures of 600°C, 900°C and 1100°C. The phase evolution and microstructure of the sample were investigated by X-ray fluorescence (XRF), thermogravimetric analysis (TGA), X-ray diffraction (XRD), scanning electron microscopy (SEM), energy-dispersive X-ray spectroscopy (EDXS) and transmission electron microscopy (TEM). Through Rietveld refinement method the phases were quantified. The results showed that the clay minerals in the raw material were kaolinite, quartz, illite and a great amount of amorphous (presumably diatomite). The calcination at 1100°C allowed to crystalize most of the phases other than diatomite, allowing to quantify the amount of diatomite present in the material when compared with the raw sample. No crystallization of diatomite was observed at any of the evaluated temperatures. Besides, it was found by HRTEM that diatomite has a short-range ordering, d-spacings were measured and correlated with possible crystalline phases showing cristobalite/tridymite-like
crystals, even in the raw sample, these crystalline phases correspond to cryptocrystals. These findings allow to improve the understanding of complex natural minerals containing diatomite through the implementation of a systematic use of different characterization techniques for its adequate phase determination and quantification.

CM02.06.11
Amorphous Germanium Material Evaluation for Evanescent Wave Sensors for MWIR and LWIR Sensing Applications
Eveline Postelniciu1, Peter Su1, Danhao Ma1, Raitao Wen2, Ruturaj Pujari3, Ryan Kosciolek4, Venita Boodhoo5, Ron Synowicki5, Jurgen Michel6, Lionel C. Kimerling1, Kazumi Wada7 and Anuradha Agarwal1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2J.A. Woollam Company, Inc., Lincoln, Nebraska, United States.

Room temperature deposited amorphous germanium (Ge) material has been evaluated for evanescent sensing applications in the Midwave and Longwave infrared regions (MWIR and LWIR). The advantage of amorphous Ge is that it can be used to sense a wide variety of organic molecules for both biomedical and environmental sensing and its room temperature processing is very economically efficient. Thin films of amorphous Ge were obtained using various processing approaches: Sputter Deposition, Electron Beam Evaporation (E-beam), and Physical Vapor Deposition (or thermal evaporation).

Films were characterized using X-Ray Diffraction (XRD), Fourier Transform InfraRed (FTIR) Spectroscopy, Wavelength-Dispersive (Electron) Spectroscopy (WDS), Hall Effect measurements, and Ellipsometry. It was shown that Electron Beam Evaporation yielded the purest material, with 96% Ge and 4% carbon contamination, while thermal evaporation showed only around 70% Ge and 30% of the film containing contaminants from the evaporation chamber. Ellipsometry performed on the amorphous Ge samples at a wavelength range of 1.5 to 15 microns showed that the index of refraction, n, of sputtered Ge had a lower range (2.9 – 3.4) than that of E-beam Ge (4 – 4.5). The extinction coefficients for both sputtered Ge and E-beam Ge are in a comparable range, 0 to 0.4, for the same measured wavelength range (1.5 to 15 microns), indicating low absorption losses within the material. X-Ray Diffraction confirmed the amorphous nature of the deposited Germanium. Waveguides utilizing this low loss amorphous Ge within a Si-CMOS compatible platform will be presented.

CM02.06.12
Structural Variation of (Hydrogenated) Amorphous Silicon with Density—A Classical Monte Carlo Study
Enrique Guerrero and David A. Strubbe; Physics, University of California, Merced, Merced, California, United States.

We present computational generation of hydrogenated (a-Si:H) and non-hydrogenated (a-Si) amorphous silicon structures for use in studying the electronic properties of thin-film solar cells, such as "heterojunction with intrinsic thin-layer" (HIT) cells with a-Si:H and c-Si layers. We generate structures using the Wooten-Winer-Weaire (WWW) classical-potential Monte Carlo method using our CHASSM (Computational Hydrogenated Amorphous Semiconductor Structure Maker) code, which implements a WWW scheme that can take into account Si-H bonds. We create structures of various densities and study the effect on structural parameters including bond lengths, bond angles, dihedral angles, and radial distribution functions. Abrupt transitions occur at certain critical densities (different depending on hydrogen content) which suggest crossover between different types of amorphous structures, perhaps even different phases. We investigate mechanical and spectroscopic consequences of these changes. At low densities, voids form, which are likely to constitute defects limiting polymer mobilities and may be implicated in light-induced degradation (the Staebler-Wronski effect). We mathematically characterize the voids using Voronoi polyhedra and persistent homology. We show some refinements of the Monte Carlo randomization process needed to avoid ending in crystalline structures or a class of unphysical excessively coordinated structures.

CM02.06.13
Insight into the Mechanism of Damage Initiation and Fracture of Conductive Polyurethane Nanocomposites
Spencer A. Hawkins1, Evan Sullivan2, Aimee Syred3, 4, Alirea Sarvestani3, 5 and Enrico Ferrari6; 1Physics, University of California, Merced, Merced, California, United States; 2Mechanical Engineering, Mercer University, Macon, Georgia, United States; 3Wright-Patterson Air Force Base, Air Force Research Laboratory, Dayton, Ohio, United States; 4Universal Technology Corporation, Beavercreek, Ohio, United States; 5University of Kentucky, Kentucky, Kentucky, United States.

Polyurethane (PU) is a functional copolymer whose properties bridge the gap between rubber and thermoplastics. Their excellent physical properties, such as flexibility and abrasion resistance along with their high temperature plasticity have made them an ideal structural material for application in aerospace structures, automobiles, electro-machinery vocation, etc. In an attempt to promote the formation of a conductive network within PU, we have developed an experimental technique to decorate carbon nanofibers (CNFs) with silver (Ag) nanoparticles and subsequently blended them with PU. Introduction of a small amount of CNF (coated with Ag) into the PU matrix produced a conductive nanocomposite with higher stiffness and strength compared to that of pure PU but substantially reduced the fracture toughness of the material. Here, we present a systematic and comprehensive study to understand the mechanism of damage nucleation and fracture evolution in Ag-CNF-PU nanocomposites. By mapping the surface of samples using AFM-IR, the onset of damage was monitored prior to realization of plastic deformation during in situ tensile testing. Coupled with the results of DMA analysis, we concluded that strain induced crystallization in PU and polymer debonding from CNF surface are the most detrimental mechanisms that control the fracture toughness of PU nanocomposites. These conclusions were used to develop a model that predicts the mechanical behavior of PU nanocomposites at finite deformations.

CM02.06.14
Mechanical Behavior of Highly Rejuvenated Bulk Metallic Glasses
Jie Pan and Yi Li; Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China.

Rejuvenation of metallic glasses, bringing them to higher-energy states, is of interest in improving their plasticity. However, how to achieve significant flow and rejuvenation throughout a deformed metallic glass remains challenging, and the mechanical behavior of the highly rejuvenated bulk metallic glasses is unexplored. In this presentation, we will reveal the significant improvement in compressive plasticity in a Zr-based bulk metallic glass (BMG) by structural rejuvenation, which is in stark contrast to the ageing induced brittleness. Upon constrained compression on the BMG rods at room temperature, extreme rejuvenation occurs in a large volume of BMG specimens, accompanied with a considerable amount of free volume generation, reduced hardness, Young’s modulus. As a result, shear transformation zones will be easily activated, giving rise to reduced yield strength of 1.37 GPa, much improved compressive plasticity, as well as more homogeneous deformation. The present work reveals the correlation between the deformation behavior and energy state in metallic glasses, which will help us to understand the deformation mechanism of metallic glasses, even disordered systems.

CM02.06.15
Atomistic Modeling of a Photovoltaic Material—Hydrogenated Amorphous Silicon
Raymond Atta-Fynn1, Harsh Arya2, Sominilkumar Rathi2 and Parthapratim Biswas3; 1Physics, Univ of Texas-Arlington, Arlington, Texas, United States; 2Eugenes Inc., San Jose, California, United States; 3Physics, University of Southern Mississippi, Hattiesburg, Mississippi, United States.
Hydrogenated amorphous silicon (α-Si:H) is an important electroactive and photovoltaic material of technological importance that can be quite difficult to model accurately, particularly on a large scale for electronic structure analysis. In this work, we present a novel and efficient approach which couples accelerated classical molecular dynamics with ab initio relaxation to model high-quality, large atomistic models of α-Si:H. Specifically systems containing 10,000 Si atoms and H atomic concentration of 9%-18% were simulated. The models are nearly free of coordination defects and their structural, electronic and nuclear magnetic resonance properties of the models are in good agreement with experimental data. The approach paves the way for the generation of realistic device-size atomistic networks of α-Si:H. Furthermore, the approach can be readily generalized to produce a variety of binary and ternary amorphous networks in two and three dimensions, and amorphous/crystalline heterojunctions to address the physics of photovoltaic devices.

CM02.06.16
Extreme Energy Absorption Through High Rate Deformation of Freestanding Glassy Polymer Thin Films Jinho Hyon1, Ye Eun Song1, Edwin L. Thomas1, Jason Streit2 and Richard Vaia1; 1Material Science and NanoEngineering, Rice University, Houston, Texas, United States; 2Materials & Manufacturing Directorate, Air Force Research Laboratory, Dayton, Ohio, United States.

Of all materials, only polymers exhibit a strongly dissipative melt state. If a set of deformation processes can lead to strong heating of an initially glassy polymer material, large amounts of kinetic energy can be absorbed. Normally at room temperature, glassy polymers undergoing rapid tensile loading craze, crack and then fracture with little overall energy absorption. Here we exploit the higher mobility and lower entanglement density of the chains near the free surfaces of ultrathin films to induce extensive crazing and consequently adiabatic heating by imposing a very high strain rate (~107/s) using a micro-projectile ballistic test. The near-surface thin films effects not only dramatically increase the number of crazes nucleated, but assist their subsequent growth, impingement and the accompanying large adiabatic temperature rise of the deforming film. We employ 3.0 micron diameter spherical silica projectiles propelled at incident velocities ranging from 350-800 m/s to investigate the kinetic energy (KE) absorption. Homopolymer polystyrene (PS) films with different molecular weights and film thicknesses and single component nanocomposite PS grafted nanoparticle (PSgNP) films (~1% v/v NPs with 100's of chains covalently anchored to each NP) show extraordinary high KE absorbed per unit mass of the target film (on the order of several MJ/kg, comparable to the energy density of TNT). Use of a glassy-glassy microphase separated lamellar diblock copolymer (PS-b-P2VP) to create films comprised of just a few parallel lamellae allows strong alteration of the polymer chain conformations while keeping the overall molecular weight (MW) and glass transition temperature (Tg) comparable to the PS homopolymer and grafted NP films. A block copolymer offers the additional energy absorption mechanism required for block mixing if heating takes the sample above the order to disorder transition temperature.

CM02.06.17
Evaluation of Amorphous Alumina as Effective Hydrogen Resistive Coating for Ferritic Steel Xiaohui Yao, Vrinda Soajit, Ju Li and Bilge Yildiz; Department of Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Hydrogen gas (H2) as a promising energy storage media and a clean fuel, plays a central role in future low-carbon infrastructure. Yet the storage and transportation of hydrogen gas is cumbersome due to its high diffusivity, low density and poor compressibility. Long range hydrogen delivery exploiting the existing natural gas pipeline network has been proposed and found feasible when the volume ratio of hydrogen is below 15%. But the high diffusivity of hydrogen results in nearly seven times higher permeation than natural gas. At the same time, the notorious hydrogen embrittlement effect is expected to degrade the mechanical performance of the steel and bring safety concerns. To improve the tolerance of existing pipeline steels toward high concentrations of hydrogen, as in direct transportation of hydrogen gas in these pipelines, a low-cost and effective hydrogen resistant coating is desired to be applied on the inner surface of the steel pipelines. α-Al2O3 is one of the best materials to reduce the permeation of hydrogen. But the formation of crystalline α-Al2O3 requires processing temperatures beyond the tolerance of pipeline steel. In this work, we developed two conformal coatings of amorphous Al2O3 on the surface of ferritic steel with mild formation temperature and evaluated their effectiveness as a hydrogen permeation barrier. An electrochemical testing approach was adopted for this evaluation to mimic the operation condition of hydrogen pipeline, which is featured by the ambient temperature but high H2 activity (equivalent to a high H2 pressure of 30–70 MPa). We found that amorphous Alumina also provides excellent barrier characteristics. Over 200 times permeation reduction factor was found for the coating with only 1/300 of steel thickness. The micro-structure of the two coatings were also compared and found to be critical in the permeation performance. Currently, we are systematically assessing the effect of the microstructure, controllable by synthesis and post-anneal conditions, on the resistance of these layers against hydrogen entry and diffusion. Our result suggests that by properly managing the microstructure of the coating layer, it is possible to utilize the low temperature derived amorphous alumina as an effective hydrogen barrier coating.

CM02.06.18
Ultra-High Strength Above 10 GPa and Short-Range Atomic Order of Amorphous Boron Jessica M. Maita, Gyuho Song, Mariel Colby and Seok-Woo Lee; University of Connecticut, Storrs, Connecticut, United States.

Amorphous boron fiber has been widely used as a reinforcement filler in aerospace resin-matrix composites due to its high strength and high elastic modulus. However, its mechanical properties have not been measured accurately due to its intrinsic issues during fabrication. Amorphous boron is usually produced in single-filament reactors by chemical vapor deposition of boron on tungsten wire, and the final product is a core-shell wire with a tungsten boride core and amorphous boron shell. The diameter of this composite fiber is approximately 100 micrometers, and the thickness of the boron-shell is 40 micrometers. Traditionally, wire tension tests of the composite fiber or hollow amorphous boron fiber have been conducted but would underestimate the strength due to the greater probability of defects that exist along the long wire. Therefore, it is necessary to perform reliable mechanical tests at small length scales. Recent developments in micropillar compression and tension testing enable us to probe mechanical properties of small materials accurately. In addition, the local atomic arrangement in amorphous boron has not been clearly understood because of the complexity in its amorphous structure. Therefore, it is necessary to conduct advanced transmission electron microscopy (TEM) to analyze the local structure at atomic resolution.

In this presentation we will discuss microstructural and mechanical characterization of amorphous boron with high resolution TEM and in-situ scanning selection microscopy (SEM) micropillar compression results. TEM diffraction patterns show a unique set of three halo rings while an amorphous material usually has a single halo ring. The three halo rings imply amorphous boron would consist of the random distribution of crystallites. Fast Fourier transform (FFT) was used to confirm these crystallites consist of short-range ordered boron clusters. We will also discuss micropillar compression results, the yield strength as a function of micropillar diameter. Its ultra-high strength (~13 GPa) will be discussed in terms of its unique microstructure and the intrinsically strong atomic bonding of metallicloid materials. Our results help to provide a deeper understanding of plasticity and fracture processes in amorphous boron and will be useful in the development of mechanically robust boron-fiber composite materials.

CM02.06.19
Mass and Thermotransport in Liquid Ni-Al-Co Alloys Tanvir Ahmed1, William Yi Wang1, Zi-Kui Liu1, Irina Belova1 and Graeme Murch1; 1School of Materials Science and Engineering, Northwestern Polytechnical University, Xi’an, China; 2Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; 3School of Engineering, The University of Newcastle, Callaghan, New South Wales, Australia.
Mass and thermotransport properties in liquid Ni-Al-Co alloys are studied over a wide temperature and concentration range by using molecular dynamics (MD) simulations. The calculations are performed by means of equilibrium MD simulations in conjunction with the Green-Kubo formalism and an embedded-atom method (EAM) potential for this system developed by Pun et al. [1]. Results of simulations also allow the description of the temperature and concentration dependence of the thermodynamic factor. Furthermore, the simulations permit analysis of the heat of transport as a function of temperature and composition as well. The complete range of the diffusion properties including Osnag off-diagonal terms and partial properties are estimated for the considered temperature and concentration ranges. Overall, results of this study agree well with previous published experimental and simulation data where available. In addition, for liquid Ni-Al alloys, the calculations are also carried out with a potential [2] for comparison purposes.

CM02.06.20
Mobility of proton Carriers in Porous Conduction Phosphate Glasses Takahisa Oomura1, Takuya Yamaguchi2, Tomohiro Iijiyama2, Satoshi Tsukuda1, Junji Nishi3, Toshihara Yamashita4 and Hiroshi Kawazoe4; 1Tohoku University, Sendai, Japan; 2National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba, Japan; 3Research Institute for Electronic Science, Hokkaido University, Sapporo, Japan; 4Kawazoe Frontier Technologies Corporation, Yokohama, Japan.

Proton conduction in phosphate glasses is a historical topic in solid state ionic and glass chemistry because of their potential applications of electrolytes in various devices. A lot of studies have focused on to understand and to improve their proton conductivity. In previous proton conducting phosphate glasses, because the proton carriers were supplied from the residual water that was vaporized and come away from the melt during melting at the temperatures higher than 1000 °C, the proton carrier concentration was limited to 10^9–10^10 cm^-3. We recently developed a proton injection technique that is electrochemical substitution of alkali ions with protons termed as APS. APS enables to achieve extraordinary high proton concentration such as 10^22 cm^-3; therefore, to achieve high proton mobility is only strongly desired in order to realize high proton conductivity.

In this study, we studied the influences of the polymerization degree of phosphate glass network and kinds of alkaline-earth oxides that are typical glass network-modifiers on the proton mobility. As a result, we found that the proton mobility increases with the decreasing polymerization degree of glasses; however, the proton mobility must start to decrease when pyrophosphate ions, P_2O_7^4-, become major component in phosphate network, because the protons are deeply trapped in pyrophosphate ions rather than metaphosphate ions, (PO_3^-). Regarding to the kinds of alkaline-earth oxide modifiers, the proton mobility was higher in the glass containing BaO than the glass containing MgO. The higher proton mobility in the Ba-glass than the Mg-glass was attributed to higher ionicity of the Ba-O bond than the Mg-O bond based on P 2p and O 1s core-level XPS spectra. Based on these understandings, we designed a glass, 36HO_1/2-4NbO_5/2-2BaO-4LaO_3/2-4GeO_2-1BO_3/2-49PO_5/2, and it was prepared by APS using 36NaO_1/2-4NbO_5/2-2BaO-4LaO_3/2-4GeO_2-1BO_3/2-49PO_5/2 as a precursor glass. The proton conductivity of the glass was 1×10^-1 Scm^-1 at 280 °C in dry 5% H_2/N_2, and it was almost constant during keeping at 280 °C over 500 hours. It was also shown that the glass is stable under the condition of fuel cell operation. These properties are favored for the electrolyte in the intermediate temperature fuel cell.

CM02.06.21
Structural Characterization of Oxide Glass-Ceramic Scintillators for Radiation Detection Sarah Lombardo1, 2 and Jason Nadler1; 1Georgia Tech Research Institute, Atlanta, Georgia, United States; 2Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Glass-ceramic nanocomposite scintillators have become an attractive option as radiation detection materials. These materials provide radioisotope detection capabilities at lower cost with improved scalability, stability and mechanical robustness. However, light output required for proper energy resolution is proven a challenge as a result of light scattering from varying refractive indices and crystalline agglomeration present within the non-crystalline glass matrix. Understanding the structure-property relations of oxide glass-ceramic scintillator compositions is crucial for enhancing resolution, as these relations pertain to processing and performance. Analysis of the structure-property relations of oxide glass-ceramic scintillators has been achieved by employing techniques such as scanning and transmission electron microscopy, X-ray diffraction, and energy-dispersive X-ray spectroscopy for structural characterization. In addition, photoluminescence and radiation spectroscopy are employed for characterization of performance. These techniques allow for the identification of light output and resolution obtained as a result of heterogeneity, crystal structure, and phase composition present within these non-crystalline materials.

CM02.06.22
Fabrication of High-Dispersed Strawberry-Like P(St-co-MAA)/SiO2: Composite Microspheres and Their Applications in Cementitious Materials Guanzhi Chen1, 2; Yongjiang Xie1, 2; Xinguo Zheng1, 2; Huajian Li1, 2; Quanxiao Dong1, 2; and Shida Li1, 2; 1Railway Engineering Research Institute, China Academy of Railway Sciences, Beijing, China; 2State Key Laboratory of High Speed Railway Track Technology, Beijing, China.

Silica nanoparticles (SiO2 NPs) can be used in cementitious materials to improve their workability and mechanical properties. But avoiding the agglomeration of SiO2 NPs within the cementitious matrix are still the challenges to play the role of them effectively. In this work, the polystyrene-co-methyl acrylic acid (P(St-co-MAA)) latex particles with hydrophilic carboxylic chains grafted from the surface were first fabricated via soap-free emulsion polymerization, and then high-dispersed strawberry-like composite microspheres were prepared with the P(St-co-MAA) latex partially covered by SiO2 NPs through layer-by-layer (LBL) assembly process. The effects of such composite microspheres on the properties of cementitious materials were investigated afterwards.

The surface carboxylic content of P(St-co-MAA) latex particles was measured by conductometric titration. The morphologies of the latex particles and P(St-co-MAA)/SiO2 composite microspheres were characterized by transmission electron microscopy (TEM) and scanning electron microscopy (SEM). Thermos gravimetric analyser (TGA) and dynamic light scattering (DLS) were employed to characterize the composition and the dispersibility of the composite microspheres, respectively. After adding the composite microspheres into cementitious matrix, the hydration process of the fresh mixture was monitored by cement hydration heat analyzer. Its workability and mechanical properties were tested via conventional methods. The porosity of the hardened specimens was characterized by mercury injection method method.

The results show that the surface carboxylic content of P(St-co-MAA) latex was about 1.5×10^4 mol/g. For the P(St-co-MAA) / SiO2 composite microspheres, SiO2 NPs with the mass ratio about 5.0 wt% were anchored on the latex surface, leaving above 50 % area of the surface uncovered. Such strawberry-like composite microspheres could be easily dispersed in aqueous phase without further treatment where the poly-dispersion index (PDI) was about 0.3. The composite microspheres had no obvious effects on the fluidity of the mortar and the water absorption of the hardened specimen. But it could promote the condensation of the mortar and improve their early compressive strength and flexural strength. Compared to the blank control, the 3d compressive strength of the specimens in which the mass of composite microspheres was 4 wt% of the cement was 5 MPa higher, and the flexural strength
of those was 1 MPa higher. The modified mechanism of the composite microspheres for mortar was proposed.

CM02.06.23
Calorimetric Studies of a New La-Based Metallic Glass Jie Shen and Wei Hua Wang; Institute of Physics CAS, Beijing, China.

We have prepared a La-based MG which exhibits an unique exothermic peak occurring after the glass transition and before the onset of crystallization. The enthalpy change of the La-based MG is large, ~17% of the heat of fusion. Such a large enthalpy change enables the La-based MG to have an increase in the glass transition temperature and the β-relaxation temperature of 17 K and 30 K respectively, and a remarkable increase of the activation energy for the β-relaxation of 71%. The La-based MG exhibits an abnormal α-relaxation which shows no decrease of loss modulus at high temperature. In the stress relaxation and creep measurements, the MG gets a strong retardation with relaxation time extending from 54 s to 480 s and only 2% decrease in length after a high-temperature creep. These thermo-mechanical responses demonstrate the strong nature of its liquid: the fragility index α of the new metallic glass is only 22. The development of this new MG may provide us a new model system for investigating some fundamental issues in glassy field.

CM02.06.24
Amorphous Carbon for Hard Mask with High Etch Resistance Through Bonding Control with Various Doping Elements Min-Woo Jeong, Kun-Tae Kim, Kyung-Tae Jang, Miyoung Kim and Young-chang Joo; Seoul National Univ, Seoul, Korea (the Republic of).

As the area shrinkage of semiconductor devices for high memory density, the high aspect ratio pattern is needed such as 3D NAND flash. To create a vertical pattern with a mask, mask is needed to be thicker for etching it longer. However, a thick mask distorts the shape of the pattern with a shadowing effect. Therefore, it is necessary to have a hard mask that can be made thinner. The vertical structure is fabricated by plasma based dry etching process with hard masks, which have superior etch resistance. Therefore, it is necessary to study the properties of hard mask materials for deeply patterned devices. The hard mask should have higher etch resistant to plasma reactive gas than conventional organic soft mask for deeper patterning. It must also be easily removed after the etching process. These conditions are well satisfied with amorphous carbon, which is the most promising material for hard mask. Carbon has various atomic bonds like sp³ of diamond and sp² of graphite. The difference in carbon bond between the two materials greatly affects the properties such as mechanical and electrical properties. Amorphous carbon is known that the kind of bonding is changed according to doping element and composition. In this study, we have studied how the etch characteristics change with the change of bonding nature of amorphous carbon according to various metal element doping.

Amorphous Carbon (a-C) was deposited on SiO₂/Si substrate by DC magnetron sputter system using graphite solid target for higher purity and lower roughness than common CVD process. Metal element doping was proceeded by using 10 wt% of Si and W pre-doped target. The thin film was analyzed by Raman spectroscopy, XPS and etch characteristics were investigated by ICP etcher. We also examined the mid-range order of the a-C through the radial distribution function (RDF) using the diffraction pattern through TEM analysis. The content of Si and W in a-C was measured by XPS results, 7.39 wt% and 12.2 wt% respectively. As a result of Raman spectroscopy and XPS of doped a-C thin film, the ratio of D peak and G peak (I_D/I_G) and sp³ bonding increased, which means the increase disordered hexagonal graphite structure. Moreover, the I_D/I_G value was further increased when the heat treatment was performed up to 500 °C, which is because carbide is generated more by heat treatment. Because the Si and W form carbide in a-C film, the degree of disorder increased. In addition, when the structure of the thin film was analyzed with RDF, it was confirmed that the sp³ bond was increased with formation carbide. The increased sp³ bonding portion in amorphous C improved etch resistance, which is consistent with the tendency for mechanical performance of diamond like carbon (DLC) having high sp³ bonding. The relationship between mid-range order of doped a-C and its property was confirmed by the microstructure analysis and the measured etch resistance with various doping elements.

CM02.06.25
A String Model for the Boson Peak and Inelastic X-Ray Scattering Data of Amorphous Materials Ernesto Bianchi and Fernando Lund; Univ of Chile, Santiago, Chile.

In a continuum, solid mechanics, approximation, THz vibrations in glasses can be understood as the normal modes of vibrating strings with fixed ends on top of the Debye approximation modes. These strings scatter acoustic waves and, in a multiple scattering formulation, generate an effective (complex) index of refraction, thus describing dispersive, damped waves [1]. The attenuation and velocity dispersion as a function of frequency are qualitatively similar to that observed in glasses through Inelastic X-ray Scattering (IXS); For very low frequencies attenuation grows like frequency squared, consistent with Akhiezer damping. As frequency grows, a frequency to the fourth power behavior takes over, consistent with scattering from small objects (in this case, the strings). Finally, as frequencies around the Boson peak are reached, a new frequency squared behavior appears. The phase velocity is a decreasing function of frequency for low frequencies, and switches over to an increasing function at frequencies around the Boson peak.

The dynamic structure factor S(k,w) corresponding to these acoustic waves is calculated as an explicit function of two variables, wave vector k and frequency w. The resulting formulae provide a specific functional relationship between the Boson peak data and the IXS data. It should be possible to directly test these results, for example with glycerol glass data [2].

CM02.06.26
Cation Glass, Anion Crystal—Disorder and Order in Metal-Sulfide Thin Films Kevin Ye and Rafael Jaramillo; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Structural disorder in semiconductors is important to characterize reliably because it strongly affects materials performance, for instance by introducing potential fluctuations and electron-hole recombination sites. In a multicomponent material the differing contrast of different elements to particular characterization techniques can lead to misleading and contradictory conclusions about the nature of disorder and even the existence of crystalline volumes. We present a study of highly-disordered Cu-Zn-Sn-S (CZTS) films, deposited by physical vapor deposition at low temperature and post-annealed at different temperatures. We previously reported synchrotron x-ray absorption spectroscopy (XAS) data showing that deposition at low temperature kinetically stabilizes single-phase compositions that are well outside of the narrow solid solution of CZTS at equilibrium [1]. Here we use complementary characterization techniques to understand and quantify structural disorder: XAS (XANES and EXAFS), x-ray diffraction, and transmission electron microscopy. By combining all three techniques and numerical simulations we reach quantitative conclusions about the nature of cation disorder and the kinetics for recrystallization. We find that cations in highly-disordered CZTS are distributed nearly at random while the sulfur anions remain in a well-defined lattice. This phenomenon of cation glass, anion crystal is important to recognize for its signature in different characterization techniques. For optoelectronic devices it may be useful to design light absorbers and windows with widely varying absorption edge energy.
Thermo-Physical Properties of SrO-Al2O3 Binary System Yongxiao Gao1, Zhitao Shan1, Bowen Ruan1, Zhe Zeng1, Haizheng Tao1, Xiujian Zhao1 and Yuanzheng Yue1,2; 1State Key Laboratory of Silicate Materials for Architectures, Wuhan University of Technology, Wuhan, China; 2Department of Chemistry and Bioscience, Aalborg University, Aalborg, Denmark.

Owing to the heterogeneous nucleation at the melt-crucible interface, when using the conventional evaluating methods, such as rotating cylinder and maximum bubble pressure method, it is difficult to access the thermo-physical properties in the super-cooled region for poor glass formers. To avoid this phenomenon, here we use the containerless aerodynamic levitator laser-heated technique to measure the thermo-physical properties, i.e., density and viscosity of xSrO-(100-x) Al2O3 (35≤x≤75) binary system in the metastable super-cooled and equilibrium states. According to the average coefficient of thermal expansion (CTE) of melts calculated from the densities, we noticed that the average CTE shows a non-linear and non-monotonic tendency with increasing the content of SrO. In addition, the average CTE of these aluminate melts exhibit two local minimum at the corresponding compositions with the minimum eutectic temperature. At the same time, these eutectic compositions exhibit local maximum of glass forming ability judging from their bigger ratio values of Tg/Tm and higher viscosity at their corresponding melting points.

Design of Non-Oxide Nanocomposite Ceramic Materials with High Fracture Toughness for Extreme Applications Kaijie Ning, Priyatham Tumurugoti, Kade A. McGarrity and Holly Shulman; Inamori School of Engineering, Alfred University, Alfred, New York, United States.

Ceramic materials can possess properties that withstand extreme environments, such as high temperatures, extreme abrasion, ablation, and corrosion. Strong directional bonding, which brings about high elastic moduli and high theoretical strength, also causes these materials to be sensitive to flaws that produce catastrophic failure. The lack of fracture toughness prevents accessing high strength, preventing use of many promising ceramics in load bearing and wear applications. There are a variety of mechanisms that can be implemented to increase fracture toughness. In our work, we focus on developing novel non-oxide nanocomposite ceramic materials targeting improvement of fracture strength through atomic process control of additives, microstructural design, and an advanced 3D reconstruction technique. The boundary phase control, grain shape modification, and second phase reinforcement are of interest for sintering novel structural nanocomposites in order to reveal toughnes mechanism from different scale levels. Preliminary results of powder processing, sintering, microstructural and mechanical characterization of SiC/Si3N4 nanocomposites are reported here. It is expected that the novel designed nanocomposite ceramics would achieve much improved fracture strength compared to the traditional ceramic matrix.

It is reported that negative or no strain rate dependency of the flow stress of metallic glasses appears at high strain rate or low temperature condition[1][2]. We reveal that this curious strain rate dependency is strongly related to the timescale of glass relaxation process from a rejuvenated glass state induced by activation of shear transformation. We use a constitutive model which estimates average residence time of thermal activation process[3]. In the model we assume the relaxation process recovers the activation energy of shear transformation. Our model successfully reproduces the experimental strain rate dependency of flow stress over the wide strain rate and temperature ranges. The negative or no strain rate dependency appears when the timescale of the activation of shear transformation approaches the characteristic timescale of glass relaxation process.

Structure and Properties of Amorphous Thin Films Vary with Nanometric Thickness

International Space Station

as predicted previously, exhibited more 4-coordinated Al sites. These atomistic alterations were expected to change the amorphous thin film’s average effects. We chose atomic layer deposition (ALD) as our material deposition method, since it is a technique that can provide extremely precise, sub-

In nature there are many organisms that use crystallization via an amorphous phase in order to achieve controlled mineralization. One of the main advantages of this method is that it enables the organism to exert control over the resulting polymorph, which is not necessarily the thermodynamically-stable one, by first controlling the short-range order in the amorphous phase.

In this research we draw inspiration from nature and study the ability to control various structural aspects of amorphous materials via nanometer size control and can deposit conformal and pinhole-free amorphous films of various materials. Amorphous thin films of aluminum oxide deposited by atomic layer deposition method were found to vary structurally as a function of size; thinner films, nanometric, thickness control and can deposit conformal and pinhole-free amorphous films of various materials.

Amorphous materials, in contrast to crystalline ones, lack long-range order. Its order decays rapidly with the distance and while the local environment for a particular type of atom is quite similar, it is not identical; these fine changes in the atomistic structure of the materials lead to new and very interesting phenomena which are unique for amorphous materials. Although many aspects of science and technology rely on amorphous materials, much less research is conducted about their structure than on their crystalline counterparts.

Sample-Size and Temperature Effects on Deformation Behavior of Bulk Metallic Glasses

Chandra Sekhar Meduri and Golden Kumar; Texas Tech University, Lubbock, Texas, United States.

Bulk metallic glasses (BMGs) deform plastically through localized shear bands at room temperature. It is well established that shear banding process in BMGs depends on multiple parameters such as, the elastic constants, the sample size and processing, and the testing conditions (temperature, strain-rate, and loading geometry). Studying the effects of these variables and linking them to a unifying flow model is critical for fundamental understanding and potential applications of BMGs. In this work, we study the effects of testing temperature and sample size on nucleation and propagation of shear bands and the fracture surface through bending and tensile testing. Bending experiments show an increase in number of shear bands and plasticity with decreasing temperature. Analysis of fracture morphologies from the high-throughput tensile tests show an increasing contribution of thermal softening (through shear offset) and decreasing contribution of defect development (through coalescence of nanovoids and formation of microcracks) to the final fracture as sample size and/or temperature decreases. The results are discussed in terms of existing models for shear band formation and fracture of BMGs.

Addressing the Achilles' Heels of Amorphous Carbon with Doping—Mechanisms of Thermal and Oxidative Degradation—From Earth to the International Space Station

Filippo Mangolini1, Brandon Krick2, Tevis Jacobs3, Subarna Khanal4, Frank Streller4, J. Brandon McClimon4, James Hilbert4, Somuri Prasad5, Thomas Schaff5, James Ohlhausen5, Jennifer Lukes6, W. Gregory Sawyer7 and Robert Carpick8; 1Texas Materials Institute, Department of Mechanical Engineering, The University of Texas at Austin, Austin, Texas, United States; 2Department of Mechanical Engineering and Mechanics, Lehigh
Amorphous carbon materials are used as protective coatings in a wide range of applications owing to their unique mechanical, electrical, and optical properties. However, they suffer from two key environmental limits: insufficient thermal stability, and high reactivity in oxidizing environments. This inhibits their use in many harsh-environment technologies, such as protective coatings for aerospace components, automotive components, advanced manufacturing tools, and next-generation magnetic storage devices. Here we show that doping hydrogenated amorphous carbon films with silicon and oxygen can overcome these environmental limits and we explain the mechanisms by which these benefits occur through fundamental studies, including experiments conducted on the International Space Station.

The thermally-induced structural evolution of silicon- and oxygen-containing hydrogenated amorphous carbon (a-C:H:Si:O) was investigated in situ by X-ray photoelectron and absorption spectroscopy, as well as molecular dynamics (MD) simulations. The spectroscopic results indicate that upon high-vacuum annealing, two thermally-activated processes occur in a-C:H:Si:O: 1) ordering/clustering of sp² carbon; and 2) conversion of sp³ to sp²-bonded carbon. The experimental results are in qualitative agreement with MD simulations performed using the ReaxFF potential. MD simulations also indicate that the higher thermal stability of a-C:H:Si:O compared to hydrogenated amorphous carbon (a-C:H) derives from the lower fraction of strained carbon-carbon sp² bonds in a-C:H:Si:O compared to a-C:H, which are more likely to break at elevated temperatures.

Exposing a-C:H:Si:O to elevated temperatures under aerobic conditions or to the harsh low Earth orbit (LEO) conditions (aboard the International Space Station during the seventh Materials International Space Station Experiments mission) leads to carbon volatilization limited to the near-surface region with the formation of a silica surface layer\(^3\). This prevents the remaining underlying carbon phase from volatilization by reaction with oxygen and/or water in the environment. The incorporation of silicon and oxygen in a-C:H thus enhances the thermo-oxidative stability and resistance to the LEO conditions via a self-protecting route for carbon oxidation by creating an oxygen diffusion barrier. These findings provide a novel physically-based understanding of the superior stability of a-C:H:Si:O in harsh environments compared to a-C:H.

9:45 AM CM02.07.06
Effect of Deposition Rate and Substrate Temperature on Structure and Properties of Sputtered Metallic Glass Thin Films Sachin V. Muley\(^1\), Debaditya Chatterjee\(^1\), Felix P. Lu\(^2\) and Paul M. Voyles\(^3\); \(^1\) Materials Science and Engineering, University of Wisconsin Madison, Madison, Wisconsin, United States; \(^2\) Grainger Institute for Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States.

Physical vapor deposition offers a route to synthesizing glasses with a wide range of thermodynamic and kinetic stability. We have studied the structure and properties of Zr\(_{65}\)Cu\(_{27.5}\)Al\(_{7.5}\) thin films deposited by single target magnetron sputtering as a function of the deposition rate, substrate temperature, and residual pressure of oxygen and water vapor. Films grown starting with a base pressure of 2×10⁻⁸ Torr and low partial pressures of oxygen of 2×10⁻¹⁰ Torr and water vapor of 5×10⁻⁸ Torr exhibited a phase boundary between amorphous and crystalline states as a function of deposition rate and substrate temperature. At a deposition rate of 0.22 nm/s in 3.8 mTorr of process gas (Ar) the films were crystalline at high substrate temperatures (458K, 0.67×Ts/Tg – 498K, 0.73×Ts/Tg), but amorphous at lower substrate temperatures. At a deposition rate of 1.57 nm/s in 3.8 mTorr of Ar, the films were amorphous up to a substrate temperature of 483K (0.70×Ts/Tg). Optimizing over deposition rate and substrate temperature increased the films modulus by 34% and hardness by 11% as compared to liquid-quenched ribbons with same composition, consistent with increased density and improved stability. Fluctuation electron microscopy (FEM) experiments show that the glasses with improved mechanical properties have increased icosaedral medium range structural order. Films grown starting from poorer vacuum (base pressure ~ 5×10⁻¹⁰ Torr) with higher partial of oxygen (2×10⁻⁸ Torr) at 0.22 nm/sec in 3.8 mTorr of Ar were amorphous at substrate temperatures from 295K (0.43×Ts/Tg) to 518K (0.76×Ts/Tg). These observations suggest that enhancing properties and stability in PVD metallic glasses requires optimization of both deposition rate, which governs monolayer residence time, and substrate temperature, which influences surface diffusion. They reiterate evidence from bulk synthesis that glass forming ability is sensitive to incorporation of oxygen. Calorimetric assessment of stability also will be presented.

Fast Dynamics of Metallic Glasses at Low Dimensions Wei Hua Wang; Institute of Physics, Beijing, China.

The dynamics of metallic glasses at low dimensions such as in surface, ultrathin films, nano-scale particles were measured and studied. The dynamics and diffusion with the value of more than 10⁸ times faster than that of bulk are found far below glass transition temperature at the free surface which is more than 100 times faster than that in bulk, higher electrocatalytic activity and unique self-stabilizing catalytic performance over a long-cycling life than the commercial Pt/C catalysts in Pd-based MGs, and generation of the modulated superlattice-like nanostructure modulated nanostructure from the surface to interior, are found. The fast dynamics can be applied to form ultrastable metallic glasses with unique properties at room temperature. The observations have implications for understanding the glassy dynamics, and pave a way for controllable fabrication of unique and sophisticated nanostructure on glass to realize the properties modification.

11:00 AM CM02.07.08
Interfacial Plasticity and Strain Delocalization in Metallic Nanoglasses Jason R. Trelewicz and Bin Cheng; Stony Brook University, Stony Brook, New York, United States.

The ductility and toughness of metallic glasses are classically limited by plastic flow localizing into shear bands, a process which is augmented by the introduction of structural inhomogeneities to produce a more homogeneous plastic response. For example, in metallic glass matrix composites, ductility enhancements have been attributed to the presence of crystallites in the amorphous matrix, although the mechanisms of delocalization relating to shear band nucleation and propagation are still an active area of research. A new class of amorphous alloys that contain amorphous grains separated by “interfaces”, referred to as metallic nanoglasses, have also exhibited the ability to delocalize plastic strain and believed to result from the interfacial regions distributing shear band nucleation. Using molecular dynamics simulations, we explore the process of strain delocalization in nanoglass models produced
via high pressure consolidation of amorphous nanoparticles. Interfaces are identified in the consolidated structures using a new volumetric strain threshold criterion, and generally exhibit a larger free volume and reduced full coalesced fraction relative to the cores of the amorphous grains. Uniaxial tensile simulations are conducted on the nanoglasses with amorphous grain size and relaxation temperature systematically varied to study the conditions for effective delocalization. We find that the presence of interfaces promote distributed plasticity with a grain size effect deriving from preferential localization transpiring within the interfacial regions containing greater excess free volume. Interfacial structural state also plays an important role where relaxation at higher temperatures initiates rejuvenation and in turn, enhanced localization that manifests in the flow curves as a stress overshoot upon the formation of a dominant shear band. Our results demonstrate that finer amorphous grain sizes and interfacial regions with enhanced disorder promote a more homogenous plastic response, thus providing insights into nano-glass deformation that can be translated to alloy design through the consolidation of nanometer-sized glassy particles.

Dynamic Mechanical Analysis on the Effect of Room Temperature Aging on Sputtered Zr55Ni25Al20 Metallic Glass Anthony Kwong, Miranda Schwacke and Julia R. Greer; California Institute of Technology, Pasadena, California, United States.

Compared to bulk metallic glasses, the free-volume content is higher in sputtered metallic glasses due to the high cooling rate of the magnetron sputtering fabrication technique. This excess free volume accommodates larger amounts of local shear during deformation and improves the material’s ductility. However, not much research has been done on understanding the impact of room temperature aging on the size and distribution of free volume in sputtered metallic glass.

In our research, we sputtered five μm-thick Zr-Ni-Al onto a Si substrate and used focus ion-beam (FIB) milling to fabricate micro- and nano-sized pillars. The diameter of the pillars ranged from 300 nm to 1.3 μm with heights ranging from 900 nm to 3.9 μm, respectively. Uniaxial pillar compressions were performed on the as-sputtered Zr-Ni-Al. The elastic modulus and yield strength were measured to be 75.5 ± 12 GPa and 2.49 ± 0.24 GPa, respectively. The as-sputtered Zr-Ni-Al was aged at room temperature in a nitrogen dry box for three years and new pillars were fabricated using FIB milling and then tested under uniaxial compression. After aging, the elastic modulus and yield strength increased to 82.5 ± 4.1 GPa and 2.73 ± 0.09 GPa, respectively. To provide insight into this increase in mechanical property, we performed dynamic mechanical analysis (DMA) to determine the storage and loss modulus of the as-sputtered and aged Zr-Ni-Al.

For the DMA experiments, new pillars were fabricated on both the as-sputtered and aged Zr-Ni-Al. These pillars were tested at room temperature at frequencies between 3 and 700 Hz. The peak of the loss modulus corresponds to the activation of β relaxations in the material. For the as-sputtered and aged Zr-Ni-Al, this occurred at a frequency of 440 Hz and 450 Hz, respectively. The higher frequency of the aged metallic glass indicates that the activation energy of the β relaxations is larger. As expected, room temperature aging redistributed the free volume to a more energetically favorable configuration. Thus, even higher energy is required to relax the aged metallic glass. In addition, the magnitude of the loss modulus increased as a function of pillar diameter. The loss modulus ranged from 20 GPa to 100 GPa for pillar diameters ranging between 300 nm to 1.3 μm, respectively. The total free volume in large pillars is greater than that in small pillars, thus resulting in increased loss modulus. The cooperative shear model (CSM) demonstrated that β relaxations are associated with the transition of shear transformation zones (STZs) in an elastic matrix. Utilizing CSM, the volume and activation energy of the STZs can be calculated. These findings elucidate the effect of room temperature aging on sputtered metallic glass and pave the road for future work on quantifying the activation energy and volume of STZs, the rearrangement of which is the mechanism of deformation in metallic glass.

11:30 AM CM02.07.10
Microstructure and Mechanical Properties of Metallic Nanoglasses Prepared by Nanoparticle Consolidation Omar Adjoud and Karsten Albe; TU Darmstadt, Darmstadt, Germany.

Metallic nanoglasses are amorphous materials with microstructural features analogous to nanocrystalline materials, which consist of glassy grains connected by glass-glass interfaces. They can be produced by cold-compaction of glassy nanospheres which are prepared by inert-gas condensation [1,2]. The interfaces are characterized by an excess volume [3], a lack of short range order [4], and a different composition than the glassy grains [5,6].

In this contribution, we present a detailed analysis of microstructure formation of metallic nanoglasses by molecular dynamics simulations. We analyze the atomic structure of the glassy grains and glass-glass interfaces during the consolidation process. Moreover, we discuss the thermodynamics and kinetic stability of anoglasses, structural features of the interfaces, segregation effects and the mechanical response in uniaxial tensile tests. Finally, the computational results are put in the context of experimental findings.

11:45 AM CM02.07.11
Dispersive Diffusion Fit to Heavy-Tail Relaxation in Amorphous Semiconductors and Disordered 2D Materials Matthew Grayson, Jiajun Luo and Lintao Peng; Northwestern University, Evanston, Illinois, United States.

Dispersive diffusion occurs when the diffusion "constant" in the diffusion equation obeys a power law in time. Remarkably, such processes are successful in describing diverse phenomena from dielectric relaxation in glasses to creep in strained polymers to earthquake aftershocks. In the present work two different disordered semiconductor systems - amorphous indium-gallium-zinc-oxide (a-IGZO) and exfoliated 2D black phosphorus (BP) are shown to both obey a variety of dispersive diffusion behaviors, depending upon doping and disorder strength. Transient responses in a wide range of disordered condensed matter systems show a heavy-tail relaxation behavior: the decay time constant increases as time increases, revealing a spectral distribution of time constants. However, the asymptotic behavior of such transients is notoriously difficult to measure due to the extremely rapid decay at short times and the extremely slow and decreasing decay rate at long times. This work introduces a generalized analysis method for arbitrary heavy-tail transients, which accurately fit a finite experimental dataset to one of a continuum of candidate heavy-tail functions. By plotting the transient response versus log-time and taking the derivative, a simple half-maximum line-width analysis of the derivative is shown to predict the asymptotic value within less than 1%. The dispersive diffusion transient fit is a generalized fit that includes the stretched exponential as a limiting case. The line fits and asymptotic predictions are demonstrated using experimental transient responses from historical data on amorphous silicon and amorphous InGaZnO. The remarkable ability to fit heavy-tail transients in the 2D material black phosphorus implies that the low-dimensionality of such crystalline 2D systems suffer from poor screening such that the disorder potential results in behavior that is more akin to dynamics found in amorphous materials.
Sequences of Metastable Phase Formation Determined via Ultrafast Calorimetry

Jörg F. Löfler; Laboratory of Metal Physics and Technology, Department of Materials, ETH Zurich, Zurich, Switzerland.

Initial phase formation via nucleation and growth plays an important role in the microstructure evolution upon melt solidification. I will report on novel chip-based fast differential calorimetry (FDSC) to determine thermophysical properties at rates of several $10^7$ K/s and thus to reveal the sequence of metastable phase formation during rapid solidification. In such a way we were able to determine new phase transition paths, such as solid-solid phase transformations via melting for a Au-based glass [1]. In addition, with FDSC it is possible to interrupt rapid cooling after a phase transition and then to “up-quench” the frozen structure via heating at ultrafast rates. Using this strategy, we were able to demonstrate for a Mg-based alloy that a transient quasicrystal (QC) phase nucleates first from the melt and then transforms into an equilibrium approximant phase [2]. We assume that such a transition path, which minimizes the free-energy barrier for nucleation, is likely to be a general mechanism for metastable QC-forming systems. We were also able to completely melt the QC phase mixture via suppressing the metastable-to-stable phase transition. In general, FDSC with the corresponding strategy of “up-quenching” a previously frozen structure can generate the discovery of hidden transient phases and thus the construction of metastable phase diagrams. I will show that such studies are not only key to the understanding of crystallization in metallic materials, but are also of great interest in determining nucleation mechanisms in polymeric materials, biological systems, and pharmaceutical substances.

Are Hints about Glass Forming Ability Hidden in the Liquid Structure?

Juan Wang1, Ryogo Suzuki1, Anupriya Agrawal1, 2 and Katharine Flores1, 2; 1Mechanical Engineering and Material Science, Washington University in St. Louis, St. Louis, Missouri, United States; 2Institute of Materials Science and Engineering, Washington University in St. Louis, St. Louis, Missouri, United States.

There has been concerted effort to correlate high temperature structure and dynamics of liquids with glass forming ability of alloys. Despite intense interest, identifying the structural origin of glass forming ability in metallic alloys remains a challenge due to the difficulty of describing the evolution of the long-range disordered structure from the liquid. Here, we report the cluster variance in the liquid as a potential parameter to predict glass formation. We have used molecular dynamics simulations with embedded atom method (EAM) potentials to simulate the quenching of metallic liquids resulting in crystalline, glassy or composite phases. We observe that variance in cluster fraction correlates with crystallization and hence with glass forming ability. We will show that this correlation persists in multiple binary and ternary systems. Further, it is independent of the dominant cluster type as well as the type of EAM potential used. Moreover, EAM potentials used were not custom fitted to get accurate liquid properties.

We also validated our molecular dynamics prediction of glass forming compositions with experiments. Using a high-throughput, direct laser deposition processing method to experimentally evaluate glass formation, the glass forming ability of Zr-Cu, Zr-Ni-Al, Zr-Cu-Al, and Zr-Cu-Ti was consistently found to be greatest where the variance in the fraction of the dominant cluster in the simulated liquid is minimized. The laser deposited alloy libraries further enabled an investigation of the mechanical behavior across the composition range using nanoindentation. Correlations of these properties with the simulated structures will also be discussed.

In Situ Observation of Spinodal Decomposition Process in Silicate Glass

Katsuaki Nakazawa1, Shin-ich Amma2 and Teruyasu Mizoguchi1; 1The University of Tokyo, Meguro-ku, Japan; 2New Product R&D Center, Asahi Glass Co., Ltd., Yokohama, Japan.

Mechanical and optical properties of glasses can be modified by phase separation phenomena. The number of phases, sizes of phases and especially morphologies of phases affect those properties. Morphologies of phases deeply depend on the volume fractions of the separated phases. If the volume fractions of two phases are equal, interconnected structures are fabricated, whereas non-equal volume fractions fabricate the droplet structures. The morphologies of the interconnected and droplet structures can be clearly discriminated. The interconnected structure is composed of two tubular phases which three-dimensionally entangle. The droplet structure is composed of spherical minor phases dispersed in the major phases. The process of phase separation is divided into three stages: initial, middle and final stages. In the case of spinodal decomposition, interconnectional and
amorphous ice, and liquid water observed in experiments. However, amorphous ices are quantum systems and therefore the zero-point vibration free (like states) [2]. In most cases, classical molecular dynamics (MD) simulations are able to reproduce qualitatively many of the transformations between ice, The details of the temporal changes and the coarsening of those phases will be discussed in my presentation.

Theoretical Study on Polymorphic Transformations in Amorphous Ice Rodion Belosludov1, Kirill Gets2, Ravil Zhdanov2, Vladimir Belosludov2 and Yoshiyuki Kawazoe1; 1Institute for Materials Research, Tohoku University, Sendai, Japan; 3Nikolaev Institute of Inorganic Chemistry, SB RAS, Novosibirsk, Russian Federation; 4New Industry Creation Hatchery Center, Tohoku University, Sendai, Japan.

Polymorphism, i.e. the presence of more than one amorphous state or phase in amorphous solids and liquids, is of fundamental importance in materials science [1]. Experimental and theoretical studies on very-high-density (VHDA), high-density (HDA) and low-density (LDA) ices have raised questions regarding the nature of the transformation between the amorphous forms of ice. One of the main questions is whether the amorphous ices are thermodynamically continuously connected with liquid states and can be regarded as vitrified liquids (glassy states) or distorted crystalline phases (crystal-like states) [2]. In most cases, classical molecular dynamics (MD) simulations are able to reproduce qualitatively many of the transformations between ice, amorphous ice, and liquid water observed in experiments. However, amorphous ices are quantum systems and therefore the zero-point vibration free energy is large and at low temperatures, it should be taken into account in free energy calculations. The description of various amorphous phases of ices has been performed on a molecular level in order to study the nature of amorphous polymorphism in a water system [3]. The models of very high-, high- and low-density amorphous (VHDA, HDA and LDA, respectively) ices have been modelled and the pressure-temperature phase diagram was constructed for water in the low temperature region using the combination of MD and lattice dynamics (LD) approaches. It was shown that the transformation between the amorphous phases (at positive pressure LDA → HDA, LDA → VHDA, and at negative pressure HDA → VHDA) is sharp and is a real phase transition in the classical sense at low temperatures. At positive pressure the transformation from the metastable phase HDA to the thermodynamically stable phase VHDA is a continuous transition due to kinetic impediment.

Metallic Glasses—Relating Mechanical Properties to the Relaxation Spectrum A. Lindsay Greer; Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, Cambridge, United Kingdom.

Thermomechanical processing (TMP) of metallic glasses (MGs) [1] can take them to states of higher or lower energy, describable in terms of higher or lower fictive temperature \( T_f \). Recently, there has been particular interest in achieving extremely high values of \( T_f \), as the corresponding glasses are expected to show increased plasticity [2]. This presentation moves on to consider how \( T_f \) itself is an inadequate measure. Glasses show a relaxation spectrum as a function of temperature on heating, seen, for example, in the shape of the energy-absorption peaks in dynamic mechanical analysis, or of the sub-\( T_g \) (glass-transition temperature) exothermic peaks in differential scanning calorimetry. In this spectrum, \( \alpha \)-relaxation relates to the formation of different glassy states on cooling at different rates, and describes processes occurring near \( T_g \), \( \beta \)-relaxation occurs below \( T_g \) and there are yet further processes at lower temperature [3]. We examine how the shape of the relaxation spectrum can be tailored by TMP, and how this affects the properties of MGs. We show that, for MGs with a relatively low \( T_g \) and comparing near-ultrastable with higher-energy states, the distinction between \( \alpha \)-relaxation and sub-\( T_g \) \( \beta \)-relaxation can become blurred. By combining processing techniques, for example annealing with cryogenic thermal cycling [4], one can find that a glass is simultaneously more and less relaxed: with higher hardness, yet easier onset of plastic flow. Such combinations are of clear interest in achieving more uniform plastic flow, one of the most important aims for MGs. In explaining such combinations, it is relevant to consider the heterogeneity of the MG, possibly describable as soft-spots in a comparatively rigid matrix. We consider how novel TMP may improve the properties of MGs. We consider how state-of-the-art structural characterization and atomistic modelling can assist in developing a fundamental understanding of how MG properties can be changed by TMP. And we make comparison with other families of glassy materials.

8:30 AM CM02.09.02
Topological Control on Glass Relaxation Xin Li1, Yushu Hu1, John C. Mauro2, Morten Smoedskjær3 and Mathieu Baechy4; 1University of California, Los Angeles, Los Angeles, California, United States; 2Department of Materials Science and Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States; 3Department of Chemistry and Bioscience, Aalborg University, Aalborg, Denmark.

Understanding, predicting, and controlling glass relaxation is of primary importance for the manufacturing of substrate glasses used in display applications, as any small variation in volume can result in undesirable pixel misalignment. However, no clear atomistic mechanism of structural and stress relaxation is available to date, which limits our ability to identify optimal glass compositions featuring low relaxation. Here, based on molecular dynamics simulations, we study the relaxation of a series of alkali-free calcium aluminoislate (CAS) and sodium silicate (NS) glasses with varying compositions. We observe that selected glass compositions exhibit minimal relaxation. We investigate the structural origin of this behavior by means of topological constraint theory. Based on this analysis, we demonstrate that minimal relaxation is achieved for isostatic glasses, which are both free of eigenstress and floppy modes. This highlights the crucial role of the atomic topology in controlling the propensity for relaxation.

8:45 AM CM02.09.03
Elastic Properties and Structural Relaxation of a Chain Like Polymer Manon Heili and John Kieffer; University of Michigan, Ann Arbor, Michigan, United States.

We investigate the structural reorganization process in a chain-like polymer, polyvinylidene fluoride (PVDF). A unique optical setup is used combining a miniature tensile tester placed into the optical path of a Brillouin light scattering (BLS) system, to probe the elastic properties of a sample while it is uniaxially strained. BLS yields the adiabatic moduli of the materials, while their isothermal moduli are derived from the measured stress-strain curves. This two-pronged probing approach yields data, which upon detailed analysis provides for unprecedented insights into the distribution of relaxation times associated with various Maxwell elements, as well as evidence for visco-elastic property changes that require descriptions beyond these simple models.

Upon straining, elastic moduli of the polymer drop instantaneously. However, while maintained at a constant strain, the material undergoes stress relaxation during which the load necessary to maintain this elongation decreases. During stress relaxation, both the adiabatic and isothermal moduli reduce, leaning towards the unstrained values. The structure indeed rearranges to optimize molecular packing and maximize the non-bonding interactions. A thermodynamical approach is proposed to correlate the anelastic moduals with the entropic aspects of the structural changes for this polymer.

9:00 AM CM02.09.04
A Microscopic Description of the Anelastic and Structural Relaxation of Metallic Glasses Tianjiao Lei1, Luis Rangel DaCosta1, Yonghao Sun1, 2, A. Lindsay Greer1, Ming Liu1, Zhen Lu1, Wei Hua Wang2 and Michael Atzmon1, 4; 1Materials Science and Engineering, University of Michigan-Ann Arbor, Ann Arbor, Michigan, United States; 2Institute of Physics, Chinese Academy of Sciences, Beijing, China; 3Department of Materials Science and Metallurgy, University of Cambridge, Cambridge, United Kingdom; 4Nuclear Engineering and Radiological Sciences, University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States.

Metallic glasses (MGs) possess high strength and elastic limit, but they also exhibit little macroscopic ductility due to shear band formation. Because of the disordered atomic structure, it is challenging to define defects that accommodate deformation in MGs. From observations in physical analogs, these defects have been identified as shear transformation zones (STZs), which are dissipative and thermally activated [1]. At small strains, STZs are isolated and can be reversed due to back-stress in the elastic matrix upon removal of the applied stress, which results in anelastic behavior. Recently, Ju et al. obtained a quantized hierarchy of STZs for an Al-based MG from quasi-static anelastic relaxation measurements [2]; the volume difference between STZs corresponding to adjacent peaks in the time-constant spectrum equals that of one Al atom. The volume fraction of potential STZs, i.e. atomic clusters capable of shear transformation, increases with size. After annealing at 110 °C for 1 hour, the number of potential STZs decreases, while their time constants increase. Notably, a detailed description of structural relaxation emerges: its dominant effect is on the largest, and therefore slowest, STZs. Cycling to liquid-nitrogen temperature, observed to induce rejuvenation [5], only leads to subtle changes in the anelastic behavior. The effect of the composition x above will be discussed in the context of observations on its effect on ductility [4].

β-Relaxation and Its Correlations with Properties in Metallic Glasses Hui Yang Bai, Peng Luo and Wei Hua Wang; Institute of Physics, Chinese Academy of Sciences, Beijing, China.

Metallic glasses (MGs) with structures viewed approximately as dense random packing of hard spheres offer a simple but effective model system for the study of relaxations and related issues in glass science. β-relaxation in MGs has been found to be closely bound up with the structural characterstics, formation, glass transition, deformations or flow behaviors, physical and mechanical properties, crystallization, and stability of MGs. We present the state of the art research on various aspects of the β-relaxations in model metallic glass systems and demonstrate the critical importance of these fast relaxation behaviors in understanding deformation, flow behavior, aging and rejuvenation, mechanical and physical properties of metallic glasses. We illustrate that it is an attractive prospect to incorporate the dynamic relaxations insights into the design of MG materials with extraordinary properties.

Limitations on Localized Motions in Glass-Forming Liquids—A Dynamic Light Scattering Study

The structural relaxation in glass-forming liquids is characterized by a two-step decay process. A rather fast initial relaxation (often referred to as the beta-relaxation) occurs at early times as a result of localized motions that are globally restricted. As a result of this partial decay, the dynamic structure factor displays an intermediate plateau known as the non-ergodic level. At a longer timescale, the remaining structure is able to relax globally through the so-called alpha-relaxation whose relaxation times scales with the liquid's viscosity.

Here, we review dynamic light scattering measurements of the dynamic structure factor in a variety of glass-forming liquids spanning a wide range of fragility indices, both fragile molecular liquids and strong network-forming oxides for which a careful determination of the non-ergodic level has been made. We show that this plateau level increases with decreasing fragility implying that strong network-forming liquids tend to experience less localized structural arrangements than their molecular liquid counterparts.

The Formation of Ultrastable Metallic Glasses on Cold Substrates

Peng Luo, Hai Yang Bai and Wei Hua Wang; Institute of Physics, Chinese Academy of Sciences, Beijing, China.

Vitrification from physical vapor deposition is known to be an efficient way for tuning the kinetic and thermodynamic stability of glasses and significantly improve their properties. There is a general consensus that preparing stable glasses requires the use of high substrate temperatures close to the glass transition one, Tg. Here, we challenge this empirical rule by showing the formation of Zr-based ultrastable metallic glasses at room temperature, i.e., with a substrate temperature of only 0.43Tg. By carefully controlling the deposition rate, we can improve the stability of the obtained glasses to higher values. In contrast to conventional quenched glasses, the ultrastable MGs exhibit a large increase of Tg of ~60 K, stronger resistance against crystallization, and more homogeneous structure with less order at longer distances. Our study circumvents the limitation of substrate temperature for developing ultrastable glasses, and provides deeper insight into glasses stability and their relaxation dynamics.

Recent Insights into Thermo-Mechanical Energy Storage in Metallic Glasses

Robert Maass; Department of Materials Science and Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Macroscopic properties of metallic glasses, such as Young’s modulus, plastic strain at failure, fracture toughness, corrosion resistance, or the magnetization behavior depend on the structural state of the glass. This has inspired intense research efforts focusing on the control of structural modifications in glasses that are often quantified by the stored excess enthalpy relative to an as-cast reference, rather than by the precise changes of the atomic structure.

Particularly, high enthalpy states have attracted strong interest since they improve the commonly limited room temperature ductility of metallic glasses. In this talk, we will highlight our recent efforts in this topic, paying attention to three different methods on how to store excess enthalpy in monolithic metallic glasses, including a mechanical, thermo-mechanical, and a purely thermal method. Specifically, this means we will discuss 1) how an alternating elastic load leads to energy storage and how this translates to nanoscopic property fluctuations, 2) how alternating elastic loading during cooling to cryogenic temperatures reveals a low temperature loss process that is accompanied by energy storage, and 3) how ultra-fast heating can lead to significant enthalpy storage of initially very relaxed glasses. The latter approach will be combined with in-situ x-ray measurements and atomistic simulations. Our results are discussed in terms of possible underlying mechanisms reflected in the global response.
Atomic Imprinting into Metallic Glasses

11:45 AM CM02.10.03

Spray Drying of Amorphous Nanoparticles

Mathias Steinaecker and Esther Amstad; EPFL, Lausanne, Switzerland.

Amorphous materials can have distinctly different properties compared to their crystalline counterparts. These include different dissolution rates or higher catalytic activity. Additionally, amorphous materials can serve as transient precursors for the formation of certain crystalline materials such as CaCO3. Certain materials have a low propensity to crystallize and hence, they can easily be processed into amorphous structures. Other materials have a high propensity to crystallize and are therefore extremely difficult to process into amorphous structures. To process these materials into amorphous structures without using large quantities of crystallization inhibitors, their crystallization must be kinetically arrested during early stages of their formation. This can for example be achieved through rapid cooling of melts. However, this method cannot be employed to process thermally labile substances that decompose before they melt. To overcome this limitation, we developed a microfluidic spray drier that produces small droplets that possess a very high specific surface area and hence dry very quickly. We use surface acoustic waves to produce droplets in the range of 1-10 um. The atomizer can process aqueous and non-aqueous solutions containing organic and inorganic reagents. The aerosol droplets are rapidly dried in a dedicated drying unit and the dry particles are subsequently deposited on a substrate to analyze the influence of the processing parameters on their structure and morphology.

In this talk, I will demonstrate that materials can be made amorphous if processed in sufficiently small drops that dry quickly, even if the material possesses a high propensity to crystallize and even if it is processed from low viscosity solutions where the mobility is high. I will present the influence of the formation time and processing conditions on the structure and composition of different amorphous materials, including drugs, and inorganic materials and how this knowledge can be used to produce materials with unusual structures and compositions.

Processing-Property Relationship for Additive Manufacturing of Metallic Glasses

Punnathat Bordeenithikasem and Douglas Hofmann; NASA Jet Propulsion Laboratory, Pasadena, California, United States.

Additive manufacturing (AM) or 3D printing is a disruptive technology that is revolutionizing the manufacturing industry. Metallic glasses (MGs) are considered for use in metal AM due to their desirable mechanical properties and high cooling rates achieved through the printing process. To ensure that printed MG parts are suitable for their intended applications, a more robust understanding of the processing-property relationship for AM of MGs must be developed by the scientific community. In this presentation, we investigate the feedstock purity, oxidation, and printing parameters on the mechanical and wear properties of printed MG parts, with direct comparisons to cast MG samples.

11:45 AM CM02.10.05

Atomic Imprinting into Metallic Glasses

Molding and imprinting, which are among the oldest and most widely used manufacturing techniques, have recently regained scientific interest with the demonstration of nanomolding and nanoimprinting as surface functionalization methods. Typically, imprinting involves the embossing of a hard mold into a soft material. Due to the convenient adjustability of their degree of softening, thermoplastic polymers had been the material class of choice for most imprint procedures. Metallic glasses, however, have recently been identified as ideal moldable materials, gaining popularity since they combine favorable mechanical and electrical properties. They are particularly promising for small features sizes since their lack of intrinsic structural order with potentially atomic-sized flow units suggests that they may have the ability to conform to a mold’s shape even on atomic length scales. In this presentation, we demonstrate that thermoplastic imprinting of a metallic glass can reproduce surface features with sub-angstrom accuracy through the replication of terraces from a strontium titanate single crystal surface separated by steps of unit cell height as template. The molded metallic glass replicates the ‘atomic smoothness’ of the strontium titanate, with identical roughness to the one measured on the mold even after multiple usages of the mold and with such molded metallic glass surfaces exhibiting an exceptional long-term stability of years. By providing a practical, reusable, and potentially high-throughput approach for atomic imprinting, our findings may open novel applications similar in magnitude to the development of nanoimprinting two decades ago.

SESSION CM02.11: Complex Non-Crystalline Solids

Computational Design of Lightweight Structural Materials with Triply Periodic Minimal Surfaces

Zhao Qin and Markus Buehler; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Structural materials found in nature, such as wood, bone, insect forewings, bee hive and bird beak, synergistically combine strength, stiffness and toughness with lightweight. In contrast, most manmade engineering materials do not have such multifunctional features. Among many biological materials, the ones with lightweight foam structures serve good examples to provide a variety of mechanical supporting, thermal conservation and impact shielding functions in the animal body and their external protections. Many of the basic building blocks of these lightweight, elastic, and highly dissipative materials can be categorized by triply periodic minimal surfaces (TPMS), such as structures so-called gyroid and Schwarz’ diamond, etc. TPMS have the symmetries in a similar way as crystals but they are composed of a single surface instead of 3D blocks, making their structure and mechanics unique. We try to explore the general mathematical function of TPMS and quasi-TPMS structures and use them as the input geometry to generate solid materials with innovative lattice structures. We theoretically investigate the mechanical property of these structures by using finite element method and molecule dynamics at the different scale levels and combine the modeling work with 3D printing to develop a technique that is capable of producing materials with lightweight
TPMS structures with highly predictive material functions in a consistent and reproducible way. We discover that the structural geometry plays a dominating role in governing the scaling laws of the mechanics of the material density. Our study suggests that these structures can be used as templates to design and make the 3D forms of many 2D materials including graphene, yield structures of 4.6% the density and 10 times the strength of mild steel. We expect such TPMS structures to have high stiffness, toughness, thermal conservation and impact tolerance, as well as lightweight, giving the material a full potential for protection with energy efficiency for production and transportation.

1:45 PM CM02.11.02
Soft Fibrous Materials with Inter-Fiber Adhesion Catalin Picu, Vineet Negi and Ahmed Sengab; MANE, Rensselaer Polytechnic Institute, Troy, New York, United States.

Many soft materials of biological and industrial interest are composed from nanofibers. In such cases, inter-fiber adhesion may produce fiber bundling and organization on scales larger than that of individual components. A type of network structure, entirely stabilized by adhesion, which was not described previously in the literature, emerges. We describe such structures and identify the range of system parameters in which they are expected to occur. Further, we study their mechanical behavior and observe a broad range of tunable properties, including softening in tension, large strain range in which the structure responds linearly to applied strains, and adhesion-dependent elastic moduli. We consider systems with permanent cross-links and systems in which fibers are not cross-linked but interact adhesively and by excluded volume interactions. The application of these results to collagen structures and carbon nanotube buckypaper are discussed.

2:00 PM CM02.11.03
Theoretical and Experimental Investigation of Haze in Transparent Aerogels Lin Zhao1, Elise M. Strobach1, Bikram Bhatia1, Sungwoo Yang2, Amy Leroy1, Lenan Zhang1 and Evelyn N. Wang1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2The University of Tennessee at Chattanooga, Chattanooga, Tennessee, United States.

Transparent aerogel materials integrated in high-performance glazing units hold great promise to reduce building heat loss and improve indoor thermal comfort because of their ultra-low thermal conductivity. One of the primary challenges preventing the adoption of aerogels in windows is their poor visual experience. While the inherent porous structure is vital to suppress heat loss, the refractive index mismatch between the solid skeleton and air causes visible light to scatter and give rise to haze that degrades the contrast of an image when viewed through the aerogel. Previous studies on haze in aerogels relied on direct experimental characterization with little understanding of the underlying mechanisms. In this work, we investigate the haze of transparent silica aerogels using experimental measurement as well as theoretical modeling. We developed a radiative transfer model that can predict the diffuse transmittance, total transmittance, and haze of an aerogel based on its physical properties, i.e., density, mean particle size, and thickness. To validate the model, we fabricated aerogel samples with two different chemical precursors with a wide range of transparency and haze. Comparison of model predictions with experimental results measured using a UV-Vis spectrophotometer showed good agreement across the entire visible spectrum. We then used the validated model to perform a parametric study of haze and found that the haze is most sensitive to the mean particle size. Smaller particle size not only reduces the haze at a given aerogel thickness but also weakens its dependence on thickness. In addition, we developed a complementary approach that prescribes the set of aerogel properties required to achieve certain haze/transmittance targets. We believe this work advances the fundamental understanding of haze in a wide range of transparent porous materials and could help guide material development to achieve optimal optical performance.

2:15 PM CM02.11.04
On the Shape and Size of Voids in Ultra-Large Models of Hydrogenated Amorphous Silicon—A First-Principles Study Duraga P. Paudel1, Raymond Atta-Fynn2, David Drabold3 and Parthapratim Biswas1; 1Department of Physics and Astronomy, The University of Southern Mississippi, Hattiesburg, Mississippi, United States; 2Department of Physics, University of Texas, Arlington, Arlington, Texas, United States; 3Department of Physics and Astronomy, Ohio University, Athens, Ohio, United States.

We present an ab initio study of hydrogen microstructure in pure and hydrogenated amorphous silicon with particular emphasis on the shape and size of voids and the dynamics of hydrogen atoms inside the voids. By using ultra-large models of a-Si, obtained from classical molecular dynamics simulations, with a realistic volume density of voids of 0.1%~0.3%, the dynamics of Si (and H) atoms on the surface of the cavities are studied and their effects on shape and size of the voids are examined using first-principles density-functional calculations. The resulting changes (from the ab initio calculations) are compared with the corresponding data obtained from total-energy relaxation using the Stillinger-Weber potential. The size and shape of the voids are analyzed by examining the three-dimensional distributions of Si/H atoms on the surface of voids using the convex-hull approximation of the void regions and computing the radius of gyration of the corresponding convex-hull regions. A comparison of our results with those obtained from the small-angle x-ray scattering (SAXS) measurements of a-Si/a-Si:H in the Guinier approximation is also discussed.

2:30 PM CM02.11.05
Recent Advances in Thermoplastic Fabrication of Metallic Glasses Golden Kumar and Zhonglue Hu; Texas Tech University, Lubbock, Texas, United States.

Thermoplastic embossing with metallic glasses is considered as a solution for scalable manufacturing for metallic micro- and nano-structures. Despite its potential, embossing faces major challenges such as, limited aspect-ratio, expensive and non-reusable templates, inability to transfer nanostructures to materials other than metallic glasses etc. Significant advances have been made in recent years to overcome these barriers. For example, by reversing from embossing to drawing, assembled nano-tips, nano-wires, and nano-tubes with aspect-ratios exceeding 1000 can be fabricated inexpensively. These nanostructures can be transferred to plastics, semiconductors, quartz, or other metals. Macroscopic structures obtained by machining can be downsized to nanoscale features without using lithography by manipulating the viscous, capillary, and adhesive stresses. The templates can be non-destructively separated from metallic glasses by minimizing the thermal expansion mismatch. Drawing approach can be readily adapted for high-throughput fabrication and testing of nanoscale test specimens, enabling rapid screening of size-effects in mechanical, thermal, and electrical behavior. Recent progress and future directions in thermoplastic fabrication and nanoscale testing of metallic glasses will be discussed.

2:45 PM CM02.11.06
Atomistic Simulations of Amorphous Functional Materials by Combining Machine Learning and DFT Volker Deringer; University of Cambridge, Cambridge, United Kingdom.

Understanding the links between atomic structure, chemical bonding, and macroscopic properties in amorphous materials is a formidable task. Quantum-mechanical atomistic simulations, prominently based on density-functional theory (DFT), have played important roles in this - but are computationally expensive, and can describe complex solids only in small model structures. Novel interatomic potentials based on machine learning (ML) have recently garnered a lot of attention in the computational physics community, as they achieve close-to DFT accuracy but at only a fraction of the cost.
In this talk, I will argue that ML-based interatomic potentials are particularly useful for studying amorphous solids, and that they can be combined with established DFT methods for gaining new insight into this important materials class. I will first describe a Gaussian Approximation Potential (GAP) for amorphous carbon [1], with a brief introduction to the underlying theoretical framework [2], and a special view on what is needed to validate potentials for the amorphous state. I will then present an application to porous and partly "graphitized" carbon structures, which are relevant for applications in batteries and supercapacitors [3]; this includes a new ML strategy for simulating the movement of Li-ions in such materials [4]. Finally, I will present very recent work on amorphous silicon (a-Si), another prototypical non-crystalline material, where ML-driven large-scale simulations have allowed us to generate structural models in good agreement with experimental findings [5], again making steps toward the routine and realistic atomistic modeling and understanding of the amorphous state.

CaO-Al₂O₃ glasses with different CaO content (45-70%) and increases with electron concentrations.
4. The electrical conductivity in C12A7:e glass is enhanced over 5 orders of magnitude by annealing around Tg. No such a pronounced conductivity change has been reported as far as we know.
5. The work function of C12A7:e glass measured by UPS was 3.0eV, which is comparable to metal Li and Ca, but chemically stable.
6. No significant difference in X/neutron RDFs was noted between e-free C12A7 and e-doped C12A7 glasses but striking difference was observed by Resonance Raman scattering.

We explain some of these results by ab initio MD simulation (PNAS 2016) and propose electride glass is a novel type amorphous semiconductor.

4:30 PM CM02.12.04

In this work we characterize the viscoelastic properties of a new class of thermoplastics called polyrotaxane glasses. The polyrotaxane glass macromolecules comprise a polyethylene glycol (PEG) chain threaded by many α-cyclodextrin beads displaying modifiable organic functional groups. X-ray diffraction and calorimetry studies confirm the amorphous nature of these materials. Above the glass transition temperature (Tg), the local cooperative motions of the polyrotaxanes can be probed by various rheological and mechanical techniques. These local motions appear to cease on experimental time scales at Tg, yet secondary relaxations persist even in the apparently frozen state as the material continues to reduce free energy away from equilibrium. We elucidate the effect of chain length and bead density on the fragility and glassy dynamics of these polyrotaxane materials. The fragility of the glasses, which is determined by the extent to which viscosity deviates from the ideal Arrhenius temperature relationship due to the ceasing of local motions as Tg is approached, is characterized by rheological studies above the Tg. Below the Tg, information about the secondary relaxations is obtained by dynamic mechanical analysis. These studies bring us closer to realizing applications for these systems by expanding the scope of our understanding of their mechanical behaviour across a wide range of temperatures and frequencies.

4:45 PM CM02.12.05

Organosilica with bridging organic groups are of great interest in constructing porous materials for liquid chromatographic supports, catalysts, and adsorbents for hazardous materials, non-porous coatings to protect against corrosion or permeation, modified surfaces for composites, and even sunscreens based on nanoparticles bearing bridging organic chromophores to absorb ultraviolet light. While much has been learned of the influence of the bridging group on porosity, far less is known of its effect on the mechanical properties of the amorphous materials. To this end, we have prepared a wide range of organosilica materials as monolithic forms that permit their analysis by mechanical characterization using a Universal testing apparatus and thermal-mechanical properties by dynamic mechanical analyses. Organosilicas with bridging groups that include rigid aromatics, flexible alkynes, and heteroatom functionalized bridges were prepared by sol-gel polymerizations and air dried to afford monolithic xerogels for mechanical testing.
Lithium ion batteries have demonstrated their importance in portable electronics and as alternative to fossil based portable energy in automotive applications. This importance is expected to continue at least in the near and intermediated future. However, in the longer term electrode materials will need improved capacity and charge/discharge rates. As new anode and cathode materials are developed they are typically screened for advantageous properties by assembly into a working battery. This typically involves film fabrication from a mixture of conductive material (e.g. carbon), a binder (e.g. polyvinylidenefluoride), and the active material of interest. How this film is cast onto the current collector, the ratio of the individual components of the film, the drying procedure for the film and the final assembly of the cell can significantly alter the performance of the battery.[3,4] In order to avoid misleading information about the effectiveness of a novel active material many cells are required to validate findings.

Here we present micro-pipet measurements[5,6] which demonstrate the suitability of the technique for probing lithium ion battery materials. Specifically, we probed dispersions of active materials to determine the oxidation and reduction potentials, and the charge capacity of the material. Data obtained on candidate materials by the micro-pipet method was compared to coin cell measurements, to critically assess this technique for characterization of active battery materials.

In Situ/Operando Soft X-Ray Spectroscopy of Interfacial Processes in Energy Materials and Catalysis
Yi-Sheng Liu, Liang Zhang and Jinghua Guo; Lawrence Berkeley National Lab, Berkeley, California, United States.

The energy materials and devices have been largely limited in a framework of thermodynamic and kinetic concepts or atomic and nanoscale. Synchrotron radiation based x-ray spectroscopic techniques, especially in-situ/operando capabilities, offer unique characterization in many important energy materials of energy conversion, energy storage and catalysis in regards to the functionality, complexity of material architecture, chemistry and interactions among constituents within.

It has been found that the microstructure and composition of materials as well as the microstructure evolution process have a great influence on performances in a variety of fields, e.g., energy conversion and energy storage materials, chemical and catalytic processes. In-situ/operando x-ray characterization technique offers an opportunity to uncover the phase conversion, chemical environment change of elements and other very important information of solid/gas and solid/liquid interfaces in real time. We will present soft x-ray spectroscopy characterization techniques, e.g. soft x-ray absorption spectroscopy (XAS) and resonant inelastic soft x-ray scattering (RIXS), and the development of in situ/operando soft x-ray spectroscopy characterization of interfacial phenomena in energy materials and devices.

We will present a number of the experimental studies that successfully revealed the catalytic and electrochemical reactions in real time, e.g. solid (Au film)/liquid (water) electrochemical interface, Mg-ion and Li-S batteries, and solid-state hydrogen storage materials [1-5]. The experimental results demonstrate that in-situ/operando soft x-ray spectra characterization techniques provide the unique information for understanding the real reaction mechanism.

Enabling Ultrafast Interfacial Li-Transport in Layered-Oxide Cathodes
Bo-Hun Wen, Ping-Chun Tsai, Menghsuan S. Pan and Yet-Ming Chiang; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

In order to design electrode materials for optimal combinations of energy and power, it is essential to understand kinetic barriers at all applicable length scales and over a wide range of state-of-charge. Here, using a recently developed single-electrode-particle characterization method,1 we investigate the rate-limiting transport mechanisms in NMC and NCA cathodes. EIS and PITT measurements have been performed on single secondary particles of ~25 μm size, as a function of charge voltage and liquid electrolyte composition. We find that with increasing charge voltage, transport is increasingly limited by surface reaction kinetics; thus increasing the exchange current density is critical to obtaining high capacity utilization at high voltage. Upon performing the single-particle measurements in electrolytes containing salts with different anion groups, we find that electrolytes containing LiTFSI salt have, surprisingly, an order of magnitude higher exchange current density compared to electrolytes containing LiPF6 salt, and that this improvement is retained to high charge voltages. The improved interfacial kinetics lead to a significantly higher materials utilization during fast charge/discharge, in both the single-particle measurements and in experiments on macroscopic composite electrodes. Possible origins of the strong anion species dependence of interfacial kinetics, and interfacial characterization in these systems, will be presented.

This work was supported as part of the NorthEast Center for Chemical Energy Storage (NECCES), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Award # DE-SC0012583. P.-C. Tsai thanks the Ministry of Science and Technology, Taiwan (MOST 104-2917-I-006-006), for financial support.

Interfacial Studies of the Solid Electrolyte Interphase Hans-Georg Steinerueck1, Chuntian Cao1,2, Iwnetim I. Abate1,2 and Michael F. Toney1; 1SSRL Materials Science Division, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 2Department of Materials Science and Engineering, Stanford University, Stanford, California, United States.

The solid electrolyte interphase (SEI) is an interfacial layer formed on lithium ion battery (LiB) anode surfaces due to electrolyte decomposition at low potentials outside the electrolyte’s electrochemical stability window, and is a major source for capacity losses. Due to its electrically insulating and solvent diffusion prohibiting nature, its growth is in principle self-limiting. The ideal SEI can thus prevent further decomposition once formed, while allowing for ion conduction. However, in real systems, where electrodes experience volume and morphological changes, continued SEI growth renders LiB cyclability issues. Despite extensive research efforts to investigate the SEI, open questions still remain. These include the SEI formation processes, the SEI composition and thickness, as well as the structure-function relationship to the electrochemical cycling performance.

In a reductionist approach, we utilized simple and well-defined model systems to study SEI formation, growth, and evolution, in order to obtain an atomic scale fundamental understanding of the occurring processes. We have combined in situ x-ray reflectivity (XRR) and ex situ x-ray photoelectron spectroscopy (XPS) to probe the structure and chemistry of the SEI on two different substrates, i.e. oxide terminated crystalline silicon (Si) and pristine silicon carbide (SiC). We used various electrochemical cycling conditions, including galvanostatic, cyclic voltammetry and potential holds, for different electrolytes, such as lithium hexafluorophosphate (LiPF6) in ethylene carbonate (EC)/dimethyl carbonate (DMC). Our results of the thickness, density, roughness, porosity, and composition of the SEI show significant differences between Si and SiC. Specifically, the formation of lithium fluoride (LiF) is significantly suppressed by the presence of a surface oxide, which we attribute to its electrically insulating nature. We compare and contrast our results with recent studies of the electrocatalytic formation of LiF on metal surfaces [1]. Through combining these observations with our findings that the SEI on silicon contains low ion-conductivity lithium silicates, we hypothesize the native oxide is beneficial if a thin and smooth SEI layer is desired, but may be counterproductive if a fast ion-conduction SEI is desired.

Furthermore, we compared our XRR and XPS results with electrochemical data using a cone-cell, which eliminates parasitic currents, and were able to “count” each electron/Li-ion passed into the Si and SEI. Thus, we uniquely disentangled the Si lithiation and SEI contributions to electrochemical current measurements, yielding ultra-sensitive insights into SEI properties. This approach is even more sensitive when a non-active material such as SiC is utilized. [1] Strmcnik et al., Nature Catalysis 2018, 1, 255.

Investigating Molecular Structures at Interface Using Nanogap Surface-Enhanced Raman Spectroscopy Guang Yang1, Robert Sacci1, Ilia Ivanov2, Rose Ruther1, Kevin Hays3, Pengfei Cao2, Gabriel Veith1, Nancy J. Dudney1, Tomonori Saito2, Daniel Hallinan5 and Jagjit Nanda4; 1Materials Science and Technology Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Department of Materials Science and Engineering, Stanford University, Stanford, California, United States; 3Chemical & Biomedical Engineering Department, Florida State University, Tallahassee, Florida, United States.

Understanding the aprotic solution structures at the immediate vicinity of solid/liquid interface (SLI) is critically important for next generation lithium ion battery development. Yet, it is still challenging to investigate the carbonate profiles close to the diffuse layer (about 10 nm) at SLI due to the lack of a highly surface sensitive tool. In this work, we demonstrate the structures of commonly used carbonate solvents (ethylene carbonate (EC) and diethyl carbonate (DEC)) and a carbonate additive (fluoroethylene carbonate (FEC)) in a Li-ion battery electrolyte can be determined at ~17 nm above the electrode surface. This is only enabled by a nanogap surface-enhanced Raman spectroscopy (SERS) technique. SERS stems from the amplification of local electromagnetic (EM) field generated by localized surface plasmons. The local EM-field is extremely intense within metallic nanogap (~10 nm) due to the coupling effect among adjacent nanoparticles. We have developed methods to assemble gold nanoparticles (Au NPs) into large area (cm²) monolayers, which ensures the formation of long-range ordered nanogap arrays. The interparticle gap can be tuned between 1 and 4 nm by surface ligands of different sizes. The SERS enhancement factor (EF) of the carbones in this study was found to depend on the molecular polarizability, with the maximum EF at ~10⁵ found for EC and FEC. Compared to EC, several vibration modes in FEC, such as C=O skeletal deformation, ring breathing band and C=O stretching band, shift to higher frequencies because of the displacement of a hydrogen atom by a much heavier fluorine atom in a methylene bridge. This counterintuitive observation against the commonly used “ball and spring” model in vibrational spectroscopy is mostly due to the increased bond strength in the FEC ring versus that of EC. A second order empirical polynomial of a single indeterminate best describes the correlation between the SERS band and the corresponding mode in the neat solvent.

9:45 AM BREAK
Design of safe lithium ion batteries require innovations in advanced characterization of electrochemical reactions at nanoscale. Real time microscopy provides new opportunities to observe and monitor lithium ion storage mechanisms at unprecedented resolutions. We demonstrate the shortage and gaps in the field of lithium ion batteries that require advanced real time microscopy. In particular we show that in-situ transmission electron microscopy (TEM) is fundamental to discover mechanisms of ion conductivity, structural degradation and transformations, and other structural phenomena associate with the behavior of electrodes. Using liquid-cell TEM, we will show the charge and discharge mechanisms in lithium-air batteries depends on the contribution of electrical conductivity and ionic conductivity to allow Li2O2 decomposition. We also show that the oxygen release from oxide cathodes can trigger structural transformations that results in thermal runaway chain events. Using open-electrochemical cell TEM, we demonstrate lithium storage through conversion, intercalation, and alloying mechanisms.

Visualizing Intercalation Events in Ultrathin Graphite Electrodes
Madeline Stark, Hailey Kim, Judy Cheng and Scott C. Warren; University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, United States.

Near the atomic limit, layered materials such as graphite, transition metal dichalcogenides, and black phosphorous demonstrate enhanced transparency, conductivity, and storage capacity, making them attractive electrode materials for battery and optoelectronic applications. To develop sustainable energy storage devices, however, it is critical to understand electrode-electrolyte interactions. In particular, elucidating the mechanisms of intercalation, SEI formation, and ion transport are areas of active research. To explore these processes in-situ, we have developed a planar battery cell that enables us to visualize intercalation events during charge and discharge cycles. In this work, we focus on the electrochemical intercalation of bisulfate into ultrathin graphite as a model for aqueous intercalation. This compound is of interest, since it exhibits well-defined staging and can be reversibly cycled, paralleling battery technologies, but in an aqueous environment. Our work highlights the important factors to consider when designing an electrochemical cell for aqueous intercalation, specifically in a strongly oxidizing electrolyte, and describes a cell design that enables in-situ optical imaging of both bulk and ultrathin graphite. Qualitatively, we image the intercalation process under an optical microscope, and observe intercalation, deformation, and degradation of the material during cyclic voltammetry and galvanostatic cycling. By visualizing the process of intercalation in-situ, we can acquire and analyze complex image sequences to extract information about the rate of ion transport and diffusion in bulk and ultrathin graphite. To correlate optical images with charge transfer, we perform in-situ reflectance measurements as well as Raman spectroscopy at distinct locations in the bulk crystal and on individual graphite flakes. By coupling optical images with in-situ spectoscopic techniques, we gain insight into how intercalation events and charge transfer occur in a bulk crystal compared to a few-layer electrode. In addition, our observation of differences in color and charge transfer between bulk and ultrathin flakes of varying morphologies highlights the importance of understanding the factors that affect intercalation. The presence of edge sites and grain boundaries are of particular interest since they present a likely pathway to initiate intercalation. Defects within the layers can also lead to degradation and non-uniform charging of the material. However, the role that edges, grain boundaries, and defects play in the ion transport mechanism between the layers of ultrathin materials is not well understood. Thus, we can utilize transmission electron microscopy to study these features in individual graphite flakes prior to intercalation. Combining highly-resolved information about intrinsic defects with spatially-resolved dynamics through optical imaging would provide critical insight into the mechanism of intercalation in 2D electrodes.

Insertion and Conversion Based Electrochemical Energy Storage Systems—Complementary Insights from Ex Situ, In Situ and Operando Spectroscopy, Diffraction and Electrochemistry Studies
Amy C. Marschilok1, 2, Kenneth Takeuchi1 and Esther Takeuchi1; 1Stony Brook University, Stony Brook, New York, United States; 2Brookhaven National Laboratory, Upton, New York, United States.

Conceptually, there are two related electrochemical storage mechanisms for electrochemical energy storage materials: insertion where an ion inserts into a structure on reduction and then is removed from the structural lattice upon oxidation, and conversion where there is a chemical reaction leading to a new material or phase. For some materials, each of these mechanisms may participate at different stages of the electrochemical redox process, where the kinetics for ion and electron transport can play a deterministic role regarding which process dominates at a particular state of (de)charge. Complementary insights gained from ex situ, in situ, and operando spectroscopy, diffraction and electrochemistry studies will be highlighted in this presentation, emphasizing materials which undergo both insertion and conversion processes.

11:15 AM CM03.02.04
In Situ Investigation of Multi-Step Lithiation of Tin Sulfide
Sooyeon Hwang1, Zhenpeng Yao2, Lei Zhang1, Maosen Fu3, Kai He1, Liqiang Mai1, Christopher Wolverton1 and Dong Saj1; 1Brookhaven National Laboratory, Upton, New York, United States; 2Northwestern University, Evanston, Illinois, United States; 3Wuhan University of Technology, Wuhan, China; 4Northwestern Polytechnical University, Xi'an, China.

Materials adopting two-dimensional (2D) layered structure have been actively explored as electrode for lithium ion batteries since their unique crystal structures is beneficial for lithium ions to be intercalated between layers [1]. Metal chalcogenides which have 2D layered structure have demonstrated intriguing multi-step reaction with lithium ions; for example, it is known that lithiation of tin disulfide (SnS2) takes place via intercalation, conversion, and alloying[2]. As electrochemical properties are highly dependent on how these complicated reactions proceed, investigation of the reaction pathways in in situ analysis is of importance to improve the electrochemical properties of electrode materials. However, thorough understanding of each reaction mechanism of SnS2 is still missing and full scenario of lithiation dynamics remains elusive.

In this work, we examine the dynamic lithiation process of tin disulfide using in situ transmission electron microscopy (TEM) and first-principles calculations[3]. Structural evolutions induced by lithium insertion are reflected in diffraction peak shift, appearance and disappearance of peaks; thus, we could distinguish reaction steps by the modifications in diffraction profiles. We find 4 sequential steps of lithiation reaction: intercalation, disordering, conversion and alloying, which is different from well-known three stages. Disordering step is suggested for the first time. After Li ions are intercalated between S-S layer, rock-salt phase is formed by the disordering of Sn and Li cations. As all the octahedral sites are filled with cations in rock-salt phase, intercalation channel can be restricted. In order for further lithiation, decomposition of rock-salt phase may be inevitable, resulting in a conversion reaction. First principles calculations are conducted not only to elucidate the ground state reaction pathways but to validate the founding from experiments. Due to discrepancies between lithiation reactions at equilibrium state and empirical results, we simulate non-equilibrium reaction pathways using non-equilibrium phase searching method [4]. Calculation results corroborate that rearrangement of cations would not increase the energy of whole system and the formation of rock-salt phase is energetically more favorable than other Li-xSnS2 polymorphs, which is well-matched with real-time TEM observation.

When Lithium Travels in Solid-State Disorder for Novel Device Prototypes to Store Energy, Sense the Environment or Emulate Data

Jennifer L. Hynes, Level 3, Room 300

Next generation of energy storage and sensors may largely benefit from fast Li⁺ ceramic electrolyte conductors to allow for safe and efficient batteries and real-time monitoring anthropogenic CO₂. Recently, Li-solid state conductors based on Li-garnet structures received attention due to their fast transfer properties and safe operation over a wide temperature range. Through this presentation basic theory and history of Li-garnets will first be introduced and critically reflected towards new device opportunities demonstrating that these electrolytes may be the start of an era to not only store energy or sense the environment but also to emulate data and information based on simple electrochemistry device architectures.

In the first part we focus on the fundamental investigation of the electro-chemo-mechanic characteristics and design of disordered to crystallizing Li-garnet electrode architectures with advantages in energy density, scalability, electrode architecture complexity and cost as alternatives to the state-of-the-art high-rate anode materials Li₄Ti₅O₁₂.

The maximum power output and minimum charging time of a lithium-ion battery – key parameters for its use in, for example, transportation applications – depend on structural conductivity. As well, how the discharge/charge rate and capacity can be tuned by varying the composite electrode structure, ionic transport within the active particles represents a fundamental limitation. Thus, to achieve high rates, particles are frequently reduced to nanosize dimensions despite this being disadvantageous in terms of volumetric packing density as well as cost, stability, and sustainability considerations. As an alternative to nanoscaling, we show that complex niobium tungsten oxides with topologically frustrated polyhedral arrangements and dense nm-scale particle morphologies can rapidly and reversibly intercalate large quantities of lithium.

Multielectrode redox, buffered volume expansion, and extremely fast lithium transport approaching that of a liquid lead to extremely high volumetric capacities and rate performance as very recently reported in both the literature and presented at this conference. As a complement, we have now performed high-resolution structural and operando spectroscopy to provide detailed insight into the chemical and physical evolution of SnO₂ nanocrystalline hollow nanoparticle clusters in a battery to elucidate the mechanisms of lithium storage.

Characterisation of these phenomena and complex material evolution will be presented with structural and chemical insights from operando X-ray diffraction and multi-edge X-ray absorption spectroscopy as well as neutron diffraction and nuclear magnetic resonance spectroscopy. The direct measurement of solid-state lithium diffusion coefficients (D₃Li) with pulsed field gradient NMR demonstrates room temperature D₃Li values of 10⁻¹²–10⁻¹¹ m²·s⁻¹ in the niobium tungsten oxides, which is several orders-of-magnitude faster than typical electrode materials and corresponds to a characteristic diffusion length of ~10 μm for a 1 minute discharge. Materials and mechanisms that enable lithium ion transport in minutes have implications for high power applications, fast charging devices, all-solid-state batteries, and general approaches to electrode design and material discovery.

X-Ray Tomography Studies of Ceramic Solid Electrolytes for Solid-State Battery Applications

Munekazu Motoyama, Takayuki Yamanoto and Yasutoshi Iriyama; Nagoya University, Nagoya, Japan.

All solid-state batteries are promising solutions for high energy density storage devices. Absence of volatile liquid elements in the system mitigates the safety hazards encountered in conventional batteries. Ceramic electrolytes have showcased outstanding ionic conductivities and high shear modulus, however have stability and processing challenges still exist. While theoretical studies suggested that solid electrolytes with shear moduli greater than 8.5 GPa can mitigate Li dendrite formation, recent experiments have shown contradictory results. So far, the studies to understand the failure mechanism in ceramic electrolytes have been primarily surface based ex-situ characterization/imaging techniques. Toward the goal of understanding processing-structure relationships for practical design of solid electrolytes, the present study tracks structural transformations in solid electrolytes processed at three different temperatures (1050, 1100, and 1150 °C) using synchrotron X-ray tomography. A subvolume of 300 μm3 captures the heterogeneity of the solid electrolyte microstructure while minimizing the computational intensity associated with 3D reconstructions. While the porosity decreases with increasing temperature, the underlying connectivity of the pore region increases. Solid electrolytes with interconnected pores short circuit at lower critical current densities than samples with less connected pores. These insights provide insight into the importance of microstructure on device performance.

Multi-Modal Characterization of Li10GeP2S12 Solid Electrolyte Stability in Solid-State Lithium Metal Batteries

Andrew L. Davis1, Kevin N. Wood2, Regina Garcia-Mendez2, Kuan-Hung Chen3, Eric Kazyk4, Jeff Sakamoto5, Glenn Teeter2 and Neil P. Dasgupta1;1 Mechanical Engineering, University of Michigan, Ann Arbor, Michigan, United States; 2 National Renewable Energy Laboratory, Golden, Colorado, United States; 3 Materials Science and Engineering, University of Michigan, Ann Arbor, Michigan, United States.

Solid-state batteries based on ultra-high ionic conductivity solid electrolytes are a promising technology to increase battery lifetime and capacity, and reduce safety concerns associated with usage of a flammable liquid electrolyte. In recent years, sulfide solid electrolytes such as Li10GeP2S12 (LGPS) have achieved ionic conductivities comparable to or higher than that of traditional liquid electrolytes. Despite these promising breakthroughs, viable high capacity and high energy density sulfide solid-state batteries have proved elusive. The small electrochemical stability window of sulfide electrolyte materials leads to undesirable reactions at the electrode/electrolyte interface against both high voltage cathode materials and Li metal anodes. This forms a solid electrolyte interphase (SEI), which dramatically degrades battery performance. To gain a deeper fundamental understanding of the dynamic evolution of the SEI, as well as its spatially varying composition and phase, the LGPS-Li metal interface was characterized by electrochemical measurements, operando X-ray photoelectron spectroscopy (XPS), in-situ auger spectroscopy, scanning electron microscopy (SEM), and optical microscopy. This allowed for quantitative evaluation of time dependent degradation of the interface, which occurs due to the evolution of a variety of decomposition by-products. Operando XPS was used to correlate distinct decomposition products with corresponding increases in overpotential. In-situ Auger, SEM and optical Mapping of the surface shows spatial inhomogeneities leading to preferential lithium plating and corresponding Li10GeP2S12 breakdown. By performing complementary electrochemical measurements of bulk solid-state batteries employing Li metal, electrochemical signatures associated with interfacial degradation can be identified. Using these techniques and the new mechanistic insights gained, rational interfacial design strategies are identified that can provide a pathway to limit interfacial instability and improve battery performance.

In Situ Scanning Electron Microscope Observations of Li Plating/Stripping Reactions on Oxide Solid Electrolytes

Munekazu Motoyama, Takayuki Yamanoto and Yasutoshi Iriyama; Nagoya University, Nagoya, Japan.

The theoretical capacity of Li metal anode (3860 mAh g−1) is more than ten times greater than those of other practical anodes such as graphite and LiTiO2 for lithium ion battery. However, Li dendrites cause short-circuit in liquid electrolytes during cycles of Li plating/stripping. On the other hand, since inorganic solid electrolytes (e.g. Li2Zr2O7) have been expected to prevent dendrite growth, all-solid-state-lithium battery (SSLB) has been regarded to innovate battery technology and enable the use of Li metal anode. Hence, it is important to obtain the fundamental understanding of Li plating/striping processes on solid-state electrolytes. We have studied the Li plating/stripping reactions with lithium phosphorous oxyxinitride (LiPON) glass electrolyte and Li4La2Zr2Ta2O12 (LLZ(Ta0.4)) coated with thin current collector (CC) films of Cu, Ni, W, and Pt. The Li nucleation sites are supposed to exist at solid/solid interfaces in “lithium-free”-thin-film SSLB [2]. Hence, the nuclei must push either electrode or electrolyte to create their own spaces. This process is associated with generation of significant strain energies. This study applies an in-situ scanning-electron microscope (SEM) observation technique to the investigation on the Li nucleation/growth and dissolution processes with various CC films (Cu, Ni, W, Pt, Au). Cu, Ni, and W are unable to form specific alloy phases with Li and Au form alloy phases with Li. The top and bottom surfaces of a Li4La2Zr2Ta2O12 sheet (Ohara Co.) were coated with 2.5-μm-thick LiPON layers by RF magnetron sputtering. Additionally, a LLZ(Ta0.4) plate (Toshiba Manufacturing Co. Ltd.) with a thickness of 0.5 mm was used as an electrolyte [3]. A current collector film (i.e. Cu, Ni, W, Pt, Au) was deposited on the top LiPON surface and LLZ(Ta0.4) surface by pulsed laser deposition (PLD). A Li film with a thickness of 2 to 3 μm was deposited within an area of 9.0 mm in diameter on the other side of a cell as the counter electrode by vacuum evaporation. The results of dynamic observations of Li plating/stripping and Li alloying/dealloying on LiPON and LLZ(Ta0.4) coated with thin metal CC films via an in-situ SEM technique will be discussed.

The authors gratefully acknowledge JSPS 17H04894 and ALCA-SPRING for the financial supports.

Multimodal X-Ray Characterization of Operating Electrochemical Energy Storage Systems

Johanna N. Weker; SLAC National Accelerator Lab, Menlo Park, California, United States.

The shift from fossil fuels toward clean, renewable energy will require significant improvements in rechargeable battery technology for electric vehicles. Current battery technology limits electric vehicles to a short travel range, slow recharge, and costly price tag. Li-ion batteries promise the high specific capacity required to replace the internal combustion engine with a number of possible earth abundant electrode materials; however, setbacks such as capacity fading hinder the full capability of these rechargeable batteries. In the search for better electrode materials, multimodal X-ray characterization spanning many relevant length scales during typical battery operation is vital in understanding and overcoming the failure mechanisms of these materials. We will discuss our multimodal approach combining information from high resolution X-ray microscopy and spectra-microscopy, micro- and nano-tomography, X-ray diffraction, and X-ray absorption spectroscopy to track electrochemical, morphological, and structural changes in the electrode material in real time during typical battery operation.

Revealing Nanoscale Passivation and Corrosion Mechanisms of Reactive Battery Materials in Gas Environments

Yuzhang Li and Yi Cui; Stanford University, Stanford, California, United States.

Lithium (Li) metal is a high-capacity anode material (3,860 mAh g⁻¹) that can enable battery chemistries beyond Li-ion. However, Li metal is highly reactive and repeatedly consumed when exposed to liquid electrolyte (during battery operation) or the ambient environment (throughout battery manufacturing). Studying these corrosion reactions on the nanoscale is especially difficult due to the high chemical reactivity of both Li metal and its surface corrosion films. Here, we directly generate pure Li metal inside an environmental transmission electron microscope (TEM), revealing the nanoscale passivation and corrosion process of Li metal in oxygen (O₂), nitrogen (N₂), and water vapor (H₂O). We find that while dry O₂ and N₂(99.9999 vol%) form uniform passivation layers on Li, trace water vapor (~1 vol%) disrupts this passivation and forms a porous film on Li metal that allows gas to penetrate and continuously react with Li. To exploit the self-passivating behavior of Li in dry conditions, we introduce a simple dry-N₂ pretreatment of Li metal to form a protective layer of Li nitride prior to battery assembly. The fast ionic conductivity and stable interface of Li nitride results in improved battery performance with dendrite-free cycling and low voltage hysteresis. Our work reveals the detailed process of Li metal passivation/corrosion and demonstrates how this mechanistic insight can guide engineering solutions for Li metal batteries.

Operando Characterization of Lithium Metal Plating and Stripping Using Grazing Incidence Small Angle X-Ray Scattering

Robert M. Kasse¹,², Natalie R. Geise³, Hans-Georg Steinrueck² and Michael F. Toney³; Materials Science and Engineering, Stanford University, Stanford, California, United States; ²Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, California, United States; ³Chemistry, Stanford University, Stanford, California, United States.

Emerging technologies such as electric vehicles, which rely on high energy density batteries, necessitate the development of advanced materials to replace those currently being used in traditional lithium ion devices. Anodes employing lithium metal are the most promising given their high specific capacity (3,860 mAh/g) and low electrochemical potential (~3.04 V vs SHE). However, lithium metal is highly unstable with large irreversible capacity losses occurring during plating and stripping due to electrolyte decomposition and formation of electrochemically inactive ‘dead’ lithium. To allow for the intelligent design of lithium protection strategies, a fundamental understanding of the plating and stripping behavior is needed, particularly during the first cycle.

These dynamic processes occurring during battery operation require operando characterization. Thus, we have performed grazing incidence small angle X-ray scattering (GISAXS) during the lithium plating and stripping process in order to probe the morphology of plated lithium. Investigating the surface of a copper film in an operating lithium-copper cell, we are able to determine the lithium metal growth mechanism and particle growth rates as a function of relevant battery parameters including electrolyte composition and cycling protocol. The nucleation and growth mechanism is very sensitive to electrolyte impurities and cycling protocol, due to the different solid electrolyte interphase (SEI) formed on the copper surface under different conditions. Fluorine-containing SEI components formed at high potentials due to impurity decomposition create a more uniform current distribution leading to monodisperse columnar growth of Li metal, compared to nonuniform deposition in a baseline electrolyte. A fundamental understanding of the effect of such parameters on lithium plating can be used to engineer high energy density batteries with enhanced safety and cycle life.

Multiscale Modeling and In Situ Visualization Analyses of Electrodeposition in Nanostructured Electrolytes

Snehashis Choudhury and Lynden Archer; Cornell University, Ithaca, New York, United States.

Electrochemical cells based on alkali metal (Li, Na) anodes have attracted significant recent attention because of their promise for producing large increases in gravimetric energy density for energy storage in batteries. To facilitate stable, long-term operation of such cells a variety of structured electrolytes have been designed in different physical forms, ranging from soft polymer gels to hard ceramics, including nanoporous versions of these ceramics that host a liquid or molten polymer in their pores. In almost every case, the electrolytes are reported to be substantially more effective than anticipated by early theories in improving uniformity of deposition and lifetime of the metal anode. These observations have been speculated to reflect the effect of electrolyte structure in regulating ion transport to the metal electrolyte interface, thereby stabilizing metal electrodeposition processes at the anode. In this work, we create and study model structured electrolytes composed of covalently linked polymer grafted nanoparticles that host a liquid electrolyte in the pores. The electrolytes exist as freestanding membranes with effective pore size that can be systematically manipulated through straightforward control of the volume fraction of the nanoparticles. By means of physical analysis and direct visualization experiments using advanced optical microscopy, we
report that at current densities approaching the diffusion limit, there is a clear transition from unstable to stable electrodeposition at Li metal electrodes in membranes with average pore sizes below 500 nm. We show that this transition is consistent with expectations from a recent theoretical analysis that takes into account local coupling between stress and ion transport at metal-electrolyte interfaces.

Coupling Operando Techniques for Unravelling the Electrochemical and Structural Mechanism of High-Performance Lithiated Nitrides as Negative Electrode Material for Li-Ion Batteries Nicolas Emery and Jean-Pierre Pereira-Ramos; ICMPE-GESMAT UMR 7182, Thiais, France.

Comprehension of redox processes and their influence on structural properties of electrode materials is a key point to improve Li-ion batteries efficiency. The rise of operando techniques leads to a better insight into these reactions due to the real-time observation of the process. In this work, we will mainly develop two examples of lithiated transition metal nitrides studies where different operando techniques were combined. Our group has clearly demonstrated layered lithiated metal nitrides can be considered as genuine Li intercalation compounds and possible negative electrode materials for Li-ion batteries [1-2]. In particular attractive properties for optimized Co and Ni contents in the Li-M-N system were proved with for instance Li$_2$Ni$_{0.5}$N exhibiting a specific capacity of 200 mAh g$^{-1}$ and an excellent cycle life. After a precise determination of the chemical composition using NRA technique, its structural mechanism under operation was studied and solved using operando XRD upon successive discharge-charge cycles [2]. A solid-solution behaviour is shown with a very limited volume variation, less than 1% which well explains electrochemical features. A superstructure is mandatory to clearly describe the operando XRD data set recorded here. Indeed, the presence of vacancies in the Li$_2$N planes allows a slight displacement of interlayered nickel ions cell inducing a negligible swelling process of the host lattice in line with a remarkable cycle life. With a specific capacity of 280 mAh g$^{-1}$ at C rate available around 1.2 V vs Li$^+$/Li, a 3D Li$_7$MnN$_4$ has been proved to be a credible alternative to LiTi$_2$O$_4$ for moderate to high power applications. The redox-mechanism and structural response upon a full electrochemical oxidation/reduction cycle have been studied using XAS and XRD in-situ operando techniques. The charge curve composed of two successive plateaus and a continuous potential increase, is well explained by two dihedral domains and a solid-solution behaviour [3]. After a MCR-ALS analysis of the Mn K-edge absorption spectra data set, three different environments related to three different Mn oxidation states involved in redox processes were isolated [4]. Using the simple concept of coordination charges and comparison with available data for appropriate reference oxides, the oxidation states of each environment were ascribed and fully explained the achieved specific capacity. By combining these two methods, a comprehensive scenario has been proposed to explain the attractive electrochemical performances of Li$_x$MnN$_4$ with the role of Mn $^{5+}$, Mn $^{6+}$ and Mn$^{7+}$ ions here stabilized by the nitride framework.

Correlative Imaging of Electrochemical Devices Over Multiple Time and Length Scales Paul Shearing; University College London, London, United Kingdom.

Electrochemical device is a term used to describe a group of technologies including fuel cells, batteries, electrolyser and super-capacitors. Whilst many of these technologies are already in common daily usage, for example Li-ion batteries that power our mobile phones, in the future electrochemical devices will play an increasing role in our lives – from fuel cells that can power our homes to high performance batteries for our cars.

At a microscopic length scale, these devices can be considered as one of a general class of porous materials, whereby the physical microstructure will influence a range of phenomena, including diffusion, catalysis and conductivity – our ability to engineer these microscopic features to maximize performance can be translated to substantial improvements in macroscopic device design. At macroscopic length scales the robustness of device design will influence the system energy and power density and its ability to safely store/convert energy over extended periods of time.

As these materials are likely to evolve over time, in response to range of processing and environmental conditions (sintering, corrosion, failure etc); understanding how these changes in microstructure can be linked to understanding of degradation and failure is pivotal to improving device lifetime and safety.

Over the past 10 years the increasingly widespread use of X-ray imaging and tomography has revolutionized our understanding of these materials; with increasing sophistication researchers have been able to characterize samples over multiple time and length scales from nm to mm and from ms to days. Here we consider examples of our work to explore these materials in three and “four” dimensions, to examine materials evolution with time. We will explore case studies that utilize both laboratory and synchrotron X-ray sources across a range of spatial and temporal domains, and examine how improvements in these imaging techniques, alongside correlative spectroscopy, is providing unprecedented insight into these materials and devices.

8:45 AM CM03.05.02

Monitoring Capacity Losses Through Operando X-Ray Diffraction in Lithium Metal Anodes Natalie R. Geise$^1$, Robert M. Kasse$^2$, Hans-Georg Steinrueck$^2$ and Michael F. Toney$^2$; Chemistry, Stanford University, Stanford, California, United States; $^2$Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, California, United States; $^3$Materials Science, Stanford University, Stanford, California, United States.

The rise of electrochemical devices has been propelled by the extraordinary properties of Li-ion batteries which have revolutionized our daily lives. However, the limited voltage capability and high cost of current anode materials, such as graphite, has informed research in lithium metal batteries (Li-MBs). In these devices, lithiation involves nucleation and growth of a reduction product at the metal-electrolyte interface. Here, we present operando X-ray diffraction (XRD) and X-ray absorption spectroscopy (XAS) techniques for elucidating the structural and chemical evolution of lithium metal anodes in Li-MBs.
Li-metal is a promising, high-capacity anode that can be incorporated into Li-ion, Li-S, and Li-air battery systems to meet the need for energy-dense batteries. Coulombic efficiency losses remain a major challenge to adoption and commercialization. These losses are driven mainly by loss of lithium to the solid electrolyte interphase (SEI) and into metallic lithium deposits that become electrically disconnected ('dead' Li) due to complex morphological changes. While protection methods, such as coatings and electrolyte additives, have yielded improved efficiencies, fundamentally understanding how these improvements are realized will allow for optimization of their design.

Here, we have developed a method of monitoring lithium metal in the anode through plating and stripping cycles via operando X-ray diffraction (XRD). We obtain quantitative results on the reversible lithium metal, dead lithium development and evolution with cycling, and lithium corrosion. Our results show the lithium metal efficiency, measured through XRD, is higher than the electrochemical Coulombic efficiency measurements. Additionally, the contribution of ‘dead’ lithium to the overall Coulombic efficiency varies much more across electrolytes and cycling conditions than the SEI does. This new experimental methodology and the understanding on the origins of capacity loss in lithium metal anodes which it enables will lead to better-designed protection layers and electrolytes which improve anode performance.

9:00 AM CM03.05.03
Plan-View Operando Video Microscopy of Li Metal Anodes Adrian J. Sanchez, Kuan-Hung Chen, Eric Kazyak and Neil P. Dasgupta; University of Michigan Ann Arbor, Ann Arbor, Michigan, United States.

Improving the safety and performance of Li metal anodes is key to enabling next generation batteries such as Li-Air and Li-Sulfur. However, the mechanisms governing poor performance of Li metal anodes are not fully understood, which hinders our ability to characterize, diagnose, and rationally design solutions to problems including dendrite growth and low Coulombic efficiency. In situ and operando analyses are well suited to study the mechanisms of battery degradation, as they avoid any sample alteration due to the disassembly of a cell.

Herein, we present a multifunctional operando visualization platform that synchronizes optical recordings with cycling electrochemistry. This platform was initially used to understand the origins of the “peaking” behavior exhibited in the voltage traces of Li symmetric cells [1]. However, by limiting the viewing angle to a cross sectional perspective, the impact of electrode surface variations, including microstructure, flaws, and chemical inhomogeneities cannot be fully accounted for. To address this, in this study, a plan view optical visualization cell was designed that maintains a highly uniform current distribution along the electrode surface and avoids mechanical deformation of the electrode. This enables correlation of dendrite nucleation location to surface features. Dendrite nucleation and pitting nucleation density are quantified as a function of current density on a Li metal surface. Additionally, the impact of pitting on the performance of a Li metal anode is directly observed. The impact of surface modifications on Li plating, including protective coatings and mechanical deformation, are also quantified. Finally, the knowledge generated on the coupled morphological and electrochemical behavior of Li metal deposition will be discussed as a potential pathway to develop battery failure diagnostics.

9:15 AM CM03.05.04
In Situ/Operando Grazing Incidence Small Angle X-Ray Scattering of Model Oxide Nanostructures for Li-Ion Battery Conversion Electrodes Jae Jin Kim1, Byeongdha Lee1, Chun Zhou2, Hyo Seon Suh2, Anil Mane1, Jeffrey Elam2, Paul Nealey2, Paul Fenter2 and Tim Fister2; 1Argonne National Laboratory, Lemont, Illinois, United States; 2The University of Chicago, Chicago, Illinois, United States.

Conversion reactions in Li ion batteries, such as the electrochemically-driven phase separation of a transition metal oxide into metal nanoparticles and lithium oxide species, are well-known to have specific capacities far beyond typical intercalation materials. However, these types of reactions invariably suffer from irreversibility and hysteresis due to their substantial volume change and kinetic barriers. Oxides also tend to have substantially lower redox potentials than thermodynamically expected values, limiting their practical use. Given the complex network of metal-rich and lithia domains evolved during lithiation, interfacial processes must play a critical role in the nucleation of the overall conversion reaction and charge/mass transport. In contrast to the complex network of nanoparticle that form during lithiation, we have studied electrode surfaces with periodic tungsten oxide waves, whose dimensions can be tuned to test the mechanical and kinetic properties of conversion reactions. Our fabrication approach uses the selective growth of ALD on block copolymers, in this case producing arrays of oxide nano-cylinders or their inverse, a film with periodic hole patterns. These electrodes are well-suited for grazing incidence small angle X-ray scattering (GISAXS), which can be used to assess the size, density, and spacing of the electrodes during the reaction. Using operando GISAXS, we find that nanoscale (50 – 80 nm) oxides undergo conversion reactions at 1.4 – 1.7 V, which is close to the theoretical value (1.65 V) and well above the discharge plateau of 0.8 – 0.9 V for micron-sized bulk powders. Insights from this study can bring a new perspective on enhancing the energy density and reversibility of conversion reactions and provide strategies for improving their overall performance.

9:30 AM CM03.05.05
Reaction with Larger Ions Avoids Fracture in a Conversion Battery Material—In Situ TEM Investigation Matthew G. Booher1, 2, Baolin Wang1, 2, 3, Marc Papakyriakou1, 4, Shuman Xia1, 3, Ting Zhu1, 2, 3 and Matthew McDowell1, 2, 3; 1Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 3The George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Demand for cheap energy storage systems has led to growing interest in the development of sodium- and potassium-ion battery systems. Conversion and alloying-type electrode materials with high specific capacity are attractive options for these batteries, but the larger volumetric expansion during reaction with sodium and potassium compared to lithium is thought to limit cycle life. The nanoscale reaction mechanisms of many electrode materials with Na+ and K+ ions are unknown, however, and they must be investigated to understand how to engineer Na and K-battery materials to undergo minimal mechanical damage due to volume changes. In this study, in situ transmission electron microscopy (TEM) experiments are used to examine the nanoscale transformations of cube-shaped FeS2 nanocrystal electrode materials as they undergo reaction with Li+, Na+, and K+. Although the FeS2 nanocrystals underwent a conversion-type reaction via a two-phase mechanism with a sharp reaction front in all cases, fracture was only observed to occur during lithiation, despite the larger volumetric changes associated with sodiation and potassiation. This difference was ascribed to dissimilar shapes of the two-phase reaction fronts during the reaction processes. Specifically, reaction fronts during lithiation were found to retain rectangular shapes with sharp corners, while sodiation and potassiation caused the reaction front to take an oval shape with blunted corners. Chemomechanical modeling of stress evolution during reaction showed that the differences in the evolution of the shape of the two-phase reaction front led to higher tensile stress concentrations and particle fracture during lithiation. The results indicate that even though larger volumetric expansions take place in Na- and K-ion battery materials, these volume changes may be managed through understanding and control of nanoscale reaction mechanisms and do not necessarily cause failure of individual particles.

9:45 AM BREAK
Designing advanced battery interfaces requires visualizing ionic, electronic, and redox pathways that indicate how local surface activation and site-specific differential reactivity impact ion-intercalation and interfacial evolution with cycling. This presentation will discuss new in-situ analytical tools based on the scanning electrochemical microscope (SECM) that incorporate functions for imaging surface redox reactivity, spectroelectrochemistry, and ionic transfer reactions for species such as Li⁺, Na⁺ and K⁺ at interfacial and bulk nanostructures in non-aqueous electrolytes.

In ionic measurements, the principle is based on SECM probes that integrate mercury micro- and nano-cap electrodes on which alkaline ions can be detected by means of fast-scan anodic stripping voltammetry. The probe potential provided chemical specificity while the probe current enables the measurement of ionic fluxes with excellent stability and linearity. We will demonstrate how these probes were used for the measurement of ion insertion sites on graphene, graphite, and silicon nanostructures. When combined with redox modes using the SECM (e.g. feedback), these probes provide a comprehensive view of how interfacial processes impact charge transfer across operating interfaces.

Complementing these powerful measurements, we will discuss how the combination of SECM with Raman spectroscopy via colocalized and simultaneous measurements of operating electrodes enables real-time correlation of electrochemical and structural information. We will show how our system is used for simultaneous imaging and time-resolved experiments of interfaces of interest for energy storage, such as redox polymers and graphene with a resolution of ~1 micron, sub-second resolution, and high signal to noise ratio. We hope our techniques will contribute to a new understanding of interfacial processes on battery structures, allowing the measurement of ionic reactivity, and elucidating the impact of interfacial processes on single reacting sites. SECM mapping reveals aspects of surface reactivity that are lost during averaging in conventional battery testing.

Cryo-Electron Microscopy for Battery Materials Yanbin Li and Yi Cui; Stanford University, Stanford, California, United States.

Cryo-electron microscopy (cryo-EM) received the 2017 Nobel Prize in Chemistry for its ability to elucidate the nanostructure of biomolecules in their native state, revolutionizing the field of structural biology. Here, we pioneer an approach to utilize this powerful technique to enable new discoveries for batteries. (Y. Li*, Y. Cui, et al. Science 2017, DOI: 10.1126/science.aam6014) and show that cryo-EM can potentially have a similar impact in materials science.

Whereas conventional transmission electron microscopy (TEM) studies are unable to preserve the native state of chemically-reactive and beam-sensitive battery materials (e.g. Li metal) after operation, such materials remain pristine at cryogenic conditions. It is then possible to atomically resolve individual Li metal atoms and their interface with the solid electrolyte interphase (SEI). We observe that dendrites in carbonate-based electrolytes grow along the <111> (preferred), <110>, or <211> directions as faceted, single-crystalline nanowires. These growth directions can change at kinks with no observable crystallographic defect. Furthermore, we reveal distinct SEI nanostructures formed in different electrolytes that explain why certain additives lead to better performance. With cryo-EM, we open up exciting new opportunities for scientific discovery, which will be critical for providing fundamental insight to battery materials design.

Electrochemical Interfacial Properties Revealed by Synergistically Combining Ambient Pressure XPS with Theory Ethan J. Crumlin1,2; Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3CESR, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Interfaces play an essential role in nearly all aspects of life and are critical for electrochemistry. Electrochemical systems ranging from high-temperature solid oxide fuel cells (SOFC) to batteries to capacitors have a wide range of important interfaces between solids, liquids, and gases which play a pivotal
role in how energy is stored, transferred, and/or converted. This talk will focus on our use of ambient pressure XPS (APXPS) to directly probe the solid/gas and solid/liquid electrochemical interface. In particular, I will discuss how we synergistically combine this powerful experimental technique with DFT theoretical insight to reveal a mechanistic understanding of electrochemical interfaces. I will highlight some of our recent investigations into CO2 adsorption phenomena on various metals. In situ APXPS and DFT together provide a comprehensive understanding of the initial adsorption processes and how oxygen and water transform CO2’s adsorption behavior. Additionally, I will highlight how theory/modeling has enhanced our knowledge of in situ/operando solid/liquid APXPS investigations including electrochemically promoted dissolution and the interaction of a magnesium electrode in a non-aqueous electrolyte. Information gained from these studies will aid in the guided design and control of future electrochemical interfaces.

11:30 AM CM03.06.04
Illuminating the Oxygen Cathode Interface of the Non-Aqueous Metal Oxygen Battery Iain Aldous and Laurence Hardwick; Univ of Liverpool, Liverpool, United Kingdom.

Improving energy storage, beyond Li-ion batteries, is an important opportunity to provide solutions for varying applications. A family of emerging battery chemistries are non-aqueous metal oxygen cells. Ideally, the cathodic reactant (oxygen) is provided from the atmosphere and electrochemically reduced in the presence of alkali metal cations to form reduced oxygen species (ROS) such as peroxides and superoxides. On charge, the formed ROS are then electrooxidised and the oxygen returned to the atmosphere and alkali metal cations reduced at the alkali metal anode to form alkali metal (Li, Na, K and Ca). Combining electrochemistry and spectroscopy has provided an understanding of how to control this mechanism through the solvation of O2, LiO2, NaO2, and CaO2. This is achieved via the manipulation of the local chemical environment of these species within the electrolyte. Additives such as water and organic redox mediators can be used to great effect in increasing capacity, rechargeability and decreasing the over potential of the system.

This talk will focus on the group’s research and findings on how to manipulate the direction of the oxygen reduction reaction in non-aqueous metal-oxygen batteries. Using in situ/in situ surface enhanced Raman spectroscopy and UV/Vis spectroscopy to characterise the electrochemical reactions occurring at the cathode interface demonstrates the group’s findings. Discussion will touch upon how oxygen electrochemistry relates to the electrode substrate and as well as the use of electrolyte additives.

Electrofied Solid/Liquid Interface Studied by Nanoelectrical and Nanoelectrochemical Atomic Force Microscopy Zhuangqun Huang1, Peter De Wolf1, Antoine Dujardin1, 2, Bede Pittenger1 and Thomas Mueller1; 1Bruker Nano Surfaces, Goleta, California, United States; 2Cellular Microbiology and Physics of Infection Group, Lille Centre for Infection and Immunity, CNRS UMR8204, INSERM U1019, Lille Regional Hospital University Centre, University of Lille, Institut Pasteur de Lille, Lille, France.

Atomic force microscopy (AFM) has been adopted for in situ and in operando electrical and electrochemical (EC) studies with nanometer resolution at electrofied solid-liquid electroactive interfaces. Recent developments include PeakForce EC-AFM for topographic and nanomechanical imaging during EC reactions on the surfaces of Li ion battery anodes,1,2 and PeakForce scanning electrochemical microscopy (SECM) for the simultaneous acquisition of local EC and conductivity information at electrified solid/liquid interfaces of nanoparticle-catalysed photoelectrodes for water splitting.2–3 In this work, we introduce these recently-developed techniques with a variety of examples in energy, biological, and semiconductor applications.

We have also developed DataCube SECM to provide highly-dimensional, big-data results allowing us to perform in-depth data mining for improved theoretical insight to reveal a mechanistic understanding of electrochemical interfaces. This talk will focus on our use of ambient pressure XPS (APXPS) to directly probe the solid/gas and solid/liquid electrochemical interface. In particular, I will discuss how we synergistically combine this powerful experimental technique with DFT theoretical insight to reveal a mechanistic understanding of electrochemical interfaces. I will highlight some of our recent investigations into CO2 adsorption phenomena on various metals. Solar-to-fuel technology promises to play a key role in realizing a carbon-neutral future by enabling renewable fuel processing for capacity-independent storage beyond current battery technologies [1]. Metal oxide catalysts enable the two-step thermochemical cycle by catalyzing the reduction of H₂O and CO₂ to produce H₂ and CO. Currently, ceria is the reference material due to its rapid kinetics, crystallographic stability, and abundance [1]. To address the low fuel production of ceria, doping with tetravalent cations and co-doping with 3+/5+ combinations are used to enhance oxygen release and thus increase maximum fuel yield [2]. However, the reaction mechanisms and kinetics of oxygen vacancy formation in doped-ceria are still unclear, and this understanding will be crucial to developing improved redox materials that will make solar-to-fuel technology economically viable.

This novel investigation utilizes in situ Raman spectroscopy under redox cycling schemes to illuminate the reaction mechanisms of oxygen vacancy formation and annihilation in 10mol% doped ceria solid solutions of the composition Ce₀.₉(Me)₀.₁O₂ with Me= La, Zr, Hf, Nb and in co-doped Ce₀.₉(Me)₀.₁O₂(NO)₀.₅O₂. In-situ Raman spectroscopy was utilized to study the chemical reduction of doped-ceria materials under H₂ atmosphere up to 900 °C and the redox cycling under alternating reducing H₂ and oxidizing CO₂ atmospheres at a constant temperature of 800 °C.

Results revealed that the peak corresponding to the triply degenerate F₂g stretching mode of the cation and oxygen ions in the cubic fluorite structure of ceria shifts to lower frequencies and decreases in intensity during reduction; these changes correspond to chemical expansion with the reduction of the cation and an increase in the oxygen vacancy concentration. Additional vacancy bands also appear at different positions depending on the dopant choice and indicate how each dopant cation facilitates the formation of oxygen vacancies.

Raman spectroscopy confirms that catalytic oxygen vacancy concentration determines the fuel yield of this process: samples with the highest fuel yield also had the largest shift of the peak corresponding to the triply degenerate F₂g when heated, suggesting the highest oxygen vacancy concentration and thus the highest oxygen storage capacity. This model experiment not only provides crucial preliminary results for understanding the mechanisms of oxygen vacancy formation in doped ceria catalysts but also provides an experimental template for future investigation of reaction mechanisms of other electrochemical materials. By utilizing Raman spectroscopy to understand the redox mechanisms of various materials, as was done in this experiment, materials scientists can optimize doping to engineer the redox performance of materials for a variety of applications.

In this work, we elucidate the influence of chemical interactions of adsorbed oxygen and water on charge transport and interfacial charge transfer of flat band potential and the charge carrier concentration. The highest photocurrent was found for distinguished concentrations of the iron group metal, demonstrating that this combinatorial approach is very useful in the search for high performance water splitting photoelectrodes.

In this context, improved understanding of these complex surface interactions will aid the development of highly efficient light absorbers as well as the integration of effective passivation and catalyst layers for these materials.

Photoelectrochemical (PEC) water splitting is a promising approach to provide carbon neutral power and renewable fuels. The chemical transformation of water into oxygen and hydrogen takes place at the surface of catalysts and photoactive materials. Consequently, the activity, efficiency, and reaction pathway are critically controlled by the material surface properties. Under PEC operating conditions, surface properties strongly depend on the surrounding environment, and they may be altered in the course of the reaction. Thereby, absorption of molecules can modify the chemistry at the surface, for example by influencing the kinetics of reactants, products, or reaction intermediates, but they can also directly impact the electronic transport properties of the photoactive material by effectively acting as surface trap states. In this context, improved understanding of these complex surface interactions will aid the development of highly efficient light absorbers as well as the integration of effective passivation and catalyst layers for these materials.

In this work, we elucidate the influence of chemical interactions of adsorbed oxygen and water on charge transport and interfacial charge transfer of photogenerated charge carriers in polycrystalline BiVO₄ thin films—a promising material for solar water splitting. The charge transfer between adsorbates and BiVO₄ is monitored in situ Kelvin probe measurements under dry nitrogen, humid nitrogen, and oxygen environments at atmospheric pressure. To gain complementary insight into the relationship between surface interactions and interfacial charge transport characteristics, we employ photoconductive AFM under the respective in situ conditions. By combining these complementary techniques, we demonstrate that adsorbed oxygen acts as a surface trap state for electrons, which enhances the built-in potential and depletes the BiVO₄ layer, resulting in an increase of the measured surface photovoltage. Furthermore, we have recently demonstrated that the low intrinsic bulk conductivity of BiVO₄ limits the electron transport through the film, and that the transport mechanism can be attributed to space charge limited current (SCLC) in the presence of trap states. By analyzing the SCLC, we estimate that the contribution of water adsorbed oxygen to the total number of shallow traps is as large as 40%. For humid environments, our results are consistent with the adsorption of water as an oriented dipole layer, which does not induce a surface charge transfer but partially inhibits the adsorption of oxygen at the surface. Disentangling the individual effects of oxygen and water on surface band alignment and charge carrier trapping underpins the importance of trap state passivation for efficient transport of photogenerated charge carriers in BiVO₄.

Carbon dioxide is one of the major contributors to global warming and the possibility of recycling this greenhouse gas is gaining attention within the scientific community. The electrochemical reduction of CO₂ (CO₂RR) is an attractive way to utilize this greenhouse gas by converting it into a broad range of useful fuel such as alcohols and hydrocarbons. The development of highly active electrocatalysts for CO₂RR is a national priority, which requires a better understanding of the fundamental reactions on various metal surfaces, along with the development of analytical tools that allow for the quantification of the reaction products. We have designed and built a comprehensive electrochemical mass spectrometry (DEMS) setup consisting of an electrochemical flow cell coupled to an MS, which demonstrated to be an excellent and versatile tool for testing the performance of electrocatalysts. The DEMS setup allows us to study the electrocatalysts under real operating conditions and to correlate the performance of the electrocatalysts with the structure of the catalyst surfaces. In this talk, we will discuss our recent results on the electrocatalysis of CO₂RR on Au, Pt, and Pt/C catalysts, and we will present a novel method for the simultaneous detection of volatile species produced during the electrocatalysis reactions.
Christopher Hahn1 and Walter Drisdell2; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Stanford University, Palo Alto, California, United States; SLAC National Accelerator Laboratory, Menlo Park, California, United States.

The primary challenge in electrochemical CO2 reduction lies in tuning the catalytic selectivity for desired solar fuels products. Molecular-scale knowledge of the catalytic mechanism for CO2 reduction is required, ideally for systems with controlled morphology that can be directly compared to first principles calculations. Achieving this control is difficult, as CO2 reduction competes with hydrogen evolution and only proceeds with appreciable efficiency at high current densities, and suffers from mass transport limitations due to low solubility of CO2. I present a new electrochemical flow cell system designed collaboratively in the Joint Center for Artificial Photosynthesis (JCAP) at Lawrence Berkeley National Laboratory and SLAC National Accelerator Laboratory, which uses a fast liquid flow design to enable grazing incidence X-ray absorption spectroscopy (XAS) and X-ray diffraction (XRD) of a smooth planar catalyst surface (top 2-4 nm) during operation. These measurements characterize the chemical state, local electronic structure, and long-range atomic structure of the catalyst surface as a function of electrochemical conditions, including full catalytic chemistry at high current density. I demonstrate the surface sensitivity and electrochemical control of the technique, and present early data on model CO2 reduction catalysts.
Conducting redox polymers have been investigate massively as an efficient cathode material. Herein we synthesis a series of quinone substituted PEDOT conducting redox polymers and investigate the effect of electron withdrawing substitutions on the redox potential of quinone in the PEDOT backbone in two electrolyte 0.1M LiClO4/MeCN a. Electron withdrawing substitutions leads to an increase of the redox potential of quinone in LiClO4/MeCN. The conductivity of PEDOT backbone is hindered by the lithiated reduced quinone. In-situ uv-vis and EQCM is used to probe the exact PEDOT doping onset potential, confirming that conductivity of quinone is hindered by lithiated reduced quinone. In situ EQCM proves that mass change in the PEDOT doping region involves cation repulsion and dopants anion uptake.

**Effect of Coating on Lithiation in LiMn2O4**

Kimberly Bassett1, Robert W. Burton2, Siddharth Desphande2, Tim Fister1, Kim Ta1, Jennifer Esbenshade1, 

Kamila Wiaderek1, Karen W. Chapman2, Jeffrey Greeley2 and Andrew Gewirth1,

1University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Purdue University, West Lafayette, Indiana, United States; 4Argonne National Laboratory, Lemont, Illinois, United States.

We utilize in-operando powder X-ray diffraction (XRD) coupled with Rietveld analysis and density functional theory (DFT) calculations to describe how a Au coating affects the degree of lithiation available in bulk LiMn2O4 (LMO) and to explore the electronic interactions between the active material and its coating.

Lithium-ion batteries enable the portable electronics industry and appear increasingly in electric and hybrid vehicles. However, capacity fade in Li-ion cathodes remains a barrier between current technologies and longer-lasting devices and vehicles. LMO is a cathode active material that experiences limited life-times due to (1) a Jahn-Teller distortion which incites the formation of the tetragonal phase below 3 V vs Li/Li+, (2) Mn2+ dissolution into the electrolyte, and (3) electrolyte degradation at high potentials. Many approaches have been developed to protect LMO from these mechanisms, such as bulk or surface doping and deposition of protective coatings on the electrode surface.

Previously we deposited a Au coating via electroless deposition onto LMO.[1] The Au-coated LMO exhibited higher capacity after prolonged cycling likely due to a decrease in Mn dissolution. However, the effect of the coating on the initial capacity of LMO is unclear.

XRD results show that the Au-coated LMO exhibits smaller lattice parameters than uncoated LMO at low voltages (3.5 V vs Li/Li+) at which lithiation should be complete. The smaller lattice parameter suggests less Li+ has intercalated into Au-coated LMO compared to uncoated LMO. Integration of the cyclic voltammograms further supports this observation because Au-coated LMO passes less charge in comparison to uncoated LMO. DFT calculations suggest that Au coatings in the LMO surface make a partially delithiated surface more thermodynamically favorable, even at potentials where fully lithiated domains are expected. Chemical bonding analysis shows enhanced hybridization between Au and LMO at partially delithiated surfaces, including strong Au-O bonding character below the Fermi level. The partially oxidized Au leads to less electron density available to complete lithiation.

**In Situ Optical Spectroscopy During Electrochemical Coloration of WO3 Thin Films**

Simon Burkhardt1, 2, Jan Luka Dornseifer1, 2, Alexander Günter Strack1, 2, Matthias T. Elm1, 2, 4, Bernhard Lani-Wayda1 and Peter J. Klar1, 2, 

1Institute of Experimental Physics I, Justus Liebig University Giessen, Giessen, Germany; 2Center for Materials Research (LaMa), Justus Liebig University Giessen, Giessen, Germany; 3Mathematical Institute, Justus Liebig University Giessen, Giessen, Germany; 4Institute of Physical Chemistry, Justus Liebig University Giessen, Giessen, Germany.

Various applications for tungsten trioxide (WO3) thin films can be anticipated. Key applications include the employment of such films in electrochromic devices or lithium-ion batteries. For example, tungsten trioxide based “Smart Windows” already have been launched commercially. Nevertheless, optimization is still desirable in order to improve decisive product properties or to substitute critical materials such as tungsten itself. In particular, the former requires a very deep understanding of the electrochemical and optical properties of WO3 thin films under operating conditions. Furthermore, a correlation of properties and morphology needs to be established as the film morphology strongly affects charge transfer, charge transport, and coloration dynamics. To simultaneously investigate electrochemical and optical properties, a specially designed electrochemical cell has been used.[1] It enables us to perform in-situ optical experiments in the application of electrochemical methods. Results from spatially and temporally resolved transmission spectroscopy during potentiostatic coloration of amorphous and polycrystalline WO3 thin films reveal a significant impact of the thin film morphology on the concentration dependent lateral diffusion of protons. The impact of morphology on results from in situ transmission spectroscopy and in-situ Raman spectroscopy during electrochemical impedance spectroscopy is also investigated.

**A Study of Direct Methane Oxidation at Ceria/Gas Electrochemical Interface**

Yoonseok Choi1, JeongDo Yoo1, Han Gil Seo1, Hyun You Kim2 and WooChul Jung3, 

1MSE, KAIST, Daejeon, Korea (the Republic of); 2MSE, Chungnam National University, Daejeon, Korea (the Republic of); 3MSE, Uppsala, Sweden.

Direct-methane-fueled solid oxide fuel cells has received great attention for near-term realization of the high-efficiency energy conversion advantages even in the absence of a hydrogen delivery infrastructure. In particular, essentially all of the successful demonstrations in the related studies included ceria, either doped or undoped, as a component. However, limited understanding of the electrochemical oxidation of methane on ceria surface hinders implementing the electrode performance comparable to hydrogen fuels. Therefore, the aim of this study is to identify the electrochemical oxidation pathways of methane (CH4) on ceria surface through applied combined theoretical and experimental analyses. The identification of the predominant species on ceria surface coupled to the mixed valence of Ce3+ and Ce4+ can be a key to clarify the reaction mechanism. Here, we propose a real-time analysis of surface adsorbates and lattice ions during the methane electrooxidation using ambient pressure X-ray photoelectron spectroscopy. We combine the AP-XPS results with AC impedance spectroscopy (ACIS) and density functional theory (DFT) calculations for atomic-level mechanisms to understand the overall processes.

**CM03.09.08**

**Multi-Dimensional Electrochemical Characterization at Sub-100 nm Length Scale**

Omur F. Dageviren, Tyler Enright, Aaron Mascaro, Yoichi Miyahara and Peter Grutter, 

McGill University, Montreal, Quebec, Canada.

Simultaneous characterization of surface structure and local electrochemical properties is essential to establish correlations between mechanical and electrochemical material properties. In this work, we demonstrate that multi-dimensional electrochemical material characterization at sub-100 nm length scales
can be routinely achieved by combining atomic force microscopy (AFM) and scanning electrochemical microscopy (SECM). We use an amplitude modulation based AFM technique to modulate the distance between the scanned probe and the substrate [1]. Using a quartz tuning fork as our oscillator integrated with a pulled pipette allows the robust operation at small oscillation amplitudes [2, 3]. The pipette is filled with electrolyte and a back electrode inserted into the pipette allows for electrochemical measurements. We exhibit the robustness of combined electrochemical measurements on different surfaces and along interfaces. Moreover, our experiments elucidate the variation of local electrochemical properties of surfaces previously assumed to be pristine. We are also able to resolve electrochemical properties across grain boundaries due to the spatial resolution afforded by our operation architecture. Most importantly, our technique enables characterization of electrochemical properties across conducting/non-conducting interfaces. Also, our technique allows for the simultaneous measurement of local electrochemical properties and topography as a function of time, which opens a new pathway for corrosion studies of materials at nanometer length scale. All in all, we demonstrate a novel approach that facilitates robust operation of a scanning electrochemical microscope with AFM feedback while revealing electrochemical properties with sub-100 nm spatial resolution as a function of time at a selected potential landscape.

CM03.09.09
Why Does Oxide-Derived Silver Work so Well as an Electrocatalyst for CO2 Reduction? An EXAFS Study
Nienke Fing1, Marijn Blommaert1, Thomas Burdyny1, Anirudh Venugopal1, Alessandro Longo2 and Wilson Smith1; 1Delft University of Technology, Delft, Netherlands; 2European Synchrotron Radiation Facility, Grenoble, France.

To be fully able to take advantage of the current rise in electricity production, we have to find means to convert the electricity in fuels for both mobile (e.g. automotive and airline) and storage applications. With electrocatalysis, we can directly use renewable electricity to convert carbon dioxide and water into valuable products such as carbon monoxide, hydrogen, ethanol, and methane. One of the main bottlenecks for this technology is to find suitable electrodes that can act as efficient, stable and selective catalysts in the electrochemical reduction of CO2.

Due to the vast possibilities in choice for electrocatalyst, we use in operando techniques such as extended X-ray absorption fine-structure spectroscopy (EXAFS) to study the difference between highly active and less active catalysts, to see if any electronic, structural or compositional changes may promote the enhanced activity. In particular, we studied the difference between a pure silver film and oxide-derived silver, a nanostructured catalyst with improved CO2 reduction performance. We found that the presence of trace amounts of oxygen in the oxide-derived silver improves the reactivity of the silver. We found a direct correlation between the faradaic efficiency (or selectivity) of carbon monoxide and the amount of oxygen present in these catalysts. The faradaic efficiency relation does not scale with electrochemical surface area, ruling out other explanations for the enhanced selectivity that are related to mass transfer limitations. Earlier studies based on X-ray photoelectron spectroscopy (XPS) were not able to identify this oxygen, most likely because in ultra-high vacuum conditions, the silver self-reduces to Ag0. This in operando EXAFS study shows how vital the participation of in situ and in operando techniques is to properly understand electrochemical systems.

CM03.09.10
In Situ XANES and PDF Analysis of Electrochemical Cycling of Defective δ-MnO2 Nanosheet Electrodes
Madeleine N. Flint, Peng Gao, Robert Koch, Alec Ladonis and Scott Mixture; Kazuo Inamori School of Engineering, Alfred University, Alfred, New York, United States.

The roles of defects in electrochemical charge storage in 2-D oxides remain largely unexplored. MnO2 nanosheets exhibit an interesting defect, where reduction of MnVI causes displacement of the MnVII out of the plane of the nanosheet, forming a “surface Frenkel” defect. The defect content dramatically impacts the capacitance, where defects improve charge storage by factors of 2 or even 3 times. In-situ XANES data showed an increase in MnII content with increasing charge state (15% for a sample with 20% cation defects, and 17% for a sample with 27% cation defects), confirming that the Faradaic redox reaction is the main charge storage mechanism. Comparing XANES and CV loop calculations indicates that the change in Mn oxidation state upon charging is a function of the overall defect content, with higher defect content yielding proportionally less Mn reduction to the trivalent state. This result suggests that the Mn vacancies serve as new sites for K+ intercalation without changing the average Mn oxidation state. The XANES data corresponds well to our synchronous X-ray PDF study, which shows a reversible expansion of ~0.5 to 1% of the in-plane lattice spacing upon charging.

CM03.09.11
High-Temperature Thin-Film Calorimetry
Hendrik Wulfmeier, Alexander Omelchenko and Holger Fritz; Clausthal Univ of Technology, Goslar, Germany.

Thermodynamic properties of thin films may differ significantly from bulk counterparts due to e.g. increased impact of surface energy or grain boundary densities. As a consequence, sophisticated approaches to determine phase transformation temperatures and enthalpies of thin films and thin-film systems are indispensable. Moreover, numerous film deposition processes include high-temperature steps which require the applicability of calorimetry at high temperatures. A topical example is the deposition of active materials for thin-film batteries which is carried out at temperatures of up to 1000 °C [1]. The thin-film calorimeter (TFC) presented here takes advantage of the extraordinarily high temperature sensitivity of piezoelectric resonators which show increased thermal insulation and, thereby, improved sensitivity. Further, the detectable amount of heat is as low as about 1 mJ. Finally, improvements of the TFC system are done by application of free-standing piezoelectric resonators which show increased thermal insulation and, thereby, improved sensitivity. Materials investigation is done on the one hand by focusing on well known systems such as tin films to confirm the functionality of the TFC system. On the other hand, promising materials for thin-film batteries are investigated. One example is Li(NixMnyCoz)O2 (NMC, x+y+z=1) where the number of phase transformations between room temperature and 850 °C depends on the atmosphere applied. Temperatures and enthalpies of the phase transformations are extracted. Obviously, the presence of air suppresses the Jahn-Teller effect and, thereby, a phase transformation at high temperatures. Aluminum doping increases the stability of NMC which becomes evident from increased phase transformation temperatures.

The Effect of Illumination on the Geometric Structure of Water Molecules on GaN(0001) Surface

Masahiro Sato1, Yuki Imazeki2, Katsushi Fujii3, Yoshihiko Nakano4 and Masakazu Sugiyama1,1 Research Center for Advanced Science and Technology, The University of Tokyo, Tokyo, Japan; 2Department of Electrical Engineering and Information Systems, The University of Tokyo, Tokyo, Japan; 3RIKEN, Tokyo, Japan; 4Global Solar Plus Initiative, The University of Tokyo, Tokyo, Japan.

First principles calculation has become a powerful tool for materials design in many fields [1]. However, theoretical design of photocatalysts has met with limited success, due to the lack of adequate modeling criteria: although photogenerated carriers accumulate at the semiconductor surface under continuous illumination, the effect of “semiconductor surface charging” on the photocatalytic activities have not been studied in detail. Thus, in our previous work, in order to handle the charged surface, we used the effective screening medium method, [2] in conjunction with density functional theory (DFT) calculations. We have modeled H atom adsorption on GaN surface and showed that the apparent adsorption energy decreases with decreasing surface electron density. In this contribution, we study in more detail the effect of illumination on the geometric structure of water molecules on GaN surface by both DFT calculations and infrared absorption spectroscopy.

The effect of UV illumination was modeled by adding excess holes to the GaN surface. The computational results show that both H atoms and -OH adsorbed on the GaN(0001) surface prefer the on-top site. Interestingly, when excess holes accumulate on the surface at low surface coverage, the hollow site becomes the most stable site for -OH even at moderate surface charge density around 10 μC/cm². On the other hand, in the case of H atoms, the on-top site remains the most stable site. At higher surface coverage (~ 1 ML), as the surface electron density decreases, the number of H atoms and -OH adsorbed on the surface decreases, i.e., the number of water molecules in the intact form increases. The number of dissociated water molecules roughly follows the “extended electron counting rule”; the maximum number of H atoms and -OH on a single Ga atom is around 3/4 - n, where n is the number of excess holes per Ga atom. In addition to the change of the geometric structure of the water wetting layer, a significant change in the O-H stretching frequency of the -OH on Ga atom is observed. The O-H stretching frequency shifts downwards as the surface electron density decrease, at the rate of ~ 2 cm⁻¹/μC/cm². Transmissin and ATR-FT(NIR) experiments are conducted to confirm this frequency shift. Although quantitative measurement of the O-H stretching frequency shift is difficult due to the strong absorption of bulk water, in line with the computational results, the red shift of the O-H stretching frequency upon UV illumination is observed. Considering the fact that water splitting involves bond cleavage, these results, which demonstrates that bond strengths change according to surface charging, indicate that surface charging has a large effect on photocatalytic reactions and should be taken into account when modeling the semiconductor/electrolyte interface.

CM03.09.13 Charge Transfer Dynamical Processes at Graphene-Transition Metal Oxides/Electrolyte Interface—Insights from In Situ Raman Spectro-Electrochemistry

Sanju Gupta and Sara B. Carrizzosa; Western Kentucky University, Bowling Green, Kentucky, United States.

Hybrids consisting of supercapacitive functionalized graphene (graphene oxide; GO reduced graphene oxide; rGO) and graphene nanosheets (MLG, electrochemically reduced GO; ErGO) and three-dimensional graphene scaffold (rGOHT; hydrothermally prepared) decorated with cobalt nanoparticles (CoNP), nanostructured cobalt (CoO and Co₃O₄) and manganese (MnO₂) oxides, assembled electrochemically facilitate chemically bridged interfaces with tunable properties. Since Raman spectroscopy can capture variations in structural and chemical bonding, Raman spectro-electrochemistry in operando i.e. under electrochemical environment with applied bias is employed to probe graphene/metal bonding and dynamic processes, 2) monitor the spectral changes with successive redox interfacial reactions, and 3) quantify the associated parameters including type and fraction of charge transfer. The transverse optical (TO) and longitudinal optical (LO) phonons above 500 cm⁻¹ belonging to CoO₃, CO₃O₄, MnO₂, and carbon-carbon bonding occurring at 1340 cm⁻¹, 1590 cm⁻¹ and 2670 cm⁻¹(belonging to D, G, and 2D bands, respectively, are analyzed with applied potential. Consistent variation in Raman band position and intensity ratio reveal structural modification, combined charge transfer due to localized orbi-tal re-hybridization and mechanical strain, all resulting in finely tuned electronic properties. Moreover, the heterogeneous basal and edge plane sites of graphene nanosheets in conjunction with transition metal oxide ‘hybrids’ reinforce efficient surface/interfacial electron transfer and available electronic density of states near Fermi level for enhanced performance. We estimated the extent and nature (n- or p-) of charge transfer complemented with Density Functional Theory calculations affected by hydration and demonstrate the synergistic coupling between graphene nanosheets and nanoscale cobalt (and manganese) oxides for applied electrochemical applications.

CM03.09.14 Replicating Bulk Electrochemistry in Multimodal Liquid Cell Microscopy

Khim Karki1, Julio A. Rodriguez Manzo1, Daan H. Alsem1, J. Tyler Mefford2, Jungjin Park3, William Chaehr4 and Norman Salmon1; 1Hummingbird Scientific, Lacey, Washington, United States; 2Department of Materials Science and Engineering, Stanford University, Stanford, California, United States.

Liquid electroanalytical measurements performed inside the transmission electron microscopy (TEM) and synchrotron X-ray microscopy (XRM) are becoming more common and are used to study a wide range of electrochemical reaction-systems at the nanoscale. This approach has already started to produce new insights on the dynamics and structural changes during processes as lithium ion insertion/extraction, dendrite formation, metal nucleation, and metal corrosion. Despite the power of this approach, the challenges associated with replicating bulk-scale electrochemistry data in the environmental cell microcopy platform are well-known. First, the hardware components are not best optimized to perform in the reduced scale environment. Second, the chips configurations such as sizes and aspect ratios of different electrodes suitable for various electroanalytical measurements are poorly designed. Here, we present an operando liquid cell TEM/XRM microscopy platform that enables true electroanalytical measurements using some model compounds, mimicking bulk behavior.

The studies presented here are performed using electrochemical cells, which consist of two microfabricated chips sandwiched with electron transparent SiNx membranes for viewing in TEM/XRM. Using a new developed hardware system with a specialized configuration of working, counter and reference electrode, we performed cyclic voltammetry studies in 0.1M CuSO₄ and 20 mM K₃Fe(CN)₅/20 mM K₃Fe(CN)₆ in 0.1M KCl solutions. In the former case the copper deposition and stripping occurs at the working electrode at distinct redox peaks and the result mimics the bulk electrochemical cells with large electrode areas and larger volume of electrolyte solution. In the latter case, the redox reaction of 20 mM ferrocyanide/ 20 mM ferricyanide in 0.1M KCl at different voltage scans show reversible electrode reaction during both the forward and reverse scans, elucidating bulk behavior. We will also present results where we compare this result to energy systems. These results and methodologies demonstrate that minimizing artefacts as well as optimizing the hardware for small volume and limited diffusion cell geometries allow mimicking the bulk data, which can be further implemented in the quantitative measurements of broader electrochemical systems.
Electrochemical concepts were recently identified as a novel route for low power voltage control of interfacial magnetism [1]. For this, electrolyte-gated structures are utilized, in which changes of magnetism can occur via capacitive and/or redox effects. Up to now, however, the underlying mechanisms at the electrode/electrolyte interface that are triggered by the applied voltage are often controversial. Solid state-, gel- and liquid electrolytes can all be utilized [1–4]. Liquid electrolytes offer a high ionic mobility and, due to electric double layer charging, an enhanced electric field at the interface. Therefore, they are favorable for achieving room-temperature effects at low voltage [4].

We present large electrochemically induced changes within several nanometers of FeOx/Fe films at room temperature utilizing a liquid alkaline electrolyte. In situ anomalous Hall effect and in situ ferromagnetic resonance demonstrate that large changes in magnetization can be achieved when applying merely 1 V. With those magnetic methods, integral magnetic changes are probed. Kerr microscopy is a powerful tool to probe and visualize the magnetic microstructure, but has not been applied during electrochemical operations yet. We designed an electrochemical cell for a Kerr microscope which allowed us, for the first time, to resolve the local impact of electrochemical redox reactions on the magnetic domain characteristics. Significant changes of the magnetic domains and the magnetization curve are observed in FeOx/Fe thin films. Changes of Fe metal thickness as well as the oxide transformation are discussed as possible key factors for the occurring phenomena.

In Situ Observation of Magnetic Changes During Electrochemical Reactions of FeOx/Fe Nanostructures Jonas Zehner, Kenny Duschek, Ivan Soldatov, Nicolas Perez, Andreas Petz, Sebastian Faehler, Rudolf Schafer, Kornelius Nielsch and Karin Leistner; IFW Dresden, Dresden, Germany.

We study thermal and mechanical properties of five Li-ion electrode materials using in situ time-domain thermoreflectance (TDTR) and picosecond acoustics during charge/discharge cycles with Li+ ions. The conversion NiO and Fe2O3 electrodes show irreversible thermal conductivity and mechanical modulus loss of up to 80% and 40% after the first cycle. The intercalating V2O5 and TiO2 electrodes exhibit reversible thermal conductivity switching as a function of Li+ content without the irreversible thermal conductivity and mechanical modulus loss. The alloying Sb electrode shows thermal conductivity switching but the switching contrast gradually decreases with cycling. We attribute these large differences in the thermal and mechanical switching properties to the existence of Li+ pathways in the crystal structure of electrode materials. While the irreversible thermal conductivity and mechanical modulus loss of conversion electrode materials are caused by the lattice disordering and loss of crystal structure of electrodes by Li+ ion penetration, the Li+ ion pathway and the crystal structures of the intercalating electrodes are maintained during cycling. This study emphasizes the role of Li+ ion pathways of the electrode materials and their thermal and mechanical properties during cycling with Li+ ions.

8:15 AM CM03.10.02
Thermal Conductivity Changes of TiO2, V2O5, NiO, Fe2O3 and Sb During Electrochemical Cycling with Li+ Ions Jungwoo Shin1, Sanghyeon kim1, HoomKee Park2, Ho Won Jang2, David G. Cahill3 and Paul V. Braun1; 1University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Materials Science and Engineering, Seoul National University, Seoul, Korea (the Republic of).

Operando Probing of Phase Transformation in Li2TiO3 Using Electronic Conductivity and Its Applications in Neuromorphic Computing Yiyang Li1, Elliot J. Fuller, Yuping He, Sapan Agarwal and A. A. Talin; Sandia National Laboratories, Livermore, California, United States.

Electrochemical ion insertion yield phase transformations in many transition metal oxides, and such materials are used as electrodes in lithium-ion batteries. Based on nucleation theory, phase transformation initiates from a supersaturation of ions. This metastable or unstable ion concentration in the miscibility gap begins nucleation and growth. While this behavior is accepted from nucleation theory, it is very difficult to quantify and observe in electrochemical insertion materials because operando techniques typically do not possess the sufficient temporal resolution (< 1 sec) and sensitivity to both the ion concentration and the crystal phase to capture the supersaturation and subsequent phase transformation process.

Operando measurement of electronic conductivity possess high temporal resolution (up to megahertz) and is extremely sensitive to small changes in conductivity that correspond to differences in ion concentration or crystal phase. We use lithium insertion into a TiO2 thin film as a model system to measure the changes in electronic conductivity as a function of ion concentration and phase separation. TiO2 transforms from a lithium-poor anatase phase to a lithium-rich titane phase upon lithium insertion. Lithium insertion into either solid solution anatase or solid solution titane increases the electronic conductivity by reducing Ti4+ to Ti3+. On the other hand, the titane phase has a lower conductivity than anatase; therefore, during the anatase-to-titane phase transformation, the electronic conductivity drops despite an overall increase in the lithium concentration. We further confirm this relationship between doping, phase transformation, and conductivity using operando Raman spectroscopy.
Because lithium doping and the anatase-to-titanate phase transformation have opposite contributions to the electronic conductivity, we are able to temporally distinguish between the two behaviors. In particular, we note that the electronic conductivity momentarily rises a few seconds after lithium is inserted, corresponding to the supersaturation of lithium dopants. Over the course of several minutes, the conductivity drops because of some conversion of anatase to titane and the restoration of each phase back to their equilibrium lithium concentrations. This *operando* electronic conductivity measurement is able to directly capture this nucleation and growth process and shows that lithium diffusion and doping is much faster than the phase transformation in Li$_2$TiO$_3$. We demonstrate how lithium insertion in the solid solution anatase can be used as a non-volatile redox transistor for neuromorphic computing. More broadly, we demonstrate an *operando* method to probe supersaturation, nucleation, and growth with extremely high sensitivity and temporal resolution.

**Combined TXM/Acoustic Study of Sudden Pouch Cell Expansion** Daniel Steinpart and Clement Bommier; Princeton University, Princeton, New Jersey, United States.

Gas formation during lithium ion battery cycling can be both subtle and dramatic. In some cases it a slow degradation of the electrolyte solvent during cycling due to impurities, over charge, over discharge, or a cumulative combination of all three. In other cases it can be sudden and dramatic expansion due to auto-catalytic cathode decomposition, SEI decomposition, or again, a combination of these and other factors.

In this study we combine electrochemical acoustic signal interpretations with in operando transmission x-ray microscopy to determine the sequences and rates associated with various gassing modes in lithium ion pouch cells.

9:00 AM CM03.11.02

**Simultaneous Operando Measurements of the Local Temperature, State of Charge and Strain Inside a Commercial Lithium-Ion Battery Pouch Cell** Stephen J. Harris1, Zhili Feng2 and Yang Ren3; 1Lawrence Berkeley National Laboratory, Berkeley, California, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3APS, Argonne National Laboratory, Argonne, Illinois, United States.

A high energy X-ray diffraction technique is employed in a new way to make operando through-thickness measurements inside a large format commercial Li-ion pouch cell. The technique, which has a sub-mm in-plane spatial resolution, simultaneously determines the local temperature, the local state of charge of each electrode separately (as opposed to the global average state of charge determined electrochemically), and the local in-plane elastic strain in each current collector, all without embedding any intrusive sensors that could alter battery behavior. As both thermal strain and mechanical strain develop during the charge-discharge cycling of the pouch cell, a novel approach developed herein makes it possible to separate them, allowing for measurement of the local temperature inside the battery. The operando experiment reveals that the temperature inside the cell is substantially higher than the external temperature. We propose that mechanical strain is due primarily to load transfer from the electrode to the current collector during lithiation, allowing determination of the local binder adhesion to its current collector. Detailed local SOC mapping illustrates non-uniform degradation of the battery pouch cell. The possibility for 3D measurements is proposed. We believe that this new approach can provide critically needed data for validation of detailed models of processes inside commercial pouch cells.

9:15 AM CM03.11.03

**Interrogating Electrolyte Decomposition Reactions in Advanced Batteries with Collector-Generator Measurements and Molecular Probes** Maureen Tang, Oliver Harris and Sophia Lee; Drexel University, Philadelphia, Pennsylvania, United States.

One of the most serious lifetime problems for established Li-ion and emerging “Beyond-Li” batteries is electrolyte degradation from unwanted side reactions. Electrolyte reduction into insoluble products causes formation and growth of the solid electrolyte interphase (SEI) and has been well-studied. However, both oxidation and reduction can also result in soluble gaseous or liquid products, which then can migrate to the opposite electrode and contribute to electrochemical activity. Such inter-electrode ‘communication’ reactions may be detrimental to battery lifetime; for example, dissolution of transition metals from the cathode and their deposition at the anode is known to accelerate capacity fade [1]. However, communication can also be beneficial when harmful products generated from the cathode are consumed by reduction at the anode [2]. Controlling chemical communication between electrodes for improved battery lifetime requires better understanding of the chemical reactions that generate soluble products. Electrochemical methods are particularly advantageous because they can directly assess the redox activity of reaction products. In particular, four-electrode generator-collector measurements such as the rotating ring-disk electrode (RRDE) are commonly used to quantify reaction selectivity in fuel cell catalysis. Despite their utility, these methods are seldom applied to nonaqueous battery research.

In this work, we apply generator-collector measurements and other electroanalytical techniques in order to understand how chemical communication between electrodes affects cell lifetime. In one application of our approach, the RRDE is used to probe mechanisms of transition metal incorporation into the SEI and their effect on through-film electron transport [3]. By using convection to control electrode cross-talk, we observe the presence of Mn contaminants from an upstream cathode at the downstream anode. Electrochemically interrogating the SEI with functionalized ferrocene mediators demonstrates that the through-film mediator reduction is much more sensitive to mediator functional group than size, indicating preferential partitioning into the organic SEI layer. Continuum-scale models to interpret the voltammetry show that incorporation of dissolved transition metals increases both the density and the activity of active sites within the SEI. We conclude that the inner, inorganic layer is responsible for preventing charge transfer through the SEI while the outer, organic layer is minimally important. Our model reconciles contradictory observations from the literature and identifies the most important components of a functional battery interface. Future work will discuss this mechanism in greater detail as well as our development of improved methods for studying these and related reactions.

9:30 AM CM03.11.04

**Using In Situ and Operando Methods to Characterize Phase Changes in Charged Lithium Nickel Cobalt Aluminum Oxide Cathode Materials** Eric
Lithium nickel cobalt aluminum oxide cathode materials (Li\textsubscript{x}Ni\textsubscript{0.8}Co\textsubscript{0.15}Al\textsubscript{0.05}O\textsubscript{3} – “NCA”) are seeing increasing use in demanding energy storage applications due to their high energy storage capacity. However, these materials can experience undesirable thermal runaway in real life applications, leading to catastrophic failures. In this presentation, I will review our work investigating the atomic scale changes that occur in NCA during thermal excursions. These studies will mostly focus on the use of in-situ transmission electron microscopy (TEM) but will include information gleaned from complementary probes such as in-situ x-ray diffraction and x-ray absorption. We have used these approaches to understand how thermal excursions can lead to bulk oxygen loss from the structure, how this oxygen loss is correlated with the movement of the transition metal ions, and how these movements lead to a series of structural changes from the spinel structure to the ‘disordered spinel’ structure to the rock-salt structure on the surface of the particles. Environmental TEM also allows us to explore how we can tune the surface activity, leading to the suppression of both oxygen loss and the initiation of the phase transitions. Finally, we will show how operando TEM approaches using electrochemical liquid-cell methods can lead to further insights into the relationship between lithium extraction and surface structural changes.

Probing Interfacial Charge Transfer Limitations of Sulfide Solid Electrolytes for All Solid-State Battery Applications Y. Shirley Meng1,2, 1University of California, San Diego, La Jolla, California, United States; 2Sustainable Power and Energy Center (SPEC), La Jolla, California, United States.

All-solid-state battery (ASSB) technology has its unique capabilities, among them the potential ability to enable the Li metal anode, operate at high voltage, along with improved safety. Among the known solid electrolytes, sulfides have shown promise due to facile battery fabrication, demonstrated high ionic conductivity, and ductility. Even though current sulfide solid electrolytes enable room temperature ASSB operation, their performance is still limited in terms of energy efficiency, power density, and the issue of dendritic growth of lithium at high current densities. All of those problems are closely related with solid-solid interfaces that arise in an ASSB. In this talk, we discuss and highlight the importance of probing and understanding interfacial phenomena with some of the advanced diagnosis techniques. Controlling and optimizing interfacial phenomena are crucial to overcome the performance obstacles to creating practical ASSB devices.

11:00 AM CM03.12.02
Operando XPS and In Situ SAM Measurements of Solid Electrolyte Interphase Formation at Lithium/Solid Electrolyte Interfaces Kevin N. Wood1, Andrew L. Davis1, K. X. Steier1, Shriram Santhanagopalan3, Chunmei Ban3, Sehee Lee4, Neil P. Dasgupta2 and Glenn Teeter3; 1Colorado School of Mines, Golden, Colorado, United States; 2University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 3National Renewable Energy Laboratory, Golden, Colorado, United States; 4University of Colorado Boulder, Boulder, Colorado, United States.

Solid electrolytes such as Li\textsubscript{10}GeP\textsubscript{2}S\textsubscript{12}(LPS), Li\textsubscript{10}GeP\textsubscript{2}S\textsubscript{12}(LGPS), and related materials show great promise for battery applications, with the potential to enable lithium-metal anodes and improve safety relative to conventional liquid electrolytes. On the other hand, many solid electrolytes are unstable against metallic lithium, and little is known about the chemical evolution of the solid electrolyte interphase (SEI) during cycling. The lack of detailed knowledge about SEI formation and evolution hinders the rational design of novel solid electrolytes with superior ionic conductivity, coupled with passivating SEI layers that facilitate interfacial charge transfer. Here we report on recent efforts to develop and apply novel operando X-ray photoelectron spectroscopy (opXPS) techniques that enable compositional and chemical-state analysis of battery interfaces during cycling. OpXPS measurements are implemented via the ‘virtual electrode’ approach, in which electrons are supplied to or extracted from an exposed interface using either an electron gun or ultraviolet light source, eliminating the need for a physical electrode and current collector. This approach enables real-time, in situ XPS measurements of an electrode/electrolyte interface under electrochemical operating conditions. Initial opXPS measurements probed the formation and evolution of the SEI between LPS and metallic lithium and documented chemically resolved overpotential losses associated with specific SEI phases during electrochemical cycling. These results are compared with experiments LGPS, and recent extensions of the virtual-electrode approach, including opXPS measurements on full cells, real-time in-situ scanning Auger microscopy (SAM) results, and the use of a low-energy Li\textsuperscript{+} ion gun to drive interfacial electrochemistry, are also described.

11:15 AM CM03.12.03
Lithium-Electrolyte Interface Characterization in All-Solid Batteries with Operando Electron and X-Ray Microscopies Natalie Seitzman1, Harvey Guthrey2, Johanna N. Weker1, Heather A. Platt1, Mowafak Al-Jassim2 and Svitlana Pylypenko1; 1Colorado School of Mines, Golden, Colorado, United States; 2SLAC National Accelerator Laboratory, Menlo Park, California, United States.

All-solid batteries offer increased theoretical capacity and wider voltage windows over traditional lithium-ion systems. Additionally, replacing flammable liquid electrolytes with a solid material provides a significant safety improvement, making solid electrolytes particularly attractive for electric vehicle applications. Lithium dendrite propagation at electrolyte surfaces, a micro- to nano-scale phenomenon, can be severely detrimental to battery lifetime. A greater understanding of fundamental processes at the lithium/anode electrolyte interface is therefore critical for the success of solid-state lithium battery systems.
Characterization of this interface comes with challenges, which include the extreme reactivity of lithium metal, narrowing the scope of experiments that can be conducted with conventional laboratory techniques, such as scanning electron microscopy (SEM). In this work, we developed operando SEM to provide high-resolution visualization of Li-Li$_2$PS$_3$ electrolyte and lithium metal electrode surfaces during cycling, and windowless EDS enabled identification of resultant lithium dendrites within the electrolyte. However, the near-surface nature of SEM and the reactivity of lithium ions to the electron beam complicate the analogy between laboratory experiments and practical batteries. Integration of surface observations from SEM with x-ray tomography experiments-in which a battery or symmetric cell can be analyzed whole—was used to increase the reliability of SEM data and to probe all anode-electrolyte interfaces at both the micro- and nano-scale.

At the micro-scale, operando X-ray computed tomography investigation revealed the same pattern of lithium migration with applied current in a sample that is more reflective of a realistic battery. Further, X-ray transmission microscopy (TXM) was utilized due to improved spatial resolution allowing the study of nano-scale features, with resolution closer to that of SEM but without reactivity of the sample to the beam. Our approach, combining SEM and X-ray operando studies, revealed lithium growth through cracks and pores in the Li-Li$_2$PS$_3$ ceramic material and demonstrated the influence of inhomogeneities in the lithium anode on dendrite growth at the electrode-electrolyte interface.

11:30 AM *CM03.12.04
Elucidating Ion Transport and Charge Transfer Behavior at Solid-Solid Interfaces via STEM Miaofang Chi; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Understanding transport behavior in solid-solid heterogeneous interfaces represents one of the most challenging problems in electrochemical systems. Sluggish ion transport and cycling instability are frequently observed at interfaces and the exact origins are unclear. These interfaces are composed of two materials with dissimilar lattice structures, distinctive chemical potentials, and can experience different responses to external stimuli. Multiple interfacial phenomena are often involved, including electrochemical and chemical reactions, elemental inter-diffusion, phase transformation, mechanical integrity, and interfacial space charge. These phenomena are spatially confined and are often correlated, complicating the mass and charge transfer behavior at interfaces and imposing challenges in their characterization. Scanning transmission electron microscopy (STEM) represents an ideal platform for studying interfacial behavior owing to its unprecedented spatial resolution. Recent new developments in STEM-based in situ and functional imaging is creating new opportunities to elucidate interfacial charge transfer behavior not previously feasible. This talk will highlight our recent studies conducted to probe the stability of solid-solid electrochemical interfaces using atomic-resolution in situ STEM and electron energy loss spectroscopy (EELS). Two systems, LiPON-Li and LLZO-Li will be compared and discussed. Observations show that while both LiPON and LLZO form a passivation layer when contacted with Li metal, their formation mechanism and equilibrium thicknesses differ significantly. Further, different responses are detected between the grain bulk and grain boundary when contacted with Li metal under an external bias; LLZO grains tend to be stable under a high external bias while grain boundaries are more prone to chemically reaction with Li. These results provide valuable insight toward the design of stable and conductive interfaces in Li metal batteries. This presentation will also focus on the application of new STEM-based techniques as applied to battery research, and will emphasize recent developments in 4-D STEM-based differential phase contrast imaging and EELS-based vibration spectroscopy.

1:30 PM *CM03.13.01
X-Ray and Optical Spectroscopy and Imaging of the Electrode/Electrolyte Interface on Intermetallic Anodes Robert Kostecki, Philip N. Ross, Hans Bechtel, Jinghua Guo, Liang Zhang, Atetegeb Haregewoin and Ivana Hasa; Lawrence Berkeley National Lab, Berkeley, California, United States.

Intermetallic anodes e.g., Si, Sn, Sb have received significant attention as a viable alternative to graphitic carbon as the negative electrode in lithium-ion batteries due to its high capacity and availability. These electrodes can theoretically store charge nearly an order of magnitude higher than graphite. However, several problems have been identified that limit its utility including large crystallographic expansion upon lithiation, which translates to particle cracking, particle isolation, and electrode delamination issues, as well as electrolyte side reactions, which affect electrochemical performance and lifetime of these electrodes in battery cells.

The key problems that have hindered practical application of intermetallic anodes in commercial Li-ion batteries are: (i) the large volume changes during cycling, which results in cracking and decrepitation of the active material, and loss of electronic connectivity and mechanical integrity in the composite electrode, (ii) inherent non-passivating behavior of silicon in organic electrolytes, which results in large irreversible capacity loss and gradual electrolyte consumption during the electrode operation. However, despite extensive research in the past four decades, the intrinsic behavior and the corresponding barriers to implementation of silicon anodes have in Li-ion systems have not been fully understood and remedied. This study involves diagnostic evaluations of silicon composite electrodes as well as studies of the properties of the individual components and their interfaces. Unraveling the basic function and operation of the SEI layer on Si, Sn, Sb and their binary and ternary alloys with transition metals to elucidate interfacial charge transfer behavior not previously feasible. This talk will highlight our recent studies conducted to probe the stability of solid-solid electrochemical interfaces using atomic-resolution in situ STEM and electron energy loss spectroscopy (EELS). Two systems, LiPON-Li and LLZO-Li will be compared and discussed. Observations show that while both LiPON and LLZO form a passivation layer when contacted with Li metal, their formation mechanism and equilibrium thicknesses differ significantly. Further, different responses are detected between the grain bulk and grain boundary when contacted with Li metal under an external bias; LLZO grains tend to be stable under a high external bias while grain boundaries are more prone to chemically reaction with Li. These results provide valuable insight toward the design of stable and conductive interfaces in Li metal batteries. This presentation will also focus on the application of new STEM-based techniques as applied to battery research, and will emphasize recent developments in 4-D STEM-based differential phase contrast imaging and EELS-based vibration spectroscopy.

Understanding the Many Length Scales of Ion Insertion Solids  

William Chueh; Materials Science and Engineering, Stanford University, Stanford, California, United States.

The availability of low-cost but intermittent renewable electricity (e.g., derived from solar and wind) underscores the grand challenge to store and dispatch energy so that it is available when and where it is needed. Redox-active materials promise the efficient transformation between electrical and chemical energy and are at the heart of carbon-neutral energy cycles. Understanding design rules that govern materials chemistry and architecture holds the key toward rationally optimizing technologies such as lithium-ion batteries and solid oxide fuel cells. Electrochemical reactions involved in these technologies span diverse length and time scales, ranging from Ångström s to meters and from picoseconds to years. As such, establishing a unified, predictive framework has been a challenge. The central question that motivates our research is, “can we understand and engineer redox reactions at the levels of electrons, ions, molecules, particles and devices using a bottom-up approach?” In this talk, I will discuss how we integrate synthesis, fabrication, in-situ characterization, modeling and data analytics to understand molecular pathways and interfacial structure, and to bridge fundamentals to energy storage and conversion technologies by establishing new design rules.

Revealing Li-Ion Battery Processes Using Operando Neutron Depth Profiling and NMR Methods  
Anne Co, Danny Liu, Jose Lorie Lopez, Daniel Lyons, Lei Cao and Philip Grandinetti; Department of Chemistry and Biochemistry, The Ohio State University, Columbus, Ohio, United States.

Rechargeable Li-ion batteries (LIBs) have been the predominant energy storage for a wide range of portable devices like cell phones, laptops and digital electronics. Non-destructive methods such as neutron depth profiling (NDP) and solid state NMR are ideal for probing Li complex formation, accumulation and transport within the battery material during charge/discharge. Currently, our work is focused on understanding the effect of an electrochemical event to the materials’ storage properties using NDP and NMR techniques in operando. Specifically we report our recent work on the preferential Li nucleation, Li trapping, Li transport in intermetallic materials like Li,Sn, Li,Si, and Li,Al, and evidence of formation and accumulation of a Li,Sn metastable phase that is correlated to capacity fade.

4:00 PM CM03.14.02  
Operando and Three-Dimensional Visualization of Ion Depletion and Lithium Growth by Stimulated Raman Scattering Microscopy  
Qian Cheng, Lu Wei, Wei Min and Yuan Yang; Columbia University, New York, New York, United States.

Visualization of ion transport in electrolyte provides fundamental understandings of electrolyte dynamics and electrolyte-electrode interaction, shedding light on material designs to enhance device performance, such as batteries and fuel cells. However, this task is extremely challenging for existing techniques due to their inability to capture the low ionic concentration (<1 M) and the fast dynamics (1-10 s) of the electrolyte. Here we show that an emerging Stimulated Raman Scattering (SRS) microscopy offers the required spatial (sub-micrometer optical resolution), temporal (faster than 1 s per frame) and chemical (around mM) sensitivities to address this challenge. In Raman, [Li+] can be probed by either Li+-solvent interaction, or vibrational mode in the anion which has the same concentration as Li+ due to electroneutrality. Utilizing this technique, we examined and provided evidence for a long-lasting question: How does Li+ concentration correlate with and contribute to the uneven deposition of lithium metal? A three-stage lithium deposition process is uncovered, each corresponding to no-depletion, partial-depletion and full-depletion regime of Li+ respectively. Further analysis reveals a previously uncharacterized spatial heterogeneity of Li+ concentration near lithium surface, and a positive feedback mechanism between the inhomogeneous growth of lithium and the local ionic concentration or flux. Finally, we demonstrate that Li,P,O, based artificial solid electrolyte interface (SEI) is effective in homogenizing Li+ concentration near lithium surface and suppressing the dangerous dendritic growth of lithium, which provides new insights into battery safety. This study shows that SRS microscopy is a powerful technique for imaging ion transport and will open various applications in materials and energy fields.

4:15 PM CM03.14.03  
Solvent Dynamics at Electrode Interfaces—Analysis of SEI Formation Pathways and Electric Fields Using Vibrational Spectroscopy  
Jarred Olson, Patrik Johansson, David Castner and Cody Schlenker; University of Washington, Seattle, Washington, United States.

At an electrode interface, redox mechanisms associated with electrolyte solvent breakdown into components of the solid-electrolyte interphase (SEI) layer are often invoked to rationalize the cycling performance of battery materials. Mechanisms of SEI formation frequently include the release of gas, whose composition serves as an indicator of subsequent chemical structures comprising the SEI. Recently, our group monitored reduction of fluoroethylene carbonate (FEC) and ethylene carbonate (EC) electrolyte solvents on silicon nanoparticles using interface-sensitive vibrational sum frequency generation (SGF) spectroscopy in tandem with electrochemistry. We observe SGF signatures that suggest carbon monoxide (CO) evolution on nano-Si proceeds at distinct lithiation potentials for different electrolyte solvents. FEC appeared to preferentially follow a 2-electron reduction pathway regardless of the degree of lithiation (potential) of silicon. However, EC appeared to be more sensitive to the degree of Si lithiation, reducing to CO only at the highest lithiation state of Si. Upon prolonged reduction of EC, we additionally observe the formation of poly(EC), which is soluble in carbonate-based electrolytes and appears to form through the release of CO2. The results of this study validate previous computational descriptions of FEC and EC reduction, as well as provide insight on a failure mechanism EC-based electrolytes impart upon Si anodes.

The phenomena responsible for the aforementioned SEI-formation processes is the intense electric field magnitude at the electrode interface. Quantification of the local field at the electrode/electrolyte junction has remained an elusive endeavor due to the lack of a reference material that is calibrated against known value. Vibrational Stark effect spectroscopy, a method historically used to characterize the strength of electric fields in enzyme active sites, commonly utilizes the C=O group as a calibrated field reporter. Thus, carbonate-based electrolyte solvents (all of which contain the C=O group) provide amendable conditions for operando characterization of electric fields confined within the electrochemical double layer. Recently, we calibrated the
sensitivity of EC, FEC and diethyl carbonate (DEC) to electric fields, demonstrating that their responsivity to an arbitrary field follows a linear trend. Referring results of the DEC/LiCoO$_2$ junction as a model system, we estimate that the field localized within the electrochemical double layer is in the MV/cm range before electrochemical cycling is induced, providing a lower boundary of field strengths prior to electrochemical cycling. As the progress of high-voltage electrode storage materials advances, understanding interfacial fields may provide new avenues for improving electrolyte stability by tailoring the interface electrostatics.

Electrode-Electrolyte Reactivity Trends and Coatings Screening at Positive Electrodes in Li-Ion Batteries Livia Giordano$^1$, Pinar Karayaylali$^1$, Yang Yu$^1$, Yu Katayama$^1$$^{3,4}$, Soo Kim$^1$, Yirui Zhang$^1$, Nenian Charles$^1$, Sokseihua Muy$^1$, Filippo Maglia$^2$, Isaac Lund$^3$ and Yang Shao-Horn$^1$; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2BMW Group, München, Germany; 3BMW Group Technology Office USA, Mountain View, California, United States; 4Department of Applied Chemistry, Yamaguchi University, Ube, Japan.

Understanding the electrochemical reactions at the interface between the positive electrode and the organic electrolyte is crucial for the rational design of Li-ion batteries towards improved capacity retention and cycle life. Commonly used positive electrodes, such as layered intercalation oxides, exhibit different degrees of chemical reactivity with carbonate-based electrolytes [1, 2], yet a comprehensive understanding of the reaction mechanisms and the parameters governing the interfacial reactivity is still lacking. Here we employed density functional theory calculations to study the reaction mechanism and reactivity trends for organic solvents at the surface of oxides. We found that solvent dissociation is thermodynamically more favorable than electrophilic attack, nucleophilic attack and dissociation with oxygen extraction from the oxide surface on layered oxides. We showed that the dissociation is accompanied by an interfacial charge transfer, where the solvent molecule is oxidized and the transition metal oxide is reduced. Solvent dissociation became thermodynamically more favorable on oxide surfaces with transition metal ions from left to right in the periodic table or by increasing transition metal oxidation state in the oxides upon delithiation, where greater solvent dissociation was found as the oxide Fermi level was lowered into the oxide O 2p band [3]. Similar driving force was found for the dissociation of ethylene carbonate (EC), ethyl methyl carbonate (EMC) and diphenyl carbonate (DPC) additive [4]. The predicted trends can explain the reactivity and the interfacial compositions observed experimentally for LiCoO$_2$, LiNi$_{0.5}$Mn$_{0.5}$O$_2$ (NMC) and Ni-rich NMC. These findings were used to identify a design principle for the screening of coating materials which can prevent the dissociation of organic carbonates.

SESSION CM03.15: Poster Session II: In Situ Investigation of Electrochemical Materials

Session Chairs: Neil Dasgupta and Matthew McDowell

Wednesday Afternoon, November 28, 2018

8:00 PM - 10:00 PM

CM03.15.01

Development of a Method to Characterize Active Sites in Photocatalysis Using In Situ Transmission Electron Microscopy Noah Glachman$^1$, Noah Geller$^1$, Alexander Shea$^1$, Khim Karki$^2$, Daan H. Alese$^1$, Julio A. Rodriguez Manzo$^2$, Norman Salmon$^2$, Deep M. Jariwala$^3$ and Eric A. Stach$^1$$^{3,4}$; 1Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania, United States; 2BMW Group, München, Germany; 3BMW Group Technology Office USA, Mountain View, California, United States; 4Nanoscale Characterization Facility, Philadelphia, Pennsylvania, United States.

Hydrogen gas has the potential to be a clean source of sustainable energy due to its high energy density. However, greenhouse gas emissions are still a major byproduct of current hydrogen production methods. Photoelectrochemistry provides a promising, environmentally friendly route to hydrogen production; however, the atomic scale mechanisms of the photocatalysts that facilitate the water splitting reaction are currently poorly understood. Further understanding of the chemical physics governing the active hydrogen evolution sites would allow for better design of photoelectrochemical devices and thus lead to improved reaction efficiencies. This will overcome one of the major barriers impeding this promising technology. We have developed a unique in-situ photoelectrochemistry transmission electron microscope (TEM) liquid cell sample holder which can be used to characterize these reactions in real time at nanometer length scales. In order to provide accurate, quantitative information, it is necessary to accurately deposit the photocatalyst of interest onto microfabricated electrodes. In this research, a precise sample deposition technique utilizing an inkjet printer has been developed along with stable suspensions of known photocatalysts, leading to site-specific deposition onto the electrode chips. These experiments will investigate the mechanisms by which selected photocatalysts induce water splitting and allow for the identification of defect features that serve as the active sites. Specifically, this experimental design allows for correlation between L-V characteristics and real time, high magnification imaging and spectroscopy, elucidating information about photocatalytic mechanisms at the nanoscale. The following photocatalysts used were chosen because the proposed mechanism for each exhibits a spatial dependence: plasmonically enhanced catalysis for Au nanoprisms and catalytically active edge sites for MoS$_2$ flakes. These experiments will lay the groundwork for the use of this novel experimental design to investigate a wide variety of photoelectrochemical systems using this in-situ approach.

CM03.15.02

In Operando Optical Microscopy and Vertex Delay Cyclic Voltammetry for Direct Observation of Lithium Dendrite Regimes Noah Hart; NICE, Mountain View, California, United States.

Understanding the mechanisms of lithium dissolution/deposition has benefited significantly from in-operando microscopy. Recent work has used optical microscopy to explore dendritic growth. Existing designs face lithium strips across from each other, with the optical instrument placed in the plane of the strips. This work presents a system that cycles lithium from the edge, rather than the face. By limiting electrochemical activity to an edge, (a) the entire electrochemical process on the electrode surface is within the optical instrument's depth of field, (b) tight control of current density can be achieved and (c) the removal of a native layer can be easily and reliably replicated, offering a high purity lithium surface unaffected by shelf-life. This system allows for unambiguous identification of which deposition/dissolution phenomena are occurring in the cell at different current densities and cycle life.

Optical observations are paired with cycling and cyclic voltammetry with vertex delays (CV). A simple V=IZ relationship is used to convert current-
controlled cycling and voltage-controlled CV, showing how directly these two regimes translate. CV is then used to explore a voltage controlled environment for the investigation. With CV a milder voltage environment can be imposed, reducing the reaction complexity and the cell can be observed via current response. This allows for a clear delineation of different reaction regimes, where kinetic, electronic and diffusion limitations are expressed clearly via current rate and regimes can run their course, independent of the requirements of cell cycling. Decoupling the reaction from a controlled current allows for more dramatic changes in the scale of the reactivity, as one regime takes over from another, with a current response that reflects their distinct bottle-necks. The optical cell allows different dendrite deposition/dissolution regimes to be unambiguously identified and studied, validating shifts between regimes and correlating them to the electrochemical response.

CM03.15.03
Asymmetric Dynamics of Ion Insertion/Extraction of Lithium Battery Electrodes by Electro-Autocatalyst and Electro-Autoinhibitor Jihyun Hong1,2, Hongbo Zhao3, Jungjin Park4, Kapil Lim1,2, William Gent6,6, Samanbir Kalirai1,4, Michael F. Toney2, William Chueh1,2 and Martin Bazant1,2,6, MSE, Stanford University, Stanford, California, United States; 2Stanford Synchrotron Radiation Lightsource, SLAC National Accelerator Laboratory, Menlo Park, California, United States; 3Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4The Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 5Department of Chemistry, Stanford University, Stanford, California, United States; 6Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Reversible insertion and extraction of a guest ion into the host crystal is the fundamental reaction underpinning insertion electrochemistry and has been widely applied to store energy and tune catalysts. It has been considered that the ion extraction and insertion reactions are reversible and following near-equilibrium paths for charge and discharge of lithium ion batteries, respectively. However, recent studies have revealed that the dynamics of the ion extraction and insertion can be altered by current density (reaction rate) and reaction direction in a phase-separating compound, Li1-xFePO4, using operando characterization techniques such as X-ray diffraction (XRD) and X-ray microscopy. We recently demonstrated that the kinetics of the reactions at solid-liquid interface governs the uniformity of ion insertion/extraction reactions by electro-autocatalyst and autoinhibitory. Here, we first show the asymmetric dynamics of ion insertion and extraction of a model solid-solution compound, lithium transition metal oxides. Combining population dynamics theory, operando XRD and scanning transmission X-ray microscopy (STXM), we show that the non-constant reaction kinetics results in the heterogeneous delithiation and homogeneous lithiation, which eventually affects the fast-charging capability of lithium ion batteries.

CM03.15.04
Controlling Interfacial Properties of Solid-State Lithium Batteries Using Atomic Layer Deposition Kirit Joshi1, Francisco Javier Quintero Cortes2, John Lewis2 and Matthew McDowell1,2, 1Georgia W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Solid-state lithium batteries (SSLiBs) could enable improved safety and higher energy density compared to traditional lithium-ion batteries due to the use of metal anodes without dendrite growth. However, successful implementation of solid electrolytes within batteries is contingent upon controlling the chemical, mechanical, and electronic properties at solid electrolyte/electrode interfaces. SSLiB interfaces can exhibit poor wetting properties, leading to interfacial void spaces and high impedance. Furthermore, many solid electrolytes are chemically unstable in contact with electrodes. This project aims to stabilize traditionally unstable interfaces between lithium metal and ceramic electrolytes through the use of atomic layer deposition (ALD) of thin film oxide protection layers. It is expected that these protection layers will improve wetting properties and prevent or slow detrimental anode-electrolyte interactions. A custom ALD instrument has been designed and constructed for this project. This fully-automated instrument allows for the deposition of ternary oxides with atomic precision. It features pneumatic control of valves, a custom LabVIEW Virtual Instrument interface, and real-time pressure feedback control. This instrument is ideal for coating nanometer-scale films on either bulk solid electrolyte pellets or on powder. The custom reactor is used to coat NASICON-type solid electrolytes, including Li1-xAlxTi2-x(PO4)3, with oxide thin films (Al2O3, ZnO). These NASICON materials are shown to readily react in contact with Li metal. The effect of these ALD protection films on electrochemical behavior and lifetime are compared to that of uncoated materials to determine whether the ALD coating improves battery performance and stability. Ultrathin oxide layers are found to improve the stability of the solid electrolytes in contact with Li during galvanostatic cycling. In particular, the ALD layers are shown to substantially extend the time to failure during cycling and to alter degradation pathways within cells. In conjunction with other students, ex situ and in situ characterization is used to uncover the evolution of these layers during cycling. These results are important for the development of stabilized, high-conductivity solid electrolytes for solid-state batteries.

CM03.15.05
Enhancing In Situ Far-Infrared Spectroelectrochemistry Sensitivity with Gold Nanostructures Luciano J. Macedo and Frank N. Crespilho; São Carlos Institute of Chemistry, University of São Paulo, São Carlos, Brazil.

Organometallic structures are fundamental building blocks in life, being crucial components of biological systems such as metalloproteins and far-infrared (FIR) spectroscopy plays a fundamental role in the identification and investigation of metal-ligand bond vibrational modes in these organometallic structures. Due to the possibility of investigating the influence of the redox state of the metal on the structural behavior, in-situ spectroelectrochemistry using this region of the electromagnetic spectrum is applied; however, this analytical approach is limited due to the low sensitivity of optical components available to date even when synchrotron light is used as source of infrared radiation. To address this issue, we utilized the surface-enhanced infrared absorption (SEIRA) effect to promote more sensitivity in the spectroscopic analyses, using surfactant-free gold nanostructures in order to avoid the interference from organic matter. As probe, we used well-known redox active organometallic probes, whose iron-carbon, iron-nitrogen, and iron-sulfur bonds vibrational modes are active in the FIR region. Thus, we observe an enhancement of the signal from these vibrational modes in the FIR spectrum when these gold nanostructures are in close interaction with these probes. Also, this absorption enhancement benefits the use of this approach in aqueous medium electrochemistry, probing more clearly the role of the metallic atom redox state on the whole organometallic structure. Based on these observations of such control of the vibrational modes in the FIR spectroscopy by electrochemistry, this approach might also be helpful to further investigate organometallic interaction with biological relevant molecules such as metalloproteins.

CM03.15.06
In Situ Study of the Reaction Processes and Mechanisms of Nanocatalysis by Enhanced Raman Spectroscopy Chen Wang; Xiamen University, Xiamen, China.

In-situ dynamic monitoring of nanocatalytic processes is of significant importance for the insightful understanding of reaction mechanisms and structure-activity relationships. Raman spectroscopy can provide fingerprint structural information. However, its sensitivity is too low to achieve the in-situ detection of trace amount of surface species on catalysts. To solve this long-standing problem, we develop a SHINERS-satellites strategy which can be used to in-situ track the nanocatalytic processes based on shell-isolated nanoparticle-enhanced Raman spectroscopy (SHINERS). In the SHINERS-satellites strategy, nanocatalysts are assembled on shell-isolated nanoparticles (SHINs), leading to the formation of SHINERS-satellites nanocomposites (Au core-silica shell-
Catalyst satellites. The Au cores can generate strong electromagnetic field to enhance the Raman signals of the species adsorbed on the catalysts, while the silica shells can isolate the influence of the Au cores on the catalysts and reactions. Therefore, SHINERS-satellites strategy can be used to in-situ detect the trace amount of active species and intermediates during nanocatalytic reactions. It is a general strategy and can be used for different kinds of nanocatalysts including monometal, bimetal, trimetal, oxide, etc. With SHINERS-satellites strategy, the reaction processors of CO oxidation on Pt- and Pd-based nanocatalysts are in-situ monitored. The intermediates including active oxygen species, Pt-C, Pd-C, etc. are in-situ detected, and the reaction mechanisms as well as structure-activity relationships are revealed at a molecular level. Furthermore, SHINERS-satellites strategy has also been used in the in-situ study of catalytic hydrogenation using the conversion of pNTP to pATP as a probe reaction. Direct spectroscopic evidences for the hydrogen spillover at interfaces are obtained, and the influence of the interfacial structures on the hydrogen spillover and reaction pathways has been revealed. At the same time, the transportation of hot electrons generated on plasmonic nanomaterials in different materials has been studied using SHINERS. It is found that hot electrons can only be transferred via semiconductors and then trigger photocatalytic reactions. This study provides not only a new strategy for the in-situ study of nanocatalysis but also molecular information of the reaction mechanisms and structure-activity relationships, thus greatly helps the rational design and development of highly efficient nanocatalysts.

CM03.15.07
Characterizing the Mechanical Failure of Solid Electrolytes Through Operando X-Ray Tomography Jared Tippens, Matthew McDowell, Francisco Javier Quintero Cortés, John Lewis, Christopher Saldana, John Miers and Haipeng Qiao; "School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; "George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Solid state batteries have attracted growing interest due to their increased safety and potentially high energy density when compared with traditional lithium-ion batteries with liquid electrolytes. Solid electrolytes have been shown to offer a greater resistance to lithium dendrite growth when using a lithium metal anode, but recent studies demonstrate that metal growth and mechanical degradation can still occur when using a ceramic ion-conducting membrane. The low fracture toughness of ceramic solid electrolytes suggests that they are susceptible to mechanical failure, particularly after cracks are initiated in the material. While several studies have been conducted to characterize the mechanical properties of solid electrolytes, little work has been done to characterize and understand the fracture process during electrochemical charging. In this work, we use operando x-ray tomography with a lab-scale computed tomography (CT) instrument to investigate the mechanical degradation process in Li1.5Al0.5Ge1.5(PO4)3 (LAGP), a NASICON-type solid electrolyte during cycling. NASICON electrolytes have garnered interest due to its high ionic conductivity. A symmetric cell with lithium metal electrodes was cycled galvanostatically, and 3D images were collected showing the morphology of the solid electrolyte at different stages of electrochemical cycling. A voxel resolution of 18 μm was obtained, allowing for thorough characterization of the microstructural evolution during the experiment. Through this methodology, the locations of crack initiation and the process of crack growth can be tracked voxel by voxel as a function of the number of galvanostatic cycles. The results show the potential for using this non-invasive method to investigate the mechanical degradation behavior of various solid electrolytes. This information paves the way to future studies in which protection layers between the electrolyte and mechanical failure could be applied to prevent or retard mechanical failure in solid electrolytes to prolong battery life.

CM03.15.08
XPS on Li Battery Related Compounds—Analysis of Inorganic SEI Phases and a Methodology for Charge Correction Kevin N. Wood, Sang-Don Han, Andrew L. Davies, Yun Xu, Andriy Zakutayev, Neil P. Dugaspta and Glenn Teeter; "National Renewable Energy Laboratory, Lakewood, Colorado, United States; "University of Michigan, Ann Arbor, Michigan, United States; "San Diego State University, San Diego, California, United States.

Accurate identification of chemical phases associated with the electrode and solid-electrolyte interphase (SEI) is critical for understanding and controlling interfacial degradation mechanisms in lithium-ion-containing battery systems. To study these critical battery materials and interfaces, X-ray photoelectron spectroscopy (XPS) is a widely used technique that provides quantitative chemical insights. However, due to the fact that a majority of chemical phases relevant to battery interfaces are poor electronic conductors, phase identification that relies primarily on absolute XPS core level binding-energies (BEs) can be problematic. Charging during XPS measurements leads to BE shifts that can be difficult to correct. These difficulties are often exacerbated by the coexistence of multiple Li-containing phases in the SEI with overlapping XPS core levels. To facilitate accurate phase identification of battery-relevant phases (and electronically insulating phases in general), we propose that BE separations between core levels present in a particular phase (e.g. BE separation between the O 1s and Li 1s core levels in Li2O) should be used as an additional constraint in order to significantly improve reliability of phase identification. This approach is applied to XPS data acquired from six battery-relevant inorganic phases including lithium metal (Li0), lithium oxide (Li2O), lithium peroxide (Li2O2), lithium hydroxide (LiOH), lithium carbonate (Li2CO3) and lithium nitride (Li3N). To demonstrate the practicality of this approach, we apply the charge-correction methodology to ex-situ and operando XPS data acquired on solid electrolytes and Si anodes materials.

CM03.15.09
Origin of Contraction Force in Artificial Muscle Based on Conducting Polymers Keiichi Kaneto, Fumito Hata and Sadahito Uto; Osaka Institute of Technology, Osaka, Japan.

Artificial muscles are interested in the application to human friendly robots, because of the noiseless and simple structure for complicated motions. Among various materials, conducting polymers are superior in operation voltage, magnitude of deformation and contraction force. These features originate from the mechanism of deformation, as well as the high electrical conductivity, flexibility and toughness of conducting polymers. Electrochemical oxidation and reduction of conducting polymers induces the electrochemomechanical deformation (ECMD) by insertion and exclusion of ions. It has been shown that the magnitude of deformation is determined by the total volume of inserted bulky ions, being up to 40% and larger than skeletal muscle of 25%. The contraction force is several tens MPa, being larger than that of skeletal muscle of 0.4 MPa. However, little is known about the origin of contraction force. The strain of ECMD in the polymer films was measured in-situ as the function of tensile stress using a laser displacement meter. The strain decreased with increasing the tensile stress, which gave the EC stress-strain curve. In this talk, the origin of EC contraction force is discussed based on EC stress-strain relationships as well as structure-activity relationships are revealed at a molecular level. Furthermore, SHINERS-satellites strategy has also been used in the in-situ study of catalytic hydrogenation using the conversion of pNTP to pATP as a probe reaction. Direct spectroscopic evidences for the hydrogen spillover at interfaces are obtained, and the influence of the interfacial structures on the hydrogen spillover and reaction pathways has been revealed. At the same time, the transportation of hot electrons generated on plasmonic nanomaterials in different materials has been studied using SHINERS. It is found that hot electrons can only be transferred via semiconductors and then trigger photocatalytic reactions. This study provides not only a new strategy for the in-situ study of nanocatalysis but also molecular information of the reaction mechanisms and structure-activity relationships, thus greatly helps the rational design and development of highly efficient nanocatalysts.

Characterizing the Mechanical Failure of Solid Electrolytes Through Operando X-Ray Tomography Jared Tippens, Matthew McDowell, Francisco Javier Quintero Cortés, John Lewis, Christopher Saldana, John Miers and Haipeng Qiao; "School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; "George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States.

Electrochemical reduction of CO2 is a promising approach towards reducing the atmospheric CO2 levels and converting CO2 to usable fuels. While a variety of electrocatalysts have been developed for CO2 reduction, a major challenge remains in minimizing co-evolution of hydrogen as well as maintaining a sufficiently high CO2 concentration in the electrolyte. Herein we report the effect of CO2 bubbles on the current density and product distribution mix during CO2 reduction. We compare and contrast against standard approaches using CO2 atmospheres and demonstrate high faradaic efficiency towards carbonaceous products using copper catalyst, as well as a sustained higher current density and propose broader implications towards scaling up.

CM03.15.10
One of the biggest obstacles in the way of battery technology development is the limited amount of information that one can obtain from the battery mechanism without taking it apart. Here we are presenting a novel nondestructive battery assessment technology that is capable of obtaining crucial information from batteries even when the cells are encased in conductive material. One important application is commercial-type cell-phone batteries, which can be analyzed with this method. The technique is based on measuring the magnetic susceptibility of active ingredients inside an electrochemical cell that is affected by the oxidation of the materials to give insights into the state of charge (SOC) of the battery, its failure mechanisms and the current distributions. The technique has been demonstrated on various cell types, defects, chemistries, and current level. The measurement is fast (a couple of seconds), and could be adapted to a range of cell types. Overall, it is hoped that this new noninvasive methodology will provide much-needed tools for the development of new battery materials and cell designs that address current and future needs.

Bismuth as Rechargeable Lithium-Ion Battery Anode—A Fundamental Study Using In Situ Synchrotron XRD and In Situ TEM
Yifei Yuan1, Wentao Yao1, Vitaliy Yurkin1, Lu Ma2, Tongchao Liu2, Farzad Mashayek1, Jun Lu2, Khalil Amine2 and Reza Shahbahzan-Yassar1; 1University of Illinois at Chicago, Chicago, Illinois, United States; 2Argonne National Laboratory, Argonne, Illinois, United States.
than current graphite anode. Among these materials, bismuth provides a high theoretical volumetric capacity of 3800mAh/cm^3 when it alloys with Li\(^+\) to form Li\(_3\)Bi. Yet, its further development has been hobbled by the unclear alloying mechanisms with Li\(^+\). In this work, we carry out real-time study of the (de)alloying kinetics of Bi nanomaterials working as a LIB anode combining both in situ synchrotron XRD and in situ TEM. In situ synchrotron XRD reflects the phase transition information of the ensemble of many Bi nanoparticles, while in situ TEM demonstrates the structural evolution of single Bi nanoparticle at both high spatial resolution and high temporal resolution. Both two methods reveal that the Li-Bi alloying is a two-step process featuring two two-phase reactions with formation of Li\(_3\)Bi as the intermediate phase. More importantly, our work reveals an energetically favorable lithiation pathway along Bi-(012) planes during the Bi-Li\(_3\)Bi phase transition process, which is further theoretically understood by DFT calculations. The fundamentals discovered in this work are expected to further guide the design of Bi-based electrode materials for battery performance enhancement in the future.

**CM03.15.17**

**Carrier Transfer from N-Type GaN Photoanode to Island-Like NiO-Catalyst for Water Oxidation Evaluated by Photoluminescence**

K. Koike\(^1\), Katsushi Fujii\(^1\), Kayo Koike\(^1\), Takenari Goto\(^2\), Shinichiro Nakamura\(^2\), Takayo Ogawa\(^1\) and Satoshi Wada\(^1\); \(^1\)RIKEN, RAP, Wako, Japan; \(^2\)RIKEN, Baton Zone Program, Wako, Japan.

The island-like NiO catalyst loaded on n-type GaN single crystal photoanode works perfectly to prevent the anodic corrosion \(^1\). The mechanism of NiO catalyst is, however, not fully understanding. Carrier transfer from GaN photoanode to NiO catalyst is expected for the prevention. The carrier transfer direction between the GaN surface and NiO-islands was proposed from our experiments recently \(^2\).

In this report, the in-situ and ex-situ photoluminescence (PL) was used for the evaluation of the carrier transportation. The samples were island-like NiO-loaded n-type GaN and bare n-type GaN. The 325.0 nm He-Cd laser was used as the excitation light. The light was used for both PL and photoelectrochemical water splitting for the in-situ measurements. The electrolyte was 1.0 mol/L NaOH aqueous solution.

The major PL peaks of n-type GaN at room temperature (RT) are near-band-edge luminescence (XL) and deep-yellow luminescence (YL). From the ex-situ PL results, the intensities of XL and YL were similar for both island-like NiO-loaded and bare n-type GaN when the excitation intensity was relatively high at about 1.0 W/cm\(^2\). The XL intensity of island-like NiO-loaded GaN decreased more than that of the bare n-type GaN when the excitation intensity was changed to 0.9 mW/cm\(^2\), whereas the YL intensities were similar for both samples. This 0.9 mW/cm\(^2\) excitation intensity is close to our commonly used photoelectrochemical excitation of 100 mW/cm\(^2\) Xe lamp.

During the photoelectrochemical reaction, the XL intensity of the bare n-type GaN decreased from the intensity without the reaction. The amount of XL intensity decreasing was much larger than that for YL. For the PL results of island-like NiO-loaded GaN, the XL intensity did not change and the YL intensity showed small decreasing with photoelectrochemical reaction from that without the reaction. The in-situ intensity change from the ex-situ intensity shows that the holes of bare n-type GaN are mainly used for the XL at the process without the photoelectrochemical reaction. On the other hand, the holes in the GaN of the island-like NiO-loaded GaN moves to the island-like NiO and would be consumed at the NiO by thermal recombination even without the photoelectrochemical reaction. The holes at the NiO are probably used for the water oxidation before the thermal recombination at the photoelectrochemical reaction. This probably shows that the holes in NiO can move more smoothly from the electrode to the reactant in the electrolyte than that in the bare GaN.

**CM03.15.18**

**In Situ Optical Absorption Spectroscopy for Investigating Point Ionic Defects Concentration and Kinetics in Mixed-Ionic-Electronic-Conductor Thin Films**

Dmitri Kalaev\(^1\), Clement Nicollet\(^1\), George F. Harrington\(^1,2\) and Harry L. Tuller\(^1\); \(^1\)Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; \(^2\)Kyushu University, Fukuoka, Japan.

Mixed ionic electronic conducting (MIEC) oxides are extensively used as electrodes in energy, electronics and catalysis applications. In particular, point ionic defects concentrations in MIECs bulk and surface and their kinetics properties are important parameters in the design of solid oxide fuel cell electrodes. Typically, the point ionic defects properties are measured electrically as function of oxygen partial pressure change to reveal the defect model. The electrical measurement can be disadvantageous, in some cases, if the contacts alter significantly the material properties or if the electrical conductivity dominates over the ionic one. Additionally, there is an increased interest in using MIEC thin films in electronics and catalysis applications that impose an additional challenge for characterizing them by other classical impedance spectroscopy and other electrical measurement techniques.

We demonstrate how the ions with optical absorption, occurring naturally or inserted on purpose in the MIECs, can be used for the characterization of the point ionic defects concentrations and kinetics in the oxides thin films. The examples will include praseodymium substituted ceria (PCO) and praseodymium oxide thin film. In these materials the praseodymium ions can have different valence states showing significant visible light absorption in one of the states. The praseodymium ions concentration and changes in their valence state can be measured, in-situ, at elevated temperatures and under a controlled oxygen partial pressure.

Applying the optical measurement technique allows, among other, to measure the oxygen vacancies ordering associated phase transition in praseodymium oxide thin film, measured previously by thermal gravimetric analysis. Finally, measuring the properties of the point ionic defects from optical absorption in heterostructures of an interchanging layers of epitaxial PCO and SrTiO\(_3\) thin films enables to study the effect of the space charge regions widths on the ionic defects concentration and the effect of a strain, induced by a lattice mismatch between the materials, on the ionic defects kinetic properties.
in situ synchrotron diffraction and X-ray absorption spectroscopy to unravel the underlying sodium storage mechanism and charge compensation behaviour is presented.

Model systems for multivalent-ion insertion can also include hybrid batteries with two mobile metal ions in the electrolyte, where a metal like Mg is plated at the negative electrode, while Li- or Na-ions are inserted at the positive electrode [2,3]. This presentation summarizes some recent results on the underlying working mechanisms in such hybrid batteries as revealed by in operando diffraction using synchrotron radiation in combination with X-ray photoelectron spectroscopy (XPS).

**In Situ Focused Ion Beam-Scanning Electron Microscope Study of Microstructural Evolution of Single Tin Particle Anode for Li-Ion Batteries**

Xinwei Zhou1, Tianyi Li1, Yi Cui2, Yuzi Liu1 and Likun Zhu1; 1Department of Mechanical and Energy Engineering, Indiana University-Purdue University Indianapolis, Indianapolis, Illinois, United States; 2Nanoscience and Technology Division, Argonne National Laboratory, Lemont, Illinois, United States.

In this study, we developed an approach to build a single particle battery in the chamber of focused-ion beam-scanning electron microscope (FIB-SEM) to monitor the microstructural evolution of a single Sn micro-particle during cycling. The experiment was performed within a ZEISS Nvision FIB-SEM at the Center for Nanoscale Materials, Argonne National Laboratory. A tin particle was attached to the tungsten probe by carbon coating using FIB deposition as positive electrode. The lithium metal was placed on the top of SEM stage as negative electrode. One drop of ionic liquid electrolyte (ILE) was placed on the top of lithium metal. The ILE was made by dissolving the lithium salt, lithium bis (trifluoromethylsulfonyl) imide (LiTFSI), in a solvent of 1-butyl-1-methylpyrrolidinum bis (trifluoromethyl-sulfonyl) imide (P3,6TFSI). The tungsten probe and the SEM stage were connected to a Keithley 6430 sub-femtoamp remote sourcemeter. Galvanostatic mode was used in all electrochemical cycling with a current of 300 pA. The particle was immersed in the ILE drop during cycling and lifted out for imaging at different states of charge. The particle was polished by FIB before imaging to remove ILE on the surface. Our results show the formation and evolution of cracks during lithiation, evolution of porous structure during delithiation and volume change during cycling. The electrochemical performance and the microstructural evolution of the Sn micro-particle during cycling are correlated.

8:45 AM CM03.16.03

**Probing Electrochemical Phase Transformation Kinetics by In Situ TEM**

Kai He; Clemson University, Clemson, South Carolina, United States.

In *situ* transmission electron microscopy (TEM) as a fast-growing technique has attracted tremendous attention in diverse scientific research because it can acquire dynamic information and allow for mechanistic understanding of various physical and chemical processes and materials systems [1]. Specifically, the advancement of *in situ* TEM in chemically reactive environments has enabled the direct real-time observation of electrochemical reactions in electrode materials for lithium ion batteries [2]. Previous studies have found different types of electrochemical reactions with lithium via various mechanisms such as intercalation, alloying, and conversion, which confirmed the lithiation processes following the thermodynamic reaction pathways. In addition to that, we would like to utilize *in situ* TEM imaging and spectroscopy approaches to build direct correlations between microstructure and electrochemistry on atomic to nanoscale and reveal the kinetics of phase transformations during the electrochemical reactions. We primarily focus on transmission metal oxides and sulfides with a large number of openings in their crystal framework, such as the spinel (FeOx) and 2D layered (CuS) structures [3, 4], to accommodate the uptake of guest Li ions. Although it is generally believed that these materials should follow the conversion reaction, we found the intermediate lithiated phases resulted from the intercalation reactions at the beginning; and more importantly, such phase transformations are sensitive to the reaction kinetics that are common in realistic battery coin cells. With further performance tests of coin-cells at various charging rates, we are able to explicitly establish the relationship that crosslinks the structure evolution, electrochemical properties, and the reaction pathways on the atomic level, and address the importance of the effects of kinetics and dimensionality on the phase transformation. Our findings provide insights into understanding phase transformation mechanisms in spinel and layered structures, and also show implications for improving performance in future design of battery electrodes.

**Investigation of Dynamic Phase Transformation of Selenium-Doped Germanium Anode during (De)Lithiation Processes Using In Operando Synchrotron X-Ray Diffraction**

Tianyi Li1, Yi Cui2, Xinwei Zhou1, 2, Melissa Meyerson1, Alan Guo1, Charles Mullins1, Yang Ren1, Qi Liu1, Yongzhu Fu3 and Likun Zhu2; 1Department of Mechanical Engineering, Purdue University, West Lafayette, Indiana, United States; 2Department of Mechanical and Energy Engineering, Indiana University Purdue University Indianapolis, Indianapolis, Indiana, United States; 3Department of Chemical Engineering, The University of Texas at Austin, Austin, Texas, United States; 4Argonne National Laboratory, Argonne, Illinois, United States.

Germanium (Ge) is an attractive candidate for high-capacity Li-ion battery anode due to its high theoretical capacity of 1384 mAh/g (for the charged
Li$_2$(Ge$_4$ phase), low operation voltage, fast bulk Li diffusion, and high electrical conductivity. However, the major challenge in the development of Ge anode is the large void that is formed in the reaction scheme, which could result in particle enlargement and electrode delamination from the current collector, thereby leading to rapid loss of specific capacity. Klavetter et al. recently reported that selenium (Se) doped Ge (GeSe) forms an inactive phase that buffers the volumetric expansion of Ge which provides better cycling life and performance [1]. Therefore, it is essential to understand the mechanisms and dynamic phase transformation that occur during battery cycling processes.

The in-operando experiment conducted by Lim at al. has shown crystal Li$_2$Ge$_4$ as the final product of lithiation and amorphous Ge at the end of Delithiation [2]. However, the crystalline change of GeSe anode material is still unclear which needs further investigation. In this study, we examined and compared the dynamic phase evolution of Ge and GeSe electrodes made of micro-particles (~5 μm in diameter) via Synchrotron X-ray diffraction (XRD) at the beamline 11-ID-C of the Advanced Photon Source at the Argonne National Laboratory. To investigate the crystalline evolution of Ge and GeSe particles, a synchrotron X-ray diffraction with a wavelength 0.1173 Å was employed to obtain diffraction data of the electrodes during in-operando condition to monitor and quantify crystalline change of active materials. Similar to Lim’s results, Li$_2$Ge$_4$ was observed as the single crystalline at the end of lithiation and no crystal Ge peak was found at the end of delithiation process for Ge. However, GeSe became amorphous at the end of the first lithiation and no crystal phase was observed thereafter. We believe that the different phase evolution is caused by the formation of a network of Li-ion super-conducting and inactive Li-Ge-Se phase at the beginning of the lithiation process.

Solid-state reactions underpin virtually all aspects of materials synthesis, operation of batteries and fuel cells, as well as ionic information technology devices. However, despite extremely high significance, these processes were traditionally studied only on the macroscopic level or via scattering techniques, providing only average information. Recent advances in scanning transmission electron microscopy (STEM) allow the visualization of solid-state transformations in materials, including those induced by electron beam influence and temperature, in real time with atomic resolution. However, the existing analytical tools allow extracting only a very small (and insufficient) portion of relevant physical and chemical information from the experimental data. Here we demonstrate a deep learning framework for full data analysis of the atomic defect dynamics and evolution from dynamic STEM data and illustrate its application for STEM “movies” from graphene and WS$_2$. The developed framework allows us to create a library of defects, map chemical transformation pathways at the atomic level, including detailed transition probabilities, and explore subtle distortions in local atomic environment around the defects of interest. In particular, we were able to extract parameters of diffusion for the sulfur vacancies and transition probabilities associated with switching between different configurations of defect complexes consisting of Mo dopant and sulfur vacancy in WS$_2$(arXiv:1803.05381), as well as to analyze evolution of topological defects in graphene. Overall, our approach allows an unprecedented insight into the nature and mechanisms of solid-state reactions and electron-beam-matter interactions on the atomic level.

SESSION CM03.17: Battery Cathodes

Session Chairs: Andrej Singer and Chongmin Wang

Thursday Morning, November 29, 2018

Hynes, Level 3, Room 300

10:00 AM CM03.17.01

Structural Analysis of Layered Li$_2$RuO$_3$ via Operando X-Ray Absorption Spectroscopy and X-Ray Diffraction Kipil Lim$^{1,2}$, Jihyun Hong$^{1,2}$, William Gent$^1$, Peter Csernica$^1$, Iwemien I. Abate$^{1,2}$, William Chueh$^1$ and Michael F. Toney$^1$; Stanford University, Stanford, California, United States; SLAC, Menlo Park, California, United States.

In the last decades, lithium-ion batteries (LIB) have significantly contributed to technological progress [1]. Recently, Li-excess layered materials are attracting interest since they exhibit high energy densities and capacities significantly higher than the commercially available layered NMC oxides [2]. Unlike conventional layered oxides where the only redox center is transition metal cations, an oxygen anion redox in the Li-excess layered material plays an important role to achieve high capacity [3]. Even though several research groups have suggested theories and tried to explain the mechanism of anion redox, the anion redox in the Li-excess layered material is still not fully understood. Understanding the electronic structural evolution of the Li-excess layered oxide is the key to understand the mechanism of the anion redox. Recently, our group reported a strong coupling between the anion redox and the transition metal migration into the Li layer during cycling in the Li$_{1+x}$[Ni,Co,Mn]$_2$O$_3$ material [4]. Their simulation predicted a reshuffling of the electronic states by the migrated transition metal and the oxidized oxygen, and the hypothesis was proved by the resonant inelastic X-ray spectroscopy (RIXS) analysis which showed a distinctive feature at the oxygen K edge spectra. Therefore, understanding the precise crystal structure is important to explain RIXS feature and understand the nature of anion redox. To build upon this work, we have selected Li$_2$RuO$_3$ as a model system, due to its good electrochemistry properties and the presence of only a single transition metal. In this work, we present how different synthesis conditions dramatically impact the properties of Li$_2$RuO$_3$. We present a combination of advanced techniques, including operando X-ray absorption spectroscopy (XAS), operando extended X-ray absorption fine structure (EXAFS), and high-resolution synchrotron X-ray diffraction to obtain a complete picture of the electronic and structural changes during cycling. This accurate structural information will be compared with the RIXS analysis to identify the mechanism of the anion redox in the Li$_2$RuO$_3$ material.

Using oxygen redox reactions to obtain higher capacity in Li-ion batteries (LIBs) is an intriguing route. Despite numerous experimental and theoretical attempts to unravel the electronic origin of oxygen redox behavior, whether the oxidation of oxygen occurs via the formation peroxo-like species or depletion of electrons from non-TM-bonding states is still, however, an open question. It is also unclear how the electron-depleted oxygen states manifest themselves in experimental observations. In this study, using Li-rich layered 4d/5d transition metal oxides and three dimensional cationic disordered cathodes as model systems, we performed density functional theory (DFT) and *ab-initio* molecular dynamics (AIMD) simulations to investigate the structural response of oxygen matrix to delithiation. The oxygen K-edge X-ray absorption near-edge spectra (XANES) were modeled using Bethe-Salpeter Equation (BSE) approach and compared with experiments, from which the oxygen redox mechanism is uncovered. This work demonstrates the effectiveness of combining experimental core-level spectroscopy with first-principles simulations to unambiguously identify the signature of oxygen reactivity, and has profound implications in understanding and exploiting the oxygen capacity in Li-rich LIB systems.

**10:30 AM CM03.17.03**

**Investigating the Nanoscale Heterogeneity of Solid Electrolyte Interphase on Amorphous Silicon from Tip Enhanced Raman Spectroscopy (TERS)**

Jagjit Nanda1, Guang Yang2, Dmitry Voylov3, Michael Naguib2, Rose Ruther1, Gabriel Veith1 and Alexei Sokolov2; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Tulane University, New Orleans, Louisiana, United States; 3The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

A key challenge of using silicon as an anode in a Li-ion battery is the dynamic nature of the solid electrolyte interphase (SEI) layer that constantly breaks and reforms due to the enormous volume changes during electrochemical cycling resulting in the loss of lithium inventory. Recent literature studies report a highly heterogeneous and multiphase nature of SEI that evolves under continuous electrochemical cycling. In this work, we report Tip Enhanced Raman Spectroscopic (TERS) study of SEI on cycled amorphous silicon (a-Si) for the first time. Amorphous silicon anode (50 nm in thickness on copper current collector) was cycled in a commercial lithium-ion battery electrolyte (1M LiPF6 in EC/DEC: 1:1 vol). TERS analysis on cycled amorphous silicon sample indicates that the nanometer scale SEI “islands” are unevenly distributed on the Si anode surface. Even for the same SEI “island”, the composition is different from point to point with inter-point distance smaller than 10 nm. In addition, the TERS spectra and mapping obtained from a-Si of differing cycle numbers suggests different SEI local compositions. The a-Si cycled for once (denoted as 1X a-Si) has rich local SEI species containing poly(ethylene oxide) (PEO) - like oligomer and lithium ethylene dicarboxylic (LEDIC, (CH2OCOOL)2). In sharp contrast, the bulk chemical information of the SEI for 1X a-Si probed by FT-IR only indicates the existence of the Li2CO3. Moreover, different vibrational modes from the same species such as LEDIC have differing TERS activity. This is due to different alignments of the enhanced near field vector versus the Raman scattering tensor of the given vibrational modes. The SEI on 5X a-Si is dominated by the LEDIC species, although Raman bands assigned to PEO oligomer and carboxylate compounds also show up. For 20X a-Si, the dominant species in the SEI is carboxylate compounds. The bands between 1450 cm-1 and 1650 cm-1 which are related to the =CO stretching and C=O stretching modes were analyzed in details for the first time. Due to its excellent spectral resolution on this type of compound, as compared to its IR counterparts, TERS is capable of probing the conformational change of the carboxylates upon their coordination to Li+ cations with nanoscale spatial resolution in sample plane.

**Multiscale Heterogeneity in Single Particles of Li-Ion Battery Cathodes Visualized with X-Ray Imaging**

Jordi Cabana; University of Illinois at Chicago, Chicago, Illinois, United States.

The existing performance limitations of Li-ion batteries can be tracked to slow transport and irreversibilities in the changes undergone by the electrode materials, often coupled with mechanical events. Tools that provide insight into the onset and propagation of these transitions are critical to identify the mechanisms of electrochemical function. This information must be generated at the level of single particles, where irreversibilities trigger degradation of the electrode architecture. Synchrotron-based X-ray microscopy currently combines high spatial resolution with a suite of possible mechanisms of chemical contrast, such as diffraction and spectroscopy. In this talk, we will discuss recent developments to image, using X-rays, electrochemical reactions in single particles of battery electrodes, with a focus on the prospects of capturing and assessing the relevance of time-resolved phenomena using *operando* measurements. These measurements avoid relaxation of components from the kinetically controlled functional state to one that is more stable under open circuit conditions. The talk will highlight the new fundamental insight generated by the tools, involving mechanisms of transformation and local dynamics of heterogeneity.

**11:00 AM CM03.17.05**

**An Operando Study of Rechargeable MnO2 Cathodes for Low Cost, High Energy Density Aqueous Batteries**

Joshua W. Gallaway1, Gautam Yadav2, Damon Turney2 and Sanjoy Banerjee; 1Northeastern University, Boston, Massachusetts, United States; 2City College of New York, New York, New York, United States.

This talk will outline the complex cycling pathways of electrolytic manganese dioxide in alkaline electrolyte, as studied by *operando* characterization in "real world" electrodes of high areal capacity. The alkaline MnO2 system is one of the safest and most inexpensive battery materials ever discovered, and is well known in primary batteries. Deeply cycling MnO2 has the potential to provide battery storage of high safety, high energy density, low toxicity, and low cost, for applications such as intermittent renewable generation backup at the scale of the power grid. Deep cycling is defined as reduction through nearly all of the theoretical capacity from Mn(IV) to Mn(II), or 617 mAh/g-MnO2, while remaining reversible. Modification of MnO2 by Bi is known to impart rechargeability, through a cycling pathway with the layered polymorph δ-MnO2 as the end member.[1-3] The molecular mechanism of this effect has previously been unknown, and typically works well only in thin electrodes of low areal capacity, lessening the potential for use in applications. However, it has recently been reported that modification by both Bi and Cu imparts rechargeability even in thick electrodes, promising high impact if this chemistry is successfully developed into practical batteries.[4]

The MnO2 proton insertion reaction involves both unit cell dilatation and multiple phase changes, which are often spatially inhomogeneous throughout the electrode.[5] We use the correlation of energy dispersive X-ray diffraction (EDXRD) to a multiscale electrochemical model to demonstrate that a phase
change to MnOOH leads to spinel formation, but this reaction is suppressed with Bi. EDXRD using high energy white beam photons allows spatially-resolved diffraction to be collected in real time within batteries through the cell containment. We further demonstrate two distinct regimes of Mn(OH)₂ formation, with Bi causing a shift from amorphous to highly crystalline discharge product. These phenomena have not previously been observed through ex situ analysis. We further use a cell modified for X-ray transparency to follow the concentrations and redox states of Mn, Bi, and Cu spatially, in real time. This is done via operando X-ray fluorescence mapping (XRF) and micron-sized spot XANES (μ-XANES). All experiments were performed on electrodes with areal capacities of ~20 mAh/cm². Modeling indicates that such cathodes have potential to result in high energy density aqueous, rechargeable batteries when paired with zinc anodes meeting the requirements for a collection of emerging applications, namely grid-scale electrical storage.[6]

Cation Ordering and Oxygen Release in LiNi₀.₅Mn₁.₅O₄ (LNMO)—In Situ Neutron Diffraction and Performance in Li-Ion Full Cells Burak Aktekin1, William Brant1, Mario Valvo1, Fernando L. Marzano2, Wolfgang Zipprich1, Daniel Brandell1 and Kristina Edstrom1; 1Department of Chemistry – Ångström Laboratory, Uppsala University, Uppsala, Sweden; 2Scania CV AB, Södertälje, Sweden; 3Volkswagen AG, Wolfsburg, Germany.

LiNi₀.₅Mn₁.₅O₄ (LNMO) is a promising spinel-type positive electrode for lithium ion batteries as it operates at high voltage and possesses high power capability. However, rapid performance degradation in full cells, especially at elevated temperatures, is a problem. There has been a considerable interest in its crystal structure as this is known to affect its electrochemical performance. LNMO can adopt a P4/mnn (cation ordered) or Pfdm (cation disordered) arrangement depending on the synthesis conditions. Most of the studies in literature agree on better electrochemical performance for disordered LNMO [1], however, a clear understanding of the reason for this behaviour is still lacking. This partly arises from the fact that synthesis conditions leading to disordering also lead to oxygen deficiency, rock-salt impurities and therefore generate some Mn³⁺ [2]. Most commonly, X-ray diffraction is used to characterize these materials, however, accurate structural analysis is difficult due to the near identical scattering lengths of Mn and Ni. This is not the case for neutron diffraction. In this study, an in-situ neutron diffraction heating-cooling experiment was conducted on slightly Mn-rich LNMO under pure oxygen atmosphere in order to investigate relationship between oxygen atmosphere and oxygen deficiency. The study shows that the first time that there is no direct relationship between oxygen loss and cation disordering, as disordering starts prior to oxygen release. Our findings suggest that it is possible to obtain samples with varying degrees of ordering, yet with the same oxygen content and free from impurities. In the second part of the study, highly ordered, partially ordered and fully disordered samples have been tested in LNMO|LiTFSI(O) full cells at 55 °C. It is shown that differences in their performances arise only after repeated cycling, while all the samples behave similarly at the beginning of the test. The difference is believed to be related to instabilities of LNMO at higher voltages, that is, in its lower lithiation states.

1:30 PM *CM03.18.01
Nucleation of Dislocations and Their Dynamics in Layered Oxides Cathode Materials During Battery Charging Andrei Singer; Department of Materials Science and Engineering, Cornell University, Ithaca, New York, United States.

Lithium-rich layered oxides (LRLO) are among the leading candidates for the next generation cathode material for energy storage, delivering 50% excess capacity over commercially used compounds. Despite excellent prospects, voltage fade has prevented effective use of the excess capacity, and a major challenge has been the lack of understanding of the mechanisms underpinning the voltage fade. I will present our recent results, where using operando three-dimensional Bragg coherent diffractive imaging, we directly observe the nucleation of a mobile dislocation network in LRLO nanoparticles. The dislocations form more readily in LRLO as compared with a classical layered oxide, suggesting a link between the defects and voltage fade. We show microscopically how the formation of partial dislocations contributes to the voltage fade. The insights allow us to design and demonstrate an effective method to recover the original high voltage functionality. Our findings reveal that the voltage fade in LRLO is reversible and call for new paradigms for improved design of oxygen-redox active materials.

2:00 PM CM03.18.02
In Situ Synchrotron X-Ray Diffraction Studies on the P2- Manganese Based Sodium Layered Oxides—Structural Evolution During Cycling Elena Gonzalez1, Wesley Dose2, Neeraj Sharma3, Teofilo Rojo1, 3 and Miguel Angel Muñoz-Marquez2; 1CIC Energigune, Miñano, Spain; 2Chemical Sciences and Engineering (CSE) Division, Argonne National Laboratory, Lemont, Illinois, United States; 3Departamento de Química Inorgànica, Universidade do País Vasco UPV/EHU, Bilbao, Spain; 4School of Chemistry, University of New South Wales, Sydney, New South Wales, Australia.

Na-ion battery research has been under focus lately due to its advantages in specific applications such as large scale power grid systems [1,2]. Among the candidates of cathode materials, layered oxides with the general formula: NaTMO₂ (TM = Cr, Mn, Fe, Co, Ni, etc.) exhibit one of the largest theoretical capacities along with simple crystal structures.[3,4]

Co- and Ni- free P2-manganese based systems possesses excellent cathode characteristics for Na-ion batteries due to combination of environmentally benign, economically favorable transition metals and high capacity, although some issues such as the Jahn-Teller distortion effect, ascribed to Mn³⁺, has to
be taken into account.[5] The importance of considering this issue has been widely studied by our group,[6,7] as well as mitigation strategies – such as doping with electrochemically active (Fe)[8] and inactive elements (Ti).[9]

Here we report the in situ synchrotron X-Ray diffraction study we have carried out to shed light on the relationship between electrochemical performance and structural evolution of different P2- Na2-xMnxFe2O4 phases (0.1≤x≤0.67) upon cycling. Lattice parameter evolution, phase fractions and sodium content in the crystal structure as a function of the charge/discharge process and at different current rates will be shown. The effect of dopants such as Ti and the mitigation of structural changes during cycling will be examined in detail.

In Operaando Tracking Ion Intercalation into 2D MXenes in Aqueous Electrolytes

Qiang Guo1, Xin Li1, Weiwei Sun1, Michael Naguib3, Stephen Jesse1, Paul Kent1, 2, Arthur P. Baddorf1 and Nina Balke1, 1Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Computer Science and Mathematics Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3Department of Physics & Engineering Physics, Tulane University, New Orleans, Louisiana, United States.

Super capacitors have drawn considerable attention for a variety of applications in portable electronics, grid and transportation systems due to their rapid power delivery and an almost unlimited cycle life. To enhance the energy stored, the intensive efforts have been devoted to exploring new electrode materials, new electrolytes, and novel cell configurations. In search for new electrode materials, two dimensional (2D) transition metal carbides-MXenes, are of particular interest owing to their excellent electrical conductivity and high volumetric capacitance[1][2]. The mechanism for high capacitance was essentially described as intercalation pseudo-capacitance arising from redox reactions of the Ti atoms. Similar to graphite or other electrode materials, MXene electrodes also show a significant change in volume when ions are intercalated. This electro-chemo-mechanical coupling can be used to get unprecedented insight into ion intercalation pathways with lateral resolution of 10’s of nm using Scanning Probe Microscopy (SPM) techniques. In this communication, we introduce contact resonance SPM which allows to extract mechanical properties and its changes under electrochemical control when ions are intercalated into MXenes.[3][4]. Therefore, it is of great importance to explore the different intercalation contributions with varying aqueous cations to the mechanical properties variations of material itself, which is required to evaluate the electrochemical long-term stability of electrode materials. Of special interest to boost energy storage is the intercalation of multivalent ions which suffers from sluggish intercalation and transport kinetics due to its ion size. By combining electrochemical dilatometry and contact resonance atomic force microscopy, the synergistic effects of smaller ion size cation and larger ion size cation are demonstrated to improve charge storage to maximize the utilization of electrode volume, as well as tune mechanical and actuation properties of Ti3C2 MXene.[5][6] Our results have important implications for quantitatively understanding the charge storage processes in intercalation compounds and provide a new path for studying the mechanical evolution of a variety of electrochemical energy storage materials.

The experiments and sample preparation in this work were supported as part of the Fluid Interface Reactions, Structures and Transport (FIRST) Center, an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science, Office of Basic Energy Sciences. The facilities to perform the experiments were provided by the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

In Situ and Ex Situ Electron Microscopy and Spectroscopy Diagnosis Guided Designing of Electrode Materials for Better Battery

Chongmin N. Yang, Pacific Northwest National Laboratory, Richland, Washington, United States.

In-situ diagnosis appears to be one of the essential methods for gaining insights as how an electrode material failure, therefore feeding back for designing and creating new materials with enhanced performances. In this presentation, I will highlight recent progress on ex-situ, in-situ and operando S/TEM for probing into the structural and chemical evolution of energy storage materials. Both ex-situ and in-situ high resolution imaging enables direct observation of structural evolution, phase transformation and their correlation with mass and charge transport, providing insights as how active materials failure during the cyclic charge and discharge of a battery. In particular, I will broadly cover the frontier of the current understanding of the interfacial process in an electrochemical cell. In perspective, my presentation will target to stimulate this field of research to re-check what has been understood and what need to be done to tackle the technical challenges facing the application of the layer structured cathode and high capacity silicon based anode.

3:00 PM BREAK
With an increasing demand for higher energy and power density of lithium ion batteries (LIBs), the coupled electrochemical-mechanical degradation of electrode materials becomes a more pressing problem. In particular, fracture and delamination of electrodes can occur during repeated charging and discharging of LIBs. An improved understanding of the mechanical behavior of electrode materials, which often evolves with the state-of-charge and cycle number, is therefore necessary for improving the performance and durability of the next generation LIBs. In this presentation, we will provide an overview of our recent work on using three complementary measurement techniques: (1) in situ electrochemical nanoindentation; (2) peel adhesion and cohesion test; and (3) electrode curvature measurement to help understand several coupled effects between mechanical and electrochemical behavior of materials on the performance and durability of high capacity electrodes. Examples include Si/polymer binder porous composite electrodes, lithium metal electrodes, and inorganic/polymer composite solid-electrolytes. The suite of complementary in situ mechanical characterization techniques can also be used to investigate mechanical behavior of a wide range of electrochemical energy storage materials under realistic working conditions.

2. Jiazhi Hu, Yikai Wang, Dawei Li, and Yang-Tse Cheng, "Effects of binder-silicon interfacial strength on the electrochemical performance and durability of silicon composite electrodes for the next generation lithium-ion batteries," J. Power Sources (under review).

Silicon is considered as a promising anode material for the next generation lithium-ion battery due to its high capacity at nanoscale. However, silicon expands up to 300% during lithiation, which induces high stresses and leads to fractures. To design silicon nanostructures that could minimize fracture, it is important to understand and characterize stress states in the silicon nanostructures during lithiation. Synchrotron X-ray microdiffraction has proven to be effective in revealing insights of mechanical stress and other mechanics considerations in small-scale crystalline structures used in many important technical applications, such as microelectronics, nanotechnology and energy systems. In the present study, an in situ synchrotron X-ray microdiffraction experiment was conducted to elucidate the mechanical stress states during the first electrochemical cycle of lithiation in single-crystalline silicon nanowires (SiNWs) in a lithium-ion battery test cell. Morphological changes in SiNWs at different levels of lithiation were also studied using scanning electron microscope (SEM). It was found from SEM observation, that lithiation commenced predominantly at the top-surface of SiNWs followed by further progression towards the bottom of the SiNWs gradually. The hydrostatic stress of the crystalline core of the SiNWs at different levels of electrochemical lithiation was determined using the in situ synchrotron X-ray microdiffraction technique. We found that the crystalline core of the SiNWs became highly compressive (up to ~325.5 MPa) once lithiation started. This finding helps unravel insights about mechanical stress states in the SiNWs during the electrochemical lithiation, which could potentially pave the path towards the fracture-free design of silicon nanostructure anode materials in the next generation lithium-ion battery. The in situ synchrotron X-ray submicron diffraction methodology as a probe of stress and thus reliability of the novel silicon nanowire anode in Li-ion battery described is also novel and could lead to enable next generation, more robust Li-ion battery technology and thus enable next generation applied energy technologies for the world.

Silicon metal anode can serve as a host-free electrode, and thus has the highest theoretical capacity compared to traditional graphite-based electrodes as well as advanced lithium-alloying anodes. The major challenge with the lithium anode is highly dendritic deposition, resulting in 'mossy' electrode and internal short-circuits. A part of underlying failure mechanisms is attributed to mechanical degradation of solid electrolyte interphase (SEI). Recent theoretical and experimental studies suggest that surface films with high elastic modulus and mechanical stability may mechanically suppress the dendrite formation. Stable lithium plating/striping with ionic liquid (IL) electrolytes, which are known to form inorganic SEI supports the suggestion. This background motivates to develop an experimental platform to measure elastic moduli of SEI formed with various electrolytes. However, most previous experimental approaches are limited to the atomic force microscopy (AFM) indentation. The approach has several sources of uncertainties such as substrate influence and inaccurate contact area due to low thickness and roughness of SEI. As a result, reported elastic modulus of SEI has several orders of magnitude variation.

In this work, we use strain induced elastic buckling instability for mechanical measurement (SIEBIMM) approach to measure the plane strain elastic modulus of SEI formed with IL electrolytes. SEI layers (~80 – 200nm) on polydimethylsiloxane (PDMS) substrates are prepared by letting thermally evaporated lithium thin films react with IL electrolytes. The formation of SEI result in large enough compressive residual stress induce elastic buckling. In situ AFM measures the thickness of SEI and the characteristic wavelength of the buckling topography to extract the plane strain modulus. The
Hydrogen is steadily emerging as the next generation fuel owing to its high gravimetric energy density (143 kJ kg⁻¹) and environmentally benign nature.

Research, Bangalore, India.

The potential advantages of lithium (Li) metal anodes have been widely touted (lowest reduction potential, etc). However, the poor stability of Li metal / liquid electrolyte interfaces leads to chronic problems, such as dendrite formation and capacity loss. The possible impact of mechanical effects on interface stability and dendrite formation is difficult to probe directly. In this study, stress evolution during lithium plating and stripping was monitored with precise in-situ measurements. The data obtained with different film thicknesses made it possible to separate the stresses associated with the lithium metal and the solid electrolyte interphase (SEI). Ex-situ morphological characterization also provided additional information. The results show that significant stresses are created in the SEI films. A basic model of the experiments provides further understanding of the stress contribution from the SEI. An analysis of the relationship between stress in the SEI and morphological stability is also presented.

**SESSION CM03.20: Electrocatalysis**

**Mechanistic Insights into the Promotional Effect of Ni Doping on Mo and W Carbide Systems @NPGC for Highly Enhanced Overall Water Splitting**

Soumyabrata Roy1, 2, Debabrata Bagchi1, 2, Saurav C. Sarma1, 2 and Sebastian C. Peter1, 2; 1New Chemistry Unit, Jawaharlal Nehru Centre For Advanced Scientific Research (JNCASR), Bangalore, India; 2School of Advanced Materials (SAMat), Jawaharlal Nehru Centre For Advanced Scientific Research, Bangalore, India.

Hydrogen is steadily emerging as the next generation fuel owing to its high gravimetric energy density (143 kJ kg⁻¹) and environmentally benign nature. The electrocatalytic process of H₂ generation involves various mechanistic steps at the catalyst surface (adsorption, desorption, spilling and electron transfer) which govern a catalyst’s activity. Transition metal (Mo, W) carbide systems are well known for electrocatalytic hydrogen evolution reaction (HER) due to their optimum proton adsorption energy (del GHads) and good electrocatalytic stability. However, there is still huge scope for improving the activities of carbide systems in terms of electrical conductivity, current densities and onset potentials for HER. We have adopted a one-step in-situ synthetic method to form Ni-doped WC and MoC nano-systems dispersed on nitrogen and phosphorus doped graphitic carbon (NPGC). The catalysts, both Ni-doped WC and MoC, have shown multi-fold improvement in activity both in terms of current densities and onset values than the undoped ones. While the NPGC enhances the electrical conductivity of the catalyst, Ni, as evident from theoretical calculations, optimises the d-band centre and free energy for proton adsorption to yield high activities. Three different percentages of Ni (5:1, 5:2 and 5:3-W/Mo:Ni precursor ratio) were doped to study the promotional effect of Ni doping. Interestingly, the doping percentage and the primary carbide phase was modulated by the extent of milling of the precursors, owing to the differential Ni-diffusion into the carbide lattice. The best electrocatalytic HER activity was observed in the non-ball milled Ni-doped MoC sample (Mo-Cr-Ni(5:1) _NB) with an onset overpotential of 120 mV and a current density of 130 mA/cm² at -370 mV (v RHE), stable up to 10000 cycles. However, the WC-Ni(5:1) BM sample showed the best activity among WC samples with a similar onset but a lesser current density of 90 mA/cm². The electronic interactions of Ni with the metal carbide motifs and the nature of the graphitic carbon were studied through XAFS, XPS and Raman studies. Both samples showed enhanced OER activity in alkaline medium with good onset values of about 1.5 V (v RHE) and current densities as high as 150 mA/cm² at 1.86 V with good stability. Thus their activity as overall water splitting catalysts triggered us to fine tune the electrolyte pH for both HER and OER activities to construct a H₂/O₂ electrolyzer with a minimum Eₘₚ between them as bifunctional catalysts. The activities of the best MoC and WC catalysts are comparable to commercial Pt/C for HER and better than IrO₂ in case of OER. The electronic and structural roles of Ni in enhancing the catalytic activity has been studied through DFT calculations, XPS and in-situ quick EXAFS studies. These studies elucidate, in real time picture, how the adsorption energies of intermediates and reaction kinetics are modulated at different catalytic sites with the promotional effect of Ni doping.

**Spectroscopic Observation of an Electrochemically Inert CO Sub-Population on Cu Electrodes Under CO Reduction Conditions in Alkaline pH**

Charumi M. Gunathunge1, Vincent Ovalle1, Yawei Li2, Michael Janik1 and Matthias Waegeler1; 1Chemistry, Boston College, Chestnut Hill, Massachusetts, United States; 2Chemical Engineering, The Pennsylvania State University, University Park, Pennsylvania, United States.

Copper is the only pure metal capable of reducing carbon dioxide to hydrocarbons at significant rates in an aqueous electrochemical environment. Therefore, it is a prototypical catalyst for the electroreduction of carbon dioxide to various economically valuable hydrocarbons, such as methane and ethylene. Surface-adsorbed CO has been identified as a common on-pathway intermediate to hydrocarbons and re-reduction correspond to the potential-
determining step of the overall process. While CO can adsorb on different adsorption sites (e.g. top or bridge) on the Cu surface, in situ spectroscopy of the copper/electrolyte interface has mostly been focused on atop-bound CO. Herein, we combine a combination of interface-selective infrared (IR) and Raman spectroscopies and DFT calculations to study the reactivity and surface dynamics of atop- and bridge-bonded CO on Cu electrodes. We show for the first time that (1) a fraction of the atop-bound CO population shifts to bridge sites when the total surface coverage is lowered below the saturation coverage (2) in contrast to atop-bound CO, bridge-bonded CO is electrochemically stable against reduction at a potential of -1.75 V vs. SHE. Our DFT calculations further reveal an unfavorable effect of the interfacial electric field on the activation barrier for the reduction of bridge-bonded CO as the underlying mechanism of the observed reactivity. In systematic pH studies, we further identify a pH-induced reconstruction of the Cu surface under operating conditions as the likely origin of the conversion of CO from atop- to bridge-sites. We will further discuss the implications associated with the co-existence of the two distinct CO populations on the electroreduction of atop-bound CO.

Operando XAFS Measurements of Water Splitting Photocatalysts Takashi Hisatomi1 and Kazunari Domen1-2; 1University of Tokyo, Tokyo, Japan; 2Center for Energy & Environmental Science, Shinshu University, Nagano-shi, Japan.

Water splitting using semiconductor photocatalysts has attracted much attention as a means of renewable hydrogen production on a large scale [1]. When a particulate semiconductor photocatalyst absorbs a photon, an electron is excited from the valence band to the conduction band, and a positive hole is left in the valence band. These excited electrons and holes can drive reduction and oxidation reactions on each photocatalyst particle, respectively. To drive the water splitting reaction efficiently, it is necessary to load nanoparticles metals and metal oxides, denoted as cocatalysts, on the photocatalyst as active sites for the hydrogen evolution reaction and the oxygen evolution reaction. Otherwise photoexcited electrons and holes just recombine without contributing to the reaction. It is also important to suppress backward reactions such as formation of water from product hydrogen and oxygen and the oxygen reduction reaction. The authors’ group has developed rhodium chromium oxide (RhCrO3) as cocatalyst effective for the overall water splitting reaction [2-5] and has revealed the structure and working mechanism.

Al-doped SrTiO3 (SrTiO3:Al) loaded with a rhodium chromium oxide (RhCrO3) as a cocatalyst (RhCrO3/SrTiO3:Al) decomposes water into hydrogen and oxygen with an apparent quantum yield of 56% at 365 nm [6]. The activity of the photocatalyst starts to decreases in 10 h when the reaction is conducted at an atmospheric pressure; however, loading of cobalt oxide species (CoOx) drastically improves the durability. It is suspected that CoOx species serves as an oxygen evolution cocatalyst and extracts holes from the photocatalyst to prevent oxidative dissolution of the Cr component in the RhCrO3 cocatalyst. In order to discuss the function of the cocatalyst species, the X-ray absorption fine structure (XAFS) of RhCrO3 and CoOx species loaded onto SrTiO3:Al were investigated operando, i.e., in water under UV light irradiation.

In this talk, recent progress and understanding of the structures, chemical states, and functionality of the cocatalysts are to be discussed

9:00 AM CM03.20.04
Visualizing Electrochemical Reactions at the Nanoscale by In Situ TEM Huidun L. Xin, M. Ge and Yong Chu; Brookhaven National Laboratory, Upton, New York, United States.

Over the past five years, we have witnessed a rapid growth in liquid and gas flow holders for TEM and X-ray microscopes. These holders have enabled direct imaging of material transformations in liquid and gaseous environments with submicron-scale to atomic-scale spatial resolution. In particular, research regarding electrode materials in lithium ion batteries and nanocatalysts in heterogeneous catalysis has greatly benefited from the emergence of these capabilities. Despite their initial success in in-situ battery studies, similar class of problems in electrocatalysis has been rarely addressed using existing liquid electrochemical holders. In this talk, I will showcase the capability of direct nanoscale visualization of electrochemical formation and degradation of electrocatalysts utilizing an operando TEM liquid holder and I will also discuss existing challenges that the in-situ EM field need to address.

The research used resources of the National Synchrotron Light Source II and the Center for Functional Nanomaterials, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Brookhaven National Laboratory under Contract No. DE-SC0012704. The research used resources of the National Synchrotron Light Source II and the Center for Functional Nanomaterials, a U.S. Department of Energy (DOE) Office of Science User Facility operated for the DOE Office of Science by Brookhaven National Laboratory under Contract No. DE-SC0012704. 9:15 AM CM03.20.05
Uncovering Biaxial Strain Effect on Kinetics of Metal Nanoparticle Catalyst Exsolution on Thin-Film Perovskite Oxides Jianue Wang1, Alexander K. Opitz1,2, Roland Blien1, Xiaohui Yao1, Guolini Vardar1, Dongha Kim1, Irawkanari Waluyo1, Adrian Hunt1, Ethan J. Crumlin2 and Bilge Yildiz1; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Institute of Chemical Technologies and Analytics, Vienna, Austria.

Environment-friendly approaches are being advanced to synthesize carbon-neutral fuels. Some of these technologies rely on catalytically highly active nanoparticles that are supported on oxides. These nanostructured catalysts exhibit enhanced activity towards desired reactions due to their high specific area, and thus, increase the efficiency of the respective system. A recent advance in such catalyst design is to exsolve catalytic metal nanoparticles at the surface of a supporting oxide. Unlike traditional deposition techniques, the nanoparticle catalysts from exsolution are anchored in the parent oxide. This strong metal-oxide interaction makes the exsolved nanoparticles more resistant against particle agglomeration as compared to the deposited ones. In addition, the exsolved particles also open up the possibility of regeneration of catalysts.

While being an exciting and promising pathway for high-performance oxido-metal composite catalysts, the approach towards exsolution has thus far been an empirical one, without a clear understanding and control of the underlying mechanisms to optimize catalyst composition, size and dispersion. Studies in the literature indicate that the exsolution products depend on both the surface chemistry (i.e. stoichiometry and composition) and bulk chemistry (i.e. composition and extended defects) of the parent oxide. However, it remains unclear how these parameters affect the exsolution process.

In this work, we aim to uncover how biaxial strain affects the exsolution process. Our hypothesis is that elastic strain in thin films can alter the reducibility (oxygen stoichiometry) and surface composition, and thereby affect the metal exsolution process. We quantify the strain effect on the materials'
reducibility and on surface cation composition. \( \text{La}_{0.6}\text{Sr}_{0.4}\text{FeO}_3 \) thin films are employed as model systems due to the well-studied defect chemistry of LSF64, and the possibility to solve metallic Fe on the surface without decomposing the perovskite lattice. Biaxial strain is introduced by growing LSF64 thin films epitaxially on substrates with different lattice constants. In-situ ambient pressure X-ray spectroscopy is employed to probe defect chemistry, surface composition, and exsolution rate on LSF64 thin-film samples at different temperatures. Coupling surface chemistry with morphological information from atomic force microscopy, we found that in-plane biaxial strain can be a powerful tool in optimizing both the onset temperature of exsolution as well as the particle dispersion of the exsolution products. The observed strain dependence of exsolution advances our abilities to control them and enhance the performance of catalysts for clean energy technologies.

In Situ Evidence of a Segregation Driven Metal-Insulator Transition at the Surface of an Epitaxial Semiconducting Manganese Thin Film Arthur P. Baddorf, Rama K. Vasudevan, Hemant Dixit, Alexander Tselev, Valentino Cooper, Panchapakesan Ganesh and Sergei V. Kalinin; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

We have established the ability to alter the conductivity and magnetism of \( \text{La}_{0.6}\text{Sr}_{0.4}\text{MnO}_3 \) film surfaces by tuning the degree of Ca segregation and the termination, which determine the Jahn-Teller distortion. This is of interest since doped manganese oxides (manganites) exhibit a rich response to an electric field, mixing electron and ionic transport and resulting in structural or electronic phase transitions. Manganites are consequently intriguing components in electrocatalysts, memristors, sensors, and solid oxide fuel cells. Interfaces, which play a key role in applications, introduce strain, off-stoichiometry, surface cation segregation, changes to octahedral rotations and Jahn-Teller coupling which open opportunities to tailor properties.

We have grown \( \text{La}_{0.6}\text{Sr}_{0.4}\text{MnO}_3 \) films by pulsed laser deposition and examined the surface structure, composition, and metallicity with in-situ studies using scanning tunneling microscopy and spectroscopy (STM/S), x-ray photoelectron spectroscopy, and first principles computation. Background oxygen pressure during growth has a strong effect on surface structural and electronic features. Deposition at 20 mTorr O2 leads to a predominantly B-site (MnO2) terminated surface with less A-site (La,Ca)O termination. Increasing the O2 pressure modestly to 50 mTorr produces mixed termination and atomically imperfect surfaces. Both growth modes result in excess Ca at the surface, with greater segregation at higher growth pressures.

STM images show that B-site surfaces have bulk surface structure, whereas A-site terminations are reconstructed. STS demonstrates that both surfaces are metallic (gapless) even though the film bulk remains semiconducting. Density functional theory (DFT) provides understanding of how two experimentally observed structural conditions lead to metallicity. First, computation reveals that the bulk ferromagnetic (FM) ordering is replaced by antiferromagnetic (AFM) ordering with increasing Ca concentration in the top layer and is more stable for 50% Ca as observed in experiments due to segregation. Second, DFT finds that \( (\text{La},\text{Ca})\text{O} \) reconstructed surfaces, where half of apical oxygen are present, are insulating with a band gap of \( \sim 0.8 \) eV. This apical oxygen increases the electron-phonon coupling, specifically a Jahn-Teller distortion, leading to insulating behavior. This information can enable better control over of manganate interfaces in a number of applications.

Research was sponsored the US Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division and the Office of Science Early Career Research Program. Research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

10:15 AM CM03.21.02
In Situ Negative Cs HRTEM Imaging of Topotactic Phase Transformation from Perovskite SrFeO3 to Brownmillerite SrFeO2.5 Yadaong Xing1, Kyeong Tae Kang2, Zhen Wang1, Bumsuk Park1, Jinsol Seo1, Jong Chan Kim1, Hu Young Jeong3, Donghoon Jang3 and Sang Ho Oh1; 1Department of Energy Science, Sungkyunkwan University, Suwon, Korea (the Republic of); 2Department of Physics, Sungkyunkwan University, Suwon, Korea (the Republic of); 3School of Materials Science and Engineering, Ulsan National Institute of Science and Technology, Ulsan, Korea (the Republic of).

SrFeO3, a candidate oxide electrode for solid oxide fuel cell, undergoes topotactic phase transformation reversibly to SrFeO2.5 at relatively low temperatures compared to other known similar class of materials due to the small difference in Gibbs free energy between the two phases. The phase transition is referred to as topotactic as the cation sublattice remains almost unchanged while oxygen ions (or vacancies) diffuses through the lattice along the specific crystallographic channels to modify the local coordination and valence states of cations. Previously X-ray diffraction and sequential STEM HAADF imaging have been used to characterize the phase transition of this type of materials. However, neither of these methods can directly observe the channeling of oxygen vacancies, which is extremely difficult due to the low scattering power of oxygen atoms. Here, we report in situ high resolution transmission electron microscopy observation of the phase transition of a 30 nm-thick SrFeO3 epitaxial thin film to SrFeO2.5 brownmillerite phase at elevated temperatures in a Cs-corrected TEM (Grand ARM300F) operated at 300 kV. The TEM lamellas were prepared by focused ion beam milling and attached on the Si MEMS chip for heating using a DENSsolutions Wildfire TEM holder. By using negative spherical aberration imaging (NCSI) technique, we successfully imaged all types of atomic columns in SrFeO3 over a quite large area, which makes it possible to observe the oxygen vacancy channeling and formation and growth of SrFeO2.5 brownmillerite phase during heating. Although real-time NCSI HRTEM movies clearly resolve the oxygen columns, it is still difficult to measure local concentration of oxygen vacancy and sublattice change by looking at dynamically varying oxygen intensity, because of the topotactic phase transformation. We have applied several analysis methods to quantitatively measure the intensity of oxygen columns and cation sublattices to visualize local dynamic motion of transition process. Besides, the inverse Fourier filtered image formed by selecting the reflections from brownmillerite phase visualizes the dynamic motion of phase distribution. It was observed that brownmillerite SrFeO2.5 phase forms and grows from many different locations simultaneously, resulting in the formation of anti-phase boundaries at junctions.

Dynamic Control and In Situ Measurements of Oxygen Nonstoichiometry and Phase of Layered Cuprate-Based Thin Films by Electrochemical Pumping Chang Sub Kim and Harry L. Tuller; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Three major criteria are essential for a good solid oxide fuel cell (SOFC) electrode: 1) mixed ionic and electronic conductivity, 2) electrocatalytic activity towards oxygen surface exchange reaction, and 3) chemical and chemo-mechanical stability. Conventional method of assessing these electro-chemo-mechanical properties requires doping different concentrations of aliovalent cations and/or controlling atmosphere. These, however, are constrained by...
solubility limits of dopants, the range of oxygen partial pressures readily experimentally achievable, and require knowledge of the applicable defect chemistry model. In this study, we control and measure oxygen defect types, concentration, and phases of oxygen by electrochemical pumping of oxygen into and out of the film utilizing a Nernst cell of the form Pt/YSZ/PCO. Two cell geometries are examined, including (1) deposition of PCO films on yttrium stabilized zirconia (YSZ) single crystal substrates (300-500 microns thick) and (2) the deposition of PCO films on highly resistive substrates (e.g. Al$_2$O$_3$ or MgO) and subsequent coverage with a YSZ film to pump oxygen. In this work, the chemical expansion of Pr$_x$Ce$_{1-x}$O$_{2-y}$ (PCO) shows the ability to reversibly release and take up substantial amounts of oxygen, even in the high oxygen partial pressure regime (ambient air down to about p$_{\text{O}_2}$ $\approx$ 10$^{-5}$ bar). While strain values of the order of 1 percent are achievable via chemical expansion and contraction, this results in dimensional changes of only on the order of 1-10 nm depending on the thickness of the PCO films. Such levels of chemical expansion are, however, sufficiently large to observe by optical means [2].

To achieve reasonable signal to noise ratios in measuring such small displacements, measurements benefit from periodic adjustment of the oxygen activity within the PCO films, achieved by electrochemical pumping of oxygen into and out of the film utilizing a Nerst cell of the form Pt/YSZ/PCO. Two cell geometries are examined, including (1) deposition of PCO films on yttrium stabilized zirconia (YSZ) single crystal substrates (300-500 microns thick) and (2) the deposition of PCO films on highly resistive substrates (e.g. Al$_2$O$_3$ or MgO) and subsequent coverage with a YSZ film to pump oxygen. In this work, the chemical expansion of Pr$_x$Ce$_{1-x}$O$_{2-y}$ (PCO) shows the ability to reversibly release and take up substantial amounts of oxygen, even in the high oxygen partial pressure regime (ambient air down to about p$_{\text{O}_2}$ $\approx$ 10$^{-5}$ bar). While strain values of the order of 1 percent are achievable via chemical expansion and contraction, this results in dimensional changes of only on the order of 1-10 nm depending on the thickness of the PCO films. Sub-Micron Resolution X-Ray Spectroscopy and X-Ray Fluorescence Imaging at the NSLS-II SRX Beamline
Andrew Kiss, Juergen Thieme and Yong Chu; National Synchrotron Light Source II, Brookhaven National Laboratory, Upton, New York, United States.

The NSLS-II is a recently built and commissioned synchrotron designed to accommodate experiments that require highly coherent and high brilliance X-rays. The generated X-ray light has a very low emittance of 0.6 mm-rad and 8 pm-rad in the horizontal and vertical directions, respectively, as well as a position stability of less than 10% of the source size in the horizontal and vertical. The ring current has been steadily increasing to provide more X-ray flux, with a current value of 375 mA and a design goal of 500 mA. Based on these storage ring parameters, NSLS-II is an ideal synchrotron for X-ray microprobe experiments. The Sub-micron Resolution X-ray Spectroscopy (SRX) beamline at NSLS-II 5-ID has been specifically designed to utilize the strengths of NSLS-II for sub-micron X-ray spectroscopy and X-ray fluorescence (XRF) imaging. Kirkpatrick-Baez (KB) mirrors focus the X-ray beam down to a sub-micron spot for high spatial resolution X-ray absorption near-edge structure (XANES) spectroscopy and XRF imaging experiments. Monochromatic X-rays ranging from roughly 4.5 to 25 keV illuminate the sample and enable XANES across a wide range of elements from titanium up to plutonium. The undulator source produces enough brilliance for roughly 10^13 ph/s at the sample, data collection time is minimized. The high X-ray flux combined with fly-scan sample motion, allow XRF imaging to be rapidly collected. This is necessary for and enables *in situ* experiments which can provide researchers more realistic conditions for their samples. Combining spectroscopy and imaging techniques allow scientists to nondestructively investigate the elemental and chemical state of their samples.

This presentation will introduce current applications of research performed at the SRX beamline, focusing on material science and energy materials, such as Li-ion batteries.

1:30 PM *CM03.22.01
Detailed Investigation of the Interfacial Electrolyte/Electrode Reactions and the Effect of Additives in Li-Ion, Li-Sulfur and Li-Air Batteries by Operando ec-(S)TEM

The high demand for new energy storage nanomaterials has created the need for novel experimental techniques that can provide real-time information on the dynamic structural changes and reactions that occur locally at the electrode/electrolyte interface inside the battery. The development of *in situ* liquid electrochemical stages for (transmission) electron microscopy (ec-(S)TEM) enables fabrication of a "nano-battery" to study the details of electrochemical processes under operando conditions. However, the high complexity of electrochemical processes during battery cycling requires careful calibration of the system to circumvent *e*-beam damage and to control the side electrochemical reactions [1]. Here we demonstrate the application of this "nano-battery" approach to rechargeable Li-ion, Li-sulfur and Li-O2 batteries. The full operation of these complex systems is yet not fully understood and typically involves multi-step electrochemical reduction/oxidation reactions, which often lead to lithium dendrite formation. There are many strategies to improve the interfacial stability of the Li anode and control/suppress Li dendrite growth, which is highly dependent on nature of electrolyte itself, such as mixture of different electrolyte solvents, salts and additives (e.g. HF, LiNO3 etc). In one example, we investigate the role of electrolyte additives on the initial stages of Li depositionstripping and the SEI layer formation. Under operando ec-(S)TEM conditions we can explore the role of the moisture that typically causes fast degradation of the electrolyte but here is used as a "catalyst" that controls the interfacial electrode/electrolyte reactions. With careful calibration of the water content, we obtain precise control of the interfacial reaction mechanism, which leads to suppression of the Li dendrite, increases Coulombic efficiency and to uniform Li grain growth [2]. Similar mechanisms have been observed with LiNO3 as an additive to control the mechanism of nucleation, growth and suppression of Li metal dendrites in Li-S batteries.

In Operando Investigations of the Surface Behavior of Cu Electrodeposition Suppressor Additives PEG and PPG
Ryan Rooney1, Kevin Schmitt1, Frank von Horsten2, Ralf Schmidt3 and Andrew Gewirth1; 1University of Illinois at Urbana-Champaign, Urbana, Illinois, United States; 2Atotech Deutschland GmbH, Berlin, Germany.

Fabrication of microelectronics relies on the dual-Damascene process in order to create metal interconnects within dielectric materials. These interconnects allow for electrical connection between nanometer sized transistors and global-scale electrical contacts. The process allows for precise trench and via formation by lithographic techniques and superconformal filling by copper (Cu) electrodeposition. Superconformal filling is accomplished by tailored electrolytes including sulfuric acid, Cu salt, and different types of organic additives.

Suppressors are an important type of additive which prevent over-deposition on substrate surfaces, promoting growth within a trench/via. PEG and PPG are...
commonly used suppressor additives. In this talk we report on the surface behavior of PEG and PPG using Raman, in-situ surface enhanced Raman spectroscopy (SERS), and in-situ electrochemical quartz crystal microbalance (EQCM) measurements. Raman and SERS are used to determine the conformational behavior of PEG and PPG as pure materials, in solution/suspension, and at a roughened Cu surface in-situ during Cu electrodeposition. For both PEG and PPG, a clear spectroscopic trend emerges of increased intensity in higher wavenumber modes in the CH stretching region as the environment is changed from pure material to solution to surface. The spectral changes associated with PEG are larger than those associated with PPG, suggesting that the relatively more hydrophilic PEG undergoes more conformational changes with surface association relative to the more hydrophobic PPG. Calculations show that the observed spectroscopic trend is associated with increased gauche character in the polymer backbone. In-situ EQCM measurements show PEG only adsors to the surface in the presence of Cl\textsuperscript{-}, consistent with previous studies of PEG. Alternately, PPG adsorbed to the surface with and without Cl\textsuperscript{-}, likely again because of the increased hydrophobic character associated with the molecule.

Revealing the Initial Stages of Metal Electrodeposition, Atom by Atom Richard Beanland\textsuperscript{1}, Haytham Hussein\textsuperscript{1}, Houari Amari\textsuperscript{2, 1}, Reinhard Maurer\textsuperscript{1}, Jon J. Peters\textsuperscript{1}, Mark Newton\textsuperscript{1} and Julie MacPherson\textsuperscript{1}; \textsuperscript{1}University of Warwick, Coventry, United Kingdom; \textsuperscript{2}Engineering, University of Liverpool, Liverpool, United Kingdom.

Electrochemical deposition has yet to realize its full technological potential, despite its widespread use in many areas. Since it takes place in a liquid electrolyte very little is known about its initial stages, which occur at the atomic level. Many potential applications require precise control at this scale, such as energy storage and conversion electrodes for water splitting, fuel cells and electrochemical reduction of carbon dioxide. Here, we use scanning transmission electron microscopy to obtain snapshots of gold electrodeposition with a time resolution of tens of milliseconds, returning to examine the same areas time and again after each new electrodeposition. Being careful to quantify and account for electron-beam induced effects, we track the movement and behaviour of individual nanoparticles and indeed individual atoms. We show the importance of electrochemically driven atom transport, atom cluster formation, reassembly and growth into nanoparticles as well as deconstruction and atomic fluxes across the electrode surface via atom bridges. These show the limitations of existing models of growth, which typically assume the need for a critical particle size above which subsequent growth occurs irreversibly with direct atom addition.

2:30 PM CM03.22.04
Defect Formation, Coarsening and Morphological Instability of Passivating Oxide Film by Environmental Transmission Electron Microscopy Xiaoxiang Yu\textsuperscript{1}, Ahmet Gulec\textsuperscript{1}, Christopher Andolina\textsuperscript{1}, Judith C. Yang\textsuperscript{1}, John H. Perepezko\textsuperscript{1}, Peter W. Voorhees\textsuperscript{1} and Laurence D. Marks\textsuperscript{1}; \textsuperscript{1}Department of Materials Science and Engineering, Northwestern University, Evanston, Illinois, United States; \textsuperscript{2}Department of Materials Science and Engineering, University of Wisconsin-Madison, Madison, Wisconsin, United States; \textsuperscript{3}Department of Chemical and Petroleum Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, United States.

We report the results of in-situ and ex-situ transmission electron microscopy observations on the early stage oxidation of Ni-based alloys. At moderate temperature (~700 °C), an epitaxial rock-salt oxide Ni\textsubscript{1-x}Cr\textsubscript{x}O initiated at the surface of Ni-Cr and Ni-Cr-Mo alloys progressing by a layer-by-layer mode. Fast surface diffusion and slow bulk transportation of cations created vacancies firstly in the oxide film of Ni-Cr, coarsened into Kirkendall voids and then diffused to the metal-oxide interface, driven by the metal/oxide misfit stresses. The voids eventually formed cavities along the metal-oxide interface. For Ni-Cr-Mo alloys, Kirkendall voids were inhibited by the fast formation of metastable Ni\textsubscript{2-x}Cr\textsubscript{x}O\textsubscript{3} (corundum structure) phase after the growth of rock-salt oxide. The results indicate that Mo doping may stabilize the cation vacancies and inhibit the Kirkendall voids formation by promoting the nucleation of corundum structure. Density functional theory calculations confirm that the thermodynamic driving force of phase transformation from rock-salt to corundum structure is increased by 0.6 eV per Mo atom.

At higher temperature (above 800 °C), however, the intrinsic morphological instability of rock-salt oxide thin film manifested due to surface stress. The nonlinear instability began at step edges by forming thicker regions and then retreated toward the thicker portion of the film, in effect “eating” a layer out of the thin film. Density functional theory calculations and continuum modeling of the elastic instability support the model for the process. Collectively, our results provide new and deeper insights into defect formation, coarsening and morphological instability of protective oxide thin film during early stage oxidation, which is critical for better understanding and designing corrosion resistant alloys.

First Principles Approach to Model Electrochemical Reactions—Understanding the Fundamental Mechanisms Behind Mg Corrosion Mira Todorova\textsuperscript{1}, Sadarsan Surendralal and Jorg U. Neugebauer; Max-Planck-Institut fuer Eisenforschung, Duesseldorf, Germany.

Ab-initio modelling using density functional theory (DFT) provides important insights into reactions at electrochemical interfaces. Observation of reactions under conditions of applied potential presents, however, a major challenge. The reason is the lack of an easily available method within commonly used DFT codes with periodic boundary conditions, which allows tuning the electrode potential. Utilising concepts from semiconductor physics we developed a novel potentiostat design. The new approach can be easily implemented in all existing periodic DFT codes. The potentiostat controls the electrode potential of the system by tuning the excess charge of the working electrode. Employing this method, we study the Mg(0001)/H\textsubscript{2}O interface under anodic polarisation conditions. The high corrosion rate under these conditions is a key obstacle to the technological application of Mg and its alloys. However, despite decade long numerous experimental and theoretical studies the mechanism behind the infamously fast corrosion rate could not be resolved. Our new approach allows to observe “in situ” the corrosion reactions at the Mg surface, such as dissociation events, proton transfer and H\textsubscript{2} evolution. Based on these insights we identify a novel and hitherto not considered reaction mechanism and explain the origins of the anomalous hydrogen evolution.

3:00 PM BREAK
Hierarchical semiconductor nanostructures have been widely investigated as solutions to energy and environmental problems due to their excellent energy storage mechanism. Furthermore, several reports have shown that MXenes can be oxidized naturally in various environments [2], therefore direct in situ/operando experiments possible or thinkable.

In this work, soft X-ray absorption spectroscopy (XAS) at the O K-edge and Ti L-edge has been applied to Ti₃C₂Tx MXenes to study the oxidation state of Ti in various environments. The dried pristine Ti₃C₂Tx MXenes have been characterized in vacuum by XAS in total electron yield mode (TEY) and X-ray photoemission electron microscopy (X-PEEM). The X-PEEM is a powerful technique to record spatially resolved XA spectra at the Ti L-edge and O K-edge on individual MXene flakes. To evaluate the effect of solvation on the MXene oxidation state, Ti₃C₂Tx MXenes dispersed in water have also been studied in situ using silicon nitride membrane-based flow cell to enable good soft X-ray transmission. For dispersed samples, XA spectra at the Ti L-edge and O K-edge were recorded in total fluorescence yield (TFY) mode.

Finally, XAS characterization of Ti₃C₂Tx MXenes deposited on gold-coated silicon nitride membrane enabled measurement under applied potential. In situ characterization of Ti₃C₂Tx MXenes under different bias voltages in 1M sulfuric acid at the Ti L-edge were performed. Partial fluorescence yield (PFY) measurements have been performed for these in-situ measurements.

The present work demonstrates that soft XAS can be applied to characterize MXenes in various conditions, which may provide new insights towards the understanding of their electrochemical charging mechanism. Advantages and limitations of the various XAS detection modes will also be discussed.

Real-Time USAXS and WAXS Studies of Morphology Evolution in 3D Nanoporous Gold During Electrochemical Dealloying

Nanoporous (NP) metals with bicontinuous ligament/pore morphology are attractive for various applications including (electro)catalysis, actuation, sensing, plasmonics and electrochemical energy storage. Those NP metals are commonly produced by (electro)chemical dealloying, during which the less noble component of a parent alloy is selectively etched away and a 3D framework is left behind. In this talk, I will present a fundamental study on microstructural and crystallographic evolutions during electrochemical dealloying in combination with in situ and operando Ultra Small Angle X-Ray Scattering (USAXS) and Wide Angle X-Ray Scattering (WAXS) experiments that we have developed to measure structural change on several length scales in real-time. The experiment was realized with the simultaneous WAXS/SAXS capability of the University of Pennsylvania’s multi-detector Dual Source and Environmental X-Ray Scattering (DEXS) facility. By controlling the voltage and measuring charge transferred, the length scale evolution of the system can be matched with the extent of dealloying. In addition, Weissmüller et al. have investigated the morphological similarities of nanoporous metal electron density and a Cahn’s spinodal decomposition model based on a Gaussian Random Field.1,2 Using this model, we can map an autocorrelation function derived numerically to the USAXS data and glean important system parameters such as specific surface area and pore to void ratio. This information can also be used to visually reconstruct the nanoporous framework as it evolves through the dealloying process.

Ultrafast Electron-Phonon Coupling in Emerging Semiconductors Xiaoyang Zhu; Columbia University, New York, New York, United States.

In this lecture, I will briefly introduce our recent efforts in understanding electron phonon coupling in molecular, nano, and hybrid semiconductors. Electron phonon coupling is essential to a broad range of charge carrier processes, such as polaron formation, Auger scattering, and charge carrier recombination. They are also responsible for electronic phase transitions and emergent properties, e.g., charge density waves and superconductivity. Our experimental strategy is to target excited state dynamics in the most direct way possible, using, e.g., femtosecond two-photon photoemission spectroscopy, optical Kerr-effect spectroscopy, and two-dimensional spectroscopies, to directly observe many-body events in the time domain. These experiments have led to recent understanding of coherent and incoherent mechanisms in exciton fission in organic semiconductors, direct and phonon-mediated Auger recombination in a bulk semiconductor, charge separation at van der Waals interfaces of transition metal dichalcogenides, and polaronic screening in lead halide perovskites. Such fundamental understandings are leading to new design principles for nano, molecular, and hybrid semiconductors.

9:00 AM CM04.01.02
Exciton Dynamics in Colloidal Metal Halide Perovskite Nanocrystals and Nanoplatelets Matthew N. Ashner1, Seung Kyun Ha1, Katherine Shulenger2 and William Tisdale2; 1Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 2Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Metal halide perovskites are a promising class of materials for a variety of applications such as solar cells and lasers. In particular, perovskites are highly defect tolerant, an effect that has been attributed to screening of charge carriers due to lattice deformations, among other mechanisms. Like other inorganic
semiconductor materials, quantum confinement causes changes in the behavior of excited charge carriers, such as a transition from free carriers to excitons as the dominant excited state. Quantum confined perovskites can be synthesized in a variety of forms, including cubic nanocrystals and nanoplatelets with a thickness of 1-3 unit cells. The nanoplatelets exhibit strong quantum confinement effects, while the cubic nanocrystals are more weakly confined due to the small exciton Bohr radius of ~5 nm. In this work, we use femtosecond transient absorption and femtosecond stimulated Raman spectroscopy to simultaneously investigate ultrafast exciton and lattice dynamics in colloidal perovskite nanocrystals and nanoplatelets. We discuss how exciton formation, energetic relaxation, and the role of lattice interactions in these processes, vary between the weakly and strongly quantum-confined regimes.

9:15 AM *CM04.01.03
Ultrafast Spectroscopy of Semiconductor Nanostructures Tonu Pullerits; Chemical Physics and NanoLund, Lund University, Lund, Sweden.

Nanowire semiconductor structures have a rich spectrum of properties related to quantum confinement which are not available in the corresponding bulk materials. Size-tunable spectrum is, perhaps, the best known and understood such property. Here we investigate dissipation and transport dynamics of various semiconductor nanowire systems and their composites. We have studied colloidal quantum dots, plasmonic metal nanoparticles, hybrid and all inorganic perovskite nanocrystals and Ruddlesden-Popper 2D perovskites. We apply a set of modern ultrafast techniques like photocurrent and fluorescence detected coherent 2D spectroscopy, transient terahertz and absorption spectroscopies revealing detailed information about photoexcitation dynamics.

As an example. Photo-generated charge carrier dynamics in Ruddlesden-Popper 2D perovskites with linear (n-BA) and branched (iso-BA) butylamine as capping cations were studied by using transient absorption and time-resolved photoluminescence spectroscopies. Both n-BA and iso-BA perovskites consist of mixed-phase 2D quantum wells with various layer thicknesses, where the photo-generated charges undergo inter-phase charge transfer from thinner quantum wells to thicker ones. By shortening the spacer from n-BA to iso-BA, the transfer rates are significantly increased, which can also diminish the charge accumulation in thin quantum wells induced by the unbalanced electron and hole charge transfer rates. Under high excitation intensity, the shorter spacing cation is found to further facilitate transport, which can compete with fast high-order carrier recombination and consequently improve the charge transfer efficiency. Intriguingly, we observe the existence of extra bulk 3D phases embedded within iso-BA perovskites, which can efficiently collect the confined charges within 2D phases and then transport them with faster carrier mobility and slower recombination rates.

Ultra-Fast and Ultra-Slow Processes Depict the (Defect) Photo-Physics of Metal-Halide Perovskite Semiconductors Annamaria Petrozza; Istituto Italiano di Tecnologia, Milano, Italy.

Semiconducting metal-halide perovskites present various types of chemical interactions which give them a characteristic fluctuating structure sensitive to the operating conditions of the device, to which they adjust. This makes the control of structure-properties relationship, especially at interfaces where the device realizes its function, the crucial step in order to control devices operation. In particular, given their simple processability at relatively low temperature, one can expect an intrinsic level of structural/chemical disorder of the semiconductor which results in the formation of defects. Here, first I will present our results on the role of structural and point defects in determining the nature and dynamic of photo-carriers in metal-halide perovskites. Then, I will discuss our understanding of key parameters which must be taken into consideration in order to evaluate the susceptibility of the perovskite crystals (2D and 3D) to the formation of defects, allowing one to proceed through a predictive synthetic procedure. Finally, I will show the correlation between the presence/formation of defects and the observed semiconductor instabilities.

10:45 AM CM04.01.05
Charge Carrier Recombination and Lattice Interactions in Bismuth-Based Perovskites Lissa Eyre, Robert L. Hoye, Tudor H. Thomas, Hannah J. Joyce and Felix Deschler; University of Cambridge, Cambridge, United Kingdom.

A promising class of lead-free perovskites for photovoltaic applications include the bismuth halides, such as MA3Bi2I9, BiOI, and Cs2AgBiBr6 [1]. Although these materials have been predicted to display defect tolerance, much like lead-halide perovskites, and already display improved stabilities and long charge carrier lifetimes, the power conversion efficiencies of the corresponding devices have lagged behind the lead-based perovskites. Potential reasons for this are being explored, for example, the disconnected nature of the bismuth halide octahedra in the crystal structure, which limits carrier mobility, and the lower levels of absorption due to indirect bandgaps [2]. We probe the behaviour of excited states in many bismuth-halide compounds with various effective dimensionalities using ultrafast transient absorption, Raman, and terahertz spectroscopy. The importance of phonons in carrier transport and hot carrier cooling is also investigated. Our findings are consistent with previous reports of strong coupling between phonons and electronic states [3]. Overall, this work indicates that bismuth-based materials have the potential to be used in efficient optoelectronic devices, but there is a need to account for the effects of strong carrier-phonon coupling and localisation of electronic states on carrier momentum and scattering rates. We therefore present charge carrier-lattice interaction strength as an important design criterion for efficient next-generation solar cells.

11:00 AM *CM04.01.06
Charge-Carrier Dynamics in Metal Halide Perovskites for Photovoltaics Laura Herz; University of Oxford, Oxford, United Kingdom.

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 21%. Yet the optoelectronic properties underpinning their performance are still the subject of debate. Here, ultrafast optical-pump THz-probe photoconductivity spectroscopy has proven to be an outstanding tool to unravel the dynamics of charge carrier recombination, and probe charge-carrier mobility mechanisms. Metal halide perovskites (stoichiometry AMX3) are particularly attractive light absorbers because their properties can be tuned through facile modification in composition and structure, e.g. throughsubstitutions of the organic A cation (e.g. methylammonium versus formamidinium), the metal M cation (e.g. Pb2+ or Sn2+) and the halide X anion (e.g. I3-). Introduction of hydrophobic cations that are too large to be incorporated into the perovskite structure, has also recently been explored, leading to electronic confinement in materials of lowered dimensionality, and better photostability.

We demonstrate how such changes affect parameters essential for photovoltaic operation, discussing the influence of composition, structure, doping and dimensionality on fundamental properties such as electronic bandstructure, charge-carrier recombination and charge-carrier diffusion lengths. We further...
discuss distinct charge-carrier recombination and scattering mechanisms and their dependences on composition and temperature.

SESSION CM04.02: Hybrid Perovskites and Nanostructures  
Session Chair: Matt Graham  
Monday Afternoon, November 26, 2018  
Hynes, Level 2, Room 201

1:30 PM *CM04.02.01  
Investigation of Electronic and Structural Dynamics in Metal-Halide Perovskites with Ultrafast Spectroscopy Felix Deschler; University of Cambridge, Cambridge, United Kingdom.

Metal-halide perovskites have emerged as promising solution-processable semiconductors for optoelectronic applications. These materials show unexpectedly high luminescence yields, long carrier lifetimes under operating conditions. Facile changes in composition during fabrication can be used to control their optical properties, and the nature of electronic states. Recently, the ad-mixture of monovalent cations to the precursor solution has been demonstrated to maximize the luminescence yields and device performance, which harvests photon-recycling effects. The properties and dynamics of the perovskites’ electronic states are controlled by their crystal structure and symmetry. Strong spin-orbit coupling was predicted to introduce Rashba-type state splitting in the electronic band structure. In combination with the soft crystal structure of the perovskite lattice, it is likely that dynamic changes occur in the electronic states during their lifetime. So far, it is not understood how such effects change after optical excitation and how they proceed during relaxation of electronic states.

In this talk I will present how we use spectroscopic techniques to study the dynamics of electronic states and crystal structure in metal-halide perovskites on ultrafast timescales. I will report results on layered and bulk lead-halide perovskites, but also on sustainable lead-free variants. I will discuss how the crystal structure affects the properties of electronic states, and how we can use these changes to create novel optoelectronic devices.

2:00 PM *CM04.02.02  
Ultrafast Non-Contact Probes of Carrier Transport and Dynamics within Semiconductor Nanostructures and Interfaces Matthew C. Beard; Chemical and Nanoscience Center, National Renewable Energy Laboratory, Golden, Colorado, United States.

Solar photoconversion in semiconductors is driven by charge generation via photon absorption, charge transport, and charge separation at the interface of the semiconductor and contacting layers. Thus, the carrier dynamics – charge separation and recombination across junctions – represent a key-determining factor in the photoconversion performance. We have developed several non-contact probes based on ultrafast spectroscopy of carrier dynamics within bulk semiconductors, nanostructures and semiconductor interfaces. Isolating spectral signatures and/or the carrier dynamics that are specific to junctions and not just the interface or bulk is challenging. We developed transient photoreflectance (TPR) as an innovative time-resolved spectroscopic probe that can directly monitor carrier dynamics within and across such junctions. In the TPR method, the change in reflectance (of a broadband probe from a specific interface is monitored as a function of pump-probe delay (Fig. 1). The reflectance can be modulated by either photogenerated free-carriers due to band filling, and/or by transient fields due to electro-optic effects when charges are separated. The spectral nature of the reflected beam provides quantitative information about the built-in field; thus, TPR is a non-contact probe of the electric field at that interface. It will present recent studies of Pb-halide perovskites single crystals, thin films, and nanostructures and semiconductor nanowires.

2:30 PM CM04.02.03  
Observation of Multiple Excitonic Dipole Oscillations in Semiconductor Nanocrystals Using Phase-Locked Interference Detection Hirokazu Tahara, Masanori Sakamoto, Toshihara Teranishi and Yoshishiko Kanemitsu; Kyoto University, Uji, Japan.

Multiple excitons in semiconductor nanocrystals (NCs) are extensively studied for advanced optoelectronic devices such as quantum dot based solar cells, photodetectors, and lasers [1,2]. In particular, carrier multiplication process via multiple excitons is investigated to clarify a fascinating mechanism that enhances the photon-to-current conversion efficiency, i.e., multiple exciton generation. In this process, excitonic coherence is considered to play an important role as predicted in theoretical investigations of the coherent superposition of single and multiple excitons [3]. However, the generation process of multiple excitons still remains unclear. Since multiple excitonic coherence appears only within the ultrafast time regime, the coherent signal is hardly observed by using conventional spectroscopic techniques. Therefore, an advanced spectroscopic technique detecting ultrafast signals is required to observe the multiple excitonic coherence.

In this study, we report on the direct observation of multiple excitonic dipole oscillations in PbS/CdS core/shell NCs by our newly developed spectroscopic technique that employs phase-locked interference detection in transient absorption measurements [4]. Since a stable phase-locked pulse pair was used as pump pulses, transient absorption signals for various time interval between the pulse pair enabled us to monitor the profiles of excitonic dipole oscillations. The transient absorption signals showed the oscillations with higher harmonic orders of the pump photon energy that was set to the single exciton resonance energy. Furthermore, the harmonic dipole oscillations exhibited a clear correlation with the generation probabilities of multiple excitons. These results show that the multiple excitonic coherences, i.e., higher harmonic dipole oscillations, are formed in the NCs. We clarified that the decay profiles of the dipole oscillations are determined as a function of the number of excitons. It is notable that the frequency of higher harmonic dipole oscillations are comparable to that of the dipole oscillation of high-energy hot excitons. This result shows that the harmonic dipole oscillations can also play an important role in the reverse process, i.e., multiple exciton generation from a single hot exciton to multiple excitons in the ground state. Part of this work was supported by JST-CREST (JPMJCR16N3) and JSPS KAKENHI (18K13481).

Quantum confinement of 2D graphene nanomesh[1], 1D graphene nanoribbons[2] and 0D graphene quantum dots[3], has paved the way for the development of promising field of nanographene optoelectronics. In this context, the synthesis of molecular graphene via bottom-up processes permits to obtain monodisperse nanographene, with defined physical and chemical properties[4]. The luminescence features exhibited by molecular graphene[5], in particular, has made these carbon-based materials of great interest for plasmonic and photonic applications, among others.

Here, we demonstrate that the stimulated emission signal of a newly synthesised and very luminescent (absolute PL quantum yield 79%) nanographene molecule, namely dibenzothiophene-sulphonilene (DBOV 1) can be optically switched in the ultrafast time regime both in solution and in the solid state. We will show that such an effect can be achieved by taking advantage of the overlap between the stimulated emission signal and the absorption of intermolecular polaronic-like species.

3:30 PM *CM04.03.01
Understanding the Features in the Ultrafast Transient Absorption and Two-Dimensional Electronic Spectra of Colloidal CdSe Quantum Dots Howe-Siang Tan; Division of Chemistry and Biological Chemistry, Nanyang Technological University, Singapore, Singapore.

We present a model to explain the various features of the transient absorption (TA) and two-dimensional electronic spectrum (2DES) of colloidal CdSe semiconductor quantum dots (QDs). The measured TA and 2DES spectra consist of contributions by the ground state bleach (GSB), stimulated emission (SE) and excited state absorption (ESA) processes associated with the three lowest energy transition of the QDs. We model the shapes of the GSB, SE and ESA spectral components after fits to the linear absorption. The spectral positions of the ESA components take into account the bieaxotropic coupling energy. In order to obtain the correct weighting of the GSB, SE and ESA components to the TA and 2DES spectra, we enumerate the set of coherence transfer pathways associated with these processes. In 2DES, various other features provide information on the inhomogeneity and homogeneity of the sample under study. We use the nodal line slope (NLS) that separates the positive and negative peaks in the 2DES spectrum to characterize the homogeneous and inhomogeneous linewidths of colloidal CdSe QDs ensembles. With a combination of experimental measurements from linear absorption, transient absorption and 2DES spectra, we devise a simulation process to quantify the ratio between the inhomogeneous and homogeneous contributions to the linewidth-broadening effects of CdSe QDs ensemble.

4:00 PM CM04.03.02
Physical Origins of the Transient Absorption Spectra and Dynamics in Thin-Film Semiconductors—The Case of BiVO4 Jason K. Cooper1, 2, Sebastian Reyes Lillo1, Lucas Hess2, Chang-Ming Jiang2, Jeffrey B. Neaton1 and Ian D. Sharp1, 2; 1Lawrence Berkeley National Lab, Berkeley, California, United States; 2Joint Center for Artificial Photosynthesis, Berkeley, California, United States; 3Walter Schottky Institut and Physik Department, Technische Universität München, Garching, Germany.

Transient absorption spectroscopy offers a unique perspective on the photogenerated carrier lifetimes of materials through the ultrafast evolution of the transient difference spectrum taken in transmission and/or reflection geometries. However, the related spectroscopic features can be challenging to interpret accurately and as such the related kinetics may be convoluted in overlapping signals of unknown origin. By co-collecting both transmission and reflection signals we extract the differential absorption of the material. We use a combination of ground state optical properties and the temperature dependent difference spectra of a model system, bismuth vanadate, to obtain an accurate model of the time dependence of the transient spectrum. From this, we have obtained the temporal evolution of the free carrier density from which a kinetic model was developed enabling a unique perspective on the governing recombination mechanisms. Importantly, the lattice temperature has been shown to play a critical role in the optical response at time delays past 10 ps. Additionally, spectral features related to coherent optical and acoustic phonons have also been identified. This comprehensive approach to analyzing and modeling the TA spectra offers a generalizable basis for understanding the complex pump-probe data, reveals thermal heating artifacts that are frequently erroneously assigned to long-lived photocarriers, and offers a path to eliminating ambiguity in analysis of photocarrier dynamics in solid state systems.

4:15 PM CM04.03.03
Plasmon-Induced Demagnetization and Magnetic Switching in Nickel Nanoparticle Arrays Mikko Kaina1, Francisco Freire-Fernández2, Jorn P. Witteveen2, Tommi K. Hakala1, Päivi Törnä1 and Sebastiaan van Dijken2; 1CSIC-ICMAB, Bellaterra, Spain; 2Department of Applied Physics, Aalto University, Espoo, Finland.
In heat-assisted magnetic recording (HAMR), a plasmonic noble metal nanoantenna acts as a near-field transducer (NFT) that reduces the switching field of high-anisotropy materials via local heating [1]. Excitation of the NFT at the plasmon resonance frequency efficiently transfers optical energy to a nanoscale region, enabling local switching at a reduced magnetic field. Noble metal nanoantennas placed on ferromagnetic films have been used for nanoscale confinement of all-optical switching (AOS) [2]. Experiments on pure ferromagnetic metals demonstrate that, despite stronger ohmic damping, they also support surface plasmon resonances. This raises the question if one could nanostructure the magnetic medium itself to trigger magnetic switching via local enhancements of the optical field. To study the effect of plasmon resonances on magnetic switching, we considered ferromagnetic nanoparticles of uniform size and shape. Plasmon resonances in single ferromagnetic nanoparticles are rather broad, several hundreds of nanometers [3]. Yet, ordering of the particles into a periodic array significantly narrows the spectral response. In this geometry, hybridization between LSPRs and the diffracted orders of the array produces intense surface lattice resonances (SLRs) that give rise to enhanced optical absorption and light-matter interaction that can be ascertained from their enhanced magneto-optical properties [4]. We report on the manipulation of magnetization by femtosecond laser pulses in a periodic array of cylindrical nickel nanoparticles. By performing experiments at different wavelengths, we show that the excitation of collective surface lattice resonances triggers demagnetization in zero field or magnetic switching in a small perpendicular field. Both magnetic effects are explained by plasmon-induced heating of the nickel nanoparticles to their Curie temperature. Model calculations confirm the strong correlation between the excitation of surface plasmon modes and laser-induced changes in magnetization [5].

Excitonic Effects in Single Layer MoS2 Probed by Two-Dimensional Electronic Spectroscopy

Margherita Maiuri1, Stefano Dal Cont1, Mattia Russo1, Junjia Wang2, Giancarlo Soavi2, Dumitru Dumcenco2, Andras Kis3, Andrea C. Ferrari2 and Giulio Cerullo1
1University of Cambridge, Cambridge, United Kingdom; 2Politecnico di Milano, Milano, Italy; 3University of Cambridge, Cambridge, United Kingdom; 4Ecole Polytechnique Federale de Lausanne, Lausanne, Switzerland.

Atomically thin Transition-metal dichalcogenides (TMDs) have promising physical properties [1,2]. Because of the strong quantum confinement effects, Coulomb interaction is poorly screened in single-layer (1L) TMDs, so that the excitons created by photo-excitation have large binding energy, up to several hundred meVs [3]. The spectrum of 1L-MoS2 is characterized by two peaks of excitonic nature at 1.9 eV and 2.05 eV, the so-called A and B excitons. They arise from optical transitions between the spin–orbit split top valence band and the bottom conduction band, around K and K'. Although, exciton dynamics in 1L TMDs have been largely studied in the last years [4], the complete understanding of the mechanisms leading to the ultrafast excitons formation and coupling is far to understood.

Here we exploit two-dimensional electronic spectroscopy (2DES) to track the sub-ps excitonic interactions within MoS2. 2DES is an interferometric-based optical technique that allows to fully resolve the non-linear response of a material. It employs a sequence of three delayed short pulses impinging on a sample to provide a series of two-dimensional excitation/detection correlation energy maps at different delays, offering a unique combination of high temporal and spectral resolution. We perform 2DES measurements on a chemical vapor deposition grown 1L-MoS2 sample, at 77K and room temperature,
using sub 20-fs visible (1.75-2.3 eV) pulses, covering both A and B transitions.

In 2DES maps we distinguish two types of contributions: the signals along the diagonal line of the excitation/detection map, and the ones out of the diagonal (cross-peaks). At early times (<20fs), we observe instantaneous positive diagonal peaks appearing at the A/A and B/B excitation/detection energies, reflecting the bleaching of the excitonic transitions, as well as two cross-peaks at the A/B and B/A coordinates, indicating correlations between A and B excitons. At later times (40-60fs) we notice a marked elongation of both A and B diagonal peaks, associated with an ultrafast (100fs) spectral diffusion. For times >200fs a strong decrease of the peaks intensity is observed. While the build-up of the diagonal peaks is instantaneous (within our temporal resolution of 20fs), we can clearly resolve the formation of the lower cross-peak, at A/B excitation/detection point. The dynamic of the lower A/B cross-peak, which is completely masked and thus impossible to observe in transient absorption measurements, cannot be simply explained in term of a phase space filling effect, but it is a strong signature that exciton dynamics in 1L-MoS₂ is dominated by more complex interactions. Our results, combined with theoretical modeling, will shed new light on the origin of exciton dynamics in 1L TMDs.

Ultrafast Dynamics of 2D Materials Studied by Transient SHG Microscopy

Hyunmin Kim; DGIST, Daegu, Korea (the Republic of).

Recently, time-resolved pump-probe spectroscopy has been extensively exploited to study ultrafast carrier dynamics of 2D materials in a femtosecond scale time resolution. In this work, we introduce a transient second harmonic generation (tr-SHG) microscopy to study the electron/phonon dynamics of atomically thin MoS₂ materials. A time-dependent sequential tr-SHG imaging on electron/phonon dynamics was monitored using a tr-SHG microscopy composed of a pump beam tuned to the A-exciton (680 nm) and a probe beam (1040 nm) generating a SHG at 520 nm having a submicron scale lateral resolution. We do believe that the tr-SHG microscopy would suggest a new way to study ultrafast carrier physics of low dimensional materials and their hybrids in a more advanced spatiotemporal fashion.

9:30 AM CM04.04.03

Observation of Chiral Phonons in Monolayer 2D Materials

Hanyu Zhu1, 2, Jun Yi1, MingYang Li2, Lifang Zhang3, Jun Xiao4, Chih-Wen Yang5, Robert A. Kaindl1, Lain-Ling Li1, Yuan Wang1, 2 and Xiang Zhang1, 2, 5University of California, Berkeley, California, United States; 2Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States; 3King Abdullah University of Science and Technology, Thuwal, Saudi Arabia; 4Nanjing Normal University, Nanjing, China.

Chirality is often found in systems with structural inversion symmetry breaking. Previously, for bosonic collective excitations in solids, chirality was only theoretically predicted but never observed. We experimentally show that phonons can exhibit intrinsic chirality in monolayer tungsten diselenide. The chiral phonons have significant implications for electron-phonon coupling in solids, lattice-driven topological states, and energy-efficient information processing. We identified the phonons by the intervalley transfer of holes through hole-phonon interactions during the indirect infrared absorption. The chirality was confirmed by the transient infrared circular dichroism arising from pseudo-angular momentum conservation. From the spectrum we further deduce the energy transferred to the phonons, which agrees with both the first principle calculation and the double-resonance Raman spectroscopy.

Ultrafast Momentum-Resolved Phonon Spectroscopy—Direct Observations of Electron-Phonon Coupling and Nonequilibrium Phonon Dynamics in the Time-Domain
Bradley Siwick1, 2, 3, Mark Stern1, 3, Martin Otto1, 3, Laurent Rene de Cotret1, 3 and Mark Sutton1, 3; 1Physics, McGill University, Montreal, Quebec, Canada; 2Chemistry, McGill University, Montreal, Quebec, Canada; 3Center for the Physics of Materials, McGill University, Montreal, Quebec, Canada.

The nature of the couplings within and between lattice and charge degrees of freedom is central to condensed matter and materials physics. These interactions are essential to phenomena as diverse as superconductivity, charge density waves and carrier mobility in semiconductors and metals. Despite their fundamental role, detailed momentum-dependent information on the strength of electron-phonon coupling (EPC) and phonon-phonon coupling (PPC) across the entire Brillouin zone has proved elusive. This talk will describe a new technique, ultrafast electron diffuse scattering (UEDS), that provides such information. By exploiting symmetry-based selection rules and time resolution, different phonon branches can be distinguished even without energy resolution. Specific applications of UEDS to 2D materials will be presented, demonstrating that UEDS patterns map the momentum-dependent relative EPC and PPC strength as well as carrier screening effects through their profound sensitivity to photoinduced changes to the phonon system.

Probing Lifetimes and Hydrodynamic Transport in Quantum Materials
Jennifer Coulter and Prineha Narang; School of Engineering and Applied Sciences, Harvard University, Cambridge, Massachusetts, United States.

The field of topological materials with strong electron-electron interactions is well established and has been the subject of research over the past few decades. In parallel, the field of photonics has made tremendous progress in connecting spatio-temporal ultrafast measurements to new quantum materials, including 2D plasmonics and Moiré structure localized potentials, to theoretical predictions. The study of the interplay between topological properties, optical properties and ultrafast dynamics in these materials has recently started to receive attention. Experimental demonstrations in a set of Dirac and type-II Weyl semimetals, materials where electrons effectively interact as massless relativistic particles (Weyl fermions) and in 3D the conduction and valence bands touch at isolated points, have shown evidence of a viscous electronic transport regime. In this regime, electron-electron scattering dominates over impurity scattering and other momentum-relaxing processes so that momentum is quasi-conserved and electron flow can be described using the formalism of hydrodynamics. This leads to a variety of surprising behaviors such as breakdown of the Wiedemann-Franz law, appearance of electron vortices, and tunable viscosity via magnetic field. Understanding these physical processes in materials is of both fundamental and practical importance, yet these problems pose unique theoretical and computational challenges. The simultaneous contribution of processes that occur on many time and length scales, not only make direct computational approaches very difficult, they also make comparisons with experimental observations challenging. Here we report a new microscopic model of this behavior using a combination of ab initio scattering methods and fluid dynamics techniques. Our work establishes a connection between the observed hydrodynamic phenomena in Weyl semimetals, crystal structure and symmetry and their experimentally observed dynamical properties.

Entangled photons offer an exquisite probe to correlated dynamics within a material system. In my talk, I shall discuss some recent experiments and our theoretical investigations into developing an input/output scattering theory approach that connects an incoming photon Fock state to an outgoing Fock state, treating both the internal (material) and photon dynamics on a consistent footing. As proof of concept, we show how entangled photons can probe the inner workings of a model system undergoing spontaneous symmetry breaking.

Ultrafast Momentum-Resolved Phonon Spectroscopy—Direct Observations of Electron-Phonon Coupling and Nonequilibrium Phonon Dynamics in the Time-Domain
Bradley Siwick1, 2, 3, Mark Stern1, 3, Martin Otto1, 3, Laurent Rene de Cotret1, 3 and Mark Sutton1, 3; 1Physics, McGill University, Montreal, Quebec, Canada; 2Chemistry, McGill University, Montreal, Quebec, Canada; 3Center for the Physics of Materials, McGill University, Montreal, Quebec, Canada.

The nature of the couplings within and between lattice and charge degrees of freedom is central to condensed matter and materials physics. These interactions are essential to phenomena as diverse as superconductivity, charge density waves and carrier mobility in semiconductors and metals. Despite their fundamental role, detailed momentum-dependent information on the strength of electron-phonon coupling (EPC) and phonon-phonon coupling (PPC) across the entire Brillouin zone has proved elusive. This talk will describe a new technique, ultrafast electron diffuse scattering (UEDS), that provides such information. By exploiting symmetry-based selection rules and time resolution, different phonon branches can be distinguished even without energy resolution. Specific applications of UEDS to 2D materials will be presented, demonstrating that UEDS patterns map the momentum-dependent relative EPC and PPC strength as well as carrier screening effects through their profound sensitivity to photoinduced changes to the phonon system.

Our findings suggest CE-LFR is a promising route for sensitive characterization of nanoscale structured materials. We show the CE-LFR is applicable for this double resonance greatly increased the light-matter interaction and hence the LFR signal. We have achieved a 47-fold increase in the LFR intensity.

Ultrafast Direct Electron Transfer at Organic Semiconductor and Metal Interfaces

The ability to control direct electron transfer can facilitate the development of new molecular electronics, light-harvesting materials and photocatalysis. However, it has been rarely reported and the molecular conformation-electron dynamics relationships remain unclear. Here, we describe direct electron transfer at buried interfaces between an organic polymer semiconductor film and a gold substrate, by observing the first dynamical electric-field-induced transition. After resonant excitation of the inter-site d-d transition at 1.55 eV, we observed a persistent change in reflectivity at the same frequency (1.55 eV), i.e. the spectral weight transfer to a Drude component at far-IR due to the insulator to metal transition, as confirmed by THz conductivity measurements. In a 30 nm thin film, the volume fraction of the photoinduced metallic phase grew with laser shots and saturated after ~20 shots. Besides the steady-state reflectivity, the transient reflectivity traces also changed shot-by-shot. There was a fast decay component which decreased with shots and eventually disappeared when a full metallic state was established at high fluences. Comparing with earlier transient reflectivity studies on the insulator to metal transition in other manganites, we believe the fast decay within first picosecond represents the recovery dynamics of the insulating phase from the photoinduced metallic phase. Based on that, we conclude parts of the photoinduced metallic phase stay persistently while other parts return back to the insulating phase in less than a picosecond. We also estimated the ratio of insulating and metallic phase in the thin film shot-by-shot.

Effect of Epitaxial Etresses on the Time Dynamics of Photoexcited Charge Carriers in InGaAs Based Superlattices

Epitaxial InGaAs films are promising material for creating photoconductive antennas for the generation and detection of THz radiation. The main disadvantage of such films is the low resistivity. This leads to a high dark current. To increase the resistivity, different approaches are used: ion implantation, epitaxial growth in low-temperature mode with doping with beryllium atoms, introduction of strained ErAs layers, etc. Another problem of InGaAs is the relatively long lifetime of the photoexcited charge carriers.

In this work the method of the carrier lifetime decrease was shown via creating of the epitaxial stress in InGaAs films. 3 types of superlattices were grown by molecular beam epitaxy: InGaAs/GaAs/InAs/InGaAs (SL1), InGaAs/GaAs/InAs (SL2), InGaAs/GaAs/InAs/InGaAs (SL3). Structure of the superlattices is a 30 period of the photoconductive layer (InGaAs) and insulator layer (InAlAs and InAs) with overall thickness ~ 500 nm. This layered system was selected to create epitaxial stresses in photoconductive layer.

XRD asymmetric scanning method ω−2θ was used to characterize epitaxial deformations. There were no stresses in SL1 sample. In SL2 samples epitaxial deformation value was ε = -0.0019, which correspond to compression deformation in InGaAs layer. In SL3 epitaxial deformation value in InGaAs layer was ε = -0.0053.

Optical-pump-probe reflectivity measurements were used for carrier dynamics investigation. Carrier dynamics was performed in wide power range. Carrier lifetime decrease on picosecond time scale was shown with decrease of the pump fluence. In addition, contribution of the nonlinear processes as two photon absorption and free carrier absorption to carrier dynamics was demonstrated. In SL3 sample with higher epitaxial stresses, decrease of the contribution of the TPA and FCA (characterized by ω parameter on time scale) on carrier dynamics was observed. For SL3 parameter ω=0.15 ps was minimal, which is contribute to laser pulse duration and carrier lifetime was 2.73 ps. That result shows, that increasing epitaxial stresses decreasing influence of nonlinear processes on carrier dynamics in InGaAs photoconductive layer and decreasing carrier lifetime.

The work was supported by Ministry of Education and Science of Russian Federation (State task no. 3.7331.2017/9.10 and grant no. 14.Z50.31.0034).

Microcavity Enhancement of Low-Frequency Raman Scattering from CsPbI3 at Room Temperature

Raman spectroscopy is a powerful laser based nonlinear optical technique for identifying chemicals and characterizing materials that has been adapted for both CW and ultra-fast pulsed excitations. Raman spectra can provide insight into numerous properties, including morphology, stress/strain, crystallinity, doping level, conductivity, local temperature, and polarizability, whether in bulk, thin film, monolayer or nanostucture form. Modern laser filters, based on volume holographic gratings amongst other approaches, now make it relatively straightforward to obtain CW Raman spectra much closer spectrally to the dispersion relation and to the vibrational modes associated with the nanostructural dimensions of the material, with broad applications to chiral purity of organics, biomolecular assemblies, hybrid organo-metal halide perovskites, and semiconductor super-lattices. However, the signal strength from LFR is typically very weak. Here we show that introducing a film of material into a photonic crystal structure, in this case a 1D optical microcavity consisting of two distributed Bragg reflector (DBR) mirrors, greatly enhances the LFR signal. This is the first demonstration of Cavity Enhanced LFR (CE-LFR).

In particular, we situated thin films of CsPbI3, which in some forms are Halide Perovskites, into a microcavity prepared from stacks of ZnS and CaF2 alternating layers. The resultant microcavities had a Quality Factor Q = 25. A TiO2 layer with a gradient in thickness was also located between the DBRs to enable tuning of the cavity resonance from a wavelength of 490 nm to 545 nm. We investigated the effect of cavity tuning on the LFR intensity. We observed that the width of the cavity peak is sufficiently broad to resonate both the incident laser and the scattered LFR peak from the CsPbI3 film. This double resonance greatly increased the light-matter interaction and hence the LFR signal. We have achieved a 47-fold increase in the LFR intensity. Our findings suggest CE-LFR is a promising route for sensitive characterization of nanoscale structured materials. We show the CE-LFR is applicable for both CW Raman and pulsed ultra-fast ISRS spectroscopy modalities.
Investigation of GHz Mechanical and Thermal Behavior of Confined Liquids with Molecular Resolution

We thank the Council of Scientific and Industrial Research (CSIR), the Department of Science and Technology (DST) and the Defence Research and Development Organization for financial assistance. We also acknowledge the DST for a J.C. Bose fellowship.

Femtosecond transient absorption (fs-TA) and Ultrafast Raman Loss Spectroscopy (URLS) have also been applied to reveal the excited state dynamics of bis(phenylethynyl)benzene (BPEB), a model system for one-dimensional molecular wires that have numerous applications in opto-electronics. It is known from the literature that in the ground state BPEB has a low torsional barrier, resulting in a mixed population of rotamers in solution at room temperature. For the excited state this torsional barrier had been calculated to be much higher. Our femtosecond TA measurements show a multi-exponential behaviour, related to the complex structural dynamics in the excited electronic state. Time-resolved, excited state URLS studies in different solvents reveal mode-dependent kinetics and picosecond vibrational relaxation dynamics of high frequency vibrations. After excitation, a gradual increase in intensity is observed for all Raman bands, which reflects the structural reorganisation of Franck-Condon excited, non-planar rotamers to a planar conformation. The time dependent peak positions of high frequency vibrations provide additional information: a rapid, sub-picosecond decrease in peak frequency, followed by a slower increase (as shown in figure 2), indicates the extent of conjugation during different phases of excited state relaxation. This study expands our understanding of the excited state of BPEB and analogous linear pi-conjugated systems, and may thus contribute to the advancement of polymeric “molecular wires”.

We thank the Council of Scientific and Industrial Research (CSIR), the Department of Science and Technology (DST) and the Defence Research and Development Organization for financial assistance. We also acknowledge the DST for a J.C. Bose fellowship.

Investigation of GHz Mechanical and Thermal Behavior of Confined Liquids with Molecular Resolution

The phenomenon of liquid structuring near interfaces is related to the liquid/interface interaction forces at distances of some molecular dimensions [1, 2]. Despite the fact that this universal structuring effect plays a key role in various fields such as heat transport, particle transport through biological membranes, nano-fluidics, microbiology and nanomechanics, the experimental investigation of liquid structuring remains challenging.

In this context, we have adapted the experimental technique of ultrafast time-domain Brillouin scattering (TDBS) [3,4] to investigate high-frequency longitudinal acoustic and thermal properties of ultrathin liquids confined between solid surfaces of different types. We will present results of TDBS used to determine the mechanical properties of ultrathin liquids with a subnanometric resolution of the liquid thickness gap. Fourier analysis of the recorded TDBS signals for different liquid thicknesses yield the value of the longitudinal speed of sound and attenuation at GHz frequencies. The TDBS thermal background recorded at different thicknesses gives insight on the evolution of the thermal properties of the sandwiched liquid structure following a variation of the liquid thickness gap. We will present several results obtained with different types of liquids (glycerol, 8CB liquid crystal, ionic liquids) highlighting in some cases liquid structuring at long distances > 10 nm at the vicinity of the solid interface, as well as thermal frustration linked to the confinement of the thermal phonons in a liquid gap dimensions matching the thermal phonons mean free path.

This pioneering TDBS experimental scheme is a first step towards the mechanical and thermal understanding of confined liquids measured through GHz ultrasonic probing.

Developing Time-Resolved Electronic Sum Frequency Generation to Probe Energy Transfer in Organic Thin Films

Organic semiconductors (OSC) represent a broad class of materials for the development of both novel electronics made exclusively from organic materials as well as the augmentation of existing inorganic semiconductors (ISC). However, incorporation of OSCs into devices on the market has been slow, in part due to a lack of understanding of fundamental processes whose function critically depend on the structure of interfacial junctions between layers in a device. To study these structure-function relationships a technique is needed with the ability to in situ monitor charge and energy transfer between the active layers of a functional device. To this end, we have developed electronic sum frequency generation (ESFG) for study of charge transfer both within purely OSC devices as well as from thin OSC films to ISC. ESFG is uniquely suited for the study of the inaccessible junctions in such devices given its interfacial selectivity in media containing a center of inversion. ESFG also has the advantage of being a purely optical technique, giving it the ability to...
study these transfer processes in functioning devices under ambient conditions. By developing heterodyne-detected ESFG (HD-ESFG) for the study of thin films, our group has been able to both resolve the phase of the measured \( \delta \phi \) spectrum and greatly increase our detection efficiency. HD-ESFG allows us to add an additional pump beam before our HD-ESFG probe, realizing time resolved ESFG (TR-ESFG) in order to track dynamics of energy and charge transfer at buried interfaces in working devices. We work demonstrates that TR-ESFG is a strong candidate in the growing list of techniques being developed to answer questions of charge and energy dynamics in OSC-ISC devices.

Ultrafast Electron Solvation Dynamics at the Origin of an Electrochemical Reaction Chain Julia Stähler; Fritz Haber Institute of the Max Planck Society, Berlin, Germany.

The formation dynamics of localized electronic states in molecular films near metal electrodes, including their propensity to act as precursor states for chemical reactions, is of example crucial for a detailed understanding of charge transport and degradation effects in batteries. We investigate the formation dynamics of small polarons and their role as intermediate electronic states in thin films of dimethyl sulfoxide (DMSO) on Cu(111) using time- and angle-resolved two-photon photoemission spectroscopy. Upon photoexcitation, a delocalized DMSO electronic state two monolayers from the Cu surface is initially populated, followed by a dynamic increase in binding energy and electronic state localization. This formation of a small polaron occurs on a 200 fs timescale, consistent with localization due to vibrational dynamics of the DMSO film. This localized state is a precursor state for an extremely long-lived surface-bound electronic state with a lifetime of several seconds and, thus, thirteen orders of magnitude longer than the small polaron. Moreover, experiments in oxygen atmosphere show that these trapped, long-lived electrons react with \( \text{O}_2 \) at the DMSO surface, likely forming \( \text{O}_2^- \). Our findings highlight the importance of interfacial electronic states near metal surfaces for electrochemical reactions despite their femtosecond lifetimes, as they are crucial precursors for long-lived, reactive states of solvents and electrolytes.

Nonlinear Terahertz and Optical Spectroscopy of Advanced Materials—Fundamentals and Applications Keith A. Nelson; Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

New developments in nonlinear terahertz spectroscopy have revealed important new insights into quantum material behavior and have opened up new possibilities for practical applications including advanced material characterization and control. Terahertz field interactions with electronic, lattice, and spin degrees of freedom have all been exploited in recent measurements. Terahertz-induced responses including quantum material phase transitions, colossal Stark shifts, and magnetization control will be illustrated. Terahertz-frequency electron paramagnetic resonance (EPR) including two-dimensional terahertz magnetic resonance will be discussed.

Time-resolved transient grating measurements of acoustic and thermal responses, in which crossed optical pulses generate an interference pattern at the sample whose spatial period determines the acoustic wavelength or the thermal transport length scale, have been conducted for some time, with applications already developed including noncontact metrology of thin films in microelectronics. Recently the measurements have revealed nondiffusive thermal transport kinetics, which provides fundamental insight into the phonons that carry thermal energy and which is a key consideration in nanoscale chemical reactions, is for example crucial for a detailed understanding of charge transport and degradation effects in batteries. We investigate the formation dynamics of small polarons and their role as intermediate electronic states in thin films of dimethyl sulfoxide (DMSO) on Cu(111) using time- and angle-resolved two-photon photoemission spectroscopy. Upon photoexcitation, a delocalized DMSO electronic state two monolayers from the Cu surface is initially populated, followed by a dynamic increase in binding energy and electronic state localization. This formation of a small polaron occurs on a 200 fs timescale, consistent with localization due to vibrational dynamics of the DMSO film. This localized state is a precursor state for an extremely long-lived surface-bound electronic state with a lifetime of several seconds and, thus, thirteen orders of magnitude longer than the small polaron. Moreover, experiments in oxygen atmosphere show that these trapped, long-lived electrons react with \( \text{O}_2 \) at the DMSO surface, likely forming \( \text{O}_2^- \). Our findings highlight the importance of interfacial electronic states near metal surfaces for electrochemical reactions despite their femtosecond lifetimes, as they are crucial precursors for long-lived, reactive states of solvents and electrolytes.

Ultrafast Anharmonic Phonon Scattering in PbTe Probed via Terahertz Emission Spectroscopy Burak Guzelturk1, 2, Mariano Trigo2, David A. Reix1, 2 and Aaron Lindenberg1, 2; 1Stanford University, Stanford, California, United States; 2SLAC National Accelerator Laboratory, Menlo Park, California, United States.

We report on the first direct and real-time measurement of ultrafast anharmonic phonon scattering in PbTe. Among IV-VI semiconductors, PbTe is an important system for infrared (IR) optoelectronics and thermoelectrics. For the latter, low lattice thermal conductivity has been identified as a key for efficient thermoelectric functionality, yet its origin has not been fully understood to date. Theoretical works supported by inelastic neutron scattering measurements pointed to the crucial role played by strong anharmonic phonon scattering between optical and acoustic phonons [1]. Also, ultrafast anharmonic scattering rates were estimated for PbTe underpinning its intrinsic impeded acoustic phonon transport [2]. However, no experimental study to date was able to time-resolve anharmonic phonon dynamics in PbTe.

Here, we observe far-IR electromagnetic radiation within the terahertz (THz) window emitted by PbTe upon ultrafast photo-excitation. This radiation emerges due to buildup of an ultrafast photocurrent close to the surface of the material and leads to the coherent excitation of IR-active optical phonons within the system. In this way, coherent detection of the radiated fields on femtosecond time-scale enables a mode-selective probe of phonon dynamics [3].

We observe that within the first ps following photo-excitation, the bare TO phonon mode (at 0.93 THz) splits into two; a higher energy mode around 1.4 THz and a lower energy mode between 0.4 – 0.8 THz. These new modes develop due to strong anharmonic coupling between TO and longitudinal acoustic (LA) phonons as theoretically predicted before [1, 2]. By monitoring the ultrafast anharmonic phonon scattering processes in real-time, we find the associated scattering rate to be \( (1 \text{ps})^{-1} \) which is in good agreement with the theoretical predictions [2, 4].

11:15 AM CM04.07.03
Ultrathin THz Waveplate as Characterized by Ultrafast Electron Pulse Edwin Sie, Clara M. Nyby and Aaron Lindenberg; Stanford University,
Manipulation of light polarization is indispensable to obtain control over the electronic properties in quantum materials. Here we show that we can change the polarization of light in the THz regime by using an ultrathin, nanometer-thick topological Weyl semimetal. We characterize the change of THz polarization using an ultrafast electron beam streaking that traverses a circular motion with respect to the THz beam. This finding offers a new promising way to enhance control over optoelectronic devices in nanometer scale.

11:30 AM *CM04.07.04
Transient Terahertz Spectroscopy—Femtosecond Dynamics of Low Energy Quasiparticle Excitations David Cooke; McGill University, Montreal, Quebec, Canada.

Terahertz pulses are coherently detected electromagnetic transients with a bandwidth spanning the 1 - 100 meV energy gap. These single cycle, phase stable pulses are powerful tools to examine low energy quasiparticle excitations in materials. Being perfectly synchronized to a fs laser pulse train, they can be used in a optical pump-THz probe geometry to time-resolve the kinetics of these excitations after optical injection or perturbation. The resulting time-energy maps can be used to determine fs dynamics of free charges, phonons, excitons, collective excitations and energy gaps resulting from many-body correlations. In this talk I will review the techniques for transient terahertz spectroscopy, specifically two-color laser plasma based sources capable of continuous coverage of the entire THz band in a single cycle pulse. I will discuss the application of transient terahertz spectroscopy to study a variety of condensed matter systems including semiconductor nanoparticles, organometallic halide perovskites and correlated electron systems. In addition, new methods of generating high field THz pulses have opened the possibility of coherently driving these quasiparticle excitations resonantly. I will discuss the current methods for generation of high field THz pulses, and some applications for controlling electron dynamics. Finally, the prospect of using shaped terahertz fields for quantum control experiments will be discussed, employing a novel pulse shaper demonstrated recently in our group. Proof of principle experiments will be discussed.

SESSION CM04.08: Ultrafast Imaging—Techniques and Applications
Session Chair: Sean Roberts
Wednesday Afternoon, November 28, 2018
Hynes, Level 2, Room 201

1:30 PM *CM04.08.01
Imaging Ultrafast Dynamics on the Nanoscale with Terahertz Scanning Tunneling Microscopy Frank A. Hegmann; University of Alberta, Edmonton, Alberta, Canada.

The ability to directly probe ultrafast phenomena on the nanoscale is essential to our understanding of excitation dynamics on surfaces and in nanomaterials. Recently, a new ultrafast scanning tunneling microscope (STM) technique that couples terahertz (THz) pulses to the scanning probe tip of an STM was demonstrated (THz-STM), showing photoexcitation dynamics of a single InAs nanodot with simultaneous 0.5 ps time resolution and 2 nm spatial resolution under ambient conditions [1]. Operation of THz-STM in ultrahigh vacuum now makes it possible to spatially-resolve subpicosecond dynamics of single molecules [2] and silicon surfaces [3] with atomic precision. Coherent control of THz-pulse-induced tunnel currents in THz-STM has also been demonstrated [3,4]. Even through THz-STM can be performed with THz-induced tunnel currents corresponding to less than 1 electron per THz pulse on average [2], extreme transient tunnel current densities of 10^7 A/cm^2 through single silicon atoms on a Si(111)-(7x7) surface have been observed, corresponding to about 500 rectified electrons tunneling in 0.5 ps across the junction [3]. This was attributed to nonequilibrium tunneling dynamics and penetration of the THz field through the metallic-like Si(111)-(7x7) surface. However, more detailed models may be required to better understand the subpicosecond tunneling dynamics induced in materials by THz-STM. This talk will discuss how THz-STM works and how it can provide new insight into ultrafast dynamics on the atomic scale, which is essential for the development of novel silicon nanoelectronics and molecular-scale devices operating at terahertz frequencies.

2:00 PM CM04.08.02
Time-Resolved (Far-) Infrared Spectroscopy at the Nanoscale Stefan Mastel, Tobias Gokus, Max Eisele and Andreas Huber; Neaspec GmbH, Martinsried, Germany.

Time-resolved optical spectroscopy from the mid- to far-infrared spectral range (0.1 – 100 THz) is a powerful tool to study the dynamics of low-energy elementary excitations in solid state systems, e.g. phonons, plasmons, and excitons on ultrafast timescales. With the development of time-resolved terahertz spectroscopy, ultrafast spectroscopy in the infrared has even reached the ultimate sub-cycle temporal limit [1,2]. In contrast to the achievements regarding the temporal resolution, the spatial resolution of far-field terahertz studies is limited by diffraction to the length scale of the probing wavelength (3 μm – 3 mm), making it impossible to access the intrinsic local response of single nanoparticles, nanodomains, or nanocrystals. To circumvent this fundamental limit, time-resolved infrared and THz spectroscopy has recently been combined with scattering-type Scanning Near-field Optical Microscopy (s-SNOM).

S-SNOM bypasses the diffraction limit, enabling optical measurements with extreme subwavelength spatial resolution down to 20 nm. s-SNOM employs the local field enhancement (hotspot) at the apex of an externally-illuminated sharp metallic atomic force microscopy (AFM) tip. In close proximity to a sample surface, the optical tip-sample near-field interaction is determined by the local dielectric properties (refractive index) of the sample. Detection of the elastically-tip-scattered light yields nanoscale resolved near-field images and spectra simultaneous to topography. By combining s-SNOM and time-resolved IR spectroscopy, for the first time, this approach enables a detailed analysis of charge-carrier dynamics in single layer materials [3,4], semiconductors [5], single nanoparticles [6], and even strongly-correlated materials [7] with femtosecond temporal and nanometer spatial resolution.

This talk will present the recent highlights in the field of ultrafast infrared spectroscopy and time-resolved terahertz time-domain spectroscopy (THz-TDS) in combination with the resolving power of s-SNOM. In addition, we introduce our first commercially available and ready-to-use THz-TDS near-field
spectroscopy system and show measurements on various test samples, such as graphene, h-BN and functional SRAM device. We achieve a spatial resolution of < 15 nm at a probe center-wavelength of 300 μm, surpassing the spatial resolution of conventional far-field terahertz spectroscopy by a factor > 2000.

2:15 PM CM04.08.03
Ultrafast Imaging of Charge Carrier Dynamics on Semiconductor Surfaces (Ebrahim Najaﬁ), 1-2, 1California Institute of Technology, Pasadena, California, United States; 2Chemours Co, Wilmington, Delaware, United States.

The spatiotemporal dynamics of nonequilibrium carriers reveal the excitation and relaxation pathways in materials. Here we report the ultrafast imaging of photoexcited carriers generated on the silicon surface by a femtosecond laser pulse. We use the scanning ultrafast electron microscopy (SUEM) technique to investigate the evolution of these carriers in space and time as the semiconductor proceeds to the ground state. We find that carrier transport after optical excitation follows the super-diffusion model with the diffusion coefficient that linearly increases with the laser fluence. However, this trend reverses at high excitation fluences. We attribute this anomaly to the generation of a large electric field by the spatial separation of photoexcited carriers, which strongly opposes carrier super-diffusion. This is evident in the second moment of the carrier distribution, obtained from the SUEM images, which reveals expansions and contractions in the carrier density. The numerical simulation of the drift-diffusion equation supports this interpretation. Our finding shines a new light on the dynamics of hot carriers in highly perturbed semiconductors by directly imaging their progression toward the ground state.

2:30 PM BREAK

3:30 PM *CM04.08.04
Spatial and Temporal Imaging of Multi-Scale Interfacial Charge Transport in Two-Dimensional Heterostructures (Libai Huang), Purdue University, West Lafayette, Indiana, United States.

Charge-transfer (CT) excitons at hetero-interfaces play a critical role in light to electricity conversion using organic and nanostructured materials. However, how CT excitons migrate at these interfaces is poorly understood. Atomically thin and two-dimensional (2D) nanostructures provide a new platform to create architectures with sharp interfaces for directing interfacial charge transport. Here we investigate the formation and transport of CT excitons in van der Waals (vdW) heterostructures based on semiconductor transition metal dichalcogenides (TMDCs) employing transient absorption microscopy (TAM) with a temporal resolution of 200 fs and spatial precision of 50 nm.

We have recently imaged the transport of interlayer CT excitons in 2D organic-inorganic vdW heterostructures constructed from WS$_2$ layers and tetracene thin films. To investigate driving force for exciton dissociation, we perform measurements on heterostructures constructed with different WS$_2$ thickness ranging from l layer to 7 layers. Photoinduced luminescence (PL) measurements confirm the formation of interlayer excitons with a binding energy of ~ 0.3 eV. Electron and hole transfer processes at the interface between monolayer WS$_2$ and tetracene thin film are very rapid, with time constant of ~ 2 ps and ~ 3 ps, respectively. TAM measurements of exciton transport at these 2D interfaces reveal coexistence of delocalized and localized CT excitons, with diffusion constant of ~ 1 cm$^2$s$^{-1}$ and ~ 0.04 cm$^2$s$^{-1}$, respectively. The high mobility of the delocalized CT excitons could be the key factor to overcome large CT exciton binding energy in achieving efficient charge separation.

We have also studied the interlayer charge transfer and recombination in WS$_2$-graphene and WS$_2$-WSe$_2$ heterostructures. We have demonstrated broadband photocarrier generation directly from interlayer CT states in WS$_2$-graphene heterostructures. Lifetime of the CT excitons has been found to be strongly dependent on interlayer stacking in epitaxial grown AA and AB stacking WS$_2$-WSe$_2$ heterostructures.

In this paper, we integrate a combination of modern and complementary ultrafast diffuse reflectance based spectroscopy and microscopy techniques to discuss the ultrafast photophysics of efficient photovoltaic materials including Cu$_2$BaSn$_x$Se$_{1-x}$ (CBTSSe) chalcogenides$^1$ for the first time. CBTSSe is a recently introduced alternative to Cu(In,Ga)(S,Se)$_2$ and Cu$_2$ZnSn$_x$Se$_{1-x}$ (CZTSSe). Ultrafast diffuse reflectance measurements enable direct examination of charge carrier processes in opaque device-relevant structures$^2$, highly light absorbing/scattering materials$^3$ or thin films deposited on metal substrates all of which cannot be studied using conventional transmission based pump-probe spectroscopy schemes. Based on broadband diffuse reflectance transient absorption spectroscopy the fingerprints of photocarrier absorption, GSB bleaching and electronic states in the vis-near IR region are investigated. Moreover, pump-probe microscopic imaging in the diffuse reflectance mode enables to localize the photoexcitation patterns and early charge carrier kinetics within the grains of only a few hundreds of nanometers and localize the kinetics of photogenerated carriers in each grain.

The CBTSSe films deposited on Mo-coated glass substrates, are studied similar to the configuration found in functional devices. We spectrally resolve a sharp ground-state bleaching (GSB) peak for CBTSSe films, formed around the band edge transition. The combination of narrow GSB peak width measured, coupled with the sharp steady state UV-Vis diffuse reflectance band edge, PL emission at the band edge and intensity independent PL shape, all point to a reduction in shallow defects and band tailing in CBTSSe relative to CZTSSe films. Furthermore, we have shown that the unique sensitivity of pump-probe microscopy and sharp electronic transitions allow for detection of small S/Se stoichiometry variations, $\Delta S \leq 0.3$, in Cu$_2$BaSn$_x$Se$_{1-x}$—Sex grains—i.e., features that are largely unresolved for ensemble spectroscopy or luminescence measurements. By noting the sharp band edge transition, we show that the band tailing issue (prevalent for CZTSSe) is largely resolved for CBTSSe. The charge carrier relaxation resolved in CBTSSe single grains, or over an ensemble of grains, however, remains faster compared to CZTSSe, pointing to the need to perhaps better understand deep traps within this absorber family. Such deep defects and fast carriers relaxations, would still impact the photocurrent and open circuit voltage of the CBTSSe devices/films examined.
Recent advances in experimental techniques that probe ultrafast dynamics and coherent effects at quantum material interfaces pose a theoretical challenge in predicting such dynamics ab initio with high spatial and temporal resolution simultaneously. Typically, computational predictions of transport phenomena employ either i) stochastic approaches, tracking particle dynamics, or ii) probabilistic approaches, describing the evolution of particle distribution functions. The Boltzmann Transport Equation (BTE), is of the latter kind, and provides the most general description of semi-classical transport. The BTE is a non-linear integro-differential equation in six dimensions which is typically solved either in the time and space-independent form, or using a number of limiting assumptions such as the single-mode relaxation time approximation. Here, we present a general theoretical and computational framework for carrier transport, which solves the full BTE using all its phase space degrees of freedom (i.e. with both real and reciprocal space resolution). Further, our method allows us to resolve contributions to the carrier distribution as a function of individual scattering events – which is often what ultrafast experimental techniques probe. We extend our framework to capture the dynamics of Peierls’ phonon BTE, making it possible to compare our results with picosecond acoustic measurements as well as the more recent coherent phonon spectroscopy techniques. Finally, analyzing the resulting surface fluxes of generated carriers we can draw direct comparisons with techniques probing Surface Acoustic Waves in the GHz range.
Mapping Atomic Motions with Ultrabright Electrons—Fundamental Space-Time Limits to Imaging Chemistry

Dwayne Miller1, 2; The Max Planck Institute for the Structure and Dynamics of Matter, Hamburg, Germany; 2Departments of Chemistry and Physics, The University of Toronto, Toronto, Ontario, Canada.

Watching atomic motions on the primary timescales of chemistry has been a long held objective. It would enable the direct observation of barrier crossing processes related to transition state concepts that link chemistry to biology. There are not only extraordinary requirements for simultaneous spatial-temporal resolution but equally important, due to sample limitations, also one on source brightness. Taking the problem to be an imaging problem, as one makes the shutter speed shorter and shorter, a brighter and brighter source is needed to maintain image contrast. With the development of ultrabright electron and x-ray sources capable of literally lighting up atomic motions, this experiment has been realized and refined to provide a general tool for probing structural dynamics on par with conventional pump-probe spectroscopy. The first studies focused on relatively simple systems. Further advances in source brightness have opened up even complex organic systems and solution phase reaction dynamics to atomic inspection. A number of different chemical reactions will be discussed from electrocatalysis with conserved stereochemistry [Jean-Ruel et al JCP B 2013], intermolecular electron transfer for organic systems [Gao et al Nature 2013; Liu et al Chem Phys Lett 2017], metal to metal electron transfer [Ishikawa et al, Science 2015], to the recent observation of coherently directed bond formation using the classic I3- system, in a process analogous to a quantum Newton’s cradle [Xian et al Nature Chem 2017]. New insight into the nuclear motions involved in spin transitions will be similarly related to coupling between electronic surfaces. These studies have discovered that there exist coherently directed bond formation using the classic I3- system, in a process analogous to a quantum Newton’s cradle [Xian et al Nature Chem 2017].

Understanding charge generation mechanism in organic solar cells is of great importance to further device optimisation. Currently, the nature and magnitude of the binding energy of charge-transfer states (CTS), an intermediate state which is critical for following charge separation process, are still under debate. Here, we demonstrate a new method for determining the dissociation energy of CTSs for a range of devices with various molecular energy levels and disorder using temperature-dependent pump-pulse photocurrent spectroscopy. We observe that dissociation of CTSs is a temperature-dependent process, from which we determine the binding energy by measuring a single activation energy over a wide temperature range. We propose a simple qualitative picture to explain the observation, based on the direct split between the bound CTSs and free carriers after charge transfer. The activation energy falls within the range of 90 ± 50 meV. Surprisingly, this binding energy does not greatly depend on the material composition or the driving energy (~150 meV) for variation) for charge separation. Such observations in the studied benchmark polymer:fullerene systems as well as polymer:non-fullerene acceptor systems reveal unexpected similarities in the energetics of CTSs formed in different electronic environments. This makes our results of general importance for understanding the photophysics at the heterojunction interface for further development of organic photovoltaics. To a broad aspect, this technique might be used for ultrafast in-operando studies of efficiency-loss states in a variety of optoelectronic devices.

Excitonic Effects in Zinc-Porphyrins Arrays Studied by Sub-25-fs UV Pulses

Jiangbin Zhang1, 2, Yifan Dong2, Andreas Jakowitz1, Akshay Rao1, Richard H. Friend1 and Artem Bakulin1; 1University of Cambridge, Cambridge, United Kingdom; 2Imperial College London, London, United Kingdom.

Synthetic porphyrins are largely exploited for artificial light-harvesting and optoelectronics due to their efficient role in energy transfer processes as donor or acceptor molecules [1]. Zinc-porphyrins (1Zn) have been used to synthesize arrays of dimers (2Zn) and hexamers (6Zn) to mimic the interactions of photosynthetic pigments [2]. The 2Zn-arrays revealed evident changes, as splittings and broadening, in the Soret absorption band (ca 415nm, S2 state) [2]. In porphyrins, an ultrafast S2→S1 internal conversion (IC) process occurs on a picosecond timescale due to the changes in the conformational configuration. Indeed, we observe that the recovery of the GSB for both 2Zn and 6Zn cases is faster with respect to the 1Zn one, thus reducing the yield of the triplet state formation. For the 1Zn case, the S1 state undergoes inter-system crossing to long-living triplet states with high efficiency. In the arrays this relaxation pathway is modified by the presence of possible dark states due to the changes in the conformational configuration. Indeed, we observe that the recovery of the GSB for both 2Zn and 6Zn cases is faster with respect to the 1Zn one, thus reducing the yield of the triplet state formation. For the 1Zn case, the S1 state undergoes inter-system crossing to long-living triplet states with high efficiency. Indeed, we observe that the recovery of the GSB for both 2Zn and 6Zn cases is faster with respect to the 1Zn one, thus reducing the yield of the triplet state formation.

Coherent Exciton-Vibrational Dynamics and Energy Transfer in Conjugated Chromophores

Sergei Tretiak; Theoretical Division and Center for Integrated Nanotechnologies (CINT), Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The role of coherence signifying concurrent electron-vibrational dynamics in complex natural and man-made systems is currently a subject of intense experimental and theoretical studies. Particularly, gaining control of this phenomenon is important for energy and charge transport when designing functional materials for various technologies, ranging from sensing, imaging, solar energy harvesting, to future optoelectronic devices. Using our Non-adiabatic EXcited-state Molecular Dynamics simulations (NEXMD) framework, we study ultrafast dynamics and exciton transport in several distinct molecular systems. These simulations reveal a ubiquitous pattern in the evolution of photoexcitation spanning dynamics of multiple electronic states. Symmetries of the excited state wavefunctions define specific form of the derivative non-adiabatic coupling driving non-adiabatic quantum transitions, which leads to a collective asymmetric vibrational excitation coupled to the electronic system. This promotes subsequent wave-like evolution of the excited state wavefunction preserving specific phases and amplitude relations across the ensemble of trajectories, facilitating efficient energy funneling. Proposed simple model explains appearance of coherent exciton-vibrational dynamics due to non-adiabatic quantum transitions, which is universal across multiple molecular systems studied. Observed relationships between spatial extent/properties of electronic wavefunctions and resulting electronic functionalities allow us to understand and to potentially manipulate excited state dynamics and energy transfer pathways in a number of organic molecular materials.

The Impact of HOMO-HOMO Offset on Charge Separation in Small Molecule Nonfullerene Organic Solar Cells

Safakath Karuthedath, Julien Gorenflot, Ru Z Liang, Pierre M. Boujuje and Frédéric Laquai; King Abdullah University of Science and Technology, Thuwal, Jeddah, Saudi Arabia.

Non-fullerene organic solar cells (NF-OSC)s now outperform fullerene-based solar cells by their higher power conversion efficiency (PCE) at similar photovoltaic layer thicknesses. However, to compete with other emerging technologies, energy losses after photon absorption need to be minimized. This raises the question: what is the minimum energy difference required to ensure quantitative exciton dissociation at the DA heterojunction? We address this issue in this communication and present the influence of $\Delta E_{\text{U}} = \text{HOMO}_{\text{donor}}-\text{HOMO}_{\text{acceptor}}$ for three different small molecule nonfullerene organic solar cells using DR3:TDDB (DR3) as electron donor blended with different small molecule acceptors, namely IC-C6-6DT-IC (ICC6), O-IDTBR, and IEICO, which gradually decrease the energy offset. We find a PCE of 8.7%, 6.4%, and 0.5% for ICC6 ($\Delta E_{\text{U}}$: 0.7 eV), O-IDTBR ($\Delta E_{\text{U}}$: 0.45 eV), and IEICO ($\Delta E_{\text{U}}$: 0.25 eV) blends under 1 sun condition, indicating a correlation of performance and energy offset. Sub-picosecond to nanosecond (ps-ns) transient absorption (TA) spectroscopy exposes: DR3:ICC6 exhibits charge generation in 20 ps, whereas in DR3:O-IDTBR charges are generated up to 500 ps. In contrast, in DR3:IEICO blends energy transfer (EnT) outcompetes charge transfer, explaining the poor PCE and indicating, the HOMO energy offset is insufficient for charge transfer and separation. In line with the device efficiency, the yield of long-lived carriers remaining at 7 ns after excitation is 65%, 44%, and <10%, respectively, for ICC6, O-IDTBR, and IEICO blends. Our results shine light on the minimum energy offset required for charge separation in all small molecule nonfullerene organic solar cells.

Impact of HOMO-HOMO Offset on Charge Separation in Small Molecule Nonfullerene Organic Solar Cells

Anna Kohler; University of Bayreuth, Bayreuth, Germany.

The mechanisms by which excitons dissociate highly efficiently in some donor-acceptor systems are still not fully understood. In this talk I aim to highlight differences and similarities that exist between the delocalisation of holes along a conjugated polymer backbone and electrons in a more or less ordered (small molecule) acceptor domain, and their impact on the overall dissociation efficiency.

3. Ultrafast Spectroscopy of Loss Processes in Nonfullerene Acceptor Bulk Heterojunction Solar Cells

Sergei Tretiak; Theoretical Division and Center for Integrated Nanotechnologies (CINT), Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The development of novel nonfullerene acceptors has recently boosted the power conversion efficiency of organic bulk heterojunction solar cells beyond an impressive 14%. However, it remains unclear which NFA structures are best to reduce further energy (voltage) and carrier (current) losses, as a precise understanding of the complex interplay between NFA structure and photophysical processes in blends and devices is still lacking. Here, we discuss for selected material systems, how the molecular structure affects the photophysics, specifically the charge separation and energy losses, which we study by ultrafast transient spectroscopy. As one example, we present BHJ systems that systematically vary in the energy offset between donor and acceptor. By using ultrafast transient spectroscopy, we demonstrate that after photoexcitation, singlet energy transfer can compete very efficiently with charge transfer, leading to low free carrier yields, and thus poor device performance. Furthermore, we show that the acceptors’ quadrupole moment is an important parameter to consider in the design of NFAs, as it determines the charge separation efficiency and simultaneously affects the open-circuit voltage of devices. Finally, we investigate the bias dependence of the device photocurrent by time-delayed collection field (TDCF) experiments and thereby identify reasons for low fill factors (FF) in polymer and small molecule / NFA systems. Specifically, we demonstrate that the fill factor is determined by two parameters: firstly, the field dependence of interfacial charge separation and secondly, non-geminate recombination of free charges competing with carrier extraction. In fact, depending on the NFA structure, field-independent charge separation is observed and thus high FFs can be achieved, if extraction of carriers kinetically outcompetes non-geminate recombination. However, other NFA structures exhibit low fill factors as charge separation is bias dependent and / or non-geminate recombination of charges competes with carrier extraction. Based on our spectroscopic insights and theoretical modeling of interface energetics and charge separation, we propose general design rules for NFAs that promise further reduction of quantum efficiency and energy losses.

The Impact of HOMO-HOMO Offset on Charge Separation in Small Molecule Nonfullerene Organic Solar Cells

Interfacial Energy and Charge Transfer for Photon Up-Conversion and Down-Conversion

Aaron P. Moon, Aaron Le, Jon A. Bender, Daniel E. Cotton, Emily K. Raulerson, Inki Lee and Sean T. Roberts; Chemistry, University of Texas at Austin, Austin, Texas, United States.

The negligible spin-orbit coupling in many organic molecules creates opportunities to alter the energy of excited electrons by manipulating their spin. In particular, molecules with a large exchange splitting have garnered interest due to their potential to undergo singlet fission (SF), a process where a molecule in a high-energy spin-singlet state shares its energy with a neighbor, placing both in a low-energy spin-triplet state. When incorporated into photovoltaic and photocatalytic systems, SF can offset losses from carrier thermalization, which account for ~50% of the energy dissipated by these technologies. Likewise, compounds that undergo SF’s inverse, triplet fusion (TF), can be paired with infrared absorbers to create structures that upconvert infrared into visible light. However, integrating materials that undergo SF or TF with existing electronics is challenging as this necessitates interfaces that can readily transfer spin-triplet excitations between these materials and bulk semiconductors, such as silicon. In this talk, I will summarize work investigating energy transfer dynamics in two key interfaces for SF and TF devices. First, I will describe work investigating how the local ordering of perylene diimide (PDI) molecules at a silicon surface impacts triplet energy transfer from PDI to silicon. We find small changes in the ordering of PDIs from their bulk structure due to strain at the silicon surface can shift their triplet energy by a few hundred meV, substantially impacting the driving force for triplet energy transfer. Second, I will discuss measurements characterizing triplet energy transfer from near-infrared absorbing PbS nanocrystals to TF materials covalently bound to their surfaces. We find PbS nanocrystals are decorated with a number of surface states. While some of these states facilitate triplet energy transfer to surface-bound molecules, others hinder it by trapping excitations. Throughout the presentation, an important theme will be use of key spectroscopic techniques, such as broad-band electronic sum frequency generation (ESFG), to visualize interfacial states involved in energy transfer between organic and inorganic systems.

MPP004.10/EP05.13.03
Singlet fission (SF) is a process that can occur in select organic molecules where a singlet exciton splits into two lower energy triplet excitons. While the intersystem crossing of singlets to triplets is typically slow in organic molecules, due to small spin orbit coupling singlet fission does not require a flip in spin and can be exceptionally fast compared to intersystem crossing. The SF process requires two chromophores whose triplet states should be approximately half of the singlet state’s energy to conserve energy. This process has applications in photovoltaics where thermalization of high energy excitations accounts for a major loss channel and limits the maximum performance of such devices. Utilizing materials that undergo efficient SF can potentially mitigate the losses these above band gap excitation experience — high energy excitations can be down converted into lower energy excitations before thermalization can occur. Perylenediimides (PDIs) are a robust class of dye molecule employed as commercial pigments that contain the proper energetics for SF. These molecules form crystalline domains in the solid state that can be readily tuned by functionalization of the molecules, thereby allowing the structure-function relationship of SF and intramolecular geometry in the solid state to be explored. The intramolecular geometry of SF chromophores has been shown to have a strong connection to the SF rate chromophores that undergo SF. A collection of PDIs with different solid state packing structures were evaluated for potential use as SF chromophores in polycrystalline thin films. Employing a combination of ultrafast femtosecond and nanosecond spectroscopy we identify the formation of triplet state spectral features and identify the SF rates for these materials. Extracted experimental rates deviate from theoretical predictions by approximately three orders of magnitude which may be attributed to differences in energetic landscape of the polycrystalline films and the dimer employed in the calculation. A series of temperature dependent spectroscopic experiments were utilized to examine the energetic requirements of SF in these polycrystalline thin films.

Singlet Fission is the process whereby one photon creates two triplet excited states. If both triplet states could be harvested by a single-junction solar cell, the solar cell efficiency would increase by up to 1/3. There has been much academic and industrial interest in developing new materials for singlet fission, but to date no material has proved ideal.

Carotenoids are the most widespread of the natural pigments, important for photosynthesis, vision, human health and industry. Work on astaxanthin [1,2] (the pigment which colours lobsters) shows that carotenoids are good candidates for singlet fission sensitizers for solar cells: they have strong absorption and fast (<100fs) singlet fission, independent of energetic driving force. There are hundreds of naturally occurring carotenoids and each of them can form a range of different dimer or aggregate structures (eg H- or J-aggregates).

To determine how carotenoid structure affects singlet fission, and how to exploit carotenoids or other polyene-type systems as singlet fission sensitizers, we use model systems to create identical dimer structures of a range of carotenoids. The model systems are made of synthetic ‘maquette’ proteins that hold the carotenoids in a specific dimer geometry. I will describe details of the photophysics of singlet fission in polyenes, showing that singlet fission is surprisingly robust to changes in conformation and does not depend on either the aggregate or intramolecular structure.

The electronic structure and exciton dynamics of organic molecules can change dramatically upon aggregation. The exciton dynamics of molecules in solution and in thin films of aggregates can be measured using transient absorption spectroscopy, but the exciton dynamics of intermediate aggregation states during thin film formation are typically unknown since measurements cannot be performed quickly enough to collect accurate transient absorption spectra of these species. By increasing the speed of data collection, the exciton dynamics of evolving material systems can be measured. A novel implementation of transient absorption spectroscopy is introduced that can measure transients with up to a 45 ps pump-probe time delay in one shot. The exciton dynamics measured during the solution deposition of a thin film is validated by comparing the initial exciton dynamics of the solution and the final exciton dynamics of the dry film to traditional transient absorption measurements. The exciton dynamics of intermediate aggregation states will be presented for the first time. The information gained using this technique can be used to modify environmental parameters during the film formation process to kinetically trap aggregates with exciton dynamics tailored for a particular application.
Probing Single Molecular Dynamics at Ultrafast Time Scales and in Nanoscale Volumes

Niek F. van Hulst1, 2; 1ICFO - Institute of Photonic Sciences, Castelldefels, Spain; 2ICREA - Catalan Institute for Research and Advanced Studies, Barcelona, Spain.

Tracing of individual molecules both in space and in time, provides super-resolution images of intra- and inter-molecular dynamic processes, all beyond the ensemble [1,2]. A host of important dynamic processes occurs on fs-ps timescale, such as electronic relaxation/dephasing, energy & charge transfer, vibrational relaxation, photo-dissociation-ionization, photo-isomerization. Yet capturing fast dynamics is fundamentally limited by the ns lifetime of the detected fluorescence. For the ensemble, fs-ps resolution is conventionally obtained by transient absorption and 2D electronic spectroscopy (2D-ES). Here first, we challenge ultrafast transient absorption of a single molecule and have set out to probe the non-linear ultrafast response of the single molecule using a broadband laser in an effective 3-pulse scheme with fluorescence detection. 2D-ES of single molecules is getting into reach [3]. Next, stimulated emission has the advantage of coherence and unity quantum efficiency, compared to fluorescence. Moreover depleting the excited state rapidly reduces photodissociation. Thus, we have set out to directly detect the stimulated emission from individual molecules and Qdots at ambient conditions, to disentangle ultrafast charge dynamics in the excited state, on fs-ps timescale [4]. Finally, we enhance the sensitivity and resolution using the local optical near-fields of plasmonic nano-antennas. Critical to the optimal coupling and enhancement is the positioning of the molecule at the local nanoscale hotspot of a resonant antenna. We apply deterministic scanning and stochastic mapping of the nanoscale plasmon-molecule interaction, to optimize the coupling strength and ultrafast interaction [5,6]. We apply the enhancement to photosynthetic complexes, LH2 [7], to detect first single FMO complexes at room temperature and assess their photon correlation.

The presented nanoscale ultrafast spectroscopy on individual molecules is of direct importance for pathway-specific detection of energy transfer and charge separation, directly & locally in light-harvesting systems [1].

Measurement of Ultrafast Carrier Dynamics in Graphene/Copper System
Cheng Dong, Weigang Ma and Xing Zhang; Department of Engineering Mechanics, Tsinghua University, Beijing, China.

Understanding of ultrafast carrier dynamics between graphene and metals at high frequencies is of great significance in graphene-based devices operating in high frequencies. Hence, we used femtosecond laser pulse-pump technique to study the energy coupling between graphene and copper, by monitoring the optical property change of graphene and copper, within 10 picoseconds after excitation of the pump beam. Sample is composed of single layer graphene grown on copper by chemical vapor deposition method. The pump beam of 400 nm is to excite the sample, and the probe beam of 800 nm is to monitor the total reflectivity change of this graphene/copper system. We observed two peaks and two valleys in measured total reflectivity signals, which reflects the optical properties. And then a slow increase in the total reflectivity signals is observed, which is dominated by the copper optical property changes. We developed a four temperature model to calculate the carrier temperature evolution of graphene and copper (phonons and electrons), and considering the energy coupling between graphene and copper is dominated by phonons. The theoretical results modulates the measured signal well. The energy coupling between graphene electrons and phonons, and energy coupling between graphene and copper are extracted from the modulation. These two energy coupling parameters provide understanding of graphene/metal-light interactions in ultrashort time domain, and provide foundation of graphene-based device applications.

Carrier Dynamics and Charge Transfer in CdSxSe1-x Lateral Nanoribbon Heterostructures
Freeman Statum, Biswadev Roy and Marvin H. Wu; Mathematics and Physics, North Carolina Central University, Durham, North Carolina, United States.

Ternary CdSxSe1-x semiconductors exhibit direct continuously composition-tunable bandgaps in the visible region and are thus of interest for applications involving emission and detection of light. Lateral nanoribbon heterojunctions offer large surface areas, short carrier diffusion lengths and lower cost of growth compared to bulk films. We characterize the evolution of photo-generated charge carriers in individual CdSxSe1-x nanoribbons using ultrafast optical spectroscopy and time resolved millimeter wave photoconductivity. Static confocal photoluminescence (PL) microscopy of these nanoribbons, which are produced through the vapor – liquid – solid technique using gold nanoparticle catalysts, show variations of ~80 – 120 nm in the locations of the PL peaks in adjacent regions due to spatially varying compositions. PL lifetime mapping via time –correlated single photon counting showed shorter lifetimes (~100 ps) in the central portion of the wider bandgap region, compared to regions near the interface. These shorter lifetimes, combined with wide field static PL measurements that show emission from the narrow bandgap region after excitation in the wider bandgap region, are consistent with transfer of photoexcited carriers. Higher (sub-picosecond) temporal resolution transient absorption (TA) microscopy measurements result in lifetimes matching those obtained via PL, TA and PL measurements with spatially separated excitation and TA probe or PL emission locations show evidence of asymmetric carrier diffusion near the interface. Time resolved photoconductivity decay curves from ensembles of nanoribbons show a system response limited nanosecond lifetime decay consistent with PL measurements, but also show a weak longer lived (~ 50 ns lifetime) component that may correspond to a small population of weakly trapped carriers not observed in PL or TA measurements.

Ultrafast Excited State Absorption in Chromophore-Functionalized Chiral Polybinaphthalenes
Jonatas Siqueira¹, Marcelo G. Vivas², Cleber Mendonça¹ and Leonardo de Boni¹; ¹Institute of Physics of São Carlos - University of São Paulo, São Carlos, Alabama, United States; ²Instituto de Ciência de Tecnologia, Universidade Federal de Alfenas, Poços de Caldas, Brazil.

The study of ultrafast chirality dynamics in the excited state has received considerable interest over the past years. Chiral polymers show particularly interesting properties for applications in emerging field of chiral photonics. Chromophore-functionalized polybinaphthalenes are an interesting class of chiral polymers given their high chirality in the ground state. Chromophore-functionalized polybinaphthalenes show a tree-like structure: they are composed of a rigid, rod-like backbone to which flexible chromophores are attached. This tree-like supramolecular architecture, the chromophores (branches) are attached to a rigid backbone (trunk), diminishes and even excludes dipolar interactions between the chromophores. In a previous study on donor-embedded polybinaphthalenes, it was demonstrated that they are a very interesting class of polymers since the dipolar interactions between the chromophores are excluded in these materials and chiral contributions are present. The spectral depletion and ultrafast dynamics of excited state absorption of four different chromophore-functionalized polybinaphthalenes, were characterized by femtosecond absorption transient spectroscopy as a first step towards the characterization of their chirality dynamics in the excited electronic state. In order to better understand the origin of chirality in this class of polymers, we aim at studying their chirality in the excited state. An initial study in this direction was the characterization of their excited state absorption and dynamics via femtosecond transient absorption technique for four chiral polybinaphthalenes. Excited state absorption (ESA) spectroscopy at femtosecond time scale was carried out to measure the relaxation times and absorption spectra of their electronic excited states. Femtosecond time-resolved ESA experiment was implemented using 150-fs pulses (775 nm) from a regenerative Ti:sapphire. ESA spectra and dynamics measurements were performed using the pulse at 387.5 nm (second harmonic of 775 nm) as a pump pulse and a white light continuum (400 - 700 nm) as a probe. We obtained excited state characteristic deactivation times shorter than 100 ps and characterized the spectral dependence of their excited state absorption. The data obtained in this study will assist us in the characterization of the chirality ultrafast dynamics on the electronic excited state of this novel class of chiral polymers.

High Contrast Photothermal (PT) Phase Imaging in the Mid-Infrared Exceeding Sub-Diffraction Limited Spatial Resolution
Panagis Samolis¹,², Shyamsunder Erramilli¹,²,³,⁴ and Michelle Y. Sander¹,²,³; ¹Department of Electrical and Computer Engineering, Boston University, Boston, Massachusetts, United States; ²Photonics Center, Boston University, Boston, Massachusetts, United States; ³Division of Materials Science and Engineering, Boston University, Boston, Massachusetts, United States; ⁴Department of Mathematics and Physics, North Carolina Central University, Durham, North Carolina, United States.

Mid-infrared (mid-IR) spectroscopy and imaging has attracted significant interest as a label-free method for material analysis based on the presence of characteristic vibrational resonances in the molecular fingerprint region. However, most mid-IR photothermal (PT) spectroscopic imaging systems so far have mostly focused on extracting amplitude information from the sample. Here, we present how characterization of phase images can result in enhanced spatial resolution and imaging contrast based on the different thermal properties of the imaging target and its surrounding environment. In a heterodyne measurement configuration with a lock-in amplifier, phase details of single particles are resolved below the spatial sub-diffraction imaging limit of the optical system in a spectral window where the amplitude images don’t show much contrast.
In the presented PT pump-probe microscopy configuration, a nanosecond pulsed mid-IR beam excites the absorption resonance of the sample while a near-IR beam is used to probe its thermo-refractive response. By detecting the scattered probe intensity in the far field with sensitive detector technology, sub-diffraction limited imaging resolution can be achieved circumventing more complex mid-IR detectors.

In traditional mid-IR imaging, if the surrounding medium and the imaging target feature similar absorption properties, this generally limits the contrast, spatial resolution and chemical specificity. Here, we demonstrate the capabilities of PT phase imaging for highly sensitive detection of weakly absorbing single particles embedded in a medium that is also resonant at the excitation wavelength.

The PT signal of our system is acquired by lock-in detection, which allows background-free detection of small modulations in the probe beam intensity with high signal to noise and enables detection of amplitude and phase signals. We investigated the phase signal of 1 μm melamine beads embedded in an 8CB liquid crystal. We demonstrate that high phase contrast can be obtained due to the different thermal properties of the imaging target and its surrounding environment even in a spectral regime where absorption of the bead and the liquid crystal is similar. By investigating the phase signal, we are able to detect the presence of single absorbers smaller than the diffraction limited spot size with high contrast and enhanced spatial resolution, in an absorbing medium. This method provides a promising pathway to detect weakly absorbing signals in an overcrowded spectral region where high absorptive signals can mask weaker contributions, which is attractive for highly sensitive chemical sensing, detection of hazardous trace materials and biological tissue analysis.

Identification of Reactive Species in Photoexcited Nanocrystalline BiFeO3 Powder by Transient Absorption Spectroscopy

Wegdan Ramadan and Detlef Bahnemann
1 Physics Department-Faculty of Science, Alexandria University, Alexandria, Egypt; 2Institut für Technische Chemie, Leibniz Universität Hannover, Hannover, Germany; 3Laboratory “Photoactive Nanocomposite Materials”, Saint Petersburg State University, Saint Petersburg, Russian Federation.

BiFeO3 (BFO) is a multiferroic semiconductor that combines antiferromagnetic and ferroelectric order well above room temperature. It has a direct band gap energy lies within a range of 2.3 to 2.8 eV hence, it can harvest visible light of the solar spectrum and an indirect band gap around 1.8 eV. The position of the conduction band, E_C, and valence band, E_V, makes it suitable for the oxidation of water and many other organic pollutants. Combining such desired properties in a simple ternary compound that comprises echo friendly and cost effective elements makes it easier to utilize it towards sustainable energy harvesting application. However, fundamental studies about photo charge carrier dynamics of BFO nanoparticles are still lacking. BFO nanocrystals having particle size ~70 nm were synthesized using sol gel method. In this work, charge carrier dynamics of BFO colloid have been investigated by means of diffuse reflectance transient absorption spectroscopy. Nanosecond transient absorption were performed at two excitation wavelengths; 335 nm (3.4 eV) that is higher than the band gap and at 532 nm (2.33 eV) which is around the bang gap energy. Measurements were carried out in the presence of methanol-N2 saturated atmosphere as a hole acceptor and in presence of N2Na2S2O8 in an alkaline medium, by using NaOH as electron acceptor. By quenching electrons using Na2S2O8 we were able to deal with holes as electrons will be quenched by the persulfate and holes will remain in the particles. Measuring the initial signal height immediately after the laser pulse, two transient absorption maxima can be observed; one sharp maximum centered at around 550 nm and a broad one around 750 nm. To relate the observed transient absorption signals to possible trapped charge carriers, we performed the same measurements in a N2-methanol environment to investigate the changes in the transient spectra. In the presence of methanol, the absorption peak at 550 nm significantly decreases, while the absorption at 750 nm remained unchanged. This indicates that the first absorption maximum can be attributed to trapped holes, which react rapidly with N2–methanol hence the decrease in the spectrum. The same set of measurements when carried out at excitation wavelength of 355 nm and the same behavior was obtained. The observed peak at 750 nm could be related to the indirect band gap which is around the same wave length. This result contradicts what was reported previously by Yasuhiro et. al. who attributed the strong absorption peak at 540 nm to the optical transition of the photoexcited electrons to the higher conduction band. The optical transient absorption of the electrons could not be clearly identified hence, more experiments still need to be carried out.
**In Situ TEM of Formation Processes of Dislocation Loops in Tungsten Under Irradiation—Comparison Between Electron and Self-Ion Irradiations**

Kazuto Arakawa, Shimane University, Matsue, Japan.

Nuclear-fission and fusion materials are degraded primarily due to the accumulation of radiation-produced lattice defects, such as point defects (self-interstitial-atoms (SIAs) and vacancies) and point-defect clusters (dislocation loops and cavities). In order to precisely predict the lifetimes of nuclear materials, accurate understanding of the origins of the defect accumulation—generation of defects and their subsequent dynamics—is crucial.

In-situ transmission electron microscopy (TEM) is a powerful technique for probing defect dynamics, in response to external stimuli such as irradiation under heating or cooling. As the irradiation sources for the in-situ TEM, electrons and ions are available. In the electron irradiation, only point defects are generated as the primary damage via knock-on displacement. In contrast, in the ion irradiation, point-defect clusters are also generated as the primary damage, which is called “collision cascade”, like neutron irradiation.

In the present study, we focus on the formation process of SIA dislocation loops in tungsten under irradiation. So far, we have revealed that the SIAs [1] and loops are intrinsically highly mobile and the loop-formation process must be governed by extrinsic “stabilizers” for them. In this study, we examine the loop stabilizers for 2000-keV electron irradiation using a high-voltage electron microscope in Osaka University in Japan and 500-keV W⁺ self-ion irradiation using an ion-accelerators combined microscope in the JANNuS-Orsay facility in France. Through the comparison between these results, we try to extract the effects of collision cascade on the loop stabilization.

**Hot-Electron Mediated Atomic Diffusion in Proton-Irradiated MgO**

Cheng-Wei Lee and Andre Schleife; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Ionizing charged-particle radiation has exciting potential to modify material properties. In particular, swift heavy ions are known to either exacerbate or mitigate damage. Controlling the modification of a material using radiation relies on a quantitative understanding of fundamental interactions between particle radiation and target material.

Since high-energy projectiles significantly drive the electronic system of the target out of equilibrium, standard atomistic simulations based on the Born-Oppenheimer approximation are no longer valid. Therefore, knowledge of non-equilibrium electron-ion physics becomes crucial: Directly after excitation by the projectile ion, the electronic system of the target is in a highly excited, non-thermalized state. Subsequent thermalization and cooling takes tens to hundreds of femtoseconds and tens of picoseconds respectively, depending on the dominant scattering mechanism and the target material. However, it is currently not well understood whether and how non-thermalized excited carriers, as well as thermalized hot carriers, affect atomic diffusion, which is the critical knowledge to understand material property change via irradiation.

In order to achieve a quantitative description of atomic diffusion under particle radiation, we propose a parameter-free first-principles simulation framework that bridges time scales from ultrafast electron dynamics directly after impact, to atomic diffusion in the presence of hot electrons. First, we simulate electronic excitations during ion irradiation using real-time time-dependent density functional theory. We then extract the probability of finding electrons in excited electronic states as occupation numbers and use them as constraint in DFT-based nudged-elastic band simulations to compute migration barrier in the presence of hot carriers.

Here we apply this framework to magnesium oxide under proton irradiation [1]. We compare the migration barrier of an oxygen vacancy in the presence of (i) non-thermalized hot electrons, (ii) thermalized Fermi-distributed electrons, and (iii) an ionized oxygen vacancy. We found that in all three cases, the migration barriers are lower than for the electronic ground state by 1.33, 0.34, and 1.07 eV respectively. Neither thermalized hot electrons nor ionization of the point defect can fully explain the enhanced diffusion under non-equilibrium conditions, hinting at a novel hot-electron mediated diffusion mechanism. Furthermore, our quantitative simulations show that this mechanism strongly depends on the projectile-ion velocity, opening the possibility of turning it on or off by varying the kinetic energy of the particle radiation. We predict that this should facilitate direct experimental observation of this effect and significantly advances current understanding of non-equilibrium electron-ion dynamics in materials under energetic particle radiation.

**Helium Irradiated Cavity Formation and Defect Energies in Ni-Based Binary Single-Phase Concentrated Solid Solution Alloys**

Cheng-Wei Lee and Andre Schleife; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Binary single-phase concentrated solid solution alloys (SP-CSAs), including Ni₈₀Co₂₀, Ni₈₀Fe₂₀, Ni₈₀Cr₂₀, Ni₈₀Pd₂₀, and Ni₈₀Mn₂₀ (in atomic percentage), were irradiated with 200 keV He⁺ ions at 500 °C. He cavity size and density distribution were systematically investigated using transmission electron microscope. Here we show that alloying elements have a clear impact on He cavity formation. Cavity size is the smallest in Ni₈₀Mn₂₀ but the largest in Ni₈₀Co₂₀. Alloying elements could also substantially affect cavity density profile. In-depth examination of cavities at peak damage region (~ 500 nm) and at low damage region (~ 300 nm) demonstrates that cavity size is depth (damage) dependent. Competition between consumption and production of vacancies and He atoms could lead to varied cavity size. Density functional theory (DFT) calculations were performed to obtain the formation and migration energies of interstitials and vacancies. Combined experimental and simulation results show that smaller energy gap between interstitial and vacancy migration energies may lead to smaller cavity size and narrower size distribution observed in Ni₈₀Mn₂₀ compared with Ni₈₀Co₂₀. The results of this study call attention to alloying effects of specific element on cavity formation and defect energetics in SP-CSAs, and could provide fundamental understanding to predict radiation effects in more complexed SP-CSAs, such as high entropy alloys.
Under neutron or ion irradiation point defects and defect clusters are formed within the displacement cascades or by diffusion of defects under irradiation fluxes. The properties of these clusters have significant impact on the evolution of the microstructure under irradiation conditions. Furthermore, solutes within the alloys may affect the defect behaviour (their relative stability and their mobility) due to their more or less large interaction with them. Atomic simulation allows to investigate properties of point defect clusters. DFT calculations are the most accurate available method to determine the impact of substitutional atoms representative of the alloying elements on the stability and mobility of clusters in particular for self interstitial clusters the mobility of which can be quite complex. The results we will present focus on Fe dilute alloys representative of reactor pressure vessel steels, tungsten representative of fusion divertors and zirconium representative of fuel cladding materials. The different possible structures small SIAs clusters can adopt will be discussed, in particular the sessile and non parallel configurations in Fe, as well as the interstitial dislocation loop. The later has been experimentally observed when they are large enough. The dependence of solute interactions as a function of solute size, chemistry or magnetism will be discussed, as well as synergy effects between solutes. Furthermore, the formation of interstitial clusters in the displacement cascade obtained by molecular dynamics (using different EAM potentials) debris will be presented.

The data we obtained are essential / fundamental / necessary to model microstructure evolution using for instance kinetic Monte Carlo simulations.

Hydrogen Promoted Vacancy Diffusivity in Cu—First-Principles and Molecular Dynamics Study
Jumping Du1, 2, W.T. Geng3, 4, Kazuto Arakawa2 and Shigenobu Ogata2, 4; 1Center for Elements Strategy Initiative for Structural Materials, Kyoto University, Kyoto, Japan; 2Department of Mechanical Science and Bioengineering, Osaka University, Osaka, Japan; 3University of Science and Technology Beijing, Beijing, China; 4Department of Materials Science, Faculty of Science and Engineering, Shimane University, Shimane, Japan.

The agglomeration of vacancies, which acts as one of the void nucleation and growth mechanisms, may cause ductile fracture in pure metals and radiation-damaged materials. It has been believed that diffusion of vacancy in metals is suppressed in hydrogen environment. The fact that excess hydrogen can enhance greatly the self-diffusion of atoms in metals has been explained by the appearance of superabundant vacancies, because the vacancy formation energy decreases substantially with increasing H concentration, while individual vacancy diffusion is supposed to be slowed down. Previous computational and theoretical studies suggest that the trapped H atoms in a H-vacancy complex impede the diffusion of vacancy by increasing the energy barrier of vacancy jumping. However, by performing first-principles calculations of appearance probability of vacancy-H configurations, the activation energy and attempt frequency of possible vacancy jumping pathways in face-centered cubic Cu, we find at certain H concentrations and temperatures, the diffusivity of vacancy jumping. However, by performing first-principles calculations of appearance probability of vacancy-H configurations, the activation energy and attempt frequency of possible vacancy jumping pathways in face-centered cubic Cu, we find at certain H concentrations and temperatures, the diffusivity of vacancy jumping increases with increasing H concentration. This effect is found to be stronger in pure Cu than in Cu-H alloy, and it is attributed to the fact that the presence of H atoms in the Cu lattice increases the energy barrier for vacancy hopping.

Formation Mechanism of Radiation-Induced Re and Os Precipitation in W and Their Influences on Mechanical Properties
Hong-Bo Zhou, Yu-Hao Li, Ying Zhang and Guang-Hong Lu; Department of Physics, Beihang University, Beijing, China.

Tungsten (W) is one of the most promising candidates for plasma facing materials (PFMs) in future fusion reactors. Rhenium (Re) and Osmium (Os) are not only the typical alloying elements but also the main productions of transmutation in W-PFMs. More importantly, Re and Os will aggregate and precipitate in W under high energy radiation, which substantially enhance the radiation hardening and embrittlement, leading to the great concerns for the life-limiting of W-PFM. So far, the formation mechanism of Re/Os-rich clusters in W as well as their influences on the mechanical properties remains to be fully elucidated.

We have investigated the interaction between Re/Os and defects in W using a first-principles method in combination with thermodynamic models in order to explore the precipitating mechanism of Re/Os under irradiation. It is found that the presence of defects can significantly reduce the total nucleation free energy change of Re/Os, and thus facilitate the nucleation of Re/Os in W. Kinetically, self-interstitial atom is shown to be easily trapped by substitutional Re/Os, and form W-Re/Os mixed dumbbell. Such W-Re/Os dumbbell combining with the substitutional Re/Os atom will transform to high stable Re/Os-Re/Os dumbbell, which can serve as a trapping centre for subsequent W-Re/Os dumbbells, leading to the growth of Re/Os-rich clusters. Consequently, an interstitial-mediated migration and aggregation mechanism for Re and Os precipitation has been proposed.

To shed light on the effects of transmutation elements on the mechanical properties of W, we further have investigated the influences of Re on the motion of 1/2<111> screw dislocation in W. It is found that the influence of Re on the dislocation motion is directly related to the distribution of Re in W. For the state of Re dispersed distribution, the addition of Re will reduce the generalized stacking fault energy (GSFE) for both 1/2<111>-[112] and 1/2<111>-[110], and improve the ductility of W. However, the influence of Re clusters (for the state of Re aggregation) on the dislocation motion is significantly different from that of dispersed Re. The presence of Re clusters will substantially increase the Peierls stress and energy, inhibiting the dislocation mobility. This will significantly exacerbate the irradiation hardening of W. Therefore, the radiation-induced precipitation of transmutation elements will degrade the mechanical properties of W.

Investigation of Hydrogen Isotope Distribution in Unirradiated and Neutron Irradiated Zircaloy-4 via Atom Probe Tomography
Elizabeth J. Kautz and Arun Devaraj; Pacific Northwest National Laboratory, Richland, Washington, United States.

Tritium is a radioactive hydrogen isotope (^3H) used in various applications. Since tritium is not naturally abundant, it must be artificially generated with Tritium Producing Burnable Absorber Rods (TPBARs), which are specifically designed to produce and capture H when irradiated with neutrons. At the center of each TPBAR, there is a lithium aluminate (LiAlO2) ceramic pellet that produces tritium upon neutron irradiation, which is then absorbed by a Zircaloy-4 tube that surrounds the LiAlO2 pellet [1]. Currently the amount of H absorbed by the Zircaloy-4 getter, and the hydrate phases formed are not well understood [2]. In order to improve predictive models and inform materials processing and design decisions, improved understanding of mechanisms responsible for hydrogen absorption and distribution in the Zircaloy-4 getter is needed. The overall goal of this work is to measure hydrogen isotopic ratios
and spatial distribution in the Zircaloy-4 getter exposed to various environments in order to provide insight into how hydrogen is absorbed in the tritium production process. In this work, comparison of atom probe tomography results from as-received, hydrided, deuterided, and tritiated Zircaloy-4 samples was performed and compared to results from neutron irradiated Zircaloy-4. Data revealed several overlapping peaks in mass spectra, and non-uniformity in hydrogen distribution after exposure to hydrogen and deuterium gases. Additionally, sample preparation procedures and user-selected experimental parameters for pulsed-laser atom probe were studied in order to determine how various parameters impact hydrogen background, and hydrogen isotope content in all Zircaloy-4 samples analyzed. Laser energies of 80-200 pJ at a pulse rate of 125 kHz were studied, and we found that measured hydrogen concentration decreased with increasing laser energy at a given pulse frequency. The work presented here is intended to serve as a baseline for application of atom probe tomography for the challenge of hydrogen isotope quantification in Zircaloy-4, with implications to other hydrogen-sensitive metal alloy systems.

SESSION CM05.03: Chemical and Polymeric Changes Under Ionizing Radiation
Session Chairs: Kazuto Arakawa and Hidehiro Yasuda
Monday Afternoon, November 26, 2018
Hynes, Level 2, Room 202

1:30 PM CM05.03.01
Structural and Electronic Changes in Prototypical Catalysts upon X-Ray Irradiation Anna Rescigno1, Amber Thompson2, Alex M. Ganose3, David O. Scanlon1 and Claire Murray4, Imperial College London, London, United Kingdom; 2University of Oxford, Oxford, United Kingdom; 3University College London, London, United Kingdom; 4Diamond Light Source, Didcot, United Kingdom.

Interactions of X-rays with crystalline matter can induce a wide range of changes. Whilst some knowledge is available for biological systems and extended solids, practically nothing is known on the effect of ionising radiation on small molecules. However, they form the basis of a range of important technologies, e.g. catalysis. In small molecule crystals radiation damage can be understood as a three step process. Primary damage is caused by the direct interaction of the incident radiation with the sample. This is followed by secondary damage through electrons as well as species which are created during the initial damage. Finally, an extended collapse of the structure can occur based on a combination of a significant number of damage processes caused by energy deposition in the crystal.

Modern characterisation techniques make extensive use of X-rays to gain information on the properties of matter. Particularly modern microfocused laboratory sources and synchrotrons with their increased radiation dosages and often lower X-ray energies present a challenge. The move towards ever more powerful X-ray sources has increased the urgency to understand the influence of radiation damage. Whilst the observation of radiation damage in itself is useful to design strategies to prevent it, it is of even greater importance to understand the why and how of radiation damage in these materials. Lessons learned from radiation damage studies can in turn give vital information to understand a material’s overall behaviour and stability.

Here, a combination of synchrotron-based X-ray powder diffraction (PXRD) and laboratory-based X-ray photoelectron spectroscopy (XPS) is used to provide insights into changes to the structure, to local chemical environments, and to the electronic structure of small molecular crystals. By combining results from both of these advanced techniques, structural changes can be directly correlated to changes of the chemical state of the metal, which also manifests itself in variations in the valence structure. A range of prototypical catalysts is investigated, based on the general formula of $\text{M}_{x}\text{COD}_{y}\text{X}_z$, where $\text{M}=\text{group 8-11 metals}, \text{COD}=\text{cyclooctadiene}$, and $\text{X}=\text{Cl, Br}$. By using appropriate timescales, the effects of radiation are followed continuously over long periods of time giving an insight into how radiation damage progresses. In order to understand the experimental observations in more detail, theoretical results from density functional theory calculations are employed. Differences in the behaviour of the materials will be discussed in the context of both structural and chemical characteristics.

The combination of diffraction and spectroscopy provides a powerful new way of following X-ray photon exposure effects on both structure and electronic structure. The characterisation processes developed are applicable beyond small molecule catalysts and the insights gained can be extended to other material systems, and inspire further investigations.

Evaluating Radical Initiators for Secondary Electron Optimization in Hafnium Oxide-Methacrylate EUV Photoresist Yasiel Cabrera, Eric Mattson, Kolade Oyekan, Yuxuan Wang and Yves J. Chabal, Department of Material Science, The University of Texas at Dallas, Richardson, Texas, United States.

Inorganic-organic hybrid nanoclusters are molecular compounds that have excellent photochemical properties for the newly emerging extreme ultraviolet lithography (EUVL). In particular, these systems have recently come into the spotlight of research due to their achievements in both high etch resistance and photosensitivity abilities thanks to their functional inorganic metal-oxide cores when exposed to ionizing radiation. In this work, we uncover the fundamental mechanisms of photoresists composed of hafnium-oxide core with terminal carboxylic acid ligands. A combination of in situ infrared (IR) spectroscopy and residual gas analyzer (RGA) measurements, together with density functional theory (DFT) provide mechanistic insight into each step of processing of the HMAA system: post-application bake (PAB), 90 eV electron irradiation, and post-exposure bake (PEB). To understand the role of ligands on electron-induced chemistry, we added co-ligand to the HMAA system -- hydroxobenzoic acid (HBA), and phenylacetic acid (PAA) -- and monitored the amount of alkyl CH produced after electron irradiation. We find that co-ligand films enhance crosslinking reactions, particularly for lower energy electrons (20eV). IR spectroscopy shows that similar amounts of CH are produced in the two systems, and analysis with RGA suggests that the ring radicals that are generated upon decarboxylation behave differently; we see the benzyl radical being released in the gas phase for PAA, while for HBA no phenyl radical is detected suggesting participation within the film.

2:00 PM CM05.03.03
When materials are atomic species-, site- or electronic orbital-selectively excited by photons with variable energy, bond breaking or reaction between specific atoms take place. It was confirmed in our group that a platinum silicide, PtSi, was successfully formed at the platinum/silicon oxide interface kept at room temperature under 25–200 keV electron irradiation. This result shows that the reaction cannot be induced by simple thermal annealing under no-electron-irradiation conditions and takes place by bond breaking of Si-O and simultaneous bond formation of Si-Pt under electron irradiation. In the present study, the synthesis of platinum silicide at the platinum/silicon oxide interface by photo-excitation was investigated using synchrotron-radiation photo emission spectroscopy and transmission electron microscopy. After photo-excitation by 80 eV photons, valence band spectrum of silicon did not change, and remarkable changes were not recognized also in Pt4f7/2 core level spectrum. On the other hand, in the case of photo-excitation by 140 eV photons, peak near the Si 3p level in the Si valence band spectrum shifts to higher energy, and a peak originating from Si3p-Pt5d bonds appears near the Fermi level. In Pt4f7/2 core level spectrum, the peaks shift to higher energy by 1.2 eV and are similar to those which are obtained from PtSi. These results indicate that valence band and Pt4f7/2 core level spectra remarkably change during PtSi formation. As mentioned above, it was confirmed that Si 2p core level excitation plays an important role in P2SiH silicide formation by reaction between silicon and platinum on Pt/SiOx thin film interface, because the binding energy of Si 2p is approximately 99 eV. In order to produce Si-Pt bonds preferentially from Si-O-Pt bonds, simultaneous breaks of Si-O and O-Pt bonds and the consequent desorption of oxygen atoms and formation of Si-Pt bonds may be required by photo-excitation. It is suggested that a core level excitation mechanism related to the Knotek and Feibelman mechanism may play an important role in silicide formation within the solid.

2:30 PM CM05.03.04
Damage Efficiency of High-Energy Ions in Ultrathin Polymer Films
Raquel S. Thomaz1, Jean-Jacques Pireaux3, Christina Trautmann2 and Ricardo M. Papaleo1; 1Catholic Univ of Rio Grande do Sul, Porto Alegre, Brazil; 3Materials Research, GSI Helmholtz Centre, Darmstadt, Germany; 2Université de Namur, Namur, Belgium.

In this contribution, we present recent results by our group aiming the investigation of the fundamental problem of damage efficiency of high-energy ions in polymers, under the spatial confinement conditions of ultrathin films. The identifiability and understanding of possible size-effects on the damage efficiency of energetic ions is crucial for several topics of interest, from radiation resistance and stability of nanomaterials and devices to biological damage at small scales. We followed the changes in radiation effects in two polymers (PMMA and PVC) as the thickness of supported films is systematically reduced from ~ 200 nm down to ~2nm to identify critical thicknesses below which the efficiency starts to deviate from bulk values. Two types of experiments were conducted using ions in an energy range from 2 MeV up to 2 GeV: one involving cratering produced by single ion impacts and another on measurements of bond-breaking rates, based on XPS spectroscopy investigations and average effects of high-fluence irradiations. Cratering efficiency decreases strongly with thickness below a critical size as large as 40nm in PMMA. Bond-breaking cross sections, in contrast, were insensitive to thickness reductions in both polymer films, even in layers as thin as 5nm. We will discuss why spatial confinement affects differently the damage efficiency of distinct types of effects, considering the degree of importance of long-range, cooperative effects of excited material along the ion tracks, and the changes in the radial profiles of deposited energy by secondary electrons in very thin layers.

2:45 PM CM05.03.05
Radiation Damage and Failure in Rubbers and Rubber Composites—Effect of Network Polydispersity
Alirea Sarvestani1,2; 1Ohio University, Athens, Ohio, United States; 2Mechanical Engineering, Mercer University, Macon, Georgia, United States.

Irradiation is recognized as one of the major environmental factors affecting the performance, strength, and durability of polymeric compounds. However, the underlying mechanism by which radiation alters the internal structure of rubbers is not well understood. It is known that ionization initiates a variety of chemical reactions in polymers. Among others, crosslinking and scission are the most important effects that markedly change the mechanics and durability of elastomers. Depending upon the radiation structure of polymers and radiation intensity, the chains may either crosslink, with a resulting increase in the network modulus, or undergo rupture that leads to degradation and softening of the network. Scission is an oxidative process that presumably happens due to direct rearrangement of a backbone into two separate entities or loss of a side-group and consequent rearrangement. Crosslinking, on the other hand, in an abstraction process that occurs when two chains join and form a larger macromolecule. Hydrogen abstraction, for example, often takes place between two irradiated polymer chains providing a potential site for crosslinking between them. We developed a continuum micromechanical model that predicts the change in mechanical properties of (filled) elastomers subjected to high-energy radiation (e.g., gamma-rays, UV, or electron beams) and finite deformations. The model demonstrates that polydispersity in internal structure of rubber network controls the elasticity, strength, and durability of rubbers subjected to irradiation. Accordingly, damage starts from scission of short strands and continues with radiation time, coupled with the magnitude of applied deformation.

The Effective Thermal Conductivity of U-10Mo Fuels with Fission (Xenon and Krypton) Gas Bubbles Present
Rafi Iasir1, Nickie J. Peters2 and Karl D. Hammond3; 1Nuclear Engineering Program, University of Missouri, Columbia, Missouri, United States; 2University of Missouri Research Reactor Facility, Columbia, Missouri, United States; 3Chemical Engineering, University of Missouri, Columbia, Missouri, United States.

Uranium alloyed with 10 wt% molybdenum (U-10Mo) is currently being developed as a potential high-density low-enrichment uranium (LEU) fuel for research nuclear reactors. Given the lower melting points of metals compared to ceramic fuels, control of the temperature—and therefore knowledge of the thermal conductivity—is important to reactor design and operation. Fission generates gas bubbles, metallic precipitates, and solutes in the fuel matrix which can change the thermal conductivity and cause swelling of the fuel. We studied the impact of distributed fission gas bubbles on the effective thermal conductivity of irradiated U-10Mo fuel using a two-dimensional finite element method (FEM). The effective thermal conductivity of the materials is calculated by solving the heat equation on a two-dimensional domain and estimating the mean temperature and heat flux. The effects of both intra- and inter-granular fission gas bubbles are discussed. A distribution representative of a gas bubble superlattice is used as a model of intra-granular bubbles, compared to less-uniform bubble arrangements. For inter-granular bubbles, the bubbles’ spatial and size distributions were estimated from a two-dimensional scanning electron microscopy (SEM) image of fission gas bubbles that had collected on grain boundaries. The obtained results are compared
with theoretical models and experimental results. The results show that the pressure inside the bubbles has minimal influence on the overall conductivity. The overall conductivity of a xenon-krypton mixture typical of fission gas is also negligibly different than that of pure xenon. Bubble arrangement is also insignificant unless a relatively wide bubble-free path through the metal exists. However, the area fraction of xenon bubbles has a significant impact on the overall thermal conductivity.

3:45 PM CM05.04.02

Simulating Electronically-Driven Structural Dynamics in Silicon with Two-Temperature Molecular Dynamics and Electronic Temperature Dependent Forcefields

Robert Darkins1, Pui-Wai Ma2, Samuel Murphy2 and Dorothy Duffy4; 1Dept. of Physics and London Centre for Nanotechnology, University College London, London, United Kingdom; 2Department of Engineering, Lancaster University, Lancaster, United Kingdom; 3Culham Centre for Fusion Energy, Abingdon, United Kingdom.

The structural evolution of materials following ultrafast laser irradiation is generally classified by two distinct regimes. At relatively low fluences thermal processes dominate, as energy transferred to the ions via electron-phonon coupling results in melting on thermal timescales. In contrast, at high fluences the dynamics are dominated by non-thermal processes. These processes drive the electrons out of thermal equilibrium with the nuclei, producing hot, transient electronic states that modify the interatomic potential energy surface. Such non-thermal processes can induce melting on sub-picosecond timescales. Two temperature molecular dynamics (2T-MD) has proved to be a very successful methodology for modelling the low fluence regime, with excellent agreement between modelling and ultrafast electron diffraction experiments. The modifications to the potential energy surface induced by high fluences have, however, proved more challenging for classical simulations. Such effects can be included in 2T-MD by the development of electronic temperature dependent forcefields that capture the dynamic effects of the modifications of the potential energy surface due to the electronic excitations. However, as the potential energy surface changes dynamically during such simulations, care must be taken to ensure energy conservation. We have developed a rigorous formulation of two-temperature molecular dynamics that ensures energy conservation in simulations that employ electronic-temperature-dependent forcefields. We have also developed an electronic-temperature-dependent forcefield for silicon that faithfully reproduces the ab initio-derived thermodynamics of the diamond phase for high electronic temperatures, and the structural dynamics observed experimentally under highly nonequilibrium conditions. We will present the details of the modelling methods, the electronic temperature dependent forcefield and the calculated atomistic dynamics of laser irradiated silicon films.

4:15 PM CM05.04.03

Nanohillock Chain Formation under Grazing Angle SHI Irradiation by Molecular Dynamics Simulations

Henrique Vazquez Muinos2, M. Schleberger1 and Flyura Djurabekova1; 1University of Helsinki, Helsinki, Finland; 2University of Duisburg-Essen, Duisburg-Essen, Germany.

It was shown previously that in layered crystals such as SrTiO3 or Mica, SHI irradiation under grazing incidence can produce chains of hillocks/grooves on the surface of the material [1-3]. These structures could be explained by the fact that at a small angle incidence, the ions travel long distances through high or low electron density pockets, giving rise to higher or lower local stopping power along the ion trajectory [1]. This hypothesis assumes that the electronic thermal conductivity does not wash away the inhomogeneities of the local energy deposition before it is transferred to the lattice, allowing the formation of the nanohillocks due to local melting. We develop a new approach to simulate SHI grazing incidence irradiation and apply it to verify the aforementioned hypothesis.

The new approach calculates the energy locally deposited by the ion based on the electronic density along the trajectory using CasP code and simulates the electronic energy redistribution and transfer to the lattice according to the two-temperature model. This energy is added to the atoms and simulated with Molecular Dynamics (MD), producing structural changes in the material such as hillocks or grooves. Simulations in SrTiO3 shows that low angle irradiation produces strongly modulated electronic energy deposition along the ion track and that the electronic thermal conductivity is not capable of washing away the initial temperature inhomogeneities. As a result, regions with higher energy deposition show stronger melting and give rise to nanohillocks. The simulated hillocks have similar length, interdistance and height as in the experiments and shows dependence on the irradiation angle and crystal structure. The hillocks and grooves observed on the surface are associated with molten and sublimated material, respectively.

This new method allows for the first time to simulate grazing angle SHI irradiation realistically, taking into account the modulation of the stopping power due to the local electron density. The good agreement with experiments not only shows that the proposed method is capable of describing correctly the low angle SHI irradiation, but also strongly supports the hypothesis that the hillock chains form due to the varying local electron density. The good agreement with experiments not only shows that the proposed method is capable of describing correctly the low angle SHI irradiation, but also strongly supports the hypothesis that the hillock chains form due to the varying local electron density along the ion track.

4:30 PM CM05.04.04

Nanoscale Thermal Transport in Ion Irradiated Sapphire—Picosecond Time Domain Thermoreflectance

Baurzhan Muminov1,2, Azat Abdullaev1, Durkhan Alimzhанов1, Jacques O’Connell1, Vladimir Shkurakov2 and Zhandos Utegulov1; 1Department of Physics, School of Science and Technology, Nazarbayev University, Astana, Kazakhstan; 2Department of Mechanical Engineering, University of California, Riverside, Riverside, California, United States; 1Centre for HRTEM, Nelson Mandela University, Port Elizabeth, South Africa; 2Flerov Laboratory of Nuclear Reactions, Joint Institute for Nuclear Research, Dubna, Russian Federation.

Sapphire (α-Al₂O₃) is radiation resistive candidate inert matrix fuel host material for fusion reactors, as well as for fusion reactors and for space station applications. The control of radiation-induced thermal conductivity degradation is a critical issue for nuclear and fusion reactor system design and validation.

We have studied nanoscale thermal conductivity k degradation in sapphire single crystals as a result of swift heavy ion (Xe, 167 MeV, ion fluence range 10¹¹ – 10¹² cm⁻²) and slow light (He, 40 keV, 10¹⁵ cm²) ion irradiation. Cross-plane near-surface thermal transport measurements made by an ultrafast optical pump-probe technique called picosecond time domain thermo-reflectance (TDTR) [1, 2] were found to be in satisfactory agreement with semi-analytical thermal conduction modeling. The decay in through-plane k at high modulation frequencies in swift heavy ion (SHI) irradiated
A1O3 demonstrates a complex interplay between heat penetration depth, phonon mean free paths, spatial extent of SHI-induced latent tracks [3], and amorphization [4]. We demonstrate that TDTR is critical for the analysis of SHI-irradiated sapphire, especially at higher doses, even if virgin sapphire does not demonstrate modulation frequency-dependent thermal conductivity. We also establish using modulation frequency-dependent TDTR that variation in k across slow light ion (SLI) irradiated/virgin subsurface sapphire regions can be spatially profiled on the scale of hundreds of nanometers. Comparing the effects of SHI and SLI irradiations on thermal conductivity of sapphire, we conclude that SLIs tend to impart less damage to the structure and cause less decay of thermal transport even at high ion doses than HSIs do. Funding by MES RK research grant (AP05130446) and state-targeted program (BR05236454) is acknowledged.

Uncertainty Quantification and Validation of Multiscale Models of the Effective Thermal Conductivity of UO2 during Reactor Operation Michael R. Tonks1, Jie Lian2, Marina Sessim1 and Xueyang Wu1; 1University of Florida, Gainesville, Florida, United States; 2Rensselaer Polytechnic Institute, Troy, New York, United States.

The microstructure of UO2 changes significantly during reactor operation, including the generation of point defects, defect clusters, fission product formation, and more. These microstructure changes cause the thermal conductivity of UO2, which is already low, to decrease even further. As part of the US Nuclear Energy Advanced Modeling and Simulation program, multiscale modeling and simulation have been used to develop a model of the thermal conductivity of UO2 that is a function of the fuel microstructure. While this model has been shown to perform well in fuel performance simulations, further validation is needed. In this project we perform uncertainty quantification on both the mesoscale and macroscale thermal conductivity models. We then compare the predicted thermal conductivity distribution to the measured thermal conductivity of UO2 samples fabricated to have various microstructures.

Strategies for Optimal Construction of Markov Chain Representations of Atomistic Dynamics and Their Application to Irradiated Materials Danny Perez and Thomas Swinburne; Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

A common way of representing the long-time dynamics of materials is in terms of a Markov chain that specifies the transition rates for transitions between metastable states. Such chains can either be analyzed directly, used to generate trajectories using kinetic Monte Carlo, or upscaled into mesoscale models such as cluster dynamics. While a number of approaches have been proposed to infer such a representation from direct molecular dynamics (MD) simulations, challenges remain. For example, as chains inferred from a finite amount of MD will in general be incomplete, quantifying their completeness and propagating these uncertainties to observables of interest is extremely desirable. In addition, making the construction of the chain as computationally affordable as possible is paramount. In this work, we simultaneously address these two questions. We first quantify the local completeness of the chain in terms of Bayesian estimators of the yet-unobserved rate, and its global completeness in terms of the residence time of trajectories within the explored subspace. We then systematically reduce the cost of creating the chain by leveraging an accelerated MD method, namely Temperature Accelerated Dynamics. We maximize the increase in residence time against the distribution of states in which additional MD is needed and the temperature at which these are respectively carried out. Using examples of defects that are relevant to the evolution of irradiated materials, we demonstrate that our approach is an efficient, fully automated, and massively-parallel scheme to efficiently explore the long-time behavior of materials.

Electronic Effects in Self-Ion Irradiated Tungsten—From Ab Initio to Experiment Andrea Sand1, Rafi Ullah1,4, Kai H. Nordlund1 and Alfredo A. Correa1; 1Department of Physics, University of Helsinki, Helsinki, Finland; 4CIC nanoGUNE, Donostia-San Sebastián, Spain; 1Quantum Simulations Group, Lawrence Livermore National Laboratory, Livermore, California, United States; 2Departamento de Fisica de Materiales, UPV/EHU, Donostia-San Sebastián, Spain.

Primary radiation damage from collision cascades has been simulated with molecular dynamics methods for several decades, yet despite early understanding that electronic effects may be significant in the highly non-equilibrium processes, such effects have proved difficult to incorporate into atomistic cascade simulations.

State-of-the-art cascade simulations now routinely include the energy losses caused by electronic stopping, but this is generally implemented through the use of a non-local friction term, with a cut-off velocity below which the stopping is considered negligible, and hence disregarded. However, in energetic cascades, the atoms with threshold velocities number in the thousands, and as a result the total energy losses change significantly with small changes in the cut-off value. We demonstrate the sensitivity of predictions of the primary damage to the choice of this essentially non-physical threshold parameter. Direct comparisons to in-situ ion irradiation and ion beam mixing experiments can be used to guide simulation methods, and we show that it is possible to find agreement for a number of cases. However, such comparisons are not possible in all materials, due to either a lack of reliable experimental data, or to the fundamental limitations of observing very small defects directly in an electron microscope. Hence there is a need to improve the treatment of electronic effects in molecular dynamics in order to increase the predictive capacity of cascade simulations.

A model for including electron-ion interactions without the use of a threshold, under a unified framework over the whole energy range relevant to cascade dynamics, has been suggested [A. Caro and M. Victoria, Phys. Rev. A 40 (1989)], but only recently implemented by Tamm and Correa [https://github.com/LLNL/USER-EPH] with a parametrization for nickel. The model describes both the electronic stopping in the high-energy regime, and electron-phonon coupling in the low-energy regime, with the magnitude of the coupling varying due to the local electronic density experienced by the ion.
As a first step towards realizing such a model in the fusion-relevant material tungsten (W), we have performed real-time dependent density functional theory (DFT-PES) calculations of the energy losses of a W projectile in W. We show by direct comparison to experimental ion implantation ranges that the electronic stopping obtained in the <100> channel, predicted by TDDFT to be only a third of the value given by SRIM, is in fact in very good quantitative agreement with experimental values. These results provide evidence of the validity of the TDDFT method even for the heavy ion W, and open the way for constructing an electron density-dependent model of the electron-ion interaction for cascade simulations in W.

**Kinetics of Point Defects Under Irradiation—From Atomic to Cluster Scales**  
Thomas Schuler¹, Luca Messina², –¹, Maylise Nastar¹, Pascal Bellon¹, Robert S. Averback² and Dallas Trinkle³, ¹SRMP, CEA Saclay, Saclay, France; ²KTH, Stockholm, Sweden; ³MatSE, University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Materials under irradiation experience an engaging competition between interrelated kinetic phenomena, namely the point defect creation rate and the long range diffusion, precipitation and elimination of atoms and defects. The modeling of such competition is hindered by the largely different time scales involved, hence requiring a multi-scale approach. We developed KineCluE, an open-source code that allows for computing cluster transport coefficients from atomic jump frequencies. These cluster transport coefficients—along with other parameters such as dissociation rates—can then be used as input parameters to cluster-based models such as cluster dynamics or object kinetic Monte Carlo to simulate micro-structure and point defect evolution over long timescales with accurate cluster kinetics. We employed this methodology to study and quantify the time-dependent effect of dilute solute additions on the fraction of inter-cascade recombined point defects. We found that point defect-solute flux coupling leads to a critical irradiation dose above which the solute effect vanishes, which was already observed experimentally. From this insight, we devised a general methodology to identify candidate solutes which increase point defect recombination under irradiation over extended periods of time. KineCluE also allows to take into account the effect of temperature, local strain, concentration and ballistic mixing on cluster kinetic properties. Some of these features will be presented in this talk.

**9:45 AM BREAK**
Many astrophysical observations indicate that standard model particles compose only 5% of the matter in the universe. Understanding the nature of dark matter and dark energy, the remaining 85%, is of fundamental importance to cosmology, astrophysics, and high energy particle physics. There are a number of attempts for direct detection of dark matter particles via an elastic interaction with detector nuclei. Astronomical observations indicate that dark matter forms a halo around our galaxy that is static or rotating much slower than the stars. Since our sun rotates around the center of the galaxy at a speed of 220 km/s, dark matter particles would, if they do interact with ordinary matter, give a momentum corresponding to this velocity to ordinary matter nuclei. Assuming dark matter particle masses of the order of 1 GeV/c^2, this would correspond to recoil energies of a few 100 eV, a typical ion irradiation energy. To date, the detectors developed could detect dark matter particles with masses > 10 GeV/c^2. In our recent work [1], we showed that potential dark matter particles in the mass range down to 200 MeV/c^2 could be detected by new kinds of single-electron resolution single crystal semiconductor detectors. The detector response can be calibrated with molecular dynamics simulations of low-energy self-recoils in the material. Moreover, since the threshold displacement energy depends on crystal direction, while the dark matter particles do not follow Earth’s rotation around its axis, the response of a single crystal detector should vary with the time of day. In this work, we used classical and time-dependent density functional theory molecular dynamics to calculate the response of the semiconductor detectors to dark matter recoils as a function of crystal direction, and using an analytical model translated this into a dependence of the signal on the time of the day. The diurnal variation could be a major benefit for distinguishing a dark matter particle signal from that of conventional particle physics standard model particles.

classification offers a path forward to the high-throughput irradiation defects quantification needed for reactor lifetime prediction and more efficient alloy development.

This research is funded by the U.S. Department of Energy Office of Nuclear Energy’s Nuclear Energy Enabling Technologies program project CFA 16-10570, Office of Fusion Energy Sciences under contract DE-AC05-76RL01830, and by the Molecular Foundry which is supported by the Office of Basic Energy Sciences, under Contract No. DE-AC02-05CH11231.

SESSION CM05.07: Mechanical Properties and Stresses Under Irradiation

Macroscopic Stresses and Strains Produced by Micorscopic Radiation Defects in Reactor Components
Sergii Dadarey1, 2, Daniel Densham2, Patrick Hurh2 and Steve Roberts2; 1UK Atomic Energy Authority, Abingdon, United Kingdom; 2Department of Materials, University of Oxford, Oxford, United Kingdom

Predicting macroscopic strains, stresses and swelling in power plant components exposed to irradiation from the observed or computed defect and dislocation microstructure is a fundamental problem of fusion power plant design that has so far eluded a practical solution. We have discovered that the problem can be addressed and solved using the fact that elasticity equations involve no characteristic spatial scale and hence admit a mathematical treatment that is an extension to that developed for the evaluation of elastic fields of defects on the nanoscale. Strains, stresses and swelling can be determined using either the integral equation formalism where the source functions are defined by the density of relaxation volumes of defects, or they develop a general finite element method (FEM) implementation, applicable to a broad range of predictive simulations of strains and stresses induced by irradiation in materials and components of any geometry in fission or fusion nuclear power plants.

2:00 PM CM05.07.02
Microstructural and Micromechanical Investigation of Irradiation Effects in Beryllium
Vabicxay Loushen1, 2, Chris Densham2, Patrick Hurh2 and Steve Roberts2; 1UK Atomic Energy Authority, Abingdon, United Kingdom; 2Department of Materials, University of Oxford, Oxford, United Kingdom

Beryllium is an essential material for reflectors and moderators in material testing nuclear reactors, plasma facing and neutron multiplier material for fusion reactor designs (ITER, DEMO), candidate material for target components in near-future multi-megawatt accelerator particle sources (LBNF), and is under extensive investigation by fission, fusion reactors and proton accelerator facilities communities. Current work reports experimental results obtained on the beryllium sample irradiated at Fermi National Accelerator Laboratory, USA, by 120GeV protons over 7 years at about 50°C up to 0.5 dpa, and beryllium samples implanted with He ions at 50 and 200°C. The microstructure was investigated by SEM/EBSD, STEM/EDX and Atom Probe Tomography, and irradiation induced hardening was measured by nanoindentation experiments.

Microstructural investigations revealed a highly inhomogeneous distribution of impurity elements in both unirradiated and irradiated conditions. Impurities were mainly localized in precipitates, and as segregations at grain boundary and dislocation lines. Low levels of Fe, Cu, Ni, C and O were also found to be homogeneously distributed in the beryllium matrix in non-irradiated state and after proton irradiation. In the proton irradiated beryllium, up to 440 appm of Li, derived from transmutation, was homogeneously distributed in solution in matrix.

Extremely high variation of nanoindentation hardness data was observed for grains with different crystallographic orientation in non-irradiated areas of the beryllium sample. After irradiation, the average hardness was increased, while anisotropy of hardness was decreased. Significant effect of irradiation on fracture properties of beryllium was noticed. The proton irradiated sample was deformed during the post-irradiation handling. Investigation of the produced cracks indicates that proton irradiation at 0.3 dpa level changes the fracture mode from transgranular cleavage to predominantly grain-boundary cracking. In the He implanted samples, microcantilevers were fabricated by focused ion beam milling and loaded via a conventional nanoindenter. Cantilevers were pre-notched so that the fracture properties of grain boundaries and basal cleavage plane, in both as-received and irradiated states, can be compared. Fracture load of both grain boundary and cleavage cantilevers increased significantly after irradiation. Deflection to fracture was found to be lower for cantilevers pre-notched in the basal cleavage plane, but the difference between two types of cantilevers was smaller in irradiated state.

2:15 PM CM05.07.03
Tensile Deformation and Fracture Mechanism of Irradiated RAFM Steel
Hiroyasu Tanigawa1, Masami Ando1, Yutai Kato1, Naoyuki Hashimoto1 and Takuya Nagasaka1; 1National Institutes for Quantum and Radiological Science and Technology, Rokkasho, Japan; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States

Reduced-activation ferritic/martensitic steels (RAFMs), such as F82H (Fe-8Cr-2W-0.2V-0.04Ta), has been developed as the structural material of fusion in-vessel components which will suffer from high dose irradiation of 14 MeV fusion neutron. The most concerned issue of RAFM steel is hardening and embrittlement which appears as the loss of plasticity and ductile-brittle transition temperature (DBTT) shift by low-temperature irradiation below 350 degrees C. The mechanistic understandings of the phenomena are essential for the prediction of those irradiation induced mechanical property changes, and the impacts of microstructure feature changes have been investigated.

RAFM steels are fully tempered martensitic steels which have microstructures contain prior-austenitic grain (PAG) boundaries and MX precipitates which formed during normalization, martensite packet, block, and lath boundaries which formed during cooling, and M23C6 which formed during tempering. High-density dislocation in the matrix and fine precipitates on various boundaries gives the steel high irradiation and heat resistance. It has been reported that the major microstructural feature of RAFM steels irradiated at low temperatures is dislocation loop formation and evolution. However, this dislocation-loop evolution is not enough to explain hardening level which was observed in irradiated RAFM based on the Orowan equation. In this study, the impact of three-dimensional morphology of martensite blocks, which is the minimum microstructural unit corresponds to the mechanical property, are discussed to investigate the deformation and fracture mechanism of irradiated RAFM steels. The three-dimensional SEM and EBSP analyses on tensile deformed unirradiated F82H, micro-tensile test on a single block in FIB, and TEM microstructural analyses on irradiated F82H are conducted.
The impact of material mechanics on the tensile property, such as stress triaxiality, is discussed to interact the observed mechanical property and microstructure.

2:45 PM CM05.07.04
Micromechanical Study of Radiation and Temperature Effects on Localized Properties of SiC-SiC Fiber Composites Yevhen Zayachuk1, David E. Armstrong1, Arthur Hussey1, Christian Deck2 and Peter Hosemann3; 1University of Oxford, Oxford, United Kingdom; 2General Atomics, San Diego, California, United States; 3University of California, Berkeley, Berkeley, California, United States.

Silicon carbide ceramics is a candidate material for the use in novel accident tolerant fuel (ATF) cladding designs. It is suggested to be used in the form of SiC-fiber reinforced SiC-matrix composite, and therefore in order to reliably predict behavior of fuel cladding it is necessary to understand mechanical properties of the individual constituents of the composite – matrix, fibers and, crucially, interphases, as well as how they are modified by radiation fields and elevated temperatures that fuel cladding is exposed to during the reactor’s operation.

Micromechanical techniques are uniquely suited for determination of such localized properties, which can be rationalized by coupling the mechanical data and the microstructural information obtained by microscopy tools. In this contribution we present the results of the microcantilever fracture (at the interphases, within fibers and in the bulk matrix), fiber push-out and nanoindentation tests on SiC-SiC fiber composite. Samples were irradiated with Si and Ne ions up to 3.9 dpa at the temperatures of up to 750°C. Micromechanical tests were performed in the temperature range of up to 700°C.

Microstructure was investigated using transmission electron microscopy (TEM), with texture information obtained with transmission Kikuchi diffraction (TKD). It was found that in the matrix the preferred grain growth direction is <111>, while in the fibers no texture was observed. Both matrix and fiber feature extensive twinning.

Hardness of matrix and fibers, as measured by nanoindentation, didn’t noticeably change as a function of dose, indicating that radiation damage in bulk SiC is minor. At the same time, cantilever testing indicated that the fracture strength of the interphase noticeably increased with the increase of dose, indicating that pyrolytic carbon that forms an interlayer is strongly affected by irradiation. On the other hand, measurements at elevated temperatures showed that the properties of matrix material significantly change with temperature – hardness decreases from ~45 GPa at room temperature to ~25 GPa at 700°C, and fracture strength decreases from ~22 GPa to ~12 GPa.

TEM was used for imaging of the crack paths in the cantilevers after fracture. It was found that in the matrix fracture is transgranular, while at the interphases it is following the fiber-interlayer boundary.

Fiber push-out measurements showed that there is a significant difference in the interfacial shear strength of the interphases, depending on where within a bundle the tested fiber is – changing from ~120 MPa at the periphery of a bundle to ~70 MPa in the center.

Experimental findings are discussed with the emphasis on the synergy of micromechanical and microstructural characterization, and how these enable better understanding and prediction of the properties of SiC fiber composites in advanced fission and fusion designs.

SESSION CM05.08: Electronic, Optical and Magnetic Changes Under Irradiation
Session Chairs: Pär Olsson and Brandon Sorbom
Tuesday Afternoon, November 27, 2018
Hynes, Level 2, Room 202

3:30 PM CM05.08.01
Electrical Characterization of He-Ion Irradiated Pd/n-SiGe Schottky Diode Mamor Mohammed; Département de Physique, University Cadi Ayyad, Faculté Polydisciplinaire Safi, Safi, Morocco.

There has been considerable interest in integrating high speed and novel devices made from Si1-xGex materials, since the alloy is compatible with the silicon based technology. Ion implantation is now a common process in the mature semiconductor industry and is widely used during several electronic devices fabrication steps. In particular, ion implantation is used to improve the fast switches and the performance of photodiodes. Moreover, it is well known that ion implantation into semiconductor materials has a profound influence on the structural and electronics properties of their surface and subsurface region. The ion implantation induces structural and electronic changes, which governs the characteristics of metal contacts formed on the semiconductor. In this presentation, we report on the electronic properties of He-ion irradiation induced defects, as determined by deep level transient spectroscopy (DLTS). In addition, we present the results obtained on temperature-dependent of the Schottky barrier height (SBHs) fabricated on He-ion irradiated n-Si0.9Ge0.1, and the impact of this irradiation on the conduction mechanism in Pd/n-Si0.9Ge0.1 Schottky barrier diodes (SBDs). The electrical properties of He-ion irradiated Pd/n-Si0.9Ge0.1 Schottky diodes were studied in a wide temperature range (100-300 K). It was found that the current flow is controlled mainly by thermionic emission. The Schottky barrier height (Φ_b) and ideality factor (n) of Pd/n-Si0.9Ge0.1 Schottky diode have been studied as a function of temperature. A decrease of Φ_b and an increase of n with decreasing temperature are observed. Additionally, linear dependence between the so-called temperature factor T_0 and temperature as well the well-known linear correlation between SBHs and ideality factors, Φ_b (n), are observed and explained in terms of inhomogeneities due to the presence of He-ion irradiation induced defects and traps with associated energy level localized in the gap.

3:45 PM CM05.08.02
Radiation Damage Effects on High-Temperature Superconductors in Fusion Conditions Brandon N. Sorbom1, Penghui Cao2, Zach Hartwig2, Stephen Jeep3, Leigh Ann Kesler3, Michael Short2, Nick Strickland2, Dennis Whyte2 and Stuart Wimbush3; 1Commonwealth Fusion Systems, Cambridge, Massachusetts, United States; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 3Robinson Research Institute, Lower Hutt, New Zealand.

Recent advances in high temperature superconductors (HTS) have opened up a new parameter space for the design of tokamak fusion pilot plants. While previously the maximum on-axis field in a superconducting tokamak was limited to ~6 T, HTS allows tokamaks to be designed with on-axis fields in
excess of 10 T, leading to smaller reactor designs, such as the ARC concept from MIT. For these designs, it is critical to determine the lifetime of modern HTS materials, e.g. Barium Copper Oxide (REBCO) high temperature superconductors (HTS) such as the BARAC (Barium/REBCO) accelerator magnets. This damage has historically been quantified as the number of displacements per atom (dpa). While dpa can be used as a rough predictor of radiation effects, the irradiation conditions also play a key role in microscopic damage formation and macroscopic property changes, as demonstrated by recent work. As HTS is irradiated, a variety of changes occur within the superconducting crystal lattice, and competing effects on the achievable critical current density \( J_c \) of the superconductor emerge. On one hand, \( J_c \) can be lowered by the displacement of atoms and creation of defect clusters through the suppression of the critical temperature, amorphization of the lattice, degradation of intergrain current transfer, and disordering of intrinsic pinning sites. On the other hand, \( J_c \) can be increased by point defects and defect clusters acting as artificial pinning centers. The combined effect of these mechanisms can be a net increase or decrease in \( J_c \). In order to better understand the microstructural changes that influence the macroscopic superconducting properties such as \( J_c \), HTS samples (2G REBCO from SuperPower) were irradiated with 1.2 MeV proton beam in the DANTE accelerator facility at MIT. The degradation of these samples was then characterized under a wide variety of HTS operating conditions at the Robinson Research Institute in New Zealand. In order to guide and interpret the experimental studies, a simulation workflow was developed by combining DARY (a binary collision approximation code), SRIM and MCNP (Monte Carlo codes for ions and neutrons/gammas, respectively), and LAMMPS (a molecular dynamics code). These simulations were performed to compare different ion energies and incident particle directions to determine the mechanisms behind the observed experimental results.

4:15 PM CM05.08.03 Effects of Ionizing Irradiation on Ferroelectric Thin Films Steven J. Brewer1, Samuel C. Williams2, Hanhan Zhou3, Jacob L. Jones3, Ryan Rudy4, Maunel Rivas5, Ronald G. Poluektov6, Evan Glaser7, Cory D. Cress7 and Nazann Bassi-Gharb8; 1George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 2School of Materials Science and Engineering, Georgia Institute of Technology, Atlanta, Georgia, United States; 3Department of Materials Science and Engineering, North Carolina State University, Raleigh, North Carolina, United States; 4U.S. Army Research Laboratory, Adelphi, Maryland, United States; 5U.S. Naval Research Laboratory, Washington, District of Columbia, United States.

In recent years, the continuous thrust toward developing microelectronic devices with greater autonomy, reduced footprint size, and large-scale interconnection has necessitated high-performance materials capable of fulfilling multiple functional roles. Ferroelectric materials, and specifically lead zirconate titanate (PZT), boast large dielectric, polarization, and electromechanical responses, making them ideal for microelectromechanical system (MEMS) sensors and actuators, energy harvesters, multilayer ceramic capacitors (MLCC), ferroelectric logic elements and relays, etc. However, many of the most compelling applications for these types of devices – space travel, satellite communications, nuclear energy, and unmanned reconnaissance – require sustained operation in extremely demanding radiation-hostile environments. Radiation, both ionizing and displacive, has been shown to substantially degrade the functional responses of ferroelectric thin films, thus rendering the development of techniques for increased radiation tolerance of these materials critically important.

In this work, a multifaceted investigation towards understanding radiation interaction with PZT thin films and strategies towards increasing radiation hardness was undertaken. Specific focus was placed on an array of critical interfaces and interactions in the ferroelectric material and device. Specifically, we address the role of the electrode material, microstructural feature (columnar vs. equiaxed grains), the effects of doping (with Mn) modifying the mobility of internal interfaces (domain walls) and point defects, and crystallization interfaces. Furthermore, a phenomenological model was developed to quantify functional behavior with total ionization dose (TID), relying on the fact that radiation induces defects and defect interactions that modify functional material response. Fitting of functional response trends as a function of TID with the phenomenological model yields two important parameters describing (i) the global susceptibility to radiation-induced induced degradation by induced defects and (ii) the rate of defect saturation in the material. Extraction and comparison of these parameters allows for quantification of defect interactions as a function of microstructural and compositional variations in ferroelectric thin films.

4:30 PM CM05.08.04 Radiation Damage in REBCO Materials for Compact Fusion Reactors Rebecca Gray and Samuel Murphy; Lancaster University, Lancaster, United Kingdom.

The advent of High Temperature Superconducting magnetic tapes has accelerated the development of compact nuclear fusion reactors. The Rare-Earth Barium Copper Oxide (REBCO) high temperature superconductors (HTS) offer high field strengths to be accessed at high temperatures (>70 K). During reactor operation high energy neutrons ejected from the plasma will damage the tapes ultimately limiting their lifetime. Experimental observation of the damage process at cryogenic temperatures is tricky without highly specialised facilities that are not currently available. Atomistic simulation of the damage cascades enables informed choices of magnetic tapes to be made. As a first step to simulating the cascades, we present a new empirical pair potential for an idealised REBCO material based on the Buckingham form fitted using thermal expansion coefficients from Density Functional Theory (DFT). Using the new potential, we determine threshold displacement energies in YBa2Cu3O7 as a function of the atom type and direction. Finally, we perform radiation damage cascades at the operational temperature and compare with similar simulations performed at the temperature where experimental data is available. A detailed comparison of the remnant defect’s population and distributions at different temperatures enable us to discuss the relevance of the available experimental data to operational conditions.

4:45 PM CM05.08.05 Charge Equilibration and Electronic Stopping for Silicon Projectiles in Silicon Cheng-Wei Lee and Andre Schleife; University of Illinois at Urbana-Champaign, Urbana, Illinois, United States.

Energetic-particle radiation is of technological interest for applications in nuclear energy, electronics in outer space, medicine, and fundamental research. As a result of the irradiation, damage forms and ultimately determines materials properties. Understanding the effects of highly energetic particle radiation is important, e.g. for improving radiation hardness and ion implantation to create quantum bits. While damage caused by irradiation is commonly simulated using Monte Carlo methods, including SRIM, this approach has severe limitations: The accuracy is poor for low projectile kinetic energies, for which band structure effects of the target compounds dominate. In addition, SRIM inherently assumes the target to be amorphous and overcoming this, e.g. using molecular dynamics simulations of primary knock-on atom events, requires accurate parametrizations of two-temperature models to account for the effect of electronic excitations.

This highlights that developing an understanding of the underlying interactions between charged, energetic particles and a material from first principles is highly important to predict evolution and dynamics of defects. Ehrenfest molecular dynamics and real-time time-dependent density functional theory have recently been shown to successfully describe electronic stopping during the early stages of radiation damage for light projectiles. At the same time, its capability to predict electronic stopping for heavy ions remains mostly unexamined.

Here we report our recent work on using this technique to compute electronic stopping of heavy (silicon) projectiles traversing silicon bulk crystals. We
Found a pronounced dependence of electronic stopping on the initial charge state of the projectile ion, which was not observed for light projectiles. Our analysis shows this can be explained by accounting for dynamics of charge equilibration in the target, and we explicitly study the influence of the impact parameter as well as contributions of core and valence electrons. From our simulations we demonstrate that off-channeling trajectories as well as semi-core electrons are needed for a direct comparison to experiment.

Developing a consistent framework based on first principles is an essential part of a multi-scale simulation approach that can accurately predict damage formation after particle irradiation. Incorporating electronic friction, e.g. by deriving accurate parameters from our first-principles simulations, into classical molecular dynamics leads to predictive accuracy. With the growing interest in swift-heavy ion particle radiation that creates strong electronic excitations, the capability of predicting across a large projectile kinetic energy range is crucial. Finally, the strong dependence on the initial condition observed in our simulations may suggest a way to control the magnitude of electronic stopping and, thus, damage, e.g. in nanometer-thin films by varying the initial charge state of the projectile ion.

9:00 AM CM05.09.01
Study the Effects of Localized Spot-by-Spot High Dose MeV Au and Ag into Silica John D. Demaree2 and Daryush Ilia1; 1Fayetteville State University, Fayetteville, North Carolina, United States; 2Weapons and Materials Research Directorate, US Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States.

In this work we have studied the change in the optical properties of Infrasil (Heraeus high-purity optical quality fused quartz silica) before and after spot-by-spot implantation of 0.785 MeV Au and 1.450 MeV Au ions using a National Electrostatics SSDH-2 tandem accelerator. The ion beams were focused to spots roughly 2mm in diameter, and after a given fluence was delivered, the substrate was moved stepwise in horizontal and vertical directions in 0.5 mm increments across an area roughly 8mm x 8mm. The fluence delivered in each overlapping spot was calculated to produce a uniform total implantation doses of Au, Ag, and (sequentially) Au + Ag ranging from 10^16/cm^2 to 10^17/cm^2. The effects of this high dose spot-by-spot method on the optical absorption were then compared with traditional raster scan implantations, in which the beam is swept over the entire area quickly, and the entire area is implanted at once. We, also, used 3D wide area microscopy and 3D laser microscopy to study the optical changes in the silica due to this spot-by-spot high dose MeV ion implantation.

The uniformly implanted area, several millimeters by several millimeters across, was studied before and after annealing, using optical absorption photo spectrometry to assess the optical change in the material and evidence of Au and Ag nanocluster formation. Rutherford Backscattering Spectrometry (RBS) was used to confirm the implantation dose and the uniformity of the implanted area. We have observed, specifically in spot-by-spot Au implanted silica, evidence of a quadrupole interaction which produces widening of the Au nanocluster absorption band beyond 530nm, and which has been seen in past studies using traditional raster scanning followed by annealing. Also, an ordered change in the index of refraction of the host by 3D microscopy correlated to the stepwise implantation in horizontal and vertical directions in 0.5 mm increments, producing 3D embedded optical structures. In this presentation we will compare the results obtained for both spot-by-spot implantation of Au and Ag into Infrasil with past raster scan implantations, and comment on the effect of this method on nanocluster formation and growth, as well as possible changes in the surface topography and 3D-well defined change in the index of refraction of this glassy material.

Use of Pure Iron and Fe-15Cr-16Ni Model Alloy to Study the Impact of Self-Ion Energy, Displacement Rate and Irradiation Temperature on Charged Particle Simulation of Void Swelling Aaron J. French, Frank A. Garner and Lin Shao; Nuclear Engineering, Texas A&M University, College Station, Texas, United States.

Void swelling of iron-base alloys under neutron irradiation is known to be very sensitive to a wide variety of material and environmental variables. Additional sensitivities arise using charged particle simulation. To enhance the credibility of charged particle simulation of neutron-induced swelling it is necessary to isolate and quantify those variables associated with ion simulation from those that are material-specific or involve segregation and phase stability, especially under the influence of surface effects, injected interstitials and segregation along ion-induced gradients in dpa rates that are characteristic of ion irradiation. Additionally, it is important to assess the impact of the much higher rates of atomic displacement used in ion irradiation compared to neutron irradiation.

First, we used pure annealed bcc Fe as a model system to avoid complexity associated with radiation-induced segregation and precipitation, studying only void swelling and dislocation changes. Two sets of irradiations were conducted on iron. The first set involved irradiations with Fe ion energies of 1, 2, 3.5 and 5 MeV, all at comparable dpa rate (1x10^-4 dpa/s) and attained dpa peak level of 100 dpa, in order to separate the separate but synergistic effects of surface and injected interstitial on swelling. Moving from lower to higher ion energy the surface and injected interstitial effects were therefore progressively separated. These two effects are both known to be sensitive to the dpa rate and to contribute to the temperature shift phenomenon.

In the second iron set the synergistic effects of temperature and displacement rate on swelling, expressed in the well-known “temperature shift” concept, was studied, using 5 MeV Fe ions at peak dpa rates of 3x10^-3, 1x10^-4, and 3x10^-4 dpa/s, to peak dpa values of 50, 75 and 100 dpa, and at irradiation temperatures of 375, 425, 475, and 525°C, respectively.

Finally, we repeated the temperature shift experiment on a pure annealed fcc Fe-15Cr-20Ni model alloy, but shifting the temperature range from 475 to 650°C, based on previous ion studies conducted on this alloy. The specimens used were drawn from the same batch used for dpa rate studies conducted in the FFTF fast reactor at 420°C where a transient shift was observed with changes in dpa rate. The lack of minor solutes (Si, P, C, especially) in this alloy preclude precipitation, but did result in some segregation of major elements along the ion depth profile.

The results provide significant insight on the complexities of using charged particle simulation at accelerated dpa rates to study neutron-induced void swelling, especially with respect to the temperature shift and transient shift phenomena.

Dynamics of Graphene Milling Under the Helium and Neon Ion Beams Alex Belianinov, Songkil Kim, Anton V. Ievlev, Ivan Vlassiouk, Matthew J. Burch, Ondrej Dyck, Xiahan Sang, Raymond R. Unocic, Sergei V. Kalinin, Stephen Jesse and Olga Ovchinnikova; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Graphene has been investigated thoroughly due to its excellent electronic, mechanical and thermal properties. This 2D material can be modified structurally, electronically and doped chemically, to utilize in the design of functional devices. Advances in ion beam-based imaging and nanofabrication techniques have offered a pathway to precisely manipulate 2D materials and offer a roadmap to create junctions, nanoribbons, and introduce dopants for new types of electronic devices. Helium ion microscope (HIM) offers “direct-write” capabilities, packaged in a machine capable of both imaging and nanofabrication with Helium and Neon gases, thus making it an excellent candidate for processing a wide range of 2D, and conventional materials.

However, despite graphene’s properties, and existing tools to take advantage of them; challenges remain in the development of workflows that can yield high-performance 2D electronic devices; where the damage at edges and the basal plane is minimized during the milling process.

In this study, we explore graphene milling by the helium and neon ion beams in order to control material’s electronic and mechanical properties. We demonstrate localized formation, growth and coalescence of nanopores, by investigating different levels of defects in graphene via Scanning Transmission Electron Microscopy. Using advanced image data analytics, we illustrate different dynamic behaviors of graphene milling depending on the material’s initial conditions. This work provides in-depth understanding of the graphene milling as it occurs, laying a foundation to develop new pathways to manufacturing 2D material based electronic devices.

Influence of the Enthalpy Landscape on the Irradiation-Induced Disordering of Minerals Mathieu Bauchy1 and Anoop Krishnan; 1University of California, Los Angeles, Los Angeles, California, United States; 2Department of Civil Engineering, Indian Institute of Technology Delhi, New Delhi, India.

Under irradiation, minerals tend to experience an accumulation of structural defects—which can ultimately lead to a disordered atomic network. Despite the critical importance of understanding and predicting irradiation-induced damage, the physical origin of the initiation and saturation of defects remains poorly understood. Here, based on molecular dynamics simulations of α-quartz, we show that the topography of the enthalpy landscape governs irradiation-induced disordering. Specifically, we show that such disordering differs from that observed upon vitrification in that, prior to saturation, irradiated quartz accesses forbidden regions of the enthalpy landscape, i.e., those that are inaccessible by simply heating and cooling. Furthermore, we demonstrate that damage saturates when the system accesses a local region of the enthalpy landscape corresponding to the configuration of an allowable liquid. At this stage, a sudden decrease in the heights of the energy barriers enhances relaxation, thereby preventing any further accumulation of defects and resulting in a defect-saturated disordered state.

10:30 AM CM05.10.02
Atomic Scale Modeling of the Effect of Forced Atomic Reactions on the Thermodynamic and Kinetic Properties of Fe-Based Alloys Under Irradiation Liangzhao Huang1, Luca Messina2, Thomas Schuler1 and Maylise Nastar1; 1DEN-Service de Recherches de Métallurgie Physique, CEA, Université Paris-Saclay, GIF-sur-Yvette, France; 2Nuclear Engineering, KTH Royal Institute of Technology, Stockholm, Sweden.

Irradiation drives materials far from equilibrium. Under sustained atomic reactions such as ballistic mixing forcing exchanges between neighboring atoms, standard thermodynamic and kinetic methods do not apply because of the loss of the microscopic detailed balance. However, the resolution of the microscopic Master Equation describing the transitions between different on-lattice configurations allows us to compute the dynamic chemical short range order (SRO) under stationary conditions. The latter depends on the atomic jump frequencies and is compared to the results of atomic kinetic Monte Carlo simulation. From the dynamic SRO computed by this theoretical approach, we define effective atomic jump frequencies, compute point defect flux coupling, and predict the solute redistribution. We analyze the effect of temperature and irradiation conditions (including ballistic mixing and recombination) on the thermodynamic and kinetic properties of a few iron-based binary alloys.

10:45 AM CM05.10.03
Irradiation-Accelerated Phase Transformations for Low-Temperature Phase Diagram Development Julie D. Tucker, Fei Teng, Li-Jen Yu, Emmanuel Marquis1, Jia-Hong Ke2 and David Srorouster1; 1Oregon State University, Corvallis, Oregon, United States; 2University of Michigan–Ann Arbor, Ann Arbor, Michigan, United States; 3Brookhaven National Laboratory, Upton, New York, United States.

Low-temperature phase data is essential for long-term applications at intermediate temperatures such as energy production. Experimental data below 500°C is limited due to the long times needed for most phases to develop. First principles techniques are supporting the need for low temperature phase data but still require validation by experiments. Irradiation generates extra point defect, enhancing kinetics at lower temperatures and can be a tool for accelerating phase transformations. In this study, we use ion beam irradiation to enhance the formation of an ordered Ni1Cr phase in the Ni-Cr-Fe system. Commercial alloys, such as alloys 625 and 690, are susceptible to mechanical property changes with thermal aging due to this ordered phase. Model and commercial alloys have been isothermally aged up to 10,000 hours and characterized via nanoindentation, atom probe tomography, synchrotron X-ray diffraction and transmission electron microscopy. Additionally, these alloys have been irradiated to 1.5 or 6 dpa to quantify the role of irradiation in accelerating the ordering kinetics. Preliminary results indicate change in stoichiometry do not change the ordering rate only the amount of ordered phase formed. Also, proton irradiation tends to accelerate the ordering process while Ni^+ ion irradiation do not lead to ordering at the dose rates explored.
Theoretical Prediction of Void Superlattice Formation under Irradiation

Yongfei Zhang, Yipeng Gao and Jian Gan; Idaho National Laboratory, Idaho Falls, Idaho, United States.

Void and gas bubble superlattices have been widely observed in various types of materials under irradiation, with the formation mechanisms still open for debate. Here, rate theory based theoretical analysis coupling thermodynamics and kinetics show that the superlattice forms by superposition of vacancy concentration waves that develop upon the instability of a uniform field. The symmetry of superlattice is governed by anisotropic interstitial diffusion, and the superlattice parameter depends on the irradiation condition including temperature and dose rate. Dependent on the nature of anisotropic interstitial diffusion, various types of void superlattices are theoretically predicted including planar ordering, simple cubic, face-centered-cubic and body-centered-cubic. The theoretic predictions on both the superlattice symmetry and parameters are demonstrated by atomic kinetic Monte Carlo simulations and are consistent with previous experimental observations. The developed theory can be used to guide experimental design for tailored microstructure using irradiation. It may also have general applications in cases involving spontaneous phase transition and anisotropic diffusion reaction.

1:30 PM ~CM05.10.05

Atomic Scale Quantification of Intergranular Segregation in Ferritic Thermally Aged or Irradiated Alloys and Steels

Bertrand Radiguet1, Philippe Pareige1, Allaia Akhatova1, Leifeng Zhang1, Patrick Todeschini2 and Frederic Christien2; 1Université de Rouen Normandie, Groupe de Physique des Matériaux, Saint Etienne du Rouvray, France; 2EMSE, Saint Etienne, France.

Phosphorous intergranular segregation can lower the cohesion between grains, resulting in steel embrittlement. Low alloyed bainitic steels used to build nuclear reactor pressure vessel (RPV) generally contain a small amount of phosphorus (in the range of 100 ppm). Continuous exposure to a low neutron dose rate irradiation at intermediate temperature (~300°C) results in radiation embrittlement of RPV steel. Since intergranular segregation of phosphorous can contribute to this embrittlement it is important to understand the effects of ageing conditions (temperature, irradiation dose), material composition and the grain boundary (GB) nature on the intensity of phosphorous intergranular segregation. Regarding to literature sources, it was revealed that the intergranular segregation values may strongly vary among different GBs. However, there is a lack of systematic studies in this field.

In order to get an accurate and representative description of the effect of GB nature different techniques are combined in this work. Atom Probe Tomography (APT) technique is utilized as the main tool and it is compared to Auger Spectroscopy for validation. GB geometry is determined from Transmission Kikuchi Diffraction (TKD) map. Firstly, this approach is validated on a Fe-0.034at%P-0.01at%C model alloy. It is shown that radiation-induced segregation caused by phosphorous interstitial complex is the dominant mechanism in under irradiation at 450°C with 10 MeV Fe5+ ions at a dose rate of 3 10^-5 dpa/s. Also a higher phosphorous segregation at curved GBs in comparison with the straight one was found. This work has also shown that GBs with high Miller index planes has significantly higher phosphorous segregation than low index GB planes.

In a second step the approach is applied to a real RPV steel thermally aged or ion irradiated. APT analyses revealed that there was a considerable element segregation (C, P, Mn, Mo, Cr, Si, Ni, …) for all boundary types. By taking into consideration all segregated chemical species, both interstitial and substitutional segregations were discussed with regard to GB types. Besides, the element segregation at carbide/matrix interfaces was also quantified. Comparison between as received and aged materials will be given.
Plastic deformation of metals and alloys containing light impurity atoms (for example, nitrogen or carbon) is often accompanied by jerky flow in mechanical tests at elevated temperatures (up to 400°C), with numerous load drops (serrations) appearing on the load–elongation curve. This phenomenon, known as the Portevin-le-Châtelier effect, is due to Dynamic Strain Aging (DSA) occurring in the material because of the interaction of solute atoms with mobile dislocations, temporarily arrested at obstacles. DSA in many cases leads to the reduced ductility and toughness, decreased ability to cold roll, etc. Irradiation leads to the appearance of radiation defects and their interactions with impurity atoms, reducing the concentration of these atoms in solid solution. These interactions significantly decrease the DSA process. It was shown [1] that with increasing irradiation dose of mild steel, the critical temperature for the onset of DSA serrations increased and the temperature range of “blue brittle” behavior narrowed. More precise understanding of the nature and magnitude of radiation defect interactions with the dislocations responsible for DSA can therefore help to mitigate its effects. 

The present work is devoted to investigations of the effect of irradiation with neutrons and alpha particles on the mechanical properties and stored energy characteristics of Arno-iron. Tensile samples were irradiated with neutrons (maximum fluence 6×10¹⁸ n/cm², E>2.35 MeV, T<50°C) in the experimental WWR-K reactor core (6 MW water-pool nuclear research reactor) and alpha particles with an energy of 50 MeV in an isochronous cyclotron U-150 to a helium concentration of 10²⁵ at. % at ≈100°C. Uniaxial tensile tests were carried out in the temperature range of 20-300°C with two nominal strain rates, \( \dot{\varepsilon} = 8.33\times10^{-4} \text{s}^{-1} \) and \( \dot{\varepsilon} = 1.67\times10^{-5} \text{s}^{-1} \). For each test temperature, the value of the critical strain energy density \( (W_c) \) was determined. In some cases, images of the surfaces were taken during tensile tests to study the features of deformation localization using digital image correlation approach. As a result of the experiments, mechanical and energy characteristics were obtained, and DSA parameters were determined as a function of irradiation. It was determined that irradiating Arno-iron with neutrons and alpha particles suppressed DSA, decreased the amplitude of serrations, and increased the activation energy of the DSA process and the critical strain when serration occur on the curves. Decreasing DSA intensity led to increase in the plasticity and We of the material. Optical metallography and electron microscopy were used to study the evolution of radiation and deformation defects. The obtained experimental data can be used in the development of theoretical models of deformation aging, as well as the finding the ways and methods to reduce the negative effects of irradiation on structural materials.

2:15 PM CM05.01.03 Accelerated Materials Testing in Low Earth Orbit Kevin Heath and Lindsay Farrell: Alpha Space Test and Research Alliance, LLC, Houston, Texas, United States.

Alpha Space (AS) provides a turn key service that allows for testing of materials in an extreme environment, space. The AS Test Platform, the Materials International Space Station Experiment Flight Facility (MISSE), provides an environment that cannot be easily duplicated on the earth. The MISSE provides testing of materials in a vacuum, while simultaneously exposing the material to a radiation environment, UV-A through UV-C light, atomic Oxygen, and temperature cycling. The MISSE-FF allows for oxidation testing of a material utilizing atomic Oxygen, which is highly reactive with all materials. Ultra-violet light degradation testing on the MISSE-FF of polymer materials or coatings is provided at an accelerated rate, because the MISSE-FF exposes the materials to UV light at Air Mass Zero. The full extent of UV-A through UV-C is applied to the sample to determine degradation, which cannot be attained in the atmosphere because air absorbs 95% of the UV-B and almost 100% of UV-C wavelengths. The MISSE-FF provides radiation testing across the full spectrum of the naturally occurring radiation spectrum, Gamma Rays through proton/neutron emissions, to determine degradation of materials. The MISSE-FF provides the ability to limit the amount of molecular contamination that can occur with the samples being tested, providing a true test of the material. Thermal Cycling provided by the MISSE-FF occurs sixteen times a day, providing an accelerated test of the interface between the coatings and the substrate they are applied upon. The thermal cycling of samples on the MISSE-FF occurs between -60 Deg. C and 120 Deg. C per cycle, controllable using various different mounting structures to keep within the sample temperature parameters. Testing with the Alpha Space MISSE-FF provides the test environment described above simultaneously, mimicking the actual effects on materials by providing a real world environment that cannot be obtained in a cost effective manner in an earth bound laboratory. The MISSE-FF flight environment tests the cross-coupling effects on materials of the various input parameters from radiation, oxidation, UV, and temperature cycling. Testing of materials on the MISSE-FF is a continuous opportunity, with sample installation and removal on a six month to twelve month cycle. This continuous testing allows for Alpha Space to provide visual degradation data via high resolution pictures during the extended test period on orbit, and sample return for final comparisons between the virgin sample witness plates and the post test samples. Alpha Space will also provide guidance to determine the best way to isolate the various effects of the environment on samples by isolating the input variables.

SESSIOCM05.12: Microstructural Stability Under Ionizing Irradiation
Session Chairs: Kazuto Arakawa and Camille Flament
Wednesday Afternoon, November 28, 2018
Hynes, Level 2, Room 202

3:30 PM CM05.12.01 Enhanced Twin Stability Against Irradiation in Nanotwinned Solid Solution Alloys Jin Li1, Dongyue Xie2, Sichuang Xue1, Cuncai Fan1, Youxing Chen1, Haiyan Wang1, Jian Wang1 and Xinghang Zhang1, 1Purdue University, West Lafayette, Indiana, United States; 2University of Minnesota, Minneapolis, Minnesota, United States; 3University of Nebraska-Lincoln, Lincoln, Nebraska, United States.

Face-centered cubic (FCC) metals are in general vulnerable to high-energy ion irradiation. Twin boundaries have been shown to improve the irradiation tolerance of FCC metals. However, nanotwins in monolithic metals are unstable during irradiation. In this study, we show that Fe solute can drastically improve irradiation stability of twin boundaries in Ag. By adding merely 1 at.% of Fe solute atoms into Ag matrix, ultra-high-density twins with an average twin thickness of ~3 nm form in Ag. In situ Kr ion irradiation studies show that defect size and density in Ag:Fe have been significantly reduced comparing with monolithic coarse-grained Ag and nanotwinned Ag. Furthermore, these extremely fine twins survived heavy ion irradiations. Density function theory calculations suggest that Fe solutes stabilize nanotwins by pinning twin boundaries. The mechanisms of enhanced radiation tolerance enabled by solute-twin boundary networks are discussed.

3:45 PM *CM05.12.02 Microstructural Evolution of Fe – 10 wt.% Cr Alloy Irradiated by Fe Ions with Carbon Implantation Camille Flament; DEN-Service de recherches
Because of their high resistance to swelling and low ductile-brittle transition temperature, high chromium ferritic-martensitic (F-M) steels are promising candidates for structural materials of Gen. IV fast neutron reactors and for fusion. The presence of carbon in F-M steels can lead to the precipitation of carbides which may have significant impact on their mechanical properties. Submitted to high neutron flux, the study of their stability under irradiation is a crucial point for reactors lifetime. In order to better understand the mechanisms induced or enhanced by irradiation at fine scale, Fe-Cr model alloys representative of F-M steels have been widely studied. It is well-known that alloys with more than 10 wt.% of Cr are interesting for their resistance to corrosion but display brittleness at temperature below 500°C and after irradiation due to the precipitation of α’ phase [1-3] Nevertheless very few studies deal with the characterization of Fe-Cr-C model alloys and the evolution of carbides under irradiation. This study proposes to characterize high purity Fe – 10 wt.% Cr alloy irradiated at high flux up to a damage of 110 dpa (SRIM2008 calculations (K.-P.)) with Fe ions at 300°C with C implantation, a way to simulate the enrichment in C observed in steels after years of irradiation in reactor. Observations by TEM after irradiation emphasize the coexistence of a\textsubscript{100}<100> and 1/2a\textsubscript{0}<111> dislocation loops homogeneously distributed in the matrix as well as carbides in high density. The mean size of carbides is about 20 nm and they are homogeneously located in intragranular position in the irradiated zone. Observations in HR-TEM show two different morphologies and crystallographic structures: spherical carbides are compatible with M23C6 with a face-centered cubic structure whereas ellipsoidal carbides display an orthorhombic structure close to the one of M6C. APT analyses confirm the enrichment in C to about 0.5 wt.% and show segregation of Cr and C in the habit plane of dislocation loops. No α’ precipitation is observed certainly due to the high density of sinks and C atoms implanted. This irradiated microstructure is compared to an un-irradiated Fe – 10Cr – 0.076C (wt.%) kept at room temperature for ten years. In that case, coarse intergranular carbides (> 200 nm) and finer intragranular carbides (< 150 nm) are observed. Selected area electron diffraction in TEM on several carbides show a face-centered cubic structure with a lattice parameter compatible with M\textsubscript{23}C\textsubscript{6}. Even though the C amount is different between both alloys, it is interesting to note that irradiation with C implantation creates a lot of small clusters of defects which enable a finer and denser microstructure of precipitates in Fe-Cr alloys compared to annealing in Fe-Cr-C alloys. It may impact the mechanical properties of alloys.

4:15 PM CM05.12.03
Stability of Carbides in Fe-Cr-C Systems Under Irradiation—An Ab Initio Based Study
Chu Chun Fu1, Maylise Nastar1, Elric Barbe1-2 and Thomas Schuler1;1 DEN-Service de Recherches de Métallurgie Physique, CEA, Université Paris-Saclay, Gif Sur Yvette, France; 2DEN-Service de Recherches Métallurgiques Appliquées, CEA, Université Paris-Saclay, Gif-sur-Yvette, France.

Fe-Cr steels are promising candidates for structural materials in advanced fission and future reactor reactors. Possible presence of carbides in these systems is well known to have significant impact on their mechanical properties. Further, the stability of the carbides can be modified due to irradiation, as shown experimentally. We address in this study mechanical, thermodynamic and kinetic properties of M\textsubscript{6}C and M\textsubscript{23}C\textsubscript{6}, being respectively the most relevant carbide in Fe-Cr-C alloys. It is known experimentally that distinct fracture mode occurs on these carbides, intra-precipitate for the former and interfacial for the latter. Under irradiation, partial amorphization and dissolution of M\textsubscript{23}C\textsubscript{6} have been observed experimentally, together with the emergence of new carbide phases, changing mechanical properties of the materials. To understand these features, density functional theory (DFT) calculations are applied to investigate the energetics, elastic moduli, and fracture properties of these carbides, as functions of the chemical composition (Fe versus Cr and the carbon concentration) in the carbides. Then, in order to evaluate the impact of irradiation, the stability of the carbides due to point-defect production and diffusion and the ballistic mixing are determined.

4:30 PM CM05.12.04
Additively Manufactured 316L Stainless Steel Behaviour Under Ion Irradiation
Anne-Hélène Puichaud1, Camille Flament1, Fernando Lomello2, Aziz Chniouë3, Marie Loyer-Pros1, Hicham Maskrot1, Frédéric Schuster1 and Jean-Luc Béchade2;1 DEN-Service de Recherches de Métallurgie Physique, CEA, Gif-sur-Yvette, France; 2DEN-Service d'Etudes Analytiques et de Réactivité des Surfaces, CEA, Gif-sur-Yvette, France; 3CEA, Université Paris-Saclay, Gif-sur-Yvette, France.

Additive manufacturing (AM) is being extensively developed as a promising technology, and already exploited in various industries in particular in biomedical and aerospace applications ([1], [2]). However, the use of AM materials in nuclear applications still requires an in depth understanding of the materials response to irradiation, and little work has been done to date [3]. The long term objective of this work is to investigate potential applications of additively manufactured materials, here 316L type stainless steel, suitable for nuclear applications. Stainless steel cubes were fabricated by selective laser melting (SLM) using commercial 316L powder, with AM fabricated materials studied as built, after a heat treatment (HT) and after a hot isostatic pressing (HIP). We performed an in depth microstructural characterisation of the as built, heat treated and HIP materials before irradiation using SEM, EBSD, TEM and nanoindentation. Fe²⁺ ion irradiations of the samples were then performed at the Joint Accelerators for Nano science and Nuclear Simulation (JANNuS, Paris Saclay, France) up to 3 dpa at 550 °C. Finally, microstructures and irradiation behaviours of the AM materials were compared to cold work 316L austenitic stainless steel. The first results of the unirradiated materials show a high microstructural anisotropy for the AM as built and HT materials with elongated grain in the direction of fabrication and a close to α fibre texture. The HIP samples however present more equiaxial grains and a loss of the α fibre texture, closer to conventional 316L. Nanoporosity and segregation of elements (Mo, Si and Mn) were observed in the as-built and HT materials while the HIP samples did not show porosity but presented a high density of precipitates. The microstructure and microchemistry of the irradiated materials were examined using a combination of TEM techniques to establish in particular the void swelling and precipitation behaviour under ion irradiation. The first microstructural characterisations at low dose show apparition of nanocavities, precipitates and a high density of dislocations.

CM05.13.01
Enhancement of Photoluminescent Properties in PBAT/MEH-PPV Blends Provoked by Gamma Radiation for Application in 3D Dosimetry João L. Souza1, Thiago Schimitberger1 and L.O. Faria2; 1Nuclear Engineering, UFMG, Belo Horizonte, Brazil; 2Materials, Centro de Desenvolvimento da Tecnologia Nuclear, Belo Horizonte, Brazil.

When using high energy clinical beams for diseases treatments, the determination of the dose distribution versus tissue depth curves, before the patient irradiation, is significant for radiotherapy planning. The procedure allows medical physicists to accurately predict the dose that will only be enough to eliminate a tumor, without affecting the tissues near the region of treatment. In this context, the developing of 3D dosimetric systems capable to previously determine the dose distribution along the tissues affected by the radiation beam is a worldwide field of investigation. Nowadays, the best dosimetric systems commercially available for the gel-based dosimeters such as PGD (Polymer Gel Dosimeter) and FGD (Fricke Gel Dosimeter). These gel dosimeters are tissue equivalent, with no angular dependence and with millimetric spatial resolution. Most 3D dosimeters are made of a continuous uniform medium which polymerizes upon irradiation. However, the small dose working range of these dosimeters (1-50 kGy) is a problem to be solved. In this work we investigate a new polymeric blend that, by means of radiation damage, can be proposed as a 3D photoluminescent radiation detector, which could operate in a much larger absorbed dose range (1 to 500 kGy). In this context, we have developed a polymeric blend made of poly(butylene adipate-co-terephthalate) copolymers (PBAT) and poly[(2-methoxy-5(2'-ethylhexyloxy)-p-phenylenevinylene) copolymer MEH-PPV. Films of PBAT are non-photoluminescent polymers. However, after exposure to high doses of gamma radiation it shows high photoluminescence (PL) output, proportional to the exposed radiation dose. When excited with blue LED, its PL intensity at 490 nm (green) can be used for high gamma dose dosimetry [1]. MEH-PPV is a naturally photoluminescent polymer that, when in solution, undergoes a gradual color change, from red to colorless, when exposed to high gamma doses ranging from 0.5 to 500 kGy. Films of PBAT/MEH-PPV have been recently proposed for 2D high dose dosimetry [2]. In this paper we have produced blends of PBAT/MEH-PPV mixed with a plasticizer in order to produce 3D dosimeters, by using DINCH - 1,2-Cyclohexane dicarboxylic acid disononyl ester plasticizer. After gamma irradiation, the 3D samples in a cylinder form, changes its color from orange (lower doses) to light green (higher doses), for doses ranging from 1 kGy to 500 kGy, respectively. FTIR data revealed that the radio-induced aromatic amines in the binary system are responsible for the observed PL at 500 nm. The PL emission spectra demonstrate that the color change in the 3D polymeric cylinders is a combination of the variation in the green color intensity of PBAT with the decreased red color intensity of MEH-PPV. UV-Vis spectrometry, DSC and DRX analysis are used to complement the discussion about the radio-induced photoluminescent properties. PBAT/MEH-PPV blends are good candidates for 3D dosimetry and bio-imaging devices.

CM05.13.02
Ionising Radiation Effects in UK Nuclear Waste Glasses—An Assessment of Key Processes Aaron R. Daubney1, 2; 1Dalton Nuclear Institute, Whitehaven, United Kingdom; 2Chemistry, University of Manchester, Manchester, United Kingdom.

The current understanding of glass behavior after exposure to a multitude of ionizing radiation fields (including alpha, beta and gamma) is under development by a growing international research effort. Understanding the physical mechanisms which cause deleterious (and sometimes even preferential) changes to a glass microstructure will underpin future policy for the disposal of high-activity nuclear wastes. By using ion beam and gamma irradiation facilities, an assessment of microstructural changes and their relation to glass mechanical and thermodynamic properties will be made.

Through coordinated research efforts, a picture of long-term glass behavior (over hundreds to thousands of years) is generated and so an understanding of key mechanisms and their application to amorphous, metastable materials such as glass are crucial. This agreement of physical mechanisms involved during multi-particle radiation fields and their relative impact to glass structure will also underpin atomistic simulations of glass corrosion processes.

CM05.13.03
Impact of Stored Mechanical Energy in Carbon Onion Resilience Under Space Radiation Gaurab Panda1, Virginia M. Ayres1, Harry Shaw2, Kan Xie1 and SK Bay3; 1Michigan State University, East Lansing, Michigan, United States; 2NASA Goddard Space Flight Center, Greenbelt, Michigan, United States; 3Bahcesehir University, Istanbul, Turkey.

Nano-carbons are a promising new approach to resolve lubrication challenges in space including vacuum, radiation and non-terrestrial temperature regimes. Planar graphite, while an excellent lubricant on earth, undergoes structural collapse in vacuum and knock-on collision generated amorphitization in response to heavy ions, a key component of the solar wind. Space lubrication candidates: carbon onions and multi-walled carbon nanotubes have shown robust performance in vacuum environments and are under investigation by our group and others for radiation and temperature resilience [1, 2, 3].

The responses of carbon onions with increasing polygonal character due to increasing temperature growth conditions were investigated under heavy ion irradiation at the Facility for Rare Isotope Beams (FRIB) at Michigan State University. The heavy ions used in these experiments were primary beams of fully stripped Calcium-48, and Argon-40 with 140 or 70 MeV per nucleon kinetic energies. Stored elastic energy, and layer number were investigated using analysis of pre- and post- irradiation high-resolution transmission electron microscope (HRTEM) images. The study indicated that as the radiation dose increased, the carbon onions tended to store more mechanical energy, which reproduces a mechanical property of growth at a higher temperature. A key consequence was that rearrangements were enabled that included conversion of radial onions to planar graphite when the starting point material had sufficiently high stored mechanical energy. Increase in number of layers was not consistent and average numbers did not show much change. However, individual specimens and standard error of the mean values could support the interpretation of an increase.

Layer rearrangement could have both positive and negative implications for the tribological performance of carbon onions in a heavy ion space environment. Ongoing rearrangements into structures that retained the excellent tribological features of the originals would be a self-healing way of dealing with radiation-induced defects. However, rearrangements that resulted in the formation of planar graphite could have negative consequences for tribological performance. This suggests that for space lubrication applications, lower temperature synthesis carbon onions, while less polygonal and more defective, are more resilient to heavy ion radiation.

Computational Design of Radiation Damage Tolerant Single-Phase Alloys Penghui Cao, Miaomiao Jin and Michael Short; Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

Understanding and predicting radiation damage are of central importance to develop radiation-tolerant structural materials for current and advanced nuclear systems. Single-phase solid solution alloys constitute attractive choices due to their promising mechanical properties and radiation tolerance. Here, by examining radiation-induced defect production and evolution in single-phase Ni-Fe alloys, we show that radiation damage resistance directly correlates with thermodynamic mixing energy. Defect numbers and sizes appear to first decrease with increasing Fe concentration, but then start to increase at the vicinity of equiatomic concentrations. The observation in damage reduction is further ascribed to the increasing heterogeneity of point defect migration across a complex potential energy landscape that results in enhancement of defect recombination. This new insight into the dynamical evolution of radiation defects implies a thermodynamic criterion for designing radiation-tolerant materials.

Photoirradiation-Induced Reversible Lattice Expansion in W-Doped TiO2 Through the Change of Its Electronic Structure Fan Feng1, Weiyi Yang1, Shuang Gao2, Linggang Zhu2 and Qi Li2; 1Institute of Metal Research, Chinese Academy of Sciences, Shenyang, China; 2Graduate School at Shenzhen, Tsinghua University, Shenzhen, China; 2Beihang University, Beijing, China.

The capability of reversible crystal lattice dimension changes on the order of 0.1% or above by external stimulations of applied force or voltage to impose external mechanical or electric forces on atoms forming the lattice had been observed in a lot of types of materials, including oxides, metals, polymers, and carbon nanостructures, which could be utilized as actuators or sensors for various technical applications. As an external stimulation, photoirradiation had been found to be effective to lead to reversible changes in materials, such as photocatalysis, photochromism, photoisomerization, and surface morphology change. In these processes, photoirradiation interacts with materials and electrons are excited internally to induce subsequent changes. If these photogenerated electrons could be designed to cause the material’s internal electronic structure to change reversibly, it should also result in a reversible crystal lattice dimension change by light irradiation.

Recently, photostriiction had been reported in several perovskite oxides due to the combination of the photovoltaic effect and the converse piezoelectric effect or the nonequilibrium of phonons. Here, we report that reversible lattice expansion comparable to those by applied force or voltage (on the order of 0.1% or above) can be induced by the on and off of UV-irradiation in an oxide of W-doped TiO2 nanotube array through the reversible changes of its electronic structure change. This photoirradiation-induced reversible lattice expansion may also be present on other material systems by proper material design if they possess one component able to produce electrons upon photoirradiation and the other component able to accumulate photogenerated electrons to induce lattice changes and release them after the photoirradiation is off. Reversible optical, electric, and magnetic property changes could also be expected due to their reversible internal electronic structure changes. Various potential applications may be found for this kind of materials, including nanoscale, photo-driving actuators or detectors.

Ionization Induced Carbon Phase Changes in Graphite Lenore S. Miller1, John D. Demaree2, Kristophor D. Behlen2, Zhang Tong1 and Daryush Ila1; 1Fayetteville State University, Fayetteville, North Carolina, United States; 2Weapons and Materials Research Directorate, US Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States; 3SURVICE Engineering Company, Belcamp, Maryland, United States.

We have studied changes in the surface of graphite before and after MeV ion bombardment, to assess the effect of ionization on the carbon phase and atomic bonding of carbon in HOPG, using X-ray photoelectron spectroscopy (XPS), Raman spectroscopy, and 3D laser microscopy. We observed the hexagonal carbon ring structure of graphene sheets in graphite using AFM, to assess any changes in carbon bond length or distortion of the hexagonal lattice due to the passage of the heavily ionizing particles. Rutherford Backscattering Spectrometry (RBS) in conjunction with XPS were used to identify impurities in the material and at the surface, and their potential impact on graphite surface properties. RBS was used because most impurities are significantly heavier than carbon, and therefore they can be easily detected and quantified without any need for substrate background subtraction. XPS was used to confirm the RBS findings, identify any differences in the distribution of impurities in the bulk and at the surface of the material before and after MeV implantation. Ion induced changes in carbon bonding, including the transformation of graphitic sp2 bonding to amorphous or diamond-like sp3 bonds were measured using Raman spectroscopy, as well as using X-rays excited C KLL to characterize the carbon phase in various high purity HPOG bombarded transformation which may be explained by rapid thermal quenching following ion-induced excitation.

Accelerated Testing of Carbon Fiber-Reinforced Shape Memory/Epoxy Polymer Composites in Low Earth Orbit Space Joon Hyoek Jang1, Seok Bin Hong1, Jungyu Kim2; Nam Seo Goo3 and Woong-Ryeol Yu1; 1Seoul National University, Seoul, Korea (the Republic of); 2Kyung Hee University, Yongin, Korea (the Republic of); 3Konkuk University, Seoul, Korea (the Republic of).

Carbon fiber reinforced shape memory polymer composites (CF-SMPCs) have been researched for space structural materials due to their high mechanical properties, lightweight, excellent shape deformability, and self-deployment properties. Long term durability of CF-SMPCs in the space environment should be guaranteed for their successful applications to aerospace engineering. In low earth orbit (LEO) space region, there are many factors, such as high vacuum, ultraviolet radiation (UV) and atomic oxygen(AO), that affect polymer matrix composites. Therefore, a predictive method is required to predict long-term properties of CF-SMPC considering these harsh environments and thus to design proper CF-SMPCs for aerospace engineering. In this study, CF-SMPCs made of CF and epoxy shape memory polymers were studied, focusing on their life prediction. First, acceleration tests were developed by exposing CF-SMPCs to LEO space environments (i.e., high vacuum, UV and AO) at elevated temperature in space environment chamber. Then, their storage moduli were measured using dynamic mechanical thermal analysis. Using time-temperature superposition principle (TTSP), a master curve was constructed to predict the long-term behavior of CF-SMPCs in LEO space. The long-term storage modulus was predicted by the linear product of the shift factors for time – three LEO environments and time - temperature superposition. Finally, a predictive model was developed to evaluate the durability of CF-SMPCs in aerospace.
In this talk, the experimental results (APT, STEM, XRD) obtained on multilayers of different wavelengths before and after thermal ageing at different interdiffusion in a bulk material. Diffusion kinetics are wavelength-dependent at this scale, different wavelengths have to be experimentally tested in order to extrapolate results for operating temperatures in the range of 400-550°C lead to long term ageing (thermal or irradiation ageing). This process is governed by thermodynamics and diffusion. Thus, to predict microstructural evolutions, an important step is to gain a better understanding of the diffusion kinetics properties in FeCrNi Austenitic stainless steels are candidates for both structures (316 L(N) steels) and cladding (AIM1-type steels). The 60-year life demonstration design and the decay of satellite peaks intensity thanks to XRD.

Corrosion Protection Coatings for Depleted Uranium Volodymyr Lobuz, Martin Hruby, Peter Cernoch, Jiri Paneck, Tomas Chmela and Pavel Krupicka, Institute of Macromolecular Chemistry AS CR, Prague, Czechia; UIP PRAHA a.s., Prague, Czechia.

The depleted uranium is still an indispensable material in numerous areas, from healthcare to arms industry; however its range of applications is limited by high reactivity and susceptibility to corrosion. The current state of art for the storage of depleted uranium stands on expensive and sophisticated procedures, as alloying with up to 20% of molybdenum or encapsulation in aluminum or steel containers. This project aims the reduction of the production costs and simplification of the technology for production and processing of depleted uranium based materials. Within current study we develop the coatings on depleted uranium stored for further reprocessing or already used in various radiation shielding applications. For lower radiation doses, up to 100 kGy, the coatings are based on polymer materials, either in form of polymeric paints from poly(2-butyl-2-oxazoline), poly(2-phenyl-2-oxazoline), series of polyesters, or as two-component curable systems: polyurethanes based on isophorone diisocyanate (ID) with Kralos (K) or Polycarbonate (PC). The coatings were reinforced with inorganic fillers (e.g. modified graphene) to prevent the diffusion of water vapor and oxygen and stabilized with hindered amines BHT or Timuvin 123 for radical scavenging.

The polyurethane layers were exposed to radiation from depleted uranium, and various doses of gamma or β radiation, and their chemical composition, thermal stability and mechanical properties were investigated by FTIR, EPR, TGA/DSC, and micro-hardness indentation. The gamma irradiation improved the thermal stability of polyurethane ID-K, but reduced for ID-PC; the glassing temperature is decreased for all polyurethane samples after every irradiation cycle. The hard polyurethane sample ID-K after irradiation become even harder and stiffer and demonstrated increased intensity of the hydroxyl (3600 cm⁻¹), carboxyl (1740 cm⁻¹) ether and ester (1500-1600 cm⁻¹) bands of FTIR spectra, usually assigned to oxidation products. It was assumed, that ID-K sample undergoes oxidation and additional cross-linking. The softer ID-PC polyurethane remained unchanged. For higher radiation doses (in range of hundreds of MGy or higher) the entirely inorganic coating, based on low melting SnF₂-SnO-P₂O₅ glass is developed. The glass powder is sprayed on the metal surface, melted at 450°C to form the uniform layer, aged at 150°C for relaxation of strains and cooled to ambient temperature. The material contains 40 wt. % of tin, used for radiation shielding together with lead and copper.

CM05.13.09 Effects of X-Ray Irradiation on Amorphous Oxide Semiconductor Thin-Film Transistors Solah Park and Jang-Yeon Kwon; Yonsei University, Incheon, Korea (the Republic of).

In recent years, digital x-ray detectors have been used in the medical device market for miniaturization, portability and rapid information transmission. When driving indirectly, electric signal is amplified by using hydrogenated amorphous silicon Thin Film Transistors (a-Si:H TFT) on the detector panel. At this time, the detector panel is continuously exposed to the x-ray, and the elements therein are also affected by the x-ray. The trend of x-ray detector market requires a high mobility device because it requires effective detection with low x-ray dose. TFT technology using oxide semiconductors (mobility of 10 cm²/Vs) has already been applied to AMOLED in the field of display. It is a suitable alternative to solve problems such as low mobility and device reliability of existing a-Si:H TFT (mobility of 0.5 cm²/Vs). The application of oxide TFT technology in medical devices can give many advantages in the construction of digital X-ray radiography system structure that can realize high resolution and high aperture ratio based on high mobility. Therefore, it will make a great contribution to the development of smart medical device system. For this, the ionizing radiation effect studies are needed to utilize oxide semiconductor TFTs in medical devices. There is a lack of research on how each semiconductor device is affected by x-ray and how long it will last. Therefore, it is necessary to investigate the change of device characteristics after x-ray irradiation, and to study the lifetime and recovery of devices.

In this presentation, we investigated the effects of typical silicon and oxide TFTs used in displays on x-ray irradiation. In particular, we have investigated the effects of different crystalline states (amorphous or crystalline) on silicon and oxide, respectively. We investigated the effect and mechanism of each device according to x-ray dosage. This result is expected to contribute to the study of x-ray radiation damage due to the difference in crystal structure between silicon and oxide TFT and to develop medical industry (Radiography, Fluoroscopy, Dental etc.) and electronic device with tolerant in x-ray environment. Furthermore, it is expected to contribute greatly to research on x-ray industry technology for non-destructive testing (NDT) of facilities and buildings.

CM05.13.10 Experimental Determination of Diffusion Kinetics After Thermal Aging of FeCrNi Nanolayers Solène Rouland, Bertrand Radiigue, Alain Billiard and Philippe Pareige; 1Normandie Univ, UNIROUEN, INSA Rouen, CNRS, GPM, Rouen; France; 2Institut FEMTO-ST, UMR 6174 CNRS, Univ. Bourgogne Franche-Comté, UTBM, Montbéliard, France.

GEMMA (GEneration IV Materials Maturity) European project aspires to validate structural materials and welded joints selected for GenIV demonstrators (e.g. ASTRID) under operating conditions by reliable conditions and simulations.

Austenitic stainless steels are candidates for both structures (316 L(N) steels) and cladding (AIM1-type steels). The 60-year life demonstration design and operating temperatures in the range of 400-550°C lead to long term ageing (thermal or irradiation ageing). This process is governed by thermodynamics and diffusion. Thus, to predict microstructural evolutions, an important step is to gain a better understanding of the diffusion kinetics properties in FeCrNi model alloys. At the typical range operating temperatures, diffusion properties of this ternary system aren’t known for the moment either after thermal or irradiation ageing.

To investigate interdiffusion at low temperature under reasonable time, it has been shown [1] that decomposition or homogeneization of the stacking of composition modulated nanolayers can be used. This kind of material is synthesized by magnetron cosputtering of metallic targets at UTBM (France). Interdiffusion coefficients as a function of annealing time at low temperatures can be extracted from [2] - concentration profiles amplitude evolution obtained by elemental analysis techniques as Atom Probe Tomography (APT) and STEM-EDS/EELS ; - the decay of satellite peaks intensity thanks to XRD. These sinusoidal modulations in composition can be described by their wavelength, corresponding to twice a layer thickness, and their amplitude. As diffusion kinetics are wavelength-dependent at this scale, different wavelengths have to be experimentally tested in order to extrapolate results for interdiffusion in a bulk material.

In this talk, the experimental results (APT, STEM, XRD) obtained on multilayers of different wavelengths before and after thermal ageing at different temperatures will be presented. The diffusion coefficients deduced from experimental results will be given.

CM05.13.11
Effect of Alloying Elements on Stacking Fault Tetrahedra (SFT) in Ni Alloys
Gaurav Arora, Dilpuneet S. Aidhy and Anus Manzoor; University of Wyoming, Laramie, Wyoming, United States.

Formation of stacking fault tetrahedra (SFT) has been widely observed both experimentally and in molecular dynamics (MD) simulations in Ni. Using MD simulations, we show that SFT formation is arrested under tensile strain. This observation is explained by our density functional theory (DFT) calculations that show the decrease in the binding energy of SFT with increasing tensile strain. These predictions are qualitatively validated in Ni-Pd alloys. In particular, adding a large atom such as Pd leads to elongation of the Ni-Ni bonds; our MD simulations indeed show no SFT formation in Ni-Pd alloys. The lack of SFT formation has also been observed in irradiated Ni-Pd systems compared to pure Ni. We further elucidate the effect of strain on the energetics of loop and void formation. In particular, we find that while the vacancy binding energy is negative for SFT, it is positive for voids and loops. However, despite positive binding energy, voids are very difficult to form due to high formation energies. For example, the formation energy of a 10-vacancy void is approximately 9 eV. Thus, our results indicate that vacancy clustering and cluster sizes could be significantly reduced via choosing larger sized alloying elements and by applying tensile strain.

CM05.13.12
Object Kinetic Monte Carlo Modelling of Microstructure Evolution Under Irradiation in Zirconium Based on Atomistic Modelling of Point Defect Clusters
Christophe Domin1, Benjamin Christiaen1, Ludovic Thuanet2, Antoine Ambard1 and Alexandre Legris2; 1EDF R&D, Mèze-Sur-Loing, France; 2UMET, Université de Lille, Villeneuve d’Ascq, France.

Zirconium alloys are used to manufacture fuel cladding as well as fuel assemblies of pressurized water nuclear reactors. Under irradiation, they can show a dimensional change commonly called growth. Experimental observations have shown that above a threshold dose, these alloys are subject to accelerated growth called “breakaway”. It has been established that the irradiation formation of <c> and <a> dislocation loops is responsible for the growth of irradiated zirconium alloys and that the appearance of <c> loops is correlated with this growth acceleration. In order to improve our understanding of the nucleation mechanisms of the <c> loops, object kinetic Monte Carlo modelling based on atomic simulations is used. Atomic-scale calculations based on the density functional theory (DFT) and empirical potentials are used to determine the properties of vacancy and self-interstitial clusters: stability and eigenstrain. In particular, DFT simulations have put in evidence the possible existence of different defect clusters (including non planar defects) with different properties prior to the formation of loops. These objects have been included, in addition to displacement cascade debris, in object kinetic Monte Carlo modelling of the microstructure evolution under irradiation. The calculated growth is compared to available experimental results.

Kinetic Study on the Evolution of Nanoceramic Coatings Under Heavy Ions Irradiation
Matteo Vanazzi1, 2, Luca Ceseracciu1, Marco Beghi2, Gaelle Gutierrez2, Celine Caber1, Jing Hu1, Meimei Li1 and Fabio Di Fonzo1; 1Istituto Italiano di Tecnologia, Milan, Italy; 2Energy Department, Politecnico di Milano, Milan, Italy; 3CEA, Paris-Saclay, France; 4Argonne National Laboratory, Argonne, Illinois, United States.

In order to qualify innovative materials for structural components and coatings, their radiation resistance must be assured. In this framework, irradiations studies with neutrons present overwhelming complications related to cost, availability and experimental time needed to reach significant levels of radiation damage. Ions irradiation has been proposed as a valid alternative to produce comparable and accessible data. Specifically, heavy ions in the MeV energy range are quite appropriate to simulate neutrons due to the low Electronic to Nuclear Stopping Power (ENSP). However, the comparison of the relative effects for neutrons and heavy ions presents intrinsic difficulties and many data are required to make it reliable. In the previous studies, we have reported on the evolution of amorphous-nanoceramic Alumina (Al2O3) coatings under heavy ions irradiations. The material was irradiated up to 450 displacements per atom (dpa), showing a general radiation-induced crystallization trend. In this work, we employ 12 MeV Au ions to irradiated Al2O3 coatings up to 3 dpa. In opposition to earlier experiments, we here concentrate on the low dpa regime, to evaluate carefully the first stages of crystallization and to obtain radiation damage values more compatible with neutrons tests. Moreover, irradiations are now performed at different temperatures (namely 400, 500 and 600 °C) in order to decouple the thermal contribution from the radiation-induced effects. A comprehensive analysis of the irradiated samples is accomplished by X-Ray Diffractometry (XRD), Transmission Electron Microscopy (TEM), Scanning-TEM (STEM) and Nano-indentation (NI). Generally, the evolution seems strictly temperature-dependent, with no structural changes at 400 °C. For the higher temperatures, results show again an intense crystallization process - even at very low dpa levels - with the formation of different crystalline phases, in relation to the test conditions. A preliminary kinetic model is proposed, based on the experimental data, and the grain-growth-related parameters are calculated. From a mechanical point of view, an evident size-effect is manifested. The formation and growth of nanometric crystalline domains increase rapidly the hardness, in accordance with the Hall-Petch relationship. In particular, for the initial stages of irradiations, an inverse Hall-Petch mechanism is observed, with a reported maximum hardness of approximately 27 GPa (ultra-hardness). To support and confirmed these evidences, irradiation tests are repeated with in-situ TEM tandem apparatus. Further tests are carried out with 1 MeV Kr ions on free-standing Alumina films, to collect dynamically microstructural changes and phases transformation. To conclude, an extensive characterization campaign is performed on ions irradiated-Al2O3 coatings. Tuning different experimental conditions (like temperature, dpa, ions), a consistent and coherent picture of the Alumina evolution under irradiation is produced.

Analysis of Helium Segregation on Surfaces of Tungsten at Different Levels of Helium Ion Irradiation
Lin Hu1, Asanka Weerasinghe1, Karl D. Hammond2; 1Chemical Engineering, University of Massachusetts Amherst, Amherst, Massachusetts, United States; 2Chemical Engineering, University of Missouri-St. Louis, Columbia, Missouri, United States; 3Nuclear Engineering, The University of Tennessee, Knoxville, Tennessee, United States.

Plasma facing components (PFCs) in nuclear fusion reactors are exposed to intense plasma heat and particle fluxes. The implantation of helium (He) atoms into these materials impacts significantly the evolution of their surface morphology and near-surface structure. In tungsten (W), a promising PFC material because of its thermomechanical properties, interstitial He atoms are very mobile and aggregate to form clusters of various sizes. Small, mobile helium clusters (Heₙ; 1 ≤ n ≤ 7) are attracted to the tungsten surface due to an elastic interaction force that drives surface segregation, and their diffusional transport
mediates the dynamics of surface morphology and near-surface microstructure.

Here, using atomistic simulations based on a reliable many-body interatomic potential, we explore helium segregation on surfaces of tungsten that has been exposed to different levels of He ion irradiation. At higher helium fluence, mobile helium clusters are subjected to cluster-defect interactions in addition to cluster-surface interactions, which complicate cluster dynamics beyond the dilute limit of helium content in the PFC material. We characterize in detail configurations generated by large-scale molecular-dynamics simulations of implanted helium evolution in plasma-exposed tungsten with W(100), W(110), W(111), and W(211) surfaces facing the plasma. We examine the effects of varying helium fluence due to increased plasma exposure of the tungsten PFC by performing systematic molecular-statics computations of small helium cluster energetics near the above low-Miller-index W surfaces as a function of distance (depth) of the cluster center from the surface on a grid of lateral locations on the surface. We analyze the defect interactions that mediate the energetics of small helium clusters migrating to the surface, taking into account that the migrating cluster also is subjected to the stress fields generated by larger helium bubbles, as well as other small clusters, and quantify the strength of these interactions for different levels of He irradiation. The outcome of this analysis is the systematic parameterization of mobile helium cluster energetics at varying levels of He irradiation through functional forms that include contributions from cluster-cluster and cluster-bubble interactions as well as cluster-surface interactions. Such parameterizations are important for developing atomistically-informed, hierarchical multiscale models of helium cluster dynamics in PFC materials.

Harsh Environments of Fast Neutrons and Extreme Temperature Effects on Amorphous Fe-Based Nano-Coatings on Steel Substrate

Ilyas
Savklyivzlyzov,2* Enver Koray Akgözan1, Zhong Zheng1 and Nikolaos Simos1;1 Süleyman Demirel University, Turkey; 2Süleyman Demirel University, Turkey; *Rutgers, The State University of New Jersey, Picataway, New Jersey, United States; Brookhaven National Lab, Upton, New York, United States.

Protective coatings on next generation nuclear reactor steels shows safe operation behavior at high temperatures and fast neutrons. The integrated studies include fast neutron irradiation, macroscopic post-irradiation evaluation, scanning electron microscopy and energy dispersive X-ray diffraction (EDXRD) to investigate irradiation-induced macroscale physio-mechanical changes in the nano-coating/substrate structures. At extreme temperatures, phase evolution and effect on crystallization/amorphization is mapped with EDXRD technique throughout the coating. With modest neutron doses of ~2x1019 n/cm2, the loss of ductility in an amorphous Fe-alloy coating on a steel substrate due to high temperature is prevented. At the higher neutron dose of ~2x1019 n/cm2, radiation-induced embrittlement behavior is observed on Fe-alloy nanostructured coating with macroscopic stress-strain analysis which implies ductility loss in the coating-substrate structure. Neutron irradiation displayed remarkable oxidation resistance of the protective Fe-based amorphous coating, which is attributed to the formation of the FeB phase in the coating. In-situ 3D space resolved EDXRD study revealed an increase amorphous-to-crystalline transition in the amorphous Fe-alloy at elevated temperatures. On the surface of the coating, mostly α-Fe phase is observed but these α-Fe phase transformed into γ-Fe phase close substrate interface. This phenomena is attributed to carbon diffusion from steel substrate to Fe based coating at high temperature annealing process. Electron microscopy was carried out to sustain the radiation-induced suppression of crystallization in the amorphous Fe-alloy nanostructured coating.

Nanoceramic Coatings—An Enabling Technology for Future Generation Nuclear Systems

Fabio Di Fonzo, Erkka J. Frankberg, Francisco Garcia Ferré, Daniele Iadicicco, Boris Paladino and Matteo Vanazzi; Istituto Italiano di Tecnologia, Milano, Italy.

In the framework of conceptually innovative nuclear reactors, next generation systems are meant to outperform current ones, by providing disruptive solutions in terms of non-proliferation, fuel cycle efficiency, radioactive waste management and safety. However, the development of future power plants is directly linked to the availability of suitable materials. The greatest challenges in this sense arise from the extremely harsh environments and the intense radiation fields to which materials will be exposed during operation. Among the other candidates, ceramic coatings are a promising solution to tackle these issues. Indeed, the deposition of ceramic coatings on traditional structural materials can provide surface engineering without affecting structural integrity. It is worth highlighting that protective coatings are already being considered as a near-term option for accident tolerant fuel (ATF) for Light Water Reactors (LWRs) while, in the case of Generation-IV (GIV) concepts and fusion systems, coatings could be used to mitigate high-temperature corrosion and tritium permeation. Here, we present a brief summary of the activities performed by the Center for Nano Science and Technology of the Istituto Italiano di Tecnologia, on the materials for advanced nuclear systems. Engineered coatings are grown on relevant structural alloys such as 1515-Ti, EUROFER-97, ZIRLO® and Zircaloy-4. Coatings are designed and processed by different methods, namely Pulsed Laser Deposition (PLD) and Magnetron Sputtering (MS). In respect to GIV systems - specifically Lead reactors - Alumina (Al2O3) layers have been characterized as anti-corrosion radiation-resistant barriers. In particular, the compatibility of PLD-grown Al2O3 in molten Lead has been proven in up to 5000 hours exposure time tests, without degradation. For what concerns fusion reactors, Yttria (Y2O3) as well as Alumina coatings have been evaluated as possible solutions against Lead-Lithium corrosion and Tritium permeation. Indeed, the obtained Tritium permeation reduction is in the order of 106-107 while the requirements indicate reduction values of about 1000. Nevertheless, Al2O3 coatings have been tested also under heavy ions irradiation, at damage levels relevant for fusion and fast reactors. The ceramic film has preserved again its integrity and stability, evolving structurally from an amorphous to an almost-completely crystalline state. Last but not least, a combined approach has been investigated for ATF claddings. An optimized multi-layered structure of metallic Chromium and transitional metal oxides has been tested in autoclave systems, simulating standard and accidental condition. Results show a strong improvement in terms of high temperature oxidation resistance. To conclude, engineered coatings represent promising candidates to face the major issues related to future nuclear technologies and allow the design of innovative and economically attractive power plants.

Studies of Electron Beam Damage on γ-FeOOH Nanoparticles

Yulia Trushkina, Cheuk-Wai Tai and German Salazar-Alvare all; Stockholm University, Stockholm, Sweden.

It is known that electron beam in transmission electron microscopy (TEM) can cause a damage of a material in various ways, i.e. a change of surface and structure of a specimen. In the case of lepidocrocite (γ-FeOOH) nanoparticles, electron beam damage is an obstacle to obtain full information about the structure from TEM measurements.

In this work we study lepidocrocite whiskers (2.5×6×200 nm2) prepared through oxidation of a green rust precursor. TEM observations show that within 10 minutes lepidocrocite structure undergoes changes under electron irradiation starting at electron dose 171 e/Å2/s. Analysis of the final structure indicates that the structure dehydroxylates topotactically to produce maghemite (γ-Fe2O3).

In this talk I will present the investigation and quantification of beam damage on lepidocrocite nanoparticles. Results from high-resolution TEM and EELS (e.g., thickness change vs dose) with and without cooling will be presented. We suggest that beam damage mechanisms for lepidocrocite nanoparticles are displacement damage and heating.
Nanoscale Chemical Phenomena Using HIM-SIMS

Axel Belianinov, Songkil Kim, Artem Trofimov, Matthew J. Burch and Olga Ovchinnikova; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

The key to advancing materials in a broad range of scientific sectors is to understand, and subsequently control, (i) the structure as well as (ii) the chemistry of surfaces and interfaces. However, significant gaps in characterization techniques hamper simultaneous chemical and physical characterization of materials with high spatial resolution and high chemical sensitivity. This work will illustrate recent nanoscale results on imaging and chemical analysis of conductive and nonconductive surfaces using a tool that combines high-resolution imaging and milling with high spatial resolution chemically sensitive approaches – a Helium Ion Microscope (HIM) with a secondary ion mass spectrometer (SIMS). This multimodal chemical imaging methodology transcends inherent individual instrument limitations, data volumes, and complicated analyses originating from an ex-situ combinatorial approach.

Data will be presented on conductive and non-conductive chemical standards as well as scientifically relevant organic-inorganic perovskite (HOIPs) materials. Ionization efficiency, sputtering, fragment detection, and other salient features of the HIM and the SIMS tools will also be presented and discussed. Overall, a combined HIM-SIMS platform offers significant potential to visualize and map active interfaces, by intertwining imaging, nanoscale elemental characterization, and data analytics; to better grasp the physical properties of materials and the mechanistic physics-chemistry interplay behind their properties.

Current Understanding of Irradiation-Induced Defect Production and Microstructural Evolution in Tunable Concentrated Solid-Solution Alloys
Yanwen Zhang1, Shijun Zhao1, Yuri Osetsky1, Hongbin Bei1 and William J. Weber2, 1; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2The University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Multicomponent concentrated solid solution alloys (CSAs) offer tunable chemical complexity. The random arrangement of multiple elemental species on a regular lattice (fcc or bcc) results in unique site-to-site lattice distortions and local disordered chemical environments. Control of chemical complexity can be achieved by substituting transition metal elements within the same period or the same group. The requirements for an alloy system with increasing chemical complexity (e.g., variation of electronic structure disorder or magnetic frustration) can be fulfilled, for example, in fcc Ni with addition of other elements, primarily 3d-transition metals (e.g., Cr, Mn, Fe, and Co). The composition of this fcc CSA system (e.g., binary, ternary, quaternary and quinternary) can be at or near equatomic concentrations, or at concentrations with one or two elemental species in large variation within solubility limits. In the case of high entropy alloys (HEAs), e.g. NiCoFeCrMn and NiCoFeCrPd, extreme chemical complexity leads to substantially reduced electron, phonon and magnon mean free paths; modified coupling strengths; and complex formation energies and migration barriers. In contrast to traditional dilute alloys, these energies have broad distributions. Moreover, defect–defect interaction strengths, such that interstitials, vacancies and defect clusters produced by displacement collisions, may create their own distributions that can be strongly affected by the intrinsic site-to-site complex disordered states. Recent results [1-5] show that tuning compositional disorder in CSAs represents a powerful tool to dramatically affect defect energetics that ultimately enhances radiation tolerance. In this presentation, current understanding on defect dynamics and microstructure evolution will be discussed through closely integrated theoretical, computational, and experimental studies.

Work supported by the Energy Dissipation to Defect Evolution Center (EDDE), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science.

Absorption of Radiation-Induced Point Defects at Crystal/Amorphous, Metal/Covalent Interfaces
Sanket S. Navale and Michael J. Demkowicz; Materials Science and Engineering, Texas A&M University, College Station, Texas, United States.

We use atomistic simulations to investigate the interaction of radiation-induced point defects with interfaces between crystalline metals and amorphous covalently-bonded solids. We select the gold (Au)/silicon (Si) binary system as a model material and construct interface models along different facets of crystalline Au and with amorphous Si (a-Si) created at different quench rates. We compute formation energies of vacancies and helium interstitials as a function of position relative to the interface and find that Au/a-Si interfaces are strong traps for defects originating from both Au and a-Si. Our work suggests that crystal/amorphous, metal/covalent interfaces, such as those found in iron/silicon oxycarbide (FeSiOOC) composites may be as affective at removing radiation-induced point defects as interfaces in polycrystalline metals composites.

Helium Nanochannels and Future Prospects for Damage-Free Helium Outgassing from Metals
Michael J. Demkowicz; Texas A&M University, College Station, Texas, United States.

Work supported by the Energy Dissipation to Defect Evolution Center (EDDE), an Energy Frontier Research Center funded by the U.S. Department of Energy, Office of Science.
In this talk, I will present the recent finding that helium (He) implanted into certain metal nanocomposites spontaneously forms networks of elongated channels, rather than a field of isolated, equiaxed precipitates. Thanks to many years of prior research—performed in large part using ion implantation and ion beam analysis facilities—we now have a complete explanation for the physical mechanisms underlying this surprising departure from classical He behavior in metals. I will explain these mechanisms and, on their basis, discuss prospects for technological applications of metal nanocomposites as He-resistant materials to be used in nuclear energy.

11:30 AM CM05.15.04

Displacive Annihilation of Point Defects in Body-Centered-Cubic Metals Qing-Jie Li1, Ju Li2 and Evan Ma1; 1Johns Hopkins University, Baltimore, Maryland, United States; 2Massachusetts Institute of Technology, Cambridge, Massachusetts, United States.

The main weak point is the ion source performance, i.e. the brightness is typically several million times less compared to electron beam sources. Recent tests with on-chip ion sources have shown great potential, opening up the way to improve the ion beam brightness by a million times. In this talk I will give an update on defect formation in graphene using different ion species and different energies (1 keV – 2 MeV). As well as an update on the applications into PBW, especially in the area of nanofluidics where we developed a new platform to image single stranded DNA molecules, used in large scale genomic mapping. Finally I will discuss our progress in the development of our new ion source, aiming for single digit nanometer proton beam spot size.

We kindly acknowledge NRF-Singapore for their support: NRF-CRP13-2014-03 and NRF-CRP13-2014-04.

2:15 PM CM05.16.03
Blister Formation at Subcritical Doses in Tungsten Irradiated by MeV Protons
Inbal Gavish Segev1, Ido Silverman1, Guy Makov2 and Eyal Yahel1; 1NRCN, Beer-Sheva, Israel; 2Materials Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel; 3SNRC, Yavne, Israel.

Tungsten samples were irradiated by 2.2 MeV protons at the Soreq Applied Research Accelerator Facility (SARAF) to doses of the order of 10^17 protons/cm^2 which are below the reported critical threshold for blister formation derived from keV range irradiation studies. Large, well-developed blisters are observed indicating that for MeV range protons the critical threshold is at least an order of magnitude lower than the lowest value reported previously. The effects of fluence, flux, and corresponding temperature on the distribution and characteristics of the obtained blisters were studied. FIB cross sections of several blisters exposed their depth and structure.

2:30 PM CM05.16.04
Feedback-Based Automated Fabrication in a Scanning Transmission Electron Microscope
Ondrej Dyck1, 2, Sergei V. Kalinin1, 2 and Stephen Jesse1, 2; 1Center for Nanophase Materials Science, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Institute for Functional Imaging of Materials, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

In recent years, a surprising number of electron beam-induced transformations have been observed in the scanning transmission electron microscope (STEM). Such transformations set the stage for harnessing the electron beam as a fabrication tool at the atomic scale, however most of these demonstrations are performed “by hand”. In the development of a tool set for atomic manipulation, feedback-based automated beam control and real-time image analysis are needed to improve the consistency, throughput, and executability of various processes. Here, we present the development of feedback-based tools which interface with the microscope through a custom scan control system. We demonstrate automation-enhanced control of crystallization, amorphization, and dopant movement. To accomplish this, we must address the challenge of detecting material alterations while concurrently attempting to manipulate the material. Because the same electron beam is used for imaging and manipulation we explore techniques to generate meaningful sample information during manipulation and use rapid, sparse scanning coupled with real-time image analysis to extract sample information with minimum beam exposure. These experiments represent the first steps toward transforming the modern STEM from a characterization to a fabrication platform.

2:45 PM CM05.16.05
Towards a Vertical Nanopillar-Based Single Electron Transistor—A High-Temperature Ion Beam Irradiation Approach
Xiaomo Xu1, 2, Karl-Heinz Heinig3, Wolfhard Möller1, Ahmed Gharbi1, Raluca Tiron1, Hans-jürgen Engelmann4, Lothar Bischoff5, Thomas Pruefer1, René Hübner1, Stefan Facsko1, Gregor Hlawacek1 and Johannes von Borany1; 1Helmholtz-Zentrum Dresden-Rossendorf, Dresden, Germany; 2Institute for Functional Imaging of Materials, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

We propose an ion irradiation based method to fabricate a single Si nanocrystal embedded in a Si(001)/SiO2/Si nanopillar layer stack as a prerequisite for manufacturing a CMOS-compatible, room-temperature Si single electron transistor. After either 50 keV broad beam Si+ or 25 keV focused Ne+ beam from a helium ion microscope (HIM) irradiation of the nanopillars (with diameter of 35 nm and height of 70 nm) at room temperature with a medium fluence (2×10^16 ions/cm^2), strong plastic deformation has been observed which hinders further device integration. This differs from predictions made by the Monte-Carlo based simulations using the program TRIDYN. We assume that it is the result from the ion beam induced amorphisation of Si accompanied by the ion hammering effect. The amorphous nano-structure behaves viscously and the surface capillary force dictates the final shape. To confirm such a theory, ion irradiation at elevated temperatures (up to 672 K) has been performed and no plastic deformation was observed under these conditions. Bright-field transmission electron microscopy micrographs confirmed the crystallinity of the substrate and nanopillars after HT-irradiation. When a semiconductor material such as silicon is heated above its amorphisation critical temperature during ion irradiation, it stays crystalline due to an interplay between ion damage and dynamic annealing process. Viscous flow does not occur for the crystalline nano-structures and the shape remains intact. This effect has been observed previously mainly for swift heavy ions and energies higher than 100 keV. Such high-temperature irradiation, when carried out on a nanopillar with Si/SiO2/Si layer stack, would induce ion beam mixing without suffering from the plastic deformation of the nanostructure. Due to a limited mixing volume, single Si-NCs would form in a subsequent rapid thermal annealing process via Oswald ripening and serve as a basic structure of a gate-all-around single electron transistor device.

SESSION CM05.17: In Situ Studies of Radiation Damage
Session Chairs: Grace Burke and Pär Olsson
Thursday Afternoon, November 29, 2018
Hynes, Level 2, Room 202

3:15 PM CM05.17.01
In Situ Studies of Nanoporous Niobium During Dealloying and Irradiation
Maria Kosmidou1, Nicolas J. Briot1, Nathan J. Madden2, Remi Dingreville3, Jessica A. Krogstad4, Khalid Hattar1, John Balk1 and Azin Akbari1; 1University of Kentucky, Lexington, Kentucky, United States; 2University of Illinois at Urbana-Champaign, Urbana-Champaign, Illinois, United States; 3Sandia National Laboratories, Albuquerque, New Mexico, United States.

Nanoporous materials are potentially advantageous in radiation environments, due to the high amount of ligament surface area that can act as a sink for...
defects produced during irradiation. A special technique, thermal dealloying in vacuum, is utilized for the formation of nanoporous refractory metals. In-situ thermal dealloying experiments in the TEM are performed on Nb-Mg alloys for fabrication of nanoporous niobium (np-Nb), where the precursor alloy composition range and dealloying temperature are the main parameters for controlling morphology and residual Mg in the final nanoporous structure. Subsequently, heavy irradiation of np-Nb at different energies and varying total ion dose are performed on samples inside the TEM, creating defect structure within ligaments, as well as possible changes in the overall porous network structure. This presentation will address the formation of np-Nb and its behavior during heavy ion irradiation, with emphasis on the ability of nanoporous structures to accommodate radiation damage.

**In Situ Measurement of the Dislocation Density of Steel During Plastic Deformation Using Ultrasound**

Vicente Salinas1,2, Claudio Aguilar3, Rodrigo Espinoza1, Fernando Lund4 and Nicolás Mujica1; 1Physics Department, Universidad de Chile, Santiago, Chile; 2Núcleo de Matemáticas, Física y Estadística, Facultad de Ciencias, Universidad Mayor, Santiago, Chile; 3Departamento de Ingeniería Química, Biotecnología y Materiales, Universidad de Chile, Santiago, Chile; 4Departamento de Ingeniería Metalúrgica y Materiales, Universidad Técnica Federico Santa María, Valparaíso, Chile.

We report results of local measurements of the speed of transverse waves in 304L steel under standard testing conditions, continuously as a function of applied load. The result, as expected, is independent of stress in the elastic regime, but there is a clear change, consistent with a proliferation of dislocations, as soon as the yield strength is reached. To interpret the results, we use a theoretical model that changes the wave speed on the interaction of elastic waves with oscillating dislocation segments. The relevant formulae quantitatively relate the change in wave velocity with dislocation density Λ and segment length L, thus obtaining a continuous relation between dislocation density and externally applied stress.

The experimental results are compared in some detail with similar measurements obtained with aluminum [1]. The change in velocity as a function of applied stress is smaller in steel than in aluminum, consistent with a higher Peierls barrier.

The theory can be worked out replacing the dislocation segments by dislocation loops [2]. Similar formulae result, in which the dislocation segment length is replaced by the dislocation loop radius. Available STEM images of dislocation loops in FeCrAl after neutron irradiation [3] suggest a density of dislocation loops sufficient to provide a measurable signal. Ultrasound could thus become a non-destructive measuring tool for dislocation density in fuel cladding alloys.

**A New Solid Solution Approach for the Study of Self-Irradiation Damage in Non-Radioactive Materials**

Tsivi Templeman2, Michael Shandalov1, Yuval Golan3 and Eyal Yahel4; 1Physics, NCNR, Beer-Sheva, Israel; 2Materials Engineering, Ben Gurion University of the Negev, Beer-Sheva, Israel.

We present a new method to produce a model system for the study of radiation damage in non-radioactive materials. The method is based on homogeneous incorporation of 229Th ions in PbS thin films using a small volume chemical bath deposition (CBD) technique. Controlled doping of the thin films with minute amounts of a-emitting radioactive elements such as thorium is expected to provide a unique path for studying self-irradiation damage in materials without the need of sealed enclosures, such as gloveboxes and hot cells.

We developed CBD process for controlled doping of PbS thin films with active 229Th and stable 232Th isotopes [1]. The 229Th-doped films were characterized using x-ray powder diffraction (XRD), which indicated a single phase material. Film morphology and thickness were determined using scanning electron microscopy (SEM). Energy dispersive spectroscopy (EDS) mapping in the analytical transmission electron microscope (A-TEM), x-ray photoelectron spectroscopy (XPS) depth profiles and a-aautoradiography indicated that the Th ions were homogeneously distributed throughout the films, suggesting Pb substitution by Th ions in the crystal lattice. Electrical resistivity studies were performed and decay-event damage accumulation was measured, followed by isochronal annealing, which presented two defect relaxation stages and additional sub-stages [2]. Photoluminescence (PL) studies of emissive defect states created in the bandgap due to self-irradiation are on the way. This is the first report on self-irradiating damage studies in IV-VI semiconductors and the resulting films present a novel method for the analysis of dilute defect systems in materials.

**In Situ Irradiation of Carbide Based Hybrides—Challenges and Differences**

Karl R. Whittle1, Tanagorn Kwannmar2, Glynn Cobourne1, W Mark Rainforth3 and Philip D. Edmondson1; 1University of Liverpool, Liverpool, United Kingdom; 2The University of Sheffield, Sheffield, United Kingdom; 3Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Binary carbide hybides based on TiC and SiC, with mixed properties of both single carbides, have been proposed for application within nuclear reactor cores. For such applications to be viable, their response to irradiation induced damage, must be more fully understood. To achieve this a selection of different TiC-SiC mixtures have been irradiated in situ, at the IVEM facility at Argonne National Laboratory, followed by high resolution electron imaging and diffraction at the University of Liverpool, and Oak Ridge National Laboratory. This analysis has indicated that there is a behavioural change with variation in composition, with increasing TiC content giving rise to a system that is more resilient to increasing levels of damage.

4:15 PM CM05.17.05
**In Situ Characterization of Single Ion Strikes in Single Crystal Silicon**

Anthony Monterrosa, James Stewart, Patrick Price, Remi Dingreville and Khalid Hattar; Sandia National Laboratory, Albuquerque, New Mexico, United States.

Understanding the evolution of damage cascades caused by energetic particle strikes has proven difficult for experimental studies. Individual cascade events occur over an extremely limited spatial and temporal scale, which has left most of their exploration to modeling efforts. However, recent in-situ transmission electron microscopy developments have been used to close this gap, allowing for detailed experimental studies of damage cascades. In-situ and ex-situ irradiations were performed at the Sandia Ion Beam Laboratory with Au ions ranging from 46 keV to 1 MeV on single crystal silicon to explore a wide range of cascade morphologies. Procession electron diffraction (PED) was used to experimentally measure the changes in volumetric strain induced by single cascade events by measuring changes in the diffraction spot area. The experimental results were coupled with a molecular dynamics (MD), which simulated the radiation damage events and provided the size, shape, and composition of the defect damage, along with virtual selected area electron
diffraction (SAED) patterns. Information from a single damage cascade can be acquired through direct comparison between the experimental diffraction patterns and the virtual SAED patterns. Additionally, the coupling of the in-situ ion beam with a dynamic transmission electron microscope (DTEM) can provide the unique capability to experimentally probe the collapse of the damage cascade on a nanosecond timescale.

Using Advanced Analytical TEM to Study Irradiation-Induced Microstructural Evolution in Fe- and Ni-Base Alloys Grace Burke1 and Joven Lim2; 1Materials Performance Centre, University of Manchester, Manchester, United Kingdom; 2UKAEA Materials Research Facility, Didcot, United Kingdom.

The requirement to predict long-term behavior of alloys used in nuclear power systems requires the ability to generate high irradiation-induced damage levels in these alloys and the ability to characterise the nanoscale changes in the microstructure leading to changes in mechanical properties. These nanoscale changes in microstructure lead to the evolution of a variety of features including solute-enriched clusters, segregation, precipitation and defects that directly affect the properties of materials. Neutrons, ions and protons all promote these nanoscale changes. Thus, the ability to generate high dose damage levels using ions or protons represents a potential route to producing microstructures that have similar characteristics to those generated by neutrons. The characterisation of these nanoscale features provides data essential for fundamental modelling efforts. This presentation will discuss advanced analytical electron microscopy studies of microstructural evolution in several Fe-base and Ni-base alloys.

CM05.18.01
Particle Irradiation Induced Defects in High Temperature Superconductor Prashanta M. Niraula1, Eiman Bokari1, Shahid Iqbal1, Lisa Paulius1, Matthew Smylie2, Ulrich Welp2, Wai-Kwong Kwok1 and Asghar Kayani1; 1Physics, Western Michigan University, Kalamazoo, Michigan, United States; 2Argonne National Laboratory, Lemont, Illinois, United States.

Particle irradiation technique can be used to induce defects in High Temperature Superconductor (HTS) such as Y$_2$Ba$_2$Cu$_3$O$_{7-x}$ (YBCO). These defects can act as pinning centers to restrict the motion of magnetic flux vortices, which as a result can increases the critical current density ($J_c$). Depending on the mass and energy of the particle and the properties of the target material, irradiation enables the creation of defects with well-controlled density and topology, such as points, clusters, collision cascades or linear tracks. Furthermore, irradiation allows for the combination of defects with different morphologies or to add to pre-existing defects at densities that are interesting for vortex pinning, all without changing the chemistry of the sample. This creates the so-called mixed pinning landscapes that have proven very effective in high magnetic fields. In this work, HTS coated conductors containing Barium zirconate nanorods as pre-existing defects were irradiated with 50 MeV copper ions at angles of 0°, 15° and 30° from the crystallographic c-axis. We observed moderate enhancement of $J_c$ at 5 K at high fields in samples irradiated at 30° and a suppression in others.

CM05.18.02
Photoluminescence Properties in Aliphatic-Aromatic Biodegradable Polymers Induced by Low Energy Radiation Elisete L. Cunha2, Thiago Schmitberger2, Victor A. Rosas1 and L.O. Faria1; 1Materials, Centro de Desenvolvimento da Tecnologia Nuclear, Belo Horizonte, Brazil; 2Nuclear Engineering, Federal University of Minas Gerais, Belo Horizonte, Brazil.

Poly(butylene adipate-co-terephthalate) (PBAT) is a biodegradable aliphatic-aromatic copolyester. The radio induction of photoluminescence (PL) properties in PBAT, after exposure to high doses of gamma radiation, was firstly reported by T. Schimitberger et al. (2014). The material shows the highest photo-stimulated luminescence emission when excited with a light-emitting diode (LED) source at wavelengths ranging from 370 to 405 nm. These new PL properties may have great potential for applications in in vitro imaging of human cancer, bio-imaging devices and radiation dosimetry. However, most of these applications are possible just for biocompatible materials. For comparison purposes, the irradiations were performed under air and O$_2$(g) atmospheres. PL emission, UV-Vis and FTIR spectrometry were used to characterize the relationship between UV doses x PL Intensities and to reveal the mechanisms behind the post-irradiation PL character in PBAT samples. Peak fitting of FTIR data using Gaussian lines indicates the radio induction of molecules attached to aromatic hydrocarbons via chain scission. The high quantum yield emission of UV-induced PL near 500 nm, observed in PBAT, is a very interesting finding because it involves the development of a new cheap biodegradable photoluminescent polymer that could find applications in radiation dosimetry and bio-imaging.

CM05.18.03
Vertical Nanowires Enhanced X-Ray Radiation Damage of Cells Qingxuan Li, Liyuan Zheng and Ming Su; Northeastern University, Boston,
Cell behavior is affected by nanostructured surface, but it remains unknown how ionizing radiation affects cells on nanostructured surface. This abstract reports an experiment investigation of X-ray radiation induced damage of cells placed on an array of vertically aligned silicon nanowires. X-ray photoelectrons and secondary electrons produced from nanowire array are measured and compared to those from a flat silicon substrate. The cell functions including morphology, viability, adhesion and proliferation have been examined and found to be drastically affected when cells are exposed to X-ray radiation, compared to those sitting on flat substrate and those only exposed to X-ray. The enhanced cell damage on nanowires upon X-ray exposure is attributed to nanowire enhanced production of photoelectrons including Auger electrons and secondary electrons, which have high escaping probability from sharp tips of nanowires. The escaped photoelectrons ionize water molecules and generate hydroxyl free radicals that can damage DNAs of cells. An inference of this work is that the contrast in scanning electron microscopy is useful in assessing the effects of nanomaterials for enhanced X-ray radiation therapy.

CM05.18.04
Study on H in Fe/W Interface by DFT Calculation Jinnming Shi and Naoyuki Hashimoto; Hokkaido University, Sapporo, Japan.

In the development of fusion reactors, tungsten (W) and reduced activation ferritic/martensitic (RAFM) steel are strong candidates as divertor and structure materials of blanket. Many researches have devoted a lot of effort on the radiation effect on W as well as on RAFM steel. Obviously, W component should be connected to RAFM steel in reactor, thus the cohesion properties between W and RAFM steel play an important role in their performance. In this study, a Fe(001)/W(001) interface configuration is built as a model for the cohesion between RAFM steel and W. The mono-vacancy and the dissolution behavior of H in the interface region are studied. This work is conducted by density functional theory (DFT) calculation. And all calculations are implemented by GPAW, a DFT calculation code. Results show that, in the interface region, the lattice of Fe and W are different from in bulk materials. The vacancy formation energy (Ev) in W side in interface region is smaller compared it in bulk W, while the Ev in Fe side in interface is slightly higher than it in bulk Fe. From Fe side to W side, the dissolution energy of hydrogen in interface increases which indicates that the H prefers to stay in Fe side and the H in W side could diffuse to Fe side since no sink effect of the interface is found. And, the effect of vacancy and H atom on strength of the Fe/W interface is investigated. Vacancy in interface region make the strength of interface decrease. At most cases, H atom also make the strength of interface decrease.

CM05.18.05
Study of Nanopatterning Formation Dynamics by Ion Beam Bombardment on GaSb Angelica Hernandez, Rene Asomoza-Palacio, Miguel Avendaño and Yuriy Kudriavtsev; CINVESTAV, Mexico City, Mexico.

Abstract: In this work we have studied the formation of ordered nanostructures on the surface of gallium antimonide (GaSb) under ion irradiation. The substrate temperature was varied from room temperature (RT) up to 300 °C. The GaSb surfaces were bombarded by using a polyatomic bismuth ion beam (Bi^{m+}), from where Bi1+ and Bi3+ were selected as the incident ions, respectively. The energy beam utilized was 15 and 30 keV, whilst the angle of incidence was chosen to be 0° or 45°. Different morphologies were observed for 45° angle of incidence and elevated substrate temperature depending on ion fluences. The morphological characteristics of nano dot patterns formed at normal incidence of the ion beam, were studied by atomic force microscopy (AFM). Also, the chemical and structural properties were characterized for micro Raman. We carried out a detailed study of the effects of substrate temperature, ion fluence, type of incident ion, energy beam and angle of incidence on the morphological characteristics of nano dot patterns.

CM05.18.06
The Effect of Radiation Fluence on the Performance of a High Voltage CMOS Monolithic Active Pixel Sensor Using TCAD Simulation Tuan A. Bui, Haip Tran, Geoffrey Reeves, Patrick W. Leech and Anthony Holland; School of Engineering, RMIT University, Melbourne, Victoria, Australia.

Pixel semiconductor detectors with position sensitivity have played a critical role in the success of high energy physics experiments. Located only a few centimeters from the collision point of the beam at the innermost layer of the ATLAS detector system, the pixel detectors and their electronics have been required to withstand a high fluence of radiation. This paper presents a simulation using computer aided design (TCAD) of the effect of variation in the flux of ionizing radiation on the performance of a high voltage complementary metal-oxide-semiconductor (HV-CMOS) monolithic active pixel sensor (MAPS). The simulation has been performed using an existing TCAD model of a single pixel HV-CMOS MAPS with an on-pixel source follower amplifier [1]. The model was based on the impact of a minimum ionization particle which generated ~280000 electron-hole pairs in a thickness of silicon of 300μm when fully depleted at 120V bias [1]. The present work has expanded the modeling of the behavior of the detector by examining the effect of variation in the fluence of radiation on the range 10^13 - 10^16 n_{eq} cm^{-2}. The induced radiation damage has been simulated using a 3-level trap model for a p-Si detector [2] to investigate the degradation in the performance of the detector as a function of varying fluence. The simulations of single event upset have also been performed on the NMOS and PMOS transistors which were used to implement the on-pixel readout circuit.

CM05.18.07
Induced Order-Disorder Transformations in Fluorite Based Oxides Michelle R. Moore1, Maulik K. Patel1-2, Susan Morgan1, David Hambly1, Kurt Sickafus1, Gianguido Baldi2 and Karl R. Whittle1; 1School of Engineering, University of Liverpool, Liverpool, United Kingdom; 2Materials Science and Technology Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States; 3Materials Science and Engineering, The University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 4Laboratoire Structures, Propriétés et Modélisation des Solides, CentraleSupelec, Gif-sur-Yvette, France; 5National Nuclear Laboratory, Seascale, United Kingdom.

Fluorites and fluoride-related materials are of interest within the nuclear context, primarily due to the use of UO2 as the predominant fuel in reactors, along with pyrochlore/zirconolite/fluorite being a key waste form for actinide immobilisation. This study examines the radiation damage response of fluoride-derivative structures within the Sr2O−H2O system. Such oxides, for example δ-Sr6H4O12, γ-Sr5H3O12 and β-Sr5H2O3, exhibit distortion away from the ideal fluorite crystal lattice undergoing an order-to-disorder transformation upon irradiation. Samples of γ-Sr6H4O12 and β-Sr5H2O3 were irradiated by 400 keV Ne and 600 keV Kr under cryogenic conditions with fluences between 1x10^16 to 1x10^17 ions cm^{-2}. Irradiations by 400 keV He were undertaken on δ-Sr6H4O12 and γ-Sr5H3O12 samples at 500°C, at fluences of 1x10^16 and 1x10^17 ions cm^{-2}.

Analysis of the induced changes has been undertaken using grazing incidence X-ray diffraction (GIXRD), Raman spectroscopy and electron imaging/diffraction, to elucidate the order to disorder transformation. The results will then be compared with similar transitions in other nuclear-related oxides, such as the pyrochlore-disordered fluorite transformation.
CM05.18.08  
Irradiation Behavior of Multi-Layer Coatings on ZIRLO for Accident Tolerant Fuel Cladding  
Jamie K. Nansen1, Maulik K. Patel1, Yongqiang Wang2 and Karl R. White1; 1School of Engineering, University of Liverpool, Liverpool, United Kingdom; 2Materials Science and Technology Division, Los Alamos National Laboratory, Los Alamos, New Mexico, United States.

The continued development of accident tolerant fuels/coatings is a key driver in the continuing nuclear renaissance, in a bid to minimize the chances of an event similar to Fukushima Daiichi repeating. As a consequence of this we have examined a range of multi-layer coatings based on Nb, Al, and C, focusing in particular on how they behave under ion irradiation as a proxy for neutron damage expected within a core. Once irradiated these coated samples underwent oxidation testing at 360 °C, modelling the conditions expected within a PWR. The coatings were irradiated with 400 keV Kr and 150 keV C, both at 300 °C, across a range of fluences, up to 9 x 10^16 ions cm^-2. The damaged materials were subsequently analysed using electron microscopy (SEM, EDX, and TEM) coupled with grazing incidence X-ray diffraction (GIXRD) and Raman spectroscopy. Results indicate there is significant improvement over uncoated ZIRLO under the same conditions, suggesting the possibility of use within a reactor core.

CM05.18.09  
Broad-Beam Simulations of Si+ Ions in Stacked Si/SiO2: Heterostructures for Meta-Stable SiOx Formation  
Christoffer Fridlund1, Kai Nordlund2 and Flyura Djurabekova 1, 2, 3; 1University of Helsinki, Department of Physics, Helsinki, Finland; 2Helsinki Institute of Physics, Helsinki, Finland.

There is no easy way to commercially manufacture Single Electron Transistors (SET) at large scale. A method for creating the nanostructures needed for operating SETs at room temperature (RT), is to use low energetic broad-beam irradiation (25 to 60 keV) inducing atom-mixing over the interfaces in a stacked Si/SiO2/Si semiconductor structure. An excessive amount of Si atoms are transferred into the SiO2 matrix from the surrounding Si layers. By controlling the fluence of the broad beam, it is possible to control the atomic density profile of the Si atoms along the axis of the irradiation.

The excessive Si in the SiO2 layer, give rise to a difference in the atomic density profile around the interfaces, and meta-stable SiOx is formed in these regions. When the system is annealed, Si nanoclusters form through self-assembly towards the center of the SiO2 slab. Both the size and the location of the nanocluster is crucial for flawless operation of the SET at RT. The diameter of the SET should be around 2 nm, and the tunneling distances should be in the range of 1.5 nm to 2.5 nm both above and below the nanocluster. A 7 nm thick SiO2 slab with 25 nm c-Si on top and 20 nm c-Si below, are cut into pillars for the simulations. We use Molecular Dynamics (MD) to simulate the 25 keV Si+ broad-beam conditions in various Si/SiO2 systems. The annealing process is simulated with Kinetic Monte Carlo (KMC) based on the density profiles from the MD simulations. The Stillinger-Weber-like Watanabe potential was used to simulate Si-Si, Si-O, and O-O interactions. The interactions of the kinetic ions were handled by the universal repulsive ZBL potential. To speed up the MD simulations, we allowed 10 ion cascades to develop consecutively (1.5 ps each), all ending with a temperature quench back to RT, alternated by a longer relaxation run (5.0 ps). Repeating the steps until the desired fluence of 1.5E16 cm^-2 was achieved.

During irradiation, the systems are shrinking along the beam direction. This is in good agreement with experiments done on similar pillars at RT. However, while the dynamics in the experiment most likely come from sputtering effects, the dynamics of the simulations are a combination of both sputtering and the hammering effect, caused by short simulation times, not allowing the system to recrystallize inbetween the ion cascades. Coordination analysis indicate some overcoordination of the O, but this is expected due to the meta-stable SiOx. Reference simulations of pure Si pillars generate the same general shape change.

The work has been funded by Svenska Kulturfonden and the European Union's Horizon 2020 research and innovation program under grant agreement No 688072.

Influence of Temperature on Nanofabrication Using Swift Heavy Silver (Ag+) Ion Irradiation on GaSb  
Satish Kumar1, 2, Ajit K. Mahapatro2 and Pusparshree Mishra1; 1DRDO, Solid State Physics Laboratory, Delhi, India; 2University of Delhi, Delhi, India.

 Gallium antimonide (GaSb) nanostructures have stimulated interest because of unique quantum confined nanoscale properties. GaSb has low band gap and high hole mobility, which makes it a suitable candidate for various potential applications such as high frequency electronics, low power consumption electronics, near to mid infrared optoelectronics, and gas/chemical/bio-sensing devices etc. Ion irradiation technique has been effectively used to fabricate several kinds of nanostructures such as nanofibers or nanodots etc. The growth of semiconductor nanostructures in a controlled manner is the key for the development of future optoelectronic devices. This technique is versatile, cost effective, well controlled and reproducible for the spontaneous fabrication of different shapes of semiconductor nanostructures.

This work presents the fabrication of GaSb nanodots using swift heavy silver (Ag+) ion irradiation with ion fluence range from 1x10^12 to 1x10^16 ions/cm^2 under normal incidence at two different temperature (300K and 77K). The GaSb epitaxial layers were grown on semi-insulating gallium arsenide (GaAs) (001) substrates using molecular beam epitaxy (MBE). The surface morphology and crystalline quality of pristine and silver ion irradiated GaSb samples were characterized using atomic force microscopy (AFM) and Raman spectroscopy techniques respectively. The AFM micrograph of pristine GaSb sample shows that the surface is featureless and smooth with minimum rms (root mean square) surface roughness of 1.51 nm. Room temperature irradiation on GaSb samples clearly indicates the formation of well defined nanodots. The nanodots seem to be uniformly distributed over the surface and they coalesce with each other give rise to bigger dots for increasing ion fluences. Over a certain ion fluence (1x10^15 ions/cm^2) a smooth surface is observed. The presence of nanodots was also observed on irradiated GaSb samples using similar parameters at low temperature (77K) ion irradiation. However, the nanodots at 77 K are not well developed and are irregularly shaped as compared to the 300 K ion irradiation. The smoothening of irradiated surface starts at earlier ion fluence (6x10^15 ions/cm^2) for 77K compared to 300K samples (1x10^14 ions/cm^2). The dot morphology at the two different temperatures are analyzed by considering the different rates of surface diffusion of adatoms. Raman spectrum for pristine GaSb sample indicates good crystalline quality of epitaxial layer. The LO and TO phonon modes are found to shift to lower wave numbers with increasing ion fluence for irradiated GaSb surfaces at both temperature (77K and 300K). This is due to the presence of tensile strain in irradiated GaSb samples. Raman analysis reveals higher disorder in silver irradiated GaSb samples at 77K compared to 300K samples.

Defect Formation on Ultrathin Films with Highly Charged Ions  
Ardak Ainabayev1, Masahito Niibe3, Mititaka Terasawa4 and Zinetula Z. Lugnapin1, 2; 1School of Nuclear Engineering, Purdue University, West Lafayette, Indiana, United States; 2Condensed Matter Physics, National Research Nuclear University MEPhI, Moscow, Russian Federation; 3Nazarbayev University, Astana, Kazakhstan; 4Laboratory of Advanced Science and Technology for Industry, Kouto, Japan.

Irradiation of ultrathin films by highly charged ions (HCl) offers a very shallow modification of the surfaces by easily controlling the density and the size of defects by changing fluence of ions (ion current and irradiation time) and the potential energies of bombarding ions. Defect formation in the samples of ultrathin films such as graphene, graphene oxide, and MoS2 by HCl irradiations were studied. Highly-charged ions
(HCl) Xeq+ (q = 22, Ekin=400 keV), were used to irradiate ultrathin films at National Nuclear Center, Astana, Kazakhstan, using a DC-60 cyclotron accelerator. Since the mechanisms of defect formation, charge neutralization and screening during HCI interaction with graphene are not clear and require further investigations [1], the study of the irradiated samples was conducted using Raman spectroscopy, atomic force microscopy (AFM), and NEXAFS (Near-Edge X-ray Absorption Fine Structure). The Raman spectroscopy (Horiba) study of the irradiated samples was conducted by a 632 nm laser wavelengths and 100x objective with a laser spot size of ~1 μm, 2 mW power and atomic force microscopy (AIST NT) measurements were carried out in a tapping mode by SUPERSHARP SILICON™ AFM probes for high resolution. NEXAFS spectroscopy measurements were carried out at the NewSUBARU BL09A beamline of the New SUBARU SPring8 LASTI facility at the University of Hyogo, using total-electron yield (TEY) method and without uncompleted correction of energy.

CM05.18.12
Influence of Temperature, Humidity and Light-Intensity on the Conductivity of Solution-Processed Zinc Oxide Thin Films
José B. Cantuária2, Giovani Gozzi1 and Lucas Fugikawa Santos1,2; 1São Paulo State University, Rio Claro, Brazil; 2IBILCE, São Paulo State University, São José do Rio Preto, Brazil.

Zinc oxide (ZnO) is a n-type transparent semiconductor which can be processed by low cost techniques, as spray-pyrolysis and spin-coating, and can be applied as active layer in a variety of electronic devices, including photodetectors and thin films transistors (TFTs). Electrical properties of ZnO TFTs, as threshold voltage, charge carrier mobility and on/off ratio, are strongly affected when the device it is exposed to room conditions. The current explanation to these effects considers the adsorption of atmospheric oxygen molecules, which acts as traps of charge carriers (electrons). In the current work, we studied the influence of environmental parameters, as temperature, humidity and light irradiance, on the electrical conductivity of spin-coated ZnO thin films. The experiments were performed using ZnO thin films with aluminum electrodes in a planar structure. The electrical current with the device biased at a fixed d.c. voltage was measured as a function of the exposure time to light from a filament/discharge lamp which simulates the solar spectrum (visible and UVA and UVB ranges). Variations on the film conductivity were interpreted as a consequence of adsorption-like and desorption-like processes of charge carrier traps, as atmospheric oxygen. As standard, we considered that desorption-like (adsorption-like) processes improves (reduces) the electrical conductivity and, as consequence, the device electrical current. We obtained that a desorption-like process dominates at the beginning of device irradiation (increasing the electrical conductivity) and, after a maximum current is reached, an adsorption-like process dominates, decreasing the electrical current until to a steady state is achieved. The concentration of carrier traps was determined from the current vs. time curves using the Henry model of adsorption and we verified that adsorption/desorption rates are exponentially dependent on time. The initial adsorption/desorption rate and the time constant of each exponential process were determined and used to evaluate the influence of the environmental parameters. This evaluation was performed using a Plackett-Burman experimental design analysis. The factorial analysis shows that the irradiance is the main factor which influences the adsorption/desorption rates. Environmental factors as the temperature and the humidity influence the overall device conductivity, however, do not presented significant influence on the adsorption/desorption rate, which is basically dependent on the irradiance in the observed range.

SYMPOSIUM EP01
TUTORIAL: Introduction to Pyroelectric, Piezoelectric, and Ferroelectric Materials
November 25 - November 25, 2018

* Invited Paper

TUTORIAL
Introduction to Pyroelectric, Piezoelectric and Ferroelectric Materials
Sunday Morning, November 25, 2018
Hynes, Level 2, Room 201

Polar materials continue to be an important class of functionality for modern applications that provides direct and indirect convolution of structure and chemistry from the atomistic to the macroscopic level. This tutorial will introduce researchers to the basic physics of polar response, its connection to fundamental structure and symmetry, synthesis of polar materials and characterization methods. Topics will also cover the connection between polar properties and desirable functionality in application such as sensing and optoelectronic properties. This tutorial will then culminate with hands-on exercises to explore the functionality, synthesize ability, and characterizability of polar materials in the Materials Project.

Optimization of Si/ZnO/PEDOT:PSS Tri-Layer Heterojunction Photodetector by Piezo-Phototronic Effect Using Both Positive and Negative Piezoelectric Charges Fangpei Li, Wenbo Peng, Zijian Pan and Yongning He; Xi'an Jiaotong University, Xi'an, China.

Piezo-phototronic effect has been extensively introduced to improve the performances of optoelectronic devices by utilizing external-strain-induced positive or negative piezoelectric charges (piezo-charges) to modulate the generation, separation, transportation, and recombination of charge carriers. However, in most cases till today, only the piezo-charges with one polarity (i.e., positive or negative) are effectively utilized. In this work, we fabricated an n-Si/n-ZnO/p-PEDOT:PSS tri-layer heterojunction photodetector (HPD) and systematically investigated the piezo-phototronic effect on its performances simultaneously utilizing both positive and negative piezo-charges for the first time.

In experiment, the photo-responses of the HPD to 405 nm and 648 nm laser illuminations under different externally applied compressive strains indicate the existence of an optimized compressive strain to achieve the maximized enhancements. For example, the photoresponsivities to 405 nm and 648 nm laser illuminations are gigantically improved, and reach 0.218 A/W (under -10.73‰ compressive strain) and 0.012 A/W (under -6.52‰ compressive strain), respectively. Compared to photoresponsivities under strain free condition, the enhancements achieve over 3000% and 1800%, respectively. Other figure of merits as a function of compressive strain, such as photocurrent and specific detectivity, also exhibit a similar optimizing tendency.

The optimizing phenomena are due to the positive and negative piezo-charges at n-Si/n-ZnO and n-ZnO/p-PEDOT:PSS interface, respectively, that introduce different adjustments to the local energy band diagrams which have either enhancing or weakening effects on the behaviors of photo-generated carriers. Under a relatively small compressive strain, the enhancing influences play a dominant role so the photo-responses are improved. As strain rises, some weakening influences outgrow others, therefore the photo-responses are degraded. This competition mechanism is a combined result of both positive and negative piezo-charges, and eventually produces an optimized modulation to the photo-responses of the HPD. Theoretical validation is implemented by finite element analysis simulations and simulation results show that the strain-induced variations in energy band diagrams in the vicinity of the n-Si/n-ZnO and n-ZnO/p-PEDOT:PSS interfaces are both in good accordance with the proposed working mechanisms.

This work not only presents the utilization of both positive and negative piezo-charges to optimize the performances of the HPD by the piezo-phototronic effect, but also provides a deep understanding of how the piezo-charges of two opposite polarities work together in one optoelectronic device, hopefully proposing the idea of introducing the piezo-phototronic effect into three-/multi-layer devices in future applications.
of 80 nm serves as bottom electrode for the CGO electrostrictor. The direct deposition yields impressive electrostrictive performances (50 m^4/C^2) and long term stability for CGO films of ca. 1 μm in thickness.

First-Principles Studies of the Effects of Oxygen Vacancies on the HfO2-Based Ferroelectric Tunnel Junction Jinho Byun, Taewon Min and Jaekwang Lee, Physics, Pusan National University, Busan, Korea (the Republic of).

Owing to the recent advances in the oxide growth technology, ferroelectricity has been stabilized even in a few nm-thick films, which makes it possible to realize the oxides-based ferroelectric tunneling junction (FTJ) combining the quantum-mechanical tunneling phenomena and switchable spontaneous polarization into novel device functionality. Among various ferroelectric oxides, HfO2 is the most promising material for FTJ devices since it has the great advantage of complementary metal-oxide-semiconductor (CMOS) process compatibility. Despite this considerable attention, the influence of oxygen vacancies on the tunneling current has not been clearly understood yet. Here, using first-principles density functional theory calculations, we explored the role of interfacial oxygen vacancy on the tunneling current in the Ti/HfO2/metal devices at the atomic scale. We find that the tunneling current in defective HfO2 is enhanced by over three orders of magnitude compared to plain HfO2 thin film. Our results show that the modulation of electronic properties via interfacial oxygen vacancy has a significant impact on HfO2-based FTJ device performance.

This research was supported by the MOTIE (Ministry of Trade, Industry & Energy (#10080643) and KSRC (Korea Semiconductor Research Consortium) support program for the development of the future semiconductor device.

9:15 AM EP01.01.04
Dynamical Mean Field Theory Investigation of Piezoresistive Thin-Film Rare Earth Compounds Contacted to Metal Electrodes Ivan Rungger1*, Evgeny Plekhanov2, Deblina Banerjee2, Andrea Droughe2, Dennis News6, Cedric Weber2 and Glenn J. Martyna4; 1National Physical Laboratory, Teddington, United Kingdom; 2Kings College London, London, United Kingdom; 3University of the Basque Country, San Sebastian, Spain; 4IBM Thomas J Watson Research Center, Yorktown Heights, New York, United States.

The emerging piezoelectric transistor technology is based on heterostructures combining piezoelectric materials and piezoresistive thin films acting as ON/OFF switches and memories. Rare earth piezoresistive compounds such as SmS, SmSe and SmTe exhibit a reversible metal-insulator phase transition driven by either light, voltage or pressure, which can be applied by the piezoelectric. For device applications the contact with the metal electrodes critically affects switching behaviour in nanoscale piezoresistive materials, which has not been studied so far. Here we present first principles calculations to model these phase transitions both in the bulk and in nanoscale thin films used in transistor applications, and predict how switching can be induced by mechanical and electrical means in nanoscale devices. Importantly, density functional theory with semi-local exchange correlation functionals cannot correctly treat the strongly correlated electrons in the f-orbitals of Sm. We overcome this limitation by using our recent implementation of the dynamical mean field theory, and show good agreement with experimental data for the electrical and mechanical switching properties.

9:30 AM EP01.01.05
Three-Dimensional Interconnected Piezoelectric Ceramic Foam Based Composites as Flexible, High-Performance Piezo/Pyroelectric Materials for Concurrenrt Mechanical and Thermal Energy Harvesting Sulin Zhang1, Qing Wang2, Guangzu Zhang3 and Peng Zhao1, 1The Pennsylvania State University, University Park, Pennsylvania, United States; 2Huzhong University of Science and Technology, Wuhan, China.

Flexible Piezoelectric (PZT)-polymer composites with superior piezoelectric effect have received much attention for a wide range of applications, particularly in energy harvesting. However, classical PZT-polymer composites with low-dimensional ceramic fillers suffer from low piezoelectricity, owing to the poor load-transfer efficiency from the polymer matrix to the active ceramic fillers. The fundamental mechanics is that the load-transfer efficiency for these composites scales with the rigidity of the polymeric matrix to that of the ceramic fillers, a value typically on the order of 10^-5. Here we introduce a cost-effectively producible ceramic-polymer composite consisting of three-dimensional (3-D) interconnected piezoelectric microfoams in polydimethylsiloxane (PDMS) matrix. The resulting composite breaks the conventional scaling law of the load-transfer efficiency, and enables continuous strain and heat transfer, giving rise to exceptionally improved piezo and pyroelectric effects as compared to those based on low-dimensional ceramic fillers. The 3-D composite is also mechanically flexible, robust, and durable, able to sustain thousands of thermomechanical cycles without noticeable degradation, while yielding stable piezo/pyroelectrical signals. We further demonstrate that combining the piezo and pyroelectric effects of the 3-D composites enable concurrent mechanical and thermal energy harvesting. These attributes, along with the scalable production, make the 3-D composite attractive to a wide range of applications in soft robotics, wearable electronics, and artificial muscles and skins, etc.

9:45 AM EP01.01.06
Potential Ferroelectric Binary Oxides Beyond Hafnia Rohit Batra1,2, Huan Tran1, Brienne Johnson, George Rossetti1, Jacob L. Jones1 and Rampi Ramprasad1; 1University of Connecticut, Storrs, Connecticut, United States; 2Georgia Institute of Technology, Atlanta, Georgia, United States; 3North Carolina State University, Raleigh, North Carolina, United States.

In the past couple of years, there have been extensive empirical and theoretical efforts to elucidate the surprising phenomenon of ferroelectricity recently discovered in hafnia (HfO2) thin films (~30 nm) [1-5]. While the origin of this unexpected ferroelectric (FE) behavior is associated with the formation of the metastable orthorhombic Pca21 phase owing to unusual thermodynamic or processing conditions [2,4], the most critical lesson to be learned from the example of hafnia is that even binary oxides can be FE if low-lying metastable (or noble) phases are present. Thus, in this contribution, we extend the findings from the case of hafnia to discover new FE binary oxides, as opposed to the traditionally explored class of perovskite-structured oxides, using computations. We employed a combination of structure search methods, first principles computations and group-theoretical considerations to find at least six simple oxides as potential ferroelectric candidates. Among them, a previously unexplored candidate, CaO2, was successfully synthesized in the polar Pca21 phase, in accordance with our theoretical predictions. Furthermore, the high occurrence (~40 %) of low-energy polar phases among the oxides considered in this work strongly advocates the possibility of discovery or engineering ferroelectricity in many more simple oxides beyond hafnia.

Kinetic Monte Carlo Simulations of Organic Ferroelectrics Tim Cornelissen, Indre Urbanaviciute and Martijn Kemerink; Linköping University, Linköping, Sweden.

Organic ferroelectric materials are emerging as a class of materials that may find application in a broad range of fields; for instance, they might solve the ‘missing memory’ problem in printed electronics. However, a full understanding of their switching kinetics on all length and time scales is still lacking. A variety of computational models have been employed to tackle this problem and to study different aspects of organic ferroelectrics. However, these are usually restricted to idealized morphologies or short time scales.

In contrast, we have developed an electrostatic model that, when used in kinetic Monte Carlo simulations, can reproduce the ferroelectric properties and kinetics on experimental time scales and for realistic 3D morphologies. We apply this model on the prototype small molecular ferroelectric trialkylbenzene-1,3,5-tricarboxamide (BTA).

We simulate hysteresis loops and depolarization curves and find a good agreement with experiments. Like the experiments, the dependence on frequency and temperature of our model results can be interpreted in the framework of thermally activated nucleation limited switching. Specifically, we find two different modes of switching, each associated with their own kinetics and energetics. One mode corresponds to a full rotation of the dipoles, while the other mode only flips the component along the polarization axis. The existence of these two modes is confirmed by molecular dynamics simulations. Both simulation methods find that the second mode has a lower coercive field and thus is the one occurring in polarization switching experiments.

We also investigate the effect of structural disorder on the ferroelectric properties. When the disorder in the system is increased, the retention time decreases dramatically, while the coercive field remains mostly unchanged. For device applications a high retention time and moderate coercive field is required. Aside from providing a detailed insight into polarization switching processes on experimental length and time scales, our model thus is also able to provide guidance in improving the performance of ferroelectric devices.

11:15 AM EP01.01.09
Lone Pair Engineering for Multi-Functional Polar Semiconductors Aron Walsh; Imperial College London, London, United Kingdom.

Beyond the group oxidation state (V), post-transition metals can adopt a lower (V-2) oxidation state, which is associated with a metal s² lone electron pair. Solid-state lone pairs, as found in the compounds formed of ions such as In(I), Sn(II), Sb(III), and Te(IV), are linked to the formation of asymmetric local coordination environments and non-centrosymmetric crystal structures [1]. Lone pairs underpin the physical properties of many piezoelectric, pyroelectric and ferroelectric materials.

I will discuss progress in the understanding of structure and reactivity of lone pair containing compounds, including the driving force for structural distortions and how they can be controlled to enable novel functionality. Applications areas to be discussed will include thermoelectric devices that incorporate high levels of phonon anharmonicity (e.g. SnSe [2]), photovoltaic cells based on photoferroic semiconductors (e.g. Pb and Sn halide perovskites [3]), as well as new classes of ternary V-VI-VII semiconductors based on Bi and Sb chalcohalides [4,5] that encompass photocatalysts, Rashba semiconductors, and topological insulators.

Sulfurization, an anion substitution to oxide materials is considered a progressive route for designing new multi-functional materials artificially and realization of unusual physical properties which do not exist in nature. Sulfur among the other anions has got major attraction due to its isoelectronic nature and large ionic radius compared to oxygen. However, the sulfurization to polycrystalline perovskite other than bulk single crystal perovskite oxides is rarely reported due to the synthetic limitation. Despite this an alternative feasible synthetic route is developed to better understand the structural and physical properties sulfur is doped quantitatively at atomic level. Sulfur doped ferroelectric perovskite [Pt(Zr,Ti)O3] is grown epitaxially by employing the thiourea (CH2,N2,S) solution at various mole ratio using sol gel method. Microscopic analyses of electronic and crystal structures reveal that oxygen ions are substituted by sulfur atoms with tetragonal distortion. In response to this structural phase transition, macroscopic ferroelectric polarization is enhanced, although a band gap is reduced. More details of theoretical calculations and experimental results will be presented in conjunction with a discussion about the potential usage of our synthetic technique in aspect of novel material design.

Nanostructured composite materials have the potential to overcome challenges in many areas of materials research, which cannot be addressed by more conventional single-phase materials. The unique properties of these composite materials often arise due to unique phenomena that occur at the interface between the phases being coupled. An additional control is the anisotropy of the individual phases and the resultant composite, which can be used to control the magnitude and direction of composite properties. For example, ferroelectric and ferromagnetic materials can be combined to form composites with enhanced multifunctional exchange coupling properties. Here, I will present on these composite materials prepared using the electrospinning technique, generating materials with controllable anisotropy and resultant properties. Specifically, Janus type nanofibers, where two phases are coupled longitudinally, are used to create an anisotropic building block that allow access to both surface and bulk properties of each phase. This novel architecture is linked to an anisotropic interface between the coupled phases, and a model is developed relating fiber composition to interfacial area and resulting functional properties. Applications of these composites as zero-power magnetic field sensors will also be presented.

Enhancement of Ferroelectricity in Perovskite Oxides by Sulfurization Muhammad Sheeran, Ill Won Kim, Chang Won Ahn and Tae Heon Kim; Department of Physics and Energy Harvest Storage Research Center, University of Ulsan, Ulsan, Korea (the Republic of).

Ferroelectric HfO2 Growth from HfCl4 –ZrO4 Solid Solution for Stress/Strain Induced Grain Formation and Defect Control at Oxide-Semiconductor Interface Mahmut Sami Kavrik1, Evgenii Chagarov1, Michael Katz2, Norman Stanford2, Albert Davydov2, Min-Hung Lee2 and Andrew Kummel2; 1University of California, San Diego, La Jolla, California, United States; 2National Institute of Standards and Technology, Gaithersburg, Maryland, United States; 3National Taiwan University, Taipei, Taiwan.

Recent findings in ferroelectric HfO2 and discovery of negative capacitance may provide unexpected improvements in CMOS due to scalability of HfO2 and ease of integration. Ferroelectricity can be induced into thin film HfO2 via doping (Al, Y, Gd, Si), but the composition window for each dopant is narrow, sometime only +/-2%. Conversely, Zr doped HfO2 has a broad stoichiometry window (+/- 15%) in which ferroelectricity can be stabilized. The mechanism for stability of the phases of HfO2, ZrO2, and HZO (H2O,Zr/2O3) were investigated with DFT-MD to determine the origin of large process window of ferroelectric phase for the binary HfZrO oxides. It was shown that for all three oxides although the bulk states of the monoclinic phase (m°) are more stable than either the orthorhombic ferroelectric (“f”) phase or tetragonal (“t”) phases and even the surface free energy does not favor f-phase formation. Instead, the higher surface area per unit cell induced by the stress/strain due to post annealing of the amorphous oxide with a crystalline capping layer such as TiN can favor the orthorhombic f-phase since it has a larger area per unit cell than the monoclinic phase; the only requirement is that epitaxial crystallization occurs over at least 5 unit cells of the capping layer. Consistent with this hypothesis, high resolution TEM images of TiN/HZO/Si gate stacks shows regions of epitaxial alignment between HZO and TiN. To improve the consistency of HZO ferroelectric gates, a new method of deposition was developed. The conventional method of Zr doping into HfO2 employs consecutive ALD cycles of ZrO2 and HfO2 in a nanolaminate structure from separate precursors. This process may limit intermixing of the Hf and Zr when the oxide is scaled to 1.5 nm as required for commercial CMOS devices. Furthermore, this process can limit the defect control at the oxide semiconductor interface due to necessity of the precise control of the oxidant between two precursors to maintain precise stoichiometry. Control of oxidant for growth of HZO on SiGe is particularly challenging since oxidant doping must be differentially controlled at the interface to avoid GeOx formation; for example, O3 intermittent dosing during growth of HZO on SiGe has been show to lower the interface defect density. In this work, an alternative method was investigated in which HfCl4 and ZrCl4 solid mixture was employed; this relies upon the vapor phase composition being a function of the solid-state composition. Ferroelectric Hf-ZrO2 was grown in Ni/HZO/TiN/Si structure from single solid mixture precursor abd >25Å/cm2 polarization was observed in 6 nm HfZrO2 grown from single solid mixture. In second step, ferroelectric Hf-ZrO2 on SiO2/Ge(001) was grown from single solid mixture precursor and MOSCAPs were fabricated. Electrical analysis revealed low defect interface formation with Dit of <3x1012 and low leakage current density of <1x10-10 (A/cm2) similar to the control HfO2 devices on SiGe.

ZnO-Activated Low Temperature Reactive Sintering of High Coercive Field Lead Zinc Niobate Based Piezoelectrics Michael Brova1, 2, Beecher H. Watson1 1, Elizabeth Kupp1, 2, Mark Fanton1, Richard Meyer1 and Gary L. Messing1, 2; 1Material Science and Engineering, The Pennsylvania State University, State College, Pennsylvania, United States; 2Materials Research Institute, The Pennsylvania State University, State College, Pennsylvania, United States; 3Applied Research Laboratory, The Pennsylvania State University, State College, Pennsylvania, United States.

A major limitation of many high performance relaxor-based ferroelectric materials is their Curie temperatures. The recently developed Pb(1-x)Zn(x)O3-Pb(Zn1/3Nb2/3)O3-PbTiO3 perovskite solid solution has a high rhombohedral to tetragonal phase transition temperature (Ts) and Curie temperature (Tc), while also possessing a large piezoelectric charge coefficient (d33), mechanical quality factor (Qm), and coercive field (Ec). In order to lower the sintering temperature and minimize number of heat treatments necessary to fabricate PIN-PZN-PT ceramics, we investigated reactive sintering of ZrO-doped PIN-PZN-PT. Reactive sintering reduced the required processing temperature from 1150°C to 800°C when compared to traditional sintering. ZrO-doping stabilized the perovskite phase, reduced the sintering temperature, and significantly increased the reaction and densification. This effect is attributed to a modification in the defect chemistry of PIN-PZN-PT perovskite and an intermediate pyrochlore phase. Electromechanical properties of reactively sintered ZrO-doped PIN-PZN-PT ceramics are compared with those synthesized by conventional sintering.
Influence of Anneal Parameters on Strained TiN Layers in Ferroelectric HfO2 Capacitors

Terary lead-based (Pb(In0.53Nb0.47)O3-Pb(Mg1/3Nb2/3)O3-PbTiO3 (PIN-PMN-PT) ferroelectric ceramics are leading candidates for next-generation textured piezoelectrics. Fabrication of those bulk textured ceramics requires high sintering temperatures of ~1200°C-1250°C to initiate epitaxial growth and long hold times to achieve full texture development. Holding at high sintering temperatures presents a significant challenge because of the volatility of certain constituents (e.g., PbO) and the limitation of developing multilayered actuators, requiring the use of platinum electrodes. In this work, we explore new doping strategies (such as CuO) to reduce the sintering temperature and through reactive sintering to initiate epitaxy at lower temperatures. The effects of CuO doping on the kinetics of perovskite phase formation and reactive sintering were studied using in situ x-ray diffraction as well as diffraction analysis on samples heated under isothermal conditions. Reactive sintering conditions of CuO-doped PIN-PMN-PT ceramics were explored by isothermally treating ceramic green bodies at temperatures below 900°C, with a relative density of 95-97% achieved at remarkably low temperatures of 790°C for 6.7 h. Using a reactive sintering approach, we adapted a reactive templated grain growth (RTGG) system using BaTiO3 microcrystal platelets to seed the phase transformation of the PIN-PMN-PT perovskite at much lower temperatures than previously demonstrated in the TGG process (~1200-1250°C).

3:30 PM DISCUSSION TIME
integration of single-crystal functional oxides films onto the flexible substrates is rare because of the challenging fabrication process. Functional oxides, showing a rich variety of complex emergent properties including memristive effects, photovoltaics, multiferroic effects and so on, have become promising high-tech functional materials beyond their traditional role as dielectrics. Therefore, integration of functional oxides thin films and flexible substrates would add a wide range of exciting applications to the flexible electronics library. Here, we demonstrate a successful fabrication of single-crystal form ferroelectric oxides films on PET flexible substrates. We will discuss the lift-off of the ferroelectric films from the growth substrate by etching a water-soluble sacrificial layer SrAl2O4 layer, the transfer of those 2D single-crystal membranes onto the PET substrates and the functional electronic properties of the resulting ferroelectric thin films/PET flexible memristors. Moreover, we will show the transfer of other oxides films using the same lift-off method and discuss some potential interesting applications like flexibe bulk photovoltaic devices and so on.

Flexible Robust and High-Density FeRAM from Organic Ferroelectric Nano-Lamellae by Self-Assembly
Menglan Guo1, Jianyong Jiang1, Jianfeng Qian1, Chen Liu1, Jing Ma1, Ce-Wen Nan1 and Yang Shen1,2; 1School of Materials Science and Engineering, State Key Lab of New Ceramics and Fine Processing, Tsinghua University, Beijing, China; 2Center for Flexible Electronics Technology, Tsinghua University, Beijing, China.

Ferroelectric memory device is endowed with high data storage density by nanostructure designing, while the robustness of ferroelectrics is also impaired. Especially for flexible memories based on organic ferroelectrics, low Curie point limits their thermal endurance and stability. Herein, we fabricate a ferroelectric random access memory (FeRAM) based on ferroelectric lamellae by self-assembly of poly(vinylene fluoride-co-trifluoroethylene). The FeRAM exhibits high data storage density and promoted thermal stability. Written data shows enhanced thermal endurance and little volatilization after thermal cycles. These results provide a novel strategy for improving robustness of organic flexible FeRAMs.

Effects of Post-Draw Processing on the Structure and Functional Properties of Electrospun PVDF-HFP Nanofibers
Adriano A. Conte1, Khosro Shirvani1, Wei Xue1, Xiao Hu1 and Vince Beachley1; 1Biomedical Engineering, Rowan University, Glassboro, New Jersey, United States; 2Mechanical Engineering, Rowan University, Glassboro, New Jersey, United States; 3Physics, Rowan University, Glassboro, New Jersey, United States.

The current surge in wearable electronics has initiated a need for alternative energy sources. Energy harvesters that employ piezoelectric materials are capable of harnessing the mechanical energy from muscular contractions to power portable devices. The present study examined the properties of polyvinylidene fluoride-hexafluoropropylene (PVDF-HFP) nanofibers fabricated from conventional electrospinning, and an automated track collector system that contains a post-drawing component. The polymer solution was originally processed by means of the traditional technique, flat-plate electrospinning, which produced a fiber arrangement with random orientations. When carrying out mechno-electrical testing and analysis these fibers yielded negligible voltage. The solution was subsequently processsed employing a post-drawing electrospinning procedure, exclusive to our research laboratory, that permitted fiber alignment and individual nanofiber post-drawing immediately upon collection, prior to total solvent evaporation. Fibers that endured post-drawing displayed an increase in crystal alignment in the direction of the fiber axis (verified by polarized FTIR), and resulted in higher voltages than undrawn fibers and fibers from the traditional electrospinning method. It was examined that fibers produced by means of the post-drawing technique, with varying draw ratios (DR=Final length/Initial length) including DR-2 and DR-3, exhibited improved piezoelectric characteristics. Mechanical properties of the nanofibers were also enhanced as a result of post-drawing. This investigation suggests that the post-drawing practice results in PVDF-HFP nanofibers that are more suitable for piezoelectric applications than conventionally electrospun nanofibers.

Epitaxial AIN Thin Film for High Performance Surface Acoustic Wave Devices
Junning Gao, Jianbai Jiang and Guoqiang Li; School of Materials Science and Engineering, South China University of Technology, Guangzhou, China.

Aluminum nitride is a wide bandgap piezoelectric semiconductor that has superior hardness and thermal conductivity. It also has the electromechanical coupling factor and dielectric constant that fit perfectly for the band width needed in bulk acoustic wave (BAW) filters which serve at tremendous quantity in smart phones. Over the years, polycrystalline thin films of AIN have been used almost exclusively as the piezoelectric substrate in commercial BAW filter products. It is also a potentially outstanding candidate for commercial surface acoustic wave (SAW) devices. However, a major disadvantage for polycrystalline AIN used in SAW devices is the existence of grain boundaries which increase insertion loss and pass band ripple. The main stream SAW filters choose LiNb(Ni)O3 single crystalline wafer as the piezo-substrate at present. To realize the full potential of AIN in SAW devices, it is necessary to refrain the negative influences of the grain boundaries, which make high quality single crystalline or epitaxial AIN highly desirable. This presentation will talk about the results of a study on the SAW devices fabricated on epitaxial AIN thin films. The films were grown on (0001) sapphire substrates by metalorganic chemical vapor deposition. The film was a c-axis oriented single crystalline AIN thin film with high density of AIN (0002) facets. The film thickness was around 100 nm. The SAW devices with center frequencies of 355 MHz and 714 MHz both exhibit much suppressed pass band ripples and improved out of band rejections comparing to those on polycrystalline thin films. It is therefore verified that the epitaxial form of AIN is better suited for high quality SAW devices.

Atomic-Scale Growth of GdFeO3 Perovskite Thin Films by a Novel Bimetallic Precursor
Christoph Bohr1, Pengmei Yu2, Mateusz Scigaj2, David Graf1, Cornina Hegemann1, Thomas Fischer1, Mariona Coll3 and Sanjay Mathur1; 1Institute for Inorganic Chemistry, University of Cologne, Cologne, Germany; 2Institut de Ciencia de Materials de Barcelona, ICMAB-CSIC, Campus UAB, Barcelona, Spain.

Multiferroic thin films of GdFeO3 are of significant importance due to their G-type antiferromagnetic behaviour and thus potential candidates for magnetic storage devices. Fabrication of single-phase GdFeO3 films is challenging due to demixing into homometallic oxides and formation of thermodynamically preferred Gd2Fe4O9. Herein we report the first selective synthesis of epitaxial GdFeO3 perovskite films through atomic layer deposition of a bimetallic precursor [GdFe(OBu)2(C5H4N)] on SrTiO3. Based on the preformed Gd-Fe bonds in the molecule, phase pure GdFeO3 films were accessible by atomic
HfO₂ films had multidomain structures composed of ferroelectric PbTiO₃. The engineering of nanoscale ferroelastic structures has attracted significant attention in the last few years. These nanostructures are reconfigurable and possess non-volatile properties, making them attractive for applications that harness the changes in electronic properties that arise at the ferroelectric-ferroelastic domain walls. applications of CeO₂-HfO₂ solid solutions have been reported in high-k dielectrics, high-k gate dielectrics, and ferroelectric switching.

Lead zirconate titanate Pb(Zr,Ti)O₃ (PZT) is a ferroelectric material with excellent dielectric and piezoelectric properties. PZT films have been prepared using various fabrication techniques such as sol-gel process, metal organic decomposition, and pulsed laser deposition. Recently, hydrothermal method has attracted increased attention because it could produce homogeneous and malleable, especially when using a high-alkaline medium and surfactant.

Lead zirconate titanate Pb(Zr,Ti)O₃ (PZT) is a ferroelectric material with excellent dielectric and piezoelectric properties. PZT films have been prepared using various fabrication techniques such as sol-gel process, metal organic decomposition, and pulsed laser deposition. Recently, hydrothermal method has attracted increased attention because it could produce homogeneous and malleable, especially when using a high-alkaline medium and surfactant.

Layer deposition experiments. The suppression of phase separation was validated by X-ray diffraction and X-ray photoelectron spectroscopy. Furthermore, magnetic properties of the material were determined by temperature dependent magnetization measurements and demonstrated comparable results as reported for thin films. Based on these results, the presented bimetallic precursor is suitable for the fabrication of high performance magnetic data storage devices.

**Fabrication of Ferroelectric CeO₂-HfO₂ Solid Solution Thin Films and Their Characterization**

Takahisa Shirai1, Sujin Choi1, Takao Shimizu2, Takanori Kiguchi1, Hiroshi Funakubo2 and Toyohiko Konno2; 1Tohoku University, Sendai, Japan; 2Tokyo Institute of Technology, Yokohama, Japan.

Lead zirconate titanate Pb(Zr,Ti)O₃ (PZT) is a ferroelectric material with excellent dielectric and piezoelectric properties. PZT films have been prepared using various fabrication techniques such as sol-gel process, metal organic decomposition, and pulsed laser deposition. Recently, hydrothermal method has attracted increased attention because it could produce homogeneous and malleable, especially when using a high-alkaline medium and surfactant.

Applying an out-of-plane dc biased voltage to the domain and superdomain patterns reveals that the ferroelastic structures in PbTiO₃ are electrically very malleable, especially when a high-alkaline medium and surfactant are added into the PZT precursor solution to dissolve the precursor source in the aqueous solution and to control the crystal growth, respectively. After hydrothermal reaction with stirring, PZT particles were separated from liquid phase and followed by rinsing and drying several times. When the surfactant was not added into the reaction solution, large-sized PZT particles with rough surfaces were synthesized. On the other hands, nano-sized PZT particles with facet were synthesized by adding the surfactant and it was confirmed that the added surfactant had the effect of inhibiting the growth of the certain faces of particles. The simple spot pattern in the electron diffraction pattern revealed that this nano-sized PZT particle synthesized by the surfactant-assisted hydrothermal method at 230°C had high crystallinity and it was a single crystal. Unlike conventional fabrication techniques with high temperature crystallization process above 600°C, PZT nanocrystals with high crystallinity were obtained by the surfactant-assisted hydrothermal synthesis.

**Engineering Domain and Superdomain Architectures in PbTiO₃ Thin Films**

Eric Langenberg1, David Burgallo Ferrón2, Megan E. Holtz3,4, Hanjong Paik1, Elias Ferreiro-Vila2, Eva H. Smith1, Hari P. Nair1, David Muller2, Gustau Catalán3, Neus Domingo4, Francisco Rivadulla2 and Darrell G. Schlenk1,2; 1Department of Materials Science and Engineering, Cornell University, Ithaca, New York, United States; 2CQUS-University of Santiago de Compostela, Santiago de Compostela, Spain; 3School of Applied and Engineering Physics, Cornell University, Ithaca, New York, United States; 4Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC, Barcelona Institute of Science and Technology, Bellaterra, Barcelona, Spain; 5Kavli Institute at Cornell for Nanoscale Science, Ithaca, New York, United States.

The engineering of ferroelastic structures has attracted significant attention in the last few years. These nanostructures are reconfigurable and non-volatile, making them attractive for applications that harness the changes in electronic properties that arise at the ferroelectric-ferroelastic domain walls or novel (nano-)electromechanical devices based on ferroelastic switching. Here, we study the interplay between epitaxial strain, film thickness, and electric field in the creation, modification, and design of distinct ferroelectric-ferroelastic domain and superdomain architectures in the archetype PbTiO₃ thin films. The suppression of phase separation was validated by X-ray diffraction and X-ray photoelectron spectroscopy. Furthermore, magnetic properties of the material were determined by temperature dependent magnetization measurements and demonstrated comparable results as reported for thin films. Based on these results, the presented bimetallic precursor is suitable for the fabrication of high performance magnetic data storage devices.
stability, however, of the electrically written a/c superdomain structures strongly depends on strain: under low tensile strain they are stable for days, whereas at moderate tensile strains they rapidly convert into a/a2 superdomains—the same equilibrium state as the a/a2-grown films.

EP01.03.08
Fabrication and Properties of Multiferroic Composites by PLD for Voltage-Driven Magneto-Optic Spatial Light Modulator Yuichi Nakamura, Naohide Kamada, Taichi Goto, Hironaga Uchida and Mitsuteru Inoue; Toyohashi University of Technology, Toyohashi, Japan; JST PRESTO, Kawaguchi, Japan.

Spatial light modulators (SLMs) are devices to control the amplitude, phase and polarization of light and are an important component of such as optical communication and optical computing systems. Magnetooptic SLM (MOSLM) using Faraday rotation can modulate light through the direction of magnetization with ultra-high speed and robustness. A voltage-driven MOSLM, which is composed of piezoelectric and magnetic materials, can be driven with relatively low power consumption. The structure in which columnar magnetic materials are embedded in the piezoelectric material is expected to increase the modulation of light easily by changing the magnetization direction of the magnetic layer. In this way, the MOSLM, simultaneous growth of the piezoelectric material such as Pb(Te1/2Zr1/2)O3 (PTZ) and BaTiO3 (BTO) and a magnetic rare earth iron garnet (Bi:RIG) is needed. In this study, we investigated the growth conditions for obtaining the aligned BTO film on nonmagnetic single crystalline Gd3Ga5O12 (GGG) substrate and Bi:RIG/BTO composites.

At first, we checked several materials which can grow epitaxially on GGG substrate by pulsed laser deposition (PLD) method since it would be required to form columnar structure by simultaneous growth technique. As a result, we found that the (111) oriented BiFeO3 (CFO) film could be grown on GGG (111) substrate. Furthermore, the CFO film preferentially oriented in the (111) plane could also be grown on CFO buffered GGG (111) substrate. Pole figure analysis of this sample revealed that the (111) oriented CFO film has two in-plane orientations in the plane. This means that this aligned film of CFO/GGG is not single crystalline feature but polycrystal with two specific crystal alignments. However this would not be a crucial issue to grow columnar structure by simultaneous growth; the relation between CFO and Bi:RIG crystal at the interface may be kept since the columnar size is usually several 10 to 100 nm order and would be smaller or comparable to the that of CFO grain. The detail about the composite films of CFO and Bi:RIG using this CFO buffered GGG substrate will be discussed. This work was supported in part by the Grants-in-Aid for Scientific Research (S) 26220902, (B) 16H04329 and Strategic international research network promotion program No. R2802.

EP01.03.09
Structural, Magnetic and Electrical Characterization of Nanoscale Ba(Ti1-xFex)O3—Stoichiometric Control Over a Multiferroic Oxide Using a Near-Room Temperature Non-Aqueous Synthesis Method Julien Lombardi1, Stephen O'Brien1 and Zheng Gai1; City College of New York, New York, New York, United States; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Low temperature chemical solution processing of nanocrystalline perovskite oxides can be attractive due to the ability to (i) enable precise control over stoichiometry and structure in the product and (ii) offer thin film integration options in device electronics for which high temperatures are not suitable. Ba(Ti1-xFex)O3 is a useful system for the exploration of multiferroic properties as a function of structure, based upon a model of interstitial substitution of the B site cation. A series of iron-substituted barium titanate nanocrystals were synthesized using a hybrid sol-gel synthesis method, known as gel-collection, at 60°C. The as-prepared nanocrystals are fully crystalline, uniform in size (~8 nm) and dispersible in polar organic solvents. The synthesis method could effectively control Fe substitution over a full range of x = 0.0, 0.1, 0.2, 0.3, 0.5, 0.75 and 1.0, enabling a systematic study of the relative effect of Fe addition to the parent BaTiO3 compound. In the case of x = 0.0-0.3, a model of Fe doping suffices with predictable trends in magnetic and dielectric behavior. In the case of x = 0.5 and up, Fe impacts the structure. Powder X-ray diffraction (XRD) initially indicated single phase nanocrystalline samples for x < 0.3. PDF analysis… size and morphology of the nanocrystals was analyzed by the transmission electron microscope (TEM) showing uniform shape and size (~8 nm) nanocrystals. Magnetic characterization (both magnetic hysteresis loops and zero field and field cooling measurements) was carried out on a magnetic properties measurement system (MPMS) and showed increased magnetization with increasing Fe ion concentration. Frequency dependent dielectric measurements were performed at room temperature on spin coated 0-3 nanocomposites of BTF and polyvinyl-pyrrolidone and show stable dielectric constants at 1 MHz of 27.0, 26.0, 24.6, 24.5, 23.6, and 22.2 for BTF samples with x = 0, 0.1, 0.2, 0.3, 0.5, and 0.75 concentrations respectively. The decrease in dielectric constant with increasing Fe concentration is due to the contribution of the electrons in the d orbital leading to a more leaky material.

EP01.03.10
Engineering Growth of Magnetostriective Thin Films by Pulsed Laser Deposition for Magnetoelastic Coupled Future Voltage Controlled Spintronic Devices Rajesh Kumar Rajagopal1, J. Arout Chelvane2 and Venimadhav Adyam1; IIT Kharagpur, West Bengal, India; Defence Metallurgical Research Laboratory, Hyderabad, India.

Multiferroic devices, consisting of coupled ferromagnetic and ferroelectric phases, are of great importance in the drive towards creating faster, smaller and more energy efficient voltage control magnetic random access memory (MRAM) devices for information storage and communication technologies. Such devices require a strong magnetoelastic coupling between the ferromagnetic and the ferroelectric interface, this is obtained by using large magnetostriiction materials as a ferromagnetic layer. Magnetostriective Fe based amorphous alloys of Fe50Co17Si12B10 (FeCoSiB) and Fe51Ga19 (GdFe) amorphous alloys are of great interest for their ultra high saturation magnetization, low coercivity, and high magnetic permeability. Wide varieties of the growth techniques are available for the fabrication of thin films, among the methods, pulsed laser deposition (PLD) is a thin film growth technique which has the advantage of stoichiometric transfer of the elements on to the substrate. By understanding the growth of amorphous thin film by PLD has the advantage of the in-situ growth of high quality epitaxial ferroelectric materials are grown at high temperature, and magnetostriactive materials can be are grown on top of the ferroelectric thin film.

In this present study, we have prepared the highly magnetostriective FeCoSiB and GdFe thin films deposited on the Si substrate using PLD. The prepared films show the soft ferromagnetic property with coercivity of 25 Oe as given in the Fig. 1(a). Pulsed laser deposition induced uniaxial anisotropy in the GdFe thin shown in Fig. 1(b). The thickness dependent composition variation of the thin film was analysed using Auger electron spectroscopy. We also present the growth of this alloy on oxide substrates, magnetotransport characteristics and magnetic domain by Magnetic force microscopy (MFM).

EP01.03.11
Growth of Orientation-Controlled (K,Na)NbO3 Thick Films at 240°C by Hydrothermal Method and Their Piezoelectric Applications Hiroshi Fujikubo1, Akinori Tateyama1, Yoshishiro Itou1, Yoshiko Nakamura1, Takao Shimizu2, Yuichiro Orimo3, Minoru Kurosawa4, Hiroshi Uchida4, Takahisa Shirasuna5, Takamori Kiguchi1, Toyohiko Konno6 and Nobuhiro Kumada3; Tokyo Institute of Technology, Yokohama, Japan; Sophia University, Tokyo, Japan; Tohoku University, Sendai, Japan; Yamazaki University, Koufu, Japan.

(K, Na)NbO3 has a relatively high piezoelectric property among lead-free piezoelectric materials with high environmental adaptability. Their films have been prepared by various methods. Hydrothermal method can prepare (K, Na)NbO3 films at low temperature [1-3] and feasible to control film composition that has been pointed out to be difficult for various preparation methods due to high deposition temperature and vapor pressure of K and Na elements. In this study, orientation-controlled (K,Na)NbO3 films with 1-100 μm in thickness were prepared by hydrothermal method and their crystal structure,
Polymer piezoelastic materials are wildly used in wearable smart devices as they are flexible lightweight, stretchable, environment-friendly and chemically stable, and poly(vinylidenefluoride-co-trifluoroethylene) (P(VDF-TrFE)) is a representative piezoelectric polymer. To construct piezoelectric polymer fibers, electrospinning is a versatile technique. Compared to randomly distributed electrospun fibers, aligned P(VDF-TrFE) fibers possess better electrical properties and larger proportion to mechanical stimuli. Here, we demonstrate a simple dynamical mechanical induced process which enables the formation of large-scale highly aligned electrospun P(VDF-TrFE) fibers obtained under low rotation speed. And the resultant fibers exhibit enhanced mechanical and piezoelastic properties and can be further used as wearable motion sensors.

We collect the initial P(VDF-TrFE) fiber using low speed rotating drum. The as-spun P(VDF-TrFE) fibers still contain residual solvent, thus they are easy to deform under applied external force. The electrospun P(VDF-TrFE) thin film is then peeled off the aluminum foil and mounted in the clamps of a linear travel stage driven by a controller for the following mechanical stretching process. As a result, the initial orientations can be globally unified, which leads to the alignment of a large amount of electrospun P(VDF-TrFE) into highly oriented fiber bundles. The ~80% aligned P(VDF-TrFE) fibers are further twisted into bundles and yarns and made into wearable sensors to monitor the bending angle of the elbow. The output signal for bending 45°, 90°, and 135° are 10.6 mV, 20.3 mV, and 42.5 mV, respectively. Furthermore, multiple P(VDF-TrFE) fiber bundles can be used in a combined way to monitor the direction of arm swing.

(XRD), atomic force microscopy (AFM), and spectroscopic ellipsometry in order to determine what thickness of ScN would produce the least amount of these domain variances. Preliminary XRD coupled scans show highly oriented ScN on Al2O3 with glancing angle scans showing no additional phases present in the ScN film. AFM surface analysis showed root mean square (RMS) roughness between 0.433 nm and 0.911 nm for films between 0.5 nm and 10 nm, corresponding to one to two monolayers of roughness. Additionally, thin films of Al1−xScxN films were deposited both on bare substrate and with the additional ScN wetting layer, at similar thicknesses to the ScN thin films. These were also characterized using XRD, AFM, and spectroscopic ellipsometry to determine the effect of the ScN thickness and domains on the Al1−xScxN film crystallinity and piezoelectric properties.

EP01.03.15 Magnetron Sputter Deposition of Pyroelectric PZT Thin Films—From Simulation to Experiment Peter K. Petrov1, Andrey Berenov1, Ryan Bower1, Sarah Fearn1, Roger Fecher1, Lars Allers2, Philippa Stephens2, Brian Moffat1, John Phair1, Valery Volpys1, and Andrey Kozylev4; 1Imperial College London, London, United Kingdom; 2Korus Technology Ltd, Newington, United Kingdom; 3Pyreos Ltd, Edinburgh, United Kingdom; 4St Petersburg Electrotechnical University “LETI”, St Petersburg, Russian Federation.

Thin films of lead zirconate titinate (PbZr1−xTiO3 - PZT) are of considerable interest for a range of applications, including piezoelectric MEMS (with x=0.52) and pyroelectric thermal IR sensing (with x=0.30 [1]). Thin films of PZT (x=0.15 to 0.42) have in the past been grown onto platinum Si substrates by sputtering from multiple metal targets [2], but there are considerable technological benefits to deposition from a single ceramic target [3].

This paper will discuss the process of magnetron sputter deposition of PZT thin films from a single ceramic target. We used Monte-Carlo simulation method based on the algorithm, presented in [4], to describe the sputter atoms transport process and their delivery on the substrate. The modeling was carried out taking into account the geometry and dimensions of the deposition system, and the sputter target erosion zone. A complementary SIMS analysis of the PZT sputter target was carried out to identify the type of sputtered particles (e.g. single atoms, binary compound, clusters), which were further used in the simulation process.

Finally, we will present the structural and electrical properties of the sputtered PZT films (e.g. crystal structure, stoichiometry, dielectric permittivity, loss, pyroelectric coefficient etc.) and discuss their dependence on the existence of particular species in the gas phase during the sputtering process.

EP01.03.16 Initiated Chemical Vapor Deposition of Multilayered P(VDF-TrFE) Thin Films—Controlling the Chemical Composition Along the Thickness Omid M. Moradi1, Ali Tufani1, Gozde Ozaydin Ince1, 2, 3 and Ibrahim B. Misirlioglu4, 5, 2; 1Materials Science and Nanoengineering, Sabanci University, Istanbul, Turkey; 2Nanotechnology Research and Application Center (SUNUM), Sabanci University, Istanbul, Turkey; 3Center of Excellence for Functional Surfaces and Interfaces (EFSUN), Sabanci University, Istanbul, Turkey; 4Faculty of Engineering and Natural Sciences, Sabanci University, Istanbul, Turkey; 5Integrated Manufacturing Technologies Research and Application Center, Sabanci University, Istanbul, Turkey.

Fabrication of ferroelectric polymers at lower temperatures, thickness control and film conformity in polymeric multilayer structures are required for full integration of the ferroelectric polymers to the modern integrated devices. Also, designing of multilayer ferroelectric films requires precise control over the deposition parameters.

We use Initiated Chemical Vapor Deposition (iCVD) method to deposit 10-30 nm ferroelectric layers and fabricate multilayer poly [(vinylidenefluoride-co-trifluoroethylene) [P(VDF-TrFE)] thin films. We control the thickness of the layers and control the chemical composition in each layer along the thickness. Also, the change in dielectric constant and dielectric loss at moderately low and high frequencies for each multilayer configuration will be discussed. Hence, we report the frequency dependency of dielectric constant, loss tangent, imaginary electric modulus of multilayered thin films.

EP01.03.17 Multiferroic Polaron in Doped Perovskite Oxides Takahiro Shimada, Tao Xu, Takayuki Kitamura and Hiroyuki Hirakata; Kyoto Univ, Kyoto, Japan.

Control over the electron behaviors is essential for the quest of the unusual coexistence of seemingly conflicting physical properties in condensed matter science. Although the coexistence of ferroelectricity, conductivity and magnetism in a single-phase material has attracted considerable attention due to the fundamental interest and tremendous technological promise, the mutually exclusive mechanisms among them hinder the discovery of multifunctional conducting multiferroics. Here, we propose a novel material design approach for electron engineering, by which we realize an unusual coexistence of these conflicting properties. We demonstrate from first-principles that the appropriate mechanical strain turns the excess electrons in doped BaTiO3 from free carrier configuration to localized polaronic state through the modulation of electron-phonon coupling. The resulting localized spin-polarized electron survives the host ferroelectricity and consequently manifests itself as multiferroic polaron. The multiferroic properties coexist with the electronic carrier configuration to localized polaronic state through the modulation of electron-phonon coupling. The resulting localized spin-polarized electron.

EP01.03.18 Theoretical Prediction of Piezoelectric and Thermodynamic Stability of New LiNbO3-type Al(Sc,In,Tl)O3 Kaoru Nakamura; CRIEPI, Yokosuka, Japan.

LiNbO3 structure, belongs to the space group of R3c, is frequently referred as “strained perovskite structure”. Recently, many compounds have found to be possible to form LiNbO3-type structure under the high-pressure condition, and some of them were quenchable phase. By systematic first-principles prediction of piezoelectricity and phase stability of possible combination of A-site and B-site ions, we have found new Al-based LiNbO3-type piezoelectric materials. Dynamical stability analysis on AlScO3, AlInO3, and AlTlO3 showed no unstable phonon mode. Formation energies of each compound were predicted to show negative value at high pressure. Predicted piezoelectric constants e33 and d33 of each compound were larger than those of LiNbO3.
Especially, $e_{33}$ and $d_{33}$ values of AlTiO$_3$ were anomalously large to be 10.7 C/m$^2$ and 56.6 pC/N. By utilizing the formalism of density functional perturbation theory, piezoelectric constants of each compound were decomposed into elastic and dielectric contribution from each atom. As a result, large piezoelectricity of Al(Sc,In,Tl)O$_3$ was found to be originated in the large strain-displacement coupling.

EP01.03.19
Effects of Structure Parameters on Piezoelectricity in Wurtzite Materials—First-Principles and Statistical-Learning Calculations

Hiroyoshi Momida and Tamio Oguchi; Osaka Univ, Osaka, Japan.

Piezoelectric wurtzite materials such as ZnO and GaN have recently received a lot of attention as piezotronics and piezo-phototronics device materials. The wurtzite-type piezoelectric materials, especially AlN, have another advantage of applicability in high-temperature environments such as sensors in automobile engines, because their noncentrosymmetric crystal structures are thermodynamically stable even at high temperatures. However, the piezoelectric constants of wurtzite-type materials are generally much smaller than those of the perovskite-based materials such as Pb(Zr,Ti)$_3$O$_5$ by a few orders. It remains a challenge to explore better piezoelectric wurtzite materials, and there have been many reports aiming to enhance piezoelectricity by element doping into parent materials. Among the wurtzite materials, the highest piezoelectricity has been experimentally discovered for ScAl$_2$N (about 25 pC/N for $x \sim 0.5$). Novel low-cost materials, which are superior to ScAl$_2$N, have not been synthesized yet as there are no clear and general material-design criteria practically usable for enhancing the piezoelectricity of wurtzite materials.

In this study, we calculate longitudinal piezoelectric constants ($e_{33}$) of more than a dozen binary wurtzite materials, which are listed in a structure database, by using the first-principles methods, and we investigate possible correlations between the piezoelectric constants and several material parameters using the statistical-learning methods [1]. As a result, it is theoretically shown that wurtzite materials with high $e_{33}$ generally have small lattice constant ratios ($c/a$) almost independent of constituent elements, and approximately expressed as $e_{33} \propto c/a - (c/a)_{b}$ with ideal lattice constant ratio ($c/a$)$_b$. We find that this relation also holds for highly-piezoelectric ternary materials such as the calculated $e_{33}$ values of ScAl$_2$N [2]. Therefore, this material-design criterion can be applied to the case in doped ternary materials. We have conducted a computational search for high-piezoelectric wurtzite materials by identifying materials with smaller $c/a$ values. It is theoretically proposed that the piezoelectricity of ZnO can be significantly enhanced by partial substitutions of Zn with Ca. Though the calculated value of $e_{33}$ of CaZn$_{0.5}$O is still smaller than that of ScAl$_2$N, we expect that CaZn$_{0.5}$O is at a definite advantage in material costs and natural abundance of constituent elements.

Physical Reality of the Preisach Model for Organic Ferroelectrics

Tim Cornelissen¹, Indre Urbanaviciute¹, Xiao Meng², Rint Sijbesma² and Martijn Kemerink¹; ¹Linköping University, Linköping, Sweden; ²Eindhoven University of Technology, Eindhoven, Netherlands.

Since the seminal work by Ferenc Preisach in 1935, the so-called Preisach model, in which a real, non-ideal ferroic material is described as the sum of a distribution of ideal ‘hysteres’, has been a cornerstone in the fields of ferromagnetism and ferroelectricity. However, the physical reality of the model in ferroelectrics has been hard to establish, limiting its further applicability and utility. Here, we show how an experimental Preisach distribution-based analysis can quantify the energetic disorder and elucidate the concomitant dispersive polarization switching kinetics common for different classes of ferroelectrics.

We experimentally determine the Preisach (hysteron) distribution for two differently structured ferroelectric systems, the liquid crystalline benzenetricarboxamide (BTA) and the polycrystalline copolymer P(VDF-TrFE). For BTA a broad circular distribution is found, in contrast to the narrow elliptical distribution for P(VDF-TrFE). We explain how this broadening can be directly related to the materials’ morphology: in BTA the ferroelectric domains consist of strongly interacting columns, while in P(VDF-TrFE) consists of non-interacting crystallites. Our explanation is supported by simulations using a simple electrostatic model. The offered insight in the shape of the Preisach distribution is especially relevant for ferroelectric multi-bit data storage applications.

The model also provides an explanation for the dispersive switching kinetics observed in most ferroelectrics, and the underlying distribution in switching times. By measuring the switching kinetics of discrete parts of the Preisach plane, we can directly extract this distribution. The combination of the Preisach model, the thermally-activated nucleation-limited switching formalism and the adapted Kolmogorov–Avrami-Ishibashi theory provides a full and consistent description of the measured macroscopic switching kinetics in terms of device morphology and energetic disorder.

Our results reveal that the in principle mathematical construct of the Preisach model has a strong physical basis and is a powerful tool to explain polarization switching processes of different types of ferroelectrics.

EP01.03.21
First-Principles Calculations of Lattice Dynamics and Thermodynamic Properties of the New Pre-Perovskite PbTiO$_3$ Phase

Mengqian Zhou¹,², Yi Wang¹, Yanhua Ji¹, Long-Qing Chen¹,² and Ce-Wen Nan¹; ¹School of Materials Science and Engineering, State Key Lab of New Ceramics and Fine Processing, Tsinghua University, Beijing, China; ²Department of Materials Science and Engineering, The Pennsylvania State University, State College, Pennsylvania, United States.

Recently, the emergence of pre-perovskite PbTiO$_3$ nanowires has attracted increasing research interests. In this work, systematic first-principles calculations were performed to investigate the lattice dynamics and thermodynamic properties of the new pre-perovskite PbTiO$_3$ phase. The stability of pre-perovskite PbTiO$_3$ at finite-temperature was analyzed in terms of the lattice contribution, and its thermodynamic properties were obtained and compared with those of cubic and tetragonal PbTiO$_3$. The pressure-temperature phase diagram for these three types of PbTiO$_3$ was established, indicating that pre-perovskite PbTiO$_3$ can be stable under negative pressure. These theoretical insights are useful for understanding the origin of phase transitions among pre-perovskite, traditional cubic and tetragonal PbTiO$_3$ phases, hence providing meaningful guidance for future experimental study and potential applications of pre-perovskite PbTiO$_3$.

A Rhombohedral Ferroelectric Phase in Epitaxially-Strained Hf$_5$Zr$_9$O$_{28}$ Thin Films

Yingfen Wei¹, Pavan Nukala¹,³, Mart Salverda¹, Sylvia Matzé², Hongjian Zhao¹, Janno Momand⁴, Arnaud S. Everhardt¹, Graeme R. Blake¹, Philippe Lecoeur⁵, Bart J. Kooi¹, Jorge Iñiguez⁶, Brahima Dkhil⁷ and Beatriz Noheda⁸; ¹University of Groningen, Groningen, Netherlands; ²Center for Nanoscience and Nanotechnology, Université Paris-Saclay, Paris, France; ³Materials Research and Technology Department, Luxembourg Institute of Science and Technology, Esch-sur-Alzette, Luxembourg; ⁴Laboratoire Structures, Propriétés et Modélisation des Solides, Université Paris-Saclay, Paris, France.

Our results reveal that the in principle mathematical construct of the Preisach model has a strong physical basis and is a powerful tool to explain polarization switching processes of different types of ferroelectrics.
After decades of searching for robust nanoscale ferroelectricity that could enable integration into the next generation memory and logic devices, hafnia-based thin films have appeared as the ultimate candidate because their ferroelectric (FE) polarization becomes more robust as the size is reduced. This exposes a new kind of ferroelectricity, whose mechanism still needs to be understood. Towards this end, thin films with increased crystal quality are needed. We report the epitaxial growth of HfO2/ZrO2 (HZO) thin films on (001)-oriented La0.6Sr0.4MnO3/SrTiO3 substrates. The films, which are under epitaxial compressive strain and are (111)-oriented, display large FE polarization values up to 34 μC/cm² and do not need wake-up cycling. Structural characterization reveals a rhombohedral phase, different from the commonly reported polar orthorhombic phase. This unexpected finding allows us to propose a compelling model for the formation of the FE phase. In addition, these results point towards nanoparticles of simple oxides as a vastly unexplored class of nanoscale ferroelectrics.

Mesoscopic Varistor Modelling Kyle Taylor and Erion Gjonaj; Institut für Theorie Elektromagnetischer Felder, Technische Universität Darmstadt, Darmstadt, Germany.

This newly developed modelling framework for the simulation of electric current flow in ZnO varistors is based on an equivalent circuit representation of the varistor microstructure where the grain boundaries are represented by nonlinear resistors in the circuit. The present approach extends on similar models introduced earlier by including the effect of mechanical stress on the grain boundary conductivity. This effect is based on the coupling between the semiconducting and the piezoelectric properties of ZnO. The stress-induced piezoelectric polarization modifies the interface charge at the grain boundaries. This changes the effective potential barrier and therefore leads to a stress induced modification of the current voltage characteristics of the grain boundary. The model used for the calculation of single grain boundary conductivities is based on the theory of Blatter et al. and Verghese et al. It includes a self-consistent solution for the interface charge and for the potential barrier of the boundary, taking into account the local stress in the grain. Using the above model, the grain boundary potential barriers are parametrized with respect to voltage and piezoelectric charge density. Such tabulated data can be easily incorporated in the modeling of larger varistor structures. 2D and 3D varistor models are constructed using appropriate Voronoi tessellations as well as measurement data obtained by EBSD scans. The mechanical stress distribution within the material is calculated by FEM. The electrical resistance of each grain boundary is then determined according to the local voltage and piezoelectric polarization charge. Finally, the electric current flow patterns within the microstructure and the corresponding current-voltage characteristic of the bulk material are obtained by solving the nonlinear circuit equations for each applied voltage and mechanical stress condition of the sample. The simulated characteristics reveal a significant sensitivity of the bulk electrical conductivity to mechanical stress. Furthermore, the simulations demonstrate the current concentration effect in the voltage breakdown region. Further topics of interest, which have been addressed by the modeling, include the influence of microstructural inhomogeneities, the investigation of the properties of purposely tailored microstructures (such as sandwiched polycrystalline layers) and the influence of sintering temperature on residual stresses and varistor characteristics.

Improvement in Magnetic Properties by Coating Surfactants on M-Type Strontium Hexaferrite Tai P. Poudel1, Deepa Guragain1, Jeetikanta Mohapatra2, Sunghyu Youn1, J. Ping Liu1 and Sanjay R Mishra1; 1Department of Physics and Material Science, University of Memphis, Memphis, Tennessee, United States; 2Department of Physics, The University of Texas at Arlington, Arlington, Texas, United States; 3Gunsan National University, Gunsan, Korea (the Republic of).

M-type SrFe2O4 were synthesized via auto consumption method and coating Polyvinylpyrrolidone (PVP) Polyethylene Glycol (PEG) and Cetyltrimethyl Ammonium Brome (CTAB) on crystals of hexaferrite. The effects of PVP, PEG and CTAB on the formation, structure, morphology, magnetic and dielectric properties of the SrFe2O4 nanoparticlewere studied. X-ray diffraction results show perfect match of phase of SrFe2O4. Morphological changes including grain and lattice parameter were seen increased with coating. With the coating of PVP, PEG and CTAB, powder particles growth can be seen in hexagonal plates. Increase in saturation magnetization, Ms, remanence magnetization,Mr, and coercivity, Hc, with different surfactant was observed. A slight increase in Curie temperature (765 K) is observed for samples coating with CTAB as compared to that of sample prepared in absence of coating. These results can be taken as coating surfactant like PVP, PEG and CTAB act as a crystallization agents, controlling the nucleation and growth of SrFe2O4 crystal. The study shows good impact on the scope of improving magnetic properties of ferrites without substitution of metal ions.

**EP01.03.25**

A Tunable Piezoelectric MEMS Sensor for the Detection of Weak Magnetic Signals Florian Niekiel1, Simon Fichtner2, Christine Kirchhof2, Dirk Meyners2, Eckhard Quandt2, Bernhard Wagner2 and Fabian Lofink1; 1Fraunhofer Institute for Silicontechnology (ISIT), Itzehoe, Germany; 2Christian-Albrechts-Universität zu Kiel, Kiel, Germany.

Piezoelectric MEMS devices are well established in the field of filters, e.g. RF filters for communication applications. The modal behavior and thus the filter characteristics are strongly affected by the in-plane and out-of-plane geometry and are therefore controlled by the design. A post-fabrication adjustment is difficult and commonly made with irreversible processes far away from application conditions, for example modifying the residual stress in the resonating structure by annealing processes. Here we present the study of a piezoelectric resonator, whose modal characteristics can be tuned using additional piezoelectric elements. This concept allows a flexible and reversible adjustment of the modal behavior in the application under operation conditions. The design is made of three parallelly-suspended cantilevers have been realized from a poly-Si layer using backside release. While the principle is generally applicable to achieve tunable piezoelectric MEMS filters, this study focuses on the use as magnetoelectric sensors for weak magnetic signals, e.g. for biomagnetic applications [1]. To achieve the sensitivity to a magnetic field, a magnetostrictive FeCoSiB layer is added on the unimorph structure. The piezoelectric and magnetostrictive layers build a magnetoelectric composite capable of converting a magnetic signal into an electrical signal via the mechanical coupling. The resonance of the cantilever structure is employed to enhance the mechanical response for certain frequencies and thus the electrical signal. The fabricated devices are used to study the fundamental relationship between sensitivity and stress in the resonator structure.

Several benefits of the presented tunable magnetoelectric sensor are anticipated. The frequency can be adjusted precisely to the magnetic signal in the measurement to get the highest benefit from the resonance effect. In addition, different measurements with varying signal frequencies can be addressed without having to change the sensor. Superimposed magnetic signals at different frequencies can be measured with a single sensor in a serial manner, due to the filter effect of the narrow-bandwidth resonance amplification.
Funding by the DFG via the Collaborative Research Center SFB 1261 is gratefully acknowledged.

EP01.03.26 A First-Principles Study of the LaAlO3/SrTiO3 (111) Interface Taewon Min, Jinho Byun and Jaeckwang Lee; Pusan National University, Busan, Korea (the Republic of).

The emergent discovery of two-dimensional electron gas (2DEG) at the LaAlO3/SrTiO3 (LAO/STO) heterostructure with n-type interface has attracted considerable attention over the past decade. Despite several mechanisms such as polar catastrophe, oxygen vacancy and cation intermixing have been suggested, the origin of 2DEG remains still unclear. Recently, unlike LAO/STO (001) interface, a wide 2DEG distribution have been reported at the LAO/STO (111) interface. According to the polar catastrophe, although the p-type 2DEG is expected at the LAO/STO (111) interface consisting of [Ti]+/[LaO3]- layers, the n-type 2DEG has been experimentally observed. Here, using a first-principles density functional theory calculations, we explore the origin of wide n-type 2DEG at LAO/STO (111) interface at the atomic scale. Compared with LAO/STO (001) interface, we find that the oxygen adsorption on the [Al]2+-terminated LAO (111) surface and following surface reconstruction play a key role in forming n-type 2DEG and the existence of critical thickness.

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (2018R1A2B6004394). This work also was supported by the MOTIE(Ministry of Trade, Industry & Energy (#10080643) and KSRC(Korea Semiconductor Research Consortium) support program for the development of the future semiconductor device.

EP01.03.27 Design and Fabrication of ZnO Nano-Architectures with High Piezoelectric Coefficient and Elastic Limit Seokiumg Yun1,4, Hoon Kim1, Dahye Shin1, Seongwoo Cho1, Changdeuck Bae1, Dongchan Jang2 and Seunghum Hong1; 1Department of Materials Science and Engineering, Korean Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 2Department of Nuclear and Quantum Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); 3Department of Energy Science, Sungkyunkwan University, Suwon, Korea (the Republic of); 4Memory Business, Samsung Electronics Co., Ltd., Hwaseong, Korea (the Republic of).

Piezoelectric ceramics are used for sensors and actuators as they have high piezoelectric coefficient. However, due to the brittle nature of ceramics coming from the fact that the size of flaw or crack determines the ultimate strength and elastic strain limit, it is still a challenge to use them for flexible or stretchable devices. In this study, we introduce ZnO truss nanostructure which shows high piezoelectric coefficient confirmed by local piezoresponse map and high elastic limit measured by nano-indentor. The photoresist SU8 was used for the template of ZnO truss structure via 3D photolithography. We used low temperature atomic layer deposition to coat the SU8 truss template with conformal ZnO thin film. The piezoelectric characteristics of the ZnO/SU8 composite truss were analyzed by Dual AC Resonance Tracking Piezoresponse Force Microscopy (DART-PFM) where the effective piezoresponse was 37.8 pm/V. This is almost three times larger than the piezoelectric coefficient reported for bulk ZnO (8–10 pm/V). The stress vs strain curve was measured by nano-indenter, and showed linear behavior up to ~4%, which is more than 10–20 times the strain limit of bulk ZnO. We expect that our novel ZnO truss nanostructure can serve as basic materials component for future haptic enhanced applications.

SESSION EP01.04: Growth of New Piezoelectric, Pyroelectric and Ferroelectric Optoelectronic Materials

Hynes, Level 1, Room 103

8:15 AM EP01.04.01 Switchable and Rectifying Conductivity in Molecular Ferroelectrics Indre Urbanaviciute, Tim Cornelissen and Martin Kemereink; Linkoping University, Linkoping, Sweden.

The broken inversion symmetry in ferroelectric semiconductors causes the bulk photovoltaic effect. The same symmetry considerations predict a non-equivalence between electrical currents flowing parallel and anti-parallel to the polarization direction. While ferroelectrically-switchable current rectification in metal-ferroelectric-metal diodes has been observed due to interfacial phenomena like injection or tunneling barrier modulation, a coupling between bulk conductivity and polarization has not been observed. Here, we present a class of molecular ferroelectrics that show a polarization-dependent bulk conductivity.1

We have synthesized disc-like semiconducting organic molecules that are functionalized with strong dipolar side groups.2 These materials self-assemble into supramolecular polymers, which provides long-range polar order that supports collective ferroelectric behavior of the side groups, as well as charge transport through the stacked semiconducting cores.

We find that the ferroelectric polarization couples to the charge transport and leads to a bulk conductivity that is both switchable and rectifying. When sweeping the applied electric field, the conductivity is switched from a high to low state at the ferroelectric coercive field. Detailed analysis of the current-voltage curves shows that the current is a combination of Ohmic and space-charge-limited currents. This demonstrates that it truly is the bulk conductivity that is modulated by the ferroelectric polarization.

A simple quasi-1D hopping model is developed to investigate the effect of the asymmetric potential caused by the polarization. This model reproduces the experimental on/off ratio using reasonable parameters.

**Photo-Induced Phenomena of Strongly Correlated YMnO$_3$ Ferroelectric Epitaxial Films**

Norifumi Fujimura, Takeshi Yoshimura, Takayuki Hasegawa and Masaaki Nakayama; Osaka Prefecture University, Osaka, Japan; University of Hyogo, Ako, Japan; Osaka City University, Osaka, Japan.

We have studied the photo-induced phenomena using strongly correlated YMnO$_3$ ferroelectric thin films. Unipolar material YMnO$_3$ is suitable for studying the effect of the ferroelectric polarization on the photo-induced current. The clear relationship between the direction of the polarization and the photo-induced current was recognized using (0001) YMnO$_3$ epitaxial films. The current switching corresponding to the polarization switching is also observed under the illumination of white light. To study the origin of the photo-induced current originated from the photo-induced carrier generation, the light energy dependence of the photo-induced current was investigated. The small peak at 1.75 eV and broad peak at around 2.5 eV are observed at room temperature. The peak at 1.75 eV corresponds to the optical absorption at 1.7 eV that generated by the electron transition between Mn 3d (xy,x$^2$- y$^2$)($e_g$ state)/O 2p hybridized band and upper Mn 3d (3z$^2$-r$^2$,$a_{1g}$ state) orbital [1]. The broad peak of photo-induced current corresponds to the broad photoluminescence excitation spectrum at around 2.5 eV, which is never observed in absorption measurement but reported as the hidden optical channel. After the introduction of the origin of photo-induced current of YMnO$_3$, it is discussed including associated with the carrier generation and the emission process, ultrafast dynamics of coherent optical phonon correlated with the antiferromagnetic transition in a hexagonal YMnO$_3$ epitaxial film is discussed.

The observations of the coherent optical phonon using a reflection-type pump-probe technique at various temperatures, excitation powers and energies were carried out. We detected an oscillatory structure with a frequency of ~5.1 THz, which is assigned to the coherent optical phonon with A1 symmetry, in a time-domain signal. It was found that the coherent optical phonon can be observed at temperatures from 10 K to room temperature, while the oscillation amplitude markedly decreases with an increase in temperature around ~70 K corresponding to the Néel temperature. The temperature dependence of the oscillation amplitude indicates that the coherent optical phonon is sensitive to the spin-lattice coupling connected with the antiferromagnetic transition [2].

**Materials Design for the Bulk Photovoltaic Effect—Theoretical Limits and Novel Materials**

The bulk photovoltaic effect (BPVE) is the generation of photocurrents in the bulk of a single-phase material. It holds advantages over traditional photovoltaics based on p-n junctions, such as above-band gap photovoltages, and current generation in the bulk without the need for interface engineering. Despite numerous theoretical and experimental research efforts into the BPVE, there has been no systematic investigation into its maximum magnitude attainable in solid-state materials. In this talk, we present an upper bound on the dominant microscopic mechanism of BPVE: the shift current response. We show that this bound depends on the band gap, band width, and geometrical properties of the material in question. As a proof of principle, we perform first-principles calculations of the response tensors of a wide variety of materials, finding that the materials in our database do not yet saturate the upper bound. This suggests that new large BPVE materials will likely be discovered by future materials research guided by the factors mentioned in this work. These results imply that small band gap materials can potentially host large BPVE. As examples, we propose materials which are tuned across a band-gap-closing phase transition from a normal semiconductor into a topological insulating phase. This class includes some inorganic layered semiconductors, such as BiTeI, and inorganic halide perovskites, such as CsPbI$_3$. We show that this results in a dramatic enhancement of photocurrent as well as an abrupt transition in its direction. Using first-principles calculations, we show that this effect is robust across different materials systems as long as such a transition into a topologically insulating phase is present.

**Band Gap Modulation and Interface Engineering in Solution Deposited BiFeO$_3$-CoO$_x$: Thin Films**

Mariona Coll, Pamela Machado, Mateusz Scigaj, Jaume Gazquez, Antonio Sanchez-Díaz, Ignasi Fina and Mariano Campoy-Quiles; ICMAB-CSIC, Bellaterra, Spain.

In this work we study the chemical substitution of the transition metal in BiFeO$_3$ by Co-ions to explore the potential to judiciously engineer the optical band gap and examine its impact on the ferroelectric properties and the photoresponse. Nonetheless, the stabilization of BiFeO$_3$:CoO$_x$(BFCC) phases shows a rather narrow growth window requiring high pressure synthetic conditions. Here by using first-principles calculations, we have been able to stabilize by epitaxial growth the perovskite BF phase modulating the band gap from 2.7 to 2.4 eV while preserving robust ferroelectricity (P$_r$ = 60 μC/cm$^2$). Photoreponse measurements performed at 520 nm and 1.5 W/cm$^2$ on 100 nm BFCC films show a clear enhancement of the current density compared to pristine BF films. Also, we observe that the magnitude of the current can be modulated by applying a voltage of a particular polarity and this effect is stronger in cobalt substituted films. Towards an all-oxide device, the use of selective layers and transparent conducting oxides are also assessed to further improve the incident photon to charge carrier efficiency of these devices. With this comprehensive study we demonstrate the complexity but also the richness of this system for future light harvesting applications.

**9:30 AM *EP01.04.05***

**Bulk Photovoltaic Effect as Quantum Mechanical Shift Current in Polar Semiconductors**

Masashi Kawasaki; 1, 2 Department of Applied Physics and Quantum Photon Electronics Center (QPEC), The University of Tokyo, Tokyo, Japan; 3RIKEN Center for Emergent Matter Science (CEMS), Wako, Japan.

We discuss a novel manifestation of quantum mechanical current flow in solids upon photoexcitation. From old days, bulk photovoltaic effect has been known to exist in non-centrosymmetric crystals such as poled ferroelectrics [1]. Naive explanation was that the drift current flows due to electric field uncompensated by insufficient formation of electric double layer on the surfaces of polar crystals. Now, it is proposed and confirmed that a quantum mechanical effect, described by the Berry’s connection of Floquet bands, drives photocurrent called “shift current” as a second order optical process [2, 3].

As a proof of principle, we perform first-principles calculations of the response tensors of a wide variety of materials, finding that the materials in our database do not yet saturate the upper bound. This suggests that new large BPVE materials will likely be discovered by future materials research guided by the factors mentioned in this work. These results imply that small band gap materials can potentially host large BPVE. As examples, we propose materials which are tuned across a band-gap-closing phase transition from a normal semiconductor into a topological insulating phase. This class includes some inorganic layered semiconductors, such as BiTeI, and inorganic halide perovskites, such as CsPbI$_3$. We show that this results in a dramatic enhancement of photocurrent as well as an abrupt transition in its direction. Using first-principles calculations, we show that this effect is robust across different materials systems as long as such a transition into a topologically insulating phase is present.

Layered van der Waals crystals like ferroelectric CunP2S6 (CIPS) provide a range of intriguing functional properties. They open a straightforward path to magnetization switching such coupling is termed as positive magnetoelctric (ME) effect.\(^\text{1}\) Craig J. Fennie proposed a theoretical scheme/criteria to design structures of spontaneous polarization and a net magnetization are mutually exclusive.\(^\text{2}\) In recent years, great attention has been paid to synthesize materials with simultaneous polarization and a net magnetization due to their constructive performance of these materials.

In the present work, we choose Bi\(_{0.5}\)Na\(_{0.5}\)TiO\(_3\) (BNT) as our ferroelectric matrix which is an excellent ferroelectric oxide with large remnant polarization looking for another strong ferroelectric oxide. Moreover, the most interesting feature observed here is the negative ME (N-ME) coupling shown by these samples. It is observed that there is a decrease of \(Tc\) ~330 °C. We substituted Ti with Fe ions systematically as \(x\) = 0, 0.005, 0.01, 0.02, 0.05, 0.1 and 0.2, using solid state reaction route. Interestingly, in this BNT based series, the solid solubility limit of Fe substitution in this BNT matrix could be increased up to 20%; giving us a broader range to test the hypothesis given by Craig J. Fennie. This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility. The research was sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U.S. Department of Energy.

11:15 AM EP01.04.08
Large Negative Magnetoelastic Effect in Fe Substituted Ferroelectric Bio\(_{2}\)Na\(_{2}\)TiO\(_{4}\) Ceramics—A Combined Experimental and Theoretical Study Mukesh Kumari1,2, Sushma Shantapuri1 and Ratnamala Chatterjee1; 1IIT Delhi, New Delhi, India; 2Physics, National University of Singapore, Singapore, Singapore.

In recent years, great attention has been paid to synthesize materials with simultaneous polarization and a net magnetization due to their constructive practical applications in spintronics and non-volatile memory.\(^\text{1}\) However, such materials are difficult to obtain as the conditions for observation of spontaneous polarization and a net magnetization are mutually exclusive.\(^\text{2}\) Craig J. Fennie proposed a theoretical scheme/criteria to design structures of perovskite oxides (ATiO\(_{3}\), A = Mn, Fe and Ni), such that a polar distortion at Ti-site (B-site of perovskite unit cell) can induce weak ferromagnetism and the direction of magnetization can be switched by application of electric field (known as magnetoelastic (ME) coupling).\(^\text{3}\) Following this scheme, in one of our earlier works,\(^\text{4}\) we have demonstrated experimentally that a partial substitution of Ti\(^+\) (B-site) with Fe\(^+\) in a pure ferroelectric system Ba\(_{2}\)Zn\(_{1-x}\)Fe\(_x\)O\(_{3}\) (BZFO) gives rise to a reasonably large ME coupling. In these samples, it was observed that the electrical polarization favors the magnetization switching such coupling is termed as positive magnetoelastic (P-ME) coupling. However, one of the major drawbacks in the BZFO series is that the solid solubility limit of Fe in the main matrix of BZT. Thus, In order to have a broader range to test the hypothesis given by Craig J. Fennie, we looked for another strong ferroelectric oxide.

In the present work, we choose Ba\(_2\)Na\(_2\)TiO\(_4\) (BNT) as our ferroelectric matrix which is an excellent ferroelectric oxide with large remnant polarization ~38 \(\mu\)C/cm\(^2\) (in comparison of BZT ~21 \(\mu\)C/cm\(^2\)) and high Curie temperature \((Tc)\) ~330 °C. We substituted Ti with Fe ions systematically as Ba\(_2\)Na\(_2\)Fe\(_x\)Ti\(_{3-x}\)O\(_{10}\) with \(x\) = 0, 0.005, 0.01, 0.02, 0.05, 0.1 and 0.2, using solid state reaction route. Interestingly, in this BNT based series, the solid solubility of Fe substitution in this BNT matrix could be increased up to 20%; giving us a broader range to test the hypothesis given by Craig J. Fennie. Moreover, the most interesting feature observed here is the negative ME (N-ME) coupling shown by these samples. It is observed that there is a decrease of ~19% (at 40 kOe) in magnetization in poled sample \((x = 0.05)\) in comparison to the unpoled one. To understand this N-ME effect, we have developed a Landau-Devonshire thermodynamic model and estimated theoretical value of ME coupling co.~430 kV/cm Oe. Our Temperature dependent dielectric studies reveal that there is a small down shift in ferroelectric Curie temperature with increasing \(x\). Ferroelectricity is still maintained in all the substituted samples.

Hydrothermal Synthesis of Yb Doped Bismuth Ferrite Crystallites and Their Structural, Magnetic and Ferroelectric Characteristics

Multiferroic materials have attracted a great deal of attention because of their ferroelectric, ferromagnetic and ferroelastic properties in a single material. They enable to control electrical polarization under the application of magnetic field, or magnetization under the application of electric field. Due to its promising feature, they have gained a remarkable usage area in non-volatile information storage, spintronics, multiple state memories and sensors. Among multiferroics, BiFeO₃ (BFO) is one of the possible candidate for room temperature multiferroic materials. There are several methods to synthesize BFO varying from conventional solid state reaction to sol-gel technique.

In this study, one of the multiferroic material, BiFeO₃ (BFO) was investigated. It was hereby with this work proposed a hydrothermal method to synthesize BFO powders. Well-crystallized BFO and Yb-doped BFO (Biₓ₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋₅₋}_{(1,3)}

Preparation of κ-Al₂O₃-Type Ferroelectric Single Crystal and Single Domain Epitaxial Thin Film and Their Properties

Shintaro Yasui¹, Koki Tachiyama¹, Tsukasa Katayama¹, Takuro Dazai¹, Yosuke Hamasaki¹, Huan He², Hui Wang², Jiajing Yu² and Mitsuhiro Ichii²
1Tokyo Institute of Technology, Yokohama, Japan; 2The University of Tokyo, Tokyo, Japan; 3National Defense Academy, Yokosuka, Japan; 4Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China.

κ-Al₂O₃, same as ε-Fe₂O₃, GaFeO₃ structures, structured materials whose space group is Pna₂̅, are one of very attractive multiferroics because of coexistence of ferroelectric and ferrimagnetic properties at room temperature. Ferroelectric property of this material has been investigated using single crystal and epitaxial thin films. However, measurement of ferroelectricity is prevented by very large leakage current in GaFeO₃ single crystal. Moreover, this structured single crystal, except to GaFeO₃, is difficult to prepare due to metastable phase. On the other hand, the measurement of ferroelectric property was achieved by formation of high quality epitaxial thin film. However their measured polarization values were one order smaller than calculated values.
one[4]. We resulted that this issue was originated to three-fold structural variant which is formed on (111)SrTiO$_3$ single crystal. Therefore, we have tried to prepare GaFeO$_3$ single crystal and then prepare single crystal k- Al$_2$O$_3$ structured thin films on GaFeO$_3$ single crystal substrate. GaFeO$_3$ single crystal was prepared by floating zone method using 10 atom oxygen pressure. Then we cut and polished this single crystal for preparation of thin films using substrate, Sc$_0.5$Fe$_{1.5}$O$_3$ epitaxial thin films were fabricated on (001)GaFeO$_3$ single crystal by pulsed laser deposition method. Growth temperature and oxygen pressure for deposition condition were 800°C and 300 mTorr, respectively. Lase image of prepared GaFeO$_3$ single crystal measured along 001 zone axis is in good agreement with simulated one. From X-ray diffraction (XRD) 2θ-θ patterns of Sc$_0.5$Fe$_{1.5}$O$_3$ and (001)GaFeO$_3$ thin films and (001)GaFeO$_3$ single crystal substrate, k-Al$_2$O$_3$ type structured Sc$_0.5$Fe$_{1.5}$O$_3$ thin film was grown along 001 direction. XRD phi scan at (013)Sc$_0.5$Fe$_{1.5}$O$_3$ and (013)GaFeO$_3$ shows two-fold peaks at same phi degree. This result indicates that prepared Sc$_0.5$Fe$_{1.5}$O$_3$ thin films is single domain epitaxial thin films without structural variant. We will report ferroelectric, dielectric, leakage, magnetic properties of GaFeO$_3$ single crystal and Sc$_0.5$Fe$_{1.5}$O$_3$ single domain epitaxial thin film. [1]T. Arima et al., Phy. Rev. B 70, 064426 (2004). [2] M. Gich et al., Adv. Mater. 26, 4645 (2014). [3] T. Katayama et al., Adv. Funct. Mater. 28, 1704789 (2018). [4]D. Stoeffler, J. Phys.: Condens. Matter 24, 185502 (2012).

1:45 PM EP01.05.02 Tunable Dielectrics from First Principles—Effect of Chemistry and Epitaxial Strain Gerhard H. Olsen, Natalie M. Dawley, Darrell G. Schlom and Craig J. Fennie; Cornell University, Ithaca, New York, United States.

Progress in miniaturization of electronic devices, such as antennas and tunable filters, relies on continued development of thin film dielectric materials. Ruddlesden-Popper (RP) oxides based on strontium titanate (STO) have emerged as promising candidate materials, as they are highly tunable by electric fields and can be operated at +10 GHz frequencies with low dielectric losses. Such films can be grown on a range of substrates by molecular-beam epitaxy (MBE), but a remaining challenge is the trade-off between dielectric performance, improved by large epitaxial strains, and the maximum thickness that can be achieved before relaxation and high dislocation density of the film occurs. Here, we use first-principles calculations to investigate the effects of modifying the STO-based dielectrics with barium titanate (BTO). While BTO-based RPs cannot be synthesized with conventional methods, metastable RP phases with high Ba content can be grown using MBE. Our calculations show that even a small chemical modification both reduces the effective strain, allowing thicker coherent films to be grown, and at the same time enhances ferroelectricity to compensate for the reduced strain.

2:00 PM EP01.05.03 Two-Dimensional Materials for Electronic Applications: Design, Discovery, and Characterization John Brehm1, Marius Chyasnavichius2, Nina Bulke3, Sahine M. Neumayer4, Michael A. Sousner4, Michael McGuire5, Panchapakesan Ganesh6, Petro Maksymovych7 and Sokrates Pantelides7; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2Air Force Research Laboratory, Dayton, Ohio, United States; 3Vanderbilt University, Nashville, Tennessee, United States.

Two-dimensional materials are of scientific and technological interest as they run the gamut of electronic classifications from metal, to semiconductor, to insulator while being able to be easily joined to other materials with controlled number of layers. Metal thiophosphates offer a rich class of 2D materials, comprising metal ions occupying octahedrally coordinated sites in the with [P$_5$S$_8$]$^{1+}$ triangular lattice, leading to a variety of magnetic, structurally correlated and polar ground states. Copper indium thiophosphate (CuInP$_2$S$_6$) is one such member of this family and has been noted for its ferrielectric characteristic. In this talk, we present the results of density functional theory calculations that explore the effect of strain on the structure and polarization of CuInP$_2$S$_6$. We show CuInP$_2$S$_6$ exhibits a negative longitudinal piezoelectric coefficient, and a strain-induced phase transition between two phases, differentiated by the relative displacement of Cu within the individual layers. The existence of two phases may also explain the experimentally observed inhomogeneity of piezoresponse observed experimentally. More generally, these calculations reveal the crucial role played by the van-der-Waals gap in defining their functional properties.

2:15 PM EP01.05.04 Voltage-tunable radio frequency (RF) electronics are critical for fifth-generation (5G) millimeter-wave telecommunications; applications include frequency-agile filters and tunable phase shifters. For the former, these materials allow handsets to communicate on many frequencies. For the latter, they enable phased-array antennas for beam-steering, which mitigates atmospheric attenuation and interference. State-of-the-art tunable materials are too lossy for these applications because the 5G network requires the use of high carrier frequencies to meet capacity demands. This problem requires new, highly-tunable, low-loss compounds that can support 5G.

Combinatorial methods provide an opportunity to rapidly screen many candidate materials, and develop better models of materials behavior as a function of composition, frequency, and applied DC voltage. These models inform the search for materials with optimal properties. The primary advantage of combinatorial experiments is that full materials systems are synthesized simultaneously, maintaining constant experimental conditions over the full sample space.

In this presentation, we will explain a novel approach to extract the frequency-dependent complex permittivity and voltage-tuning behavior of combinatorial thin-film composition spreads from DC – 110 GHz. We tested our approach on the well-studied Ba-doped SrTiO$_3$ (BSTO) system, emphasizing 5G frequency bands, and developed a unified model of the frequency dependence, voltage tunability and composition. Such models assist in the design of 5G RF electronics, and are related to thermodynamic quantities. This relationship points to a potential path connecting optimal RF performance to materials through first-principles theory.

2:30 PM *EP01.05.05 Coupling Between Ferroelectricity and Chemistry on Mesoscopic and Atomic Scales Sergei V. Kalinin; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Ferroelectricity on the nanoscale has remained a subject of much fascination in condensed matter physics for the last several decades. It is well-recognized that stability of the ferroelectric state necessitates effective polarization screening, and hence screening mechanism and screening charge dynamics become strongly coupled to ferroelectric phase stability and domain behavior. Similarly, atomic scale defects can strongly affect polarization stability and affect wall pinning and nucleation and give rise to relaxor states. In this presentation, I will illustrate several recent results on ferroelectric and ferroic – chemical coupling on mesoscopic and atomic scales. In the nanoscale systems, the ferroelectric state is fundamentally inseparable from electrochemical state of the surface, leading to emergence of coupled electrochemical-ferroelectric states. These considerations further stimulate the development of the novel SPM modalities addressing time-dependent dynamics and chemical changes during SPM imaging, and studying in situ reactions from transformations from...
atomically-resolved data. I will further delineate the applications of in-situ SPM – time of flight secondary ion mass spectrometry (ToF SIMS) to map the changes in surface chemistry during tribological and local electrochemical experiments, including ferroelectric polarization switching and pressure-induced resistance changes in oxides. On the atomic scales, significant inroads in in-situ ferroelectric behaviors can be obtained from atomically-resolved studies of ferroelectric materials that allow direct visualization of materials structures and order parameter fields. These approaches further necessitate analysis and data mining of large volumes of information, and first examples of deep learning analysis on STEM data to infer local materials behavior and kinetics of point-defect reactions will be illustrated.

This research was sponsored by the Division of Materials Sciences and Engineering, BES, DOE, and was conducted at the Center for Nanophase Materials Sciences, sponsored at Oak Ridge National Laboratory by the Scientific User Facilities Division.

Regenerative Electroceramics for High Temperature Energy Converters
Anke Weidenkaff, Wenjie Xie and Xingxing Xiao; University of Stuttgart, Stuttgart, Germany.

Electroceramics are needed for diverse energy converters (1,2). The prerequisite for a durable active material is the constant regeneration of the structure under thermochemical and heating cooling cycles. Perovskite-type ceramics as well as their nanocomposites are prospective candidates for multifunctional high temperature energy converters. Their good performance relies on their flexible crystal structure being able to accommodate defects during thermal redox processes. The design of our materials is based on theoretical predictions and a deep knowledge on composition-structure-property relationship. The perovskite structure allows diverse substitution reactions to tune the band structure, charge carrier density and mobility as well as thermal and ionic transport. The electronic mobility can become high while the thermal conductivity can be low. Strongly correlated electronic systems are employed as additional design elements for a targeted materials design (3).

The resulting high temperature oxide materials as well as low temperature intermetallic (half-Heusler) and chalcogenite phases are characterized and tested in in-situ high temperature applications to improve the efficiency and energy density of energy conversion devices.

4:30 PM *EP01.05.08
Piezo-Phototronic Effect on Performance Enhancement of Anisotype and Isotype Heterojunction Photodiode
Zijian Pan, Wenbo Peng, Fangpei Li and Yongning He; School of Microelectronics, School of Electronic and Information Engineering, Xi’an Jiaotong University, Xi’an, China.

The piezo-phototronic effect has been confirmed as a promising methodology to optimize the performances of optoelectronic devices. However, not only positive effects but also negative effects may be produced in some types of photodiodes (PDs) by the piezo-phototronic effect, resulting in the restriction of the PDs’ photoreponse performance enhancement. In order to obtain as large photoreponse performance enhancement as possible, it is essential to investigate how the piezo-phototronic effect influences the photoreponse performance of PDs with different device configurations and structures. Here, we have thoroughly investigated the piezo-phototronic effect on the photoreponse performance enhancement of anisotype (p-Si/n-ZnO) and isotype (n-Si/n-ZnO) heterojunction PDs. The experimental results show that distinct photoreponse performance enhancement of the p-Si/n-ZnO and the n-Si/n-ZnO heterojunction PDs are both achieved by the piezo-phototronic effect. The photoresponsivity enhancement can reach maximized values of 151.06% and 54.95% for the p-Si/n-ZnO and the n-Si/n-ZnO heterojunction PDs, respectively, under -1.0% externally applied compressive strain condition and 6.00 × 10⁸ W 405 nm laser illumination, additionally indicating that the magnitude of the photoreponse performance improvement of the p-Si/n-ZnO heterojunction PD is much larger than that of the n-Si/n-ZnO heterojunction PD. The fundamental working mechanisms of how the piezo-phototronic effect influences the photoreponse performances of the p-Si/n-ZnO and the n-Si/n-ZnO heterojunction PDs are systematically investigated by carefully analyzing their different energy band diagrams under a series of externally applied compressive strain conditions, to explore the in-depth physics beneath the experimental phenomenon. Our proposed mechanisms together with the finite element analysis theoretical simulation results reveal that, two positive effects are introduced to and contribute to the photoreponse performance improvement of the p-Si/n-ZnO heterojunction PD, whereas one positive effect and two negative effect are introduced to the photoreponse performance improvement of the n-Si/n-ZnO heterojunction PD. These three effects compete with each other and finally lead to a weakened photoreponse performance improvement compared with the case of the p-Si/n-ZnO heterojunction PD.

This work not only presents in-depth understandings about the piezo-phototronic effect on the photoreponse performances of PDs with different device configurations and structures, but also provides methodology guidance to achieve optimized photoreponse performances of optoelectronic devices by the piezo-phototronic effect.

A Novel CMOS Compatible III-V Semiconductor Based Ferroelectric with Intriguing Properties

Simon Fichtner1,2, Fabian Lofink2 and Bernhard Wagner1,2; 1CAU Kiel, Institute for Material Science, Kiel, Germany; 2Fraunhofer Institute for Silicon Technology, Iitzehoe, Germany.

We regret that, due to ongoing patent applications, we are as of now still unable to discuss aspects that would reveal the composition of the new ferroelectric compound (such as its crystal structure) and the intended applications or related literature. We are however certain that we will be able to share all relevant information in the end of August the latest. For the same reasons, this work is still pending journal publication.

The drive towards miniaturization of piezoelectric sensors and actuators as well as the introduction of ferroelectric functionality into integrated circuit (IC) technology have led to substantial scientific and commercial interest in ferroelectric thin-films. Many of the more important ferroelectrics are perovskite oxides, with typical disadvantages such as low paraelectric transition temperatures, non-linear displacement or compatibility issues with complementary metal-oxide-semiconductor (CMOS) technology. Here, we report experimental results of a first material of what can be expected to be a new group of CMOS compatible ferroelectrics with remarkable properties: Solid-solutions based on a technologically significant subgroup of the III-V compound semiconductors.

Virtually leakage current free polarization hysteresis loops with large remnant values of up to 110 μC/cm² are obtained on polycrystalline thin-films grown by sputter-deposition. Unypcial for a polycrystalline ferroelectric, sharp switching events give rise to an almost perfectly square hysteresis. Systematic tuning of the coercitive fields from 1.8 MV/cm to 3.5 MV/cm was achieved by varying the composition of the solid solution and, independently, via permanent process induced lateral straining of the films. Both mechanisms, as the occurrence of ferroelectricity itself, can be related to a continuous distortion of the initial III-V crystal structure with increased alloying or strain. The inverse piezoelectric effect reveals highly linear strain regimes over a wide range from -0.3% to 0.4% - a direct result of the narrow polarization switching events. Moreover, polarization inversion appears to be complete, as direct and inverse piezoelectric coefficient measurements result in largely identical absolute coefficient values for both polarization states. Measurements of the direct piezoelectric effect after annealing at up to 600°C revealed only a slight decline of the piezoelectric performance without subsequent repolarization, therefore setting a high lower limit of 600°C for the paraelectric transition temperature of the material.

We are confident that these findings could make a valuable contribution towards a more extensive implementation of ferroelectric functionality in thin-film technology.

SESSION EP01.06: Characterization of Semiconducting Piezoelectric, Pyroelectric and Ferroelectric Materials

Session Chairs: Shyam Dwaraknath and Anke Weidenkaff

Wednesday Morning, November 28, 2018

8:00 AM EP01.06.01
Flexible and Controllable Piezo-Phototronic Pressure Mapping Sensor Matrix by Organic/Inorganic Hybrid LED Array
Rongrong Bao and Caofeng Pan; Chinese Academy of Sciences, Beijing, China.

Functional tactile sensing device is mandatory for next-generation robotics and human-machine interfaces since the emulation of touching requires large-scale pressure sensor arrays with high-spatial resolution, high-sensitivity, and fast-response[1]. Some tactile sensors fabricated with organic transistors or micro-structured rubber layer pressure sensor arrays have been reported[2]. While with a resolution at the order of millimeter, these devices have not yet met the requirements for artificial skins whose spatial resolution is near 50 μm. Our group have demonstrated pressure sensor array base on piezotronic and piezophototronic effect[3]. An ultra-high resolution of 2.7 μm was derived from piezo-phototronic pressure sensor array using ZnO nanowire (NW)/p-GaN LEDs array[4]. These devices provide stable, fast response, as well as parallel-reading detections of spatial pressure distributions. However, the lacking of flexibility with a rigid sapphire substrate prevents the NW-LEDs array device from applications as smart skin; and the pressure measuring range of the device is in a relatively high pressure region. Therefore, a flexible pressure mapping system with moderate spatial-resolution become necessary and may find numerous potential applications in human-machine interfaces.

Recently, we designed and fabricated a flexible LED array composed of PEDOT:PSS and patterned ZnO NWs with a spatial resolution of 7 μm for mapping of spatial pressure distributions by using the piezo-phototronic effect. These devices possess a wide range of pressure measurements from 40 MPa to 100 MPa depending on the growth conditions of ZnO NWs. Furthermore, a LED array composed of PEDOT:PSS and CdS nanorods had been demonstrated for mapping spatial pressure distributions. The emission intensity of which depends on the local strain owing to the piezo-phototronic effect. Therefore, pressure distribution is obtained by parallel-reading the illumination intensities of LED arrays based on electrofluorescence working mechanism. The spatial resolution is achieved as high as 1.5 μm. Flexible LED device array has been prepared by Cds nanorod array on Au/Cr/Kapton substrate. The flexibility and stability of these LED arrays mapping system was studied. The outstanding flexibility, high resolution and controllability of these pressure mapping sensors provide promising technologies for future applications in biological sciences, human-machine interfacing, smart sensor and processorsystems, and even defense technology.

Ferroic and Multiferroic Behavior in Fe Doped BaTiO3 Single Crystals

Peter Finkel1, Margo L. Staruch1 and Markys G. Cain2; 1NRL, Washington, District of Columbia, United States; 2Electrosciences Ltd, Surrey, United Kingdom.

Single crystals of BaTiO3 (BTO) that have been doped at the titanium site with Fe⁺ or Mn⁺ have previously been shown to demonstrate large and recoverable electrostrain of up to 0.8 % that is thought to be due to the alignment of defects (i.e. O²⁻ vacancies) with the crystallographic symmetry in the ferroelectric state when the samples are aged.[1,2] This results in a restoring force where the ferroelectric domains favour alignment with the defect dipoles, giving rise to a large reversible strain due to repeated non-180° domain rotation. There is also the possibility that the incorporation of a magnetic ion could give rise to a magnetic signature and even possibly multiferroic coupling in these doped samples, the possibility of which has not been previously
investigated. In this presentation, results from magnetic measurements and polarization measurements with bias magnetic fields will be discussed for a 0.5% Fe doped BTO crystal. Impact of repeated cycling at different electric fields and the recoverability of this large strain will also be presented.

8:30 AM EP01.06.03 Flexible Transparent Nonvolatile Transistor Based on Aluminum-Doped Zinc Oxide/ Lead Lanthanum Zirconate Titinate Heteroepitaxial Structure Meng-Fu Tsai1, Jie Jiang2 and Ying-Hao Chu1, 3, 4; 1Department of Materials Science and Engineering, National Chiao Tung University, Hsinchu, Taiwan; 2Key Laboratory of Low Dimensional Materials and Application Technology of Ministry of Education, Xiangtan, China; 3Department of Electrophysics, National Chiao Tung University, Hsinchu, Taiwan; 4Material and Chemical Research Laboratories, Industrial Technology Research Institute, Hsinchu, Taiwan.

With the rise of Internet of Things, flexible and transparent electronic devices are expected to fulfill rising technical requirements which silicon-based electronics cannot achieve. As known to everyone, the advancement of transistors is most close to the development of technology. However, the performance of present flexible and transparent transistors have been restricted due to the poor crystallinity. In order to make a high quality nonvolatile transistor with full transparency and lower energy consuming, here, we demonstrated a transparent ferroelectric field effect transistor (TrFET) on muscovite substrate. With a high quality aluminum-doped zinc oxide as active channel layer and high transparency lead lanthanum zirconate titinate as ferroelectric layer, this heteroepitaxy performs excellent electrical properties. Moreover, this flexible TrFET not only shows high transparency and high thermal stability, but also exhibits promising stability against to mechanical strain during a series of bending tests. Our study demonstrates an unusual concept to achieve flexible transparent nonvolatile transistor for development of next-generation smart devices.

8:45 AM EP01.06.04 Organic Ferroelectric Tunnel Junctions for Synaptic Computation Sayani Majumdar; Aalto University, Espoo, Finland.

The performance of current information processors are predominantly based on complementary metal-oxide-semiconductor (CMOS) transistors. However, CMOS scaling have started to face significant challenges and besides the physical limits, the conventional computing paradigm based on binary logic and Von Neumann architecture is becoming increasingly inefficient with onset of big data revolution and growing complexity of computation. Neuromorphic computing is the state-of-the-art research trend in the field of memory and logic devices where the goal is to build a versatile computer that is efficient in terms of energy and space, homogeneously scalable to large networks of neurons and synapses, and flexible enough to run complex behavioral models of the neocortex as well as networks inspired by neural architectures. Memristors, with their gradually modified conductivity level can mimic the biological synapses. Low energy consumption, ultrafast operation and small dimensions are the most essential requirements for a memristor to perform tasks similar to a synapse and become as efficient as human brain. A ferroelectric tunnel junction (FTJ), where gradual modulation of conductance can be achieved by controlled rotation of ferroelectric domains can act very efficiently as a synapse. Also the non-volatility of the stored information in the ferroelectric memories make them even more attractive as potential candidates for future neuromorphic computing building blocks. Here, we report on the performance of FTJs with a spin-coated organic ferroelectric (P(VDF-TrFE)) tunnel barrier. We have measured up to 10% tunneling electroresistance (TER) effect in these FTJs on a semiconducting Nb-doped STO bottom electrode at room temperature that persists until the ferroelectric Curie point of P(VDF-TrFE). Also these junctions show very clear and reproducible memristive behavior based on variable amplitude and duration of the applied voltage pulses, fast switching, long data retention of the high, low and different intermediate states, short and long-term potentiation (STP & LTP) and depression and spike-time-dependent-plasticity (STDP) which is extremely promising for neuromorphic applications. Our recent experiments suggest based on the morphology of the ferroelectric film and the top electrode material, the available number of computational states in these devices can be significantly modified that can bring advantages for the synaptic computational devices.

9:00 AM EP01.06.05 Piezoelectric β-PVDF:Yb Composite with Photochromic Properties Pedro Perdigon Lagunes, Eduardo Malagon, Jimena de la Mora, Yessica P. Reyes-Castro, Octavio Estvez and Raul Herrera-Beccera; Universidad Nacional Autónoma de Mexico, Mexico City, Mexico.

Nowadays piezoelectric systems have been studied and used in interesting daily applications, such as smartphone cameras, accelerometers and microphones [1]. Another interesting area studied for piezoelectric materials is energy harvesting, as transducers capable of convert vibrations, electromagnetic waves or even wind/water flow into electric potential difference [2]; this might lead to improve our actual collection of renewable power sources, and will let us explore other energy solutions. Even though these materials are promising with their applications, there are some limitations such as energy dissipation through Joule heating [3]. In addition, the most common piezoelectric materials are based in ceramic materials, hence, they are susceptible to wear fatigue. An interesting option is to use instead piezoelectric polymers, these materials are flexible, fatigue resistant and biochemical resistant due to their chemical composition. One of the most renown materials of this type is PVDF (Poly vinylidene fluoride), a semi-crystalline fluoropolymer stable to an unexpected optical result was found; when β-PVDF:Yb is exposed to sunlight, it presents a photochromic response that correlates to the interaction electronic density of Yb3+ interacts with the polymer chains, a fixed order is promoted into the PVDF structure with a tendency of a b structure. In addition, β-PVDF is an excellent option to be used as piezoelectric material for renewable energies and sensors. In addition, this material, owing to its photochromic properties, might be used also as a wearable biosensor/actuator that tracks in real time changes on blood pressure. Nevertheless, the real challenge is to obtain a predominant β-PVDF phase; this is because PVDF, as a semi-crystalline polymer, still has an entropic tendency to rearrange its molecules in lower energy state. We solved this problem by doping the polymer with ytterbium ions (Yb3+) in different concentrations below 10% in weight. As the electronic density of Yb3+ interacts with the polymer chains, a fixed order is promoted into the PVDF structure with a tendency of a b structure. In addition, an unexpected optical result was found; when β-PVDF:Yb is exposed to sunlight, it presents a photochromic response that correlates to the interaction absorption frequencies of the Yb3+. Thus, we consider that a piezoelectric polymer with photochromic characteristics, is an interesting system to be further explored for technological applications in relevant fields.

Electro-Chemo-Mechanical Actuator Operating at Room Temperature
Eran Mishuk, Evgeniy Makagon, Sidney Cohen, Ellen Wachtel and Igor Lubomirsky; Weizmann Inst of Science, Rehovot, Israel.

Chemical expansion of a solid refers to dimensional change due to change in stoichiometry. Dimensional change due to charged defects redistribution in an electric field has been termed the electro-chemo-mechanical (ECM) effect. Such instability is clearly deleterious for batteries or fuel cells, but, as recently suggested, has potential for use in actuation[1]. A typical ECM actuator scheme includes: electrode/WB/ferroelectric-electrolyte(SE)/WB2/electrode2, where WB denotes working-body solids with large chemical expansion coefficient. The main advantage of ECM is that it can deliver simultaneously large strain and large stress, which is difficult to achieve with other actuation mechanisms. We have constructed a room temperature ECM nanocrystalline membrane actuator (2nm diameter; ≈2µm thick) with Gd-doped ceria as SE. We tested two alternatives for WB’s: (1) metal/metal oxide or (2) ceria/metal nanocrystalline composite. Electrical and electromechanical measurements demonstrated that actuator response with metal/metal oxide WB is limited by the rate of oxygen diffusion from the solid electrolyte to the metal surface. Actuators with ceria/metal composite WB provide faster response time (~20sec) and larger vertical displacement (~3.5µm). Our findings suggest that ECM may become a viable actuation mechanism.

10:00 AM EP01.06.07
A Pathway Toward 100mV Switching of Ferroelectricity
Yen-Lin Huang1, Bhagwati Prasad1, Shang-Lin Hsu1, Etvonton Bonturin1, Yunlong Tang1, Arnold S. Everhardt1, Chia-Ching Lin2, Tanay Gosavi3, S Manjapatrun4, D Nikonov5, I Young6 and Ramamoorthy Ramesh7,8; 1University of California, Berkeley, Berkeley, California, United States; 2Educational Integrated Circuits and Components Research, Intel Corporation, Hillsboro, Oregon, United States; 3Department of Physics, University of California, Berkeley, Berkeley, California, United States.

The demand for ultra low-powered high-speed devices has pushed scientists and engineers to consider new approaches that involve many aspects, such as materials engineering, device architectures, power management, etc., for the next generation electronics. Ferroelectrics offer a promising route toward a nonvolatile and low power consumption per bit operation (~10 aJ/bit) if one can switch the ferroelectric polarization by 100 mV. Here we demonstrate a reliable pathway to achieve 100 mV switching by the heterostructure: SrRuO3/La-doped BiFeO3/SrRuO3, BiFeO3 exhibits a robust ferroelectricity at room temperature and possesses a large polarization ~ 80 µC/cm2, which can be a burden during switching. Substituting Bi with La enables BiFeO3 to be switched at a lower voltage due to the suppressing of rhombohedral distortion and resulting in a reduced polarization down to ~ 40 µC/cm2 and a lower Curie temperature as well. Moreover, in order to further reduce the coercive voltage, the thickness of the ferroelectric layer also needs to be scaled. However, thinner ferroelectric films generally face multiple issues such as leakage, and depolarization effect, which will lead to an unmeasurable or degraded ferroelectricity. A detailed chemical analysis revealed a limited interdiffusion, which limits the leakage current as well, at the interface between the metal and ferroelectric layer by cross-sectional TEM/EDX. We also explore several oxide metal electrode materials, such as SrRuO3, LaNiO3, and La0.8Sr0.2MnO3, to minimize the depolarization effect and the contact potential difference. By carefully controlling the interfaces, film growth, and La doping concentration, the coercive voltage of ~100 mV can be achieved in a 20 nm La0.8Sr0.2MnO3 film. Our results not only provide a profound understanding of low-voltage ferroelectric switching as well as pave the way to the low-power information storage/processing technology.

Acoustically Driven Ferromagnetic Resonance Driven Excitation of Vacancy Centers
Sayeef Salahuddin; University of California, Berkeley, Berkeley, California, United States.

Sound waves flowing in a piezoelectric crystal could be exploited to excite a ferromagnetic resonance. Here we shall discuss our recent work that aims to exploit such ferromagnetic resonance as a way to couple to nearby defect centers. Specifically, we have studied the nitrogen vacancy centers in diamond. We find that it is indeed possible to couple to these NV centers efficiently, even at zero external magnetic field. These findings may allow drive defect centers purely electrically.

Electrically Tuned Photoelectrochemical Properties of Ferroelectric PVDF/Cu/PVDF-NaNbO3 Photoanode
Simrit Singh1; 2 and Neeraj Khare; 2 Panjab University, Chandigarh, India, Ludhiana, India; 3Physics, Indian Institute of Technology Delhi, New Delhi, India.

In recent years, photo-electrochemical (PEC) water splitting with an aim to generate hydrogen (H2) as a clean and renewable fuel has been the subject of intense research interests [1]. Ferroelectric semiconductors have been demonstrated to exhibit enhanced PEC properties as these can be polarized with the application of an external electric field resulting in a built-in potential which helps in separating out the photogenerated charge carriers. In addition to this, by changing the polarization direction, the energy band alignment at the electrode/electrolyte interface can be modulated in a way that it can help in easy transfer of the charge carriers from electrode to electrolyte [2-4]. In this paper, we investigated the PEC properties of ferroelectric PVDF/Cu/PVDF-NaNbO3 PEC cell and demonstrated that PEC properties can be tuned with ferroelectric polarization and piezophototronic effect. Photocurrent density is enhanced from ~0.71 mA/cm2 to 1.97 mA/cm2 by changing the polarization direction. Furthermore, due to flexibility and piezoelectric properties of PVDF/Cu/PVDF-NaNbO3 PEC cell, a further ~26% enhancement in the photocurrent is obtained using the piezophototronic effect. A model depicting the modulation of band alignment between PVDF and NaNbO3 with electric field is proposed to explain the observed tuning of the PEC properties. Electrochemical impedance spectroscopy measurements supports the validity of the proposed model.

PETMEM: Piezoelectronic Transduction Memory Device—A European Research Project Update
Markys G. Cain; Electrosences Ltd, Farnham, United Kingdom.

Computer clock speeds have not significantly increased since 2003, creating a challenge to invent a successor to CMOS technology able to resume the improvement in clock speed and power performance. The key requirements for a viable alternative are scalability to nanoscale dimensions - following
Moore’s Law - and simultaneous reduction of line voltage in order to limit switching power. Achieving these two aims for both transistors and memory allows clock speed to again increase with dimensional scaling, a result that would have great impact across the IT industry. PETMEM is a European partnership amongst Universities, Research Institutions, SMEs and a large company that will focus on the development of new materials and characterization tools to enable the fabrication of an entirely new low-voltage, memory element. This element makes use of internal transduction in which a voltage state external to the device is converted to an internal acoustic signal that drives an insulator-metal transition. Modelling based on the properties of known materials at device dimensions on the 15 nm scale predicts that this mechanism enables device operation at voltages an order of magnitude lower than CMOS technology (power is reduced two orders) while achieving 10Ghz operating speed. In this presentation the first two years results will be summarised with a focus on new piezoelectric and new piezoresistive materials development, and some performance properties of our first demonstrator device will be discussed.

Efficient Piezocatalytic Activity Driven by the Piezoelectric Effect of BaTiO3 Nanowires
Jiang Wu, Ni Qin and Dinghua Bao; Sun Yat-Sen University, Guangzhou, China.

Recently, a novel catalysis technology, which named piezocatalysis, has received significant attention due to independence of light irradiation. Here, we report the new advances in the piezocatalysis of BaTiO3 and further investigate the relationship between piezoelectric potential and piezocatalysis. In this work, we successfully synthesized BaTiO3 nanowires and nanoparticles by a two-step hydrothermal method. It was found that the BaTiO3 nanowires exhibit effectively enhanced piezocatalytic activity under ultrasonic vibration compared with the BaTiO3 nanoparticle. To explore the origin of the excellent piezocatalysis performance of BaTiO3 nanowires, the distribution of piezoelectric potential in these nanomaterials was simulated by the finite element method (FEM) with the aid of COMSOL multiphysics software package. On the basis of the piezoelectric potential analysis by FEM stimulation, the enhanced piezocatalytic activity of the BaTiO3 nanowires can be attributed to the larger piezoelectric potential along the polar axis. A relatively larger piezoelectric potential of the catalyst surface can induce a greater shift of conduction band and valence band, resulting in easier and faster immigration of the electrons and holes, during reacting with dissolved oxygen and hydroxyl to form superoxide radicals and hydroxyl radicals. Furthermore, we demonstrate that the intrinsic charge carriers (not piezoelectric charges) in piezoelectric crystals play the role of charge transfer in the catalysis process through regulating the concentration of charge carriers in catalyst. This study provides further understanding of piezocatalysis of piezoelectric nano-materials as well as insights on the relationship between piezoelectric potential and piezocatalysis.

Electric Field Manipulation of Ferroelectric Vortices—In Situ TEM
Christopher T. Nelson1, 2, 3, 4, Zijian Hong5, Cheng Zhang6, 7, Ajay Yadav8, Sujit Das9, Anoop R. Damodaran1, 2, Sheng-Lin Hu9, 1, James D. Clarkson1, 2, Miaofang Chi1, 2, Philip D. Rack2, 7, Long-Qing Chen8, 9, Lane W. Martin10 and Ramamoorthy Ramesh1, 2, 3, 4, 5, 6, 7, 8, 9, 10; 1Lawrence Berkeley National Laboratory, Oak Ridge, Tennessee, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3University of California Berkeley, Berkeley, California, United States; 4Pennsylvania State University, State College, Pennsylvania, United States; 5University of Tennessee, Knoxville, Knoxville, Tennessee, United States; 6University of California Berkeley, Berkeley, California, United States; 7University of California Berkeley, Berkeley, California, United States; 8University of Tennessee, Knoxville, Knoxville, Tennessee, United States.

Arrays of ferroelectric vortices formed in ferroelectric / paraelectric thin film multilayers with a predominant Néel-type rotational character [1] and emergent chirality [2] are an enticing foray into topological complexity that is typically the purview of magnetic systems. The nanometer length scale and direct electric field manipulation makes ferroelectric polarization texture an attractive counterpart to spin systems wherever parity exists. Moreover, electric field control of vortex array blocks has been demonstrated by scanning surface probe [3] in geometries where the vortex structure is degenerate with classic a1/a2 domains [4]. In this work using in situ TEM we present the electric field response of these ferroelectric vortices length scales comonat with the vortex structure (nm). In geometries where the vortex structure is highly stable, applied electric fields induce vortex asymmetry within the PTO layer manifesting as shifts of the rotation centers. In this manner the vortex structure adapts to applied fields via short range small domain wall translations without need of nucleation events. In geometries degenerate with a1/a2 domains, deterministic switching between vortex and a1/a2 structures can be achieved as in bulk [3].

Electronic Conductivity of Charged Ferroelectric Nanodomains
Stuart R. Burns2, Ye Cao3, Alexander Tselev4, Rama K. Vasudevan5, Joshua Agar6, Lane W. Martin2, Mark Huijben6, Sergei V. Kalinin7, Nagarajan Valanoor8, Anna Morozovska6, Petko Maksymovych3; 1Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 2University of New South Wales, Sydney, New South Wales, Australia; 3The University of Texas at Dallas, Dallas, Texas, United States; 4University of Aveiro, Aveiro, Portugal; 5University of California, Berkeley, Berkeley, California, United States; 6University of Twente, Enschede, Netherlands; 7National Academy of Sciences, Kyiv, Ukraine.

Ferroelectric nanodomains are inevitably created upon polarization reversal. They provide a natural setting to explore conductive properties of ferroelectrics, because the repolarization nuclei are decorated by weakly charged domain walls, and because they can be created and subsequently tuned on demand by appropriately chosen electric field. As such, nanodomains are a model system to probe presently open questions surrounding domain wall conductance, such as pathways to increase conductance (through carrier density and possibly mobility), understanding the stability of conductive walls and the origin of the screening charge.

We have measured conductance of two different kinds of ferroelectric nanodomains, aiming to maximize polarization charge in the ferroelectric volume. In the first case, a radially symmetric electric field is applied to a ferroelectric with substantial component of in-plane polarization – in our case the 100-oriented film of BiFeO3. Such nanodomains are intentionally unstable but arguably achieve the largest possible polar discontinuity. Indeed, we observe...
near-record high local conductivity for ferroelectric as well as metastability in applied electric field, producing an electronic function of a volatile resistive switch. However, the net conductance is not metallic in this case. Phase-field modeling reveals localization of polarization charge to near-electrode region, effectively screening applied electric field. We anticipate that conductance will be dramatically enhanced in the ultrathin limit, where the volume of polar discontinuity becomes comparable to the overall film thickness. On the other hand, we have investigated the signatures of inclined domain walls in lead zirconate titanate at the instance of ferroelectric switching by microwave probe, which is sensitive to the bulk volume of the film. We have again observed the largest microwave conductance among accessible polarization configurations, as well as profound metastability of nandomains in a relatively broad range of applied fields. An inspection of the dielectric properties of domain walls at and above their depinning field was carried out to separate the contributions of domain wall motion from nanodomains hysteresis. This analysis provided further evidence for electronic (rather than dispersive) origin of microwave conductance for ferroelectric structures created by localized electric fields. Finally, we will comment on the stability of the charged configurations based on detailed analytical modeling of charged domain walls in various screening scenarios. Charged domain walls appear to be generally unstable for polarization exceeding ~10 microC/cm², even with efficient supply of the screening carriers. Support provided by the U.S. Department of Energy, Basic Energy Sciences, Materials Science and Technology Division. Microscopy experiments performed at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility.

**Electrochemical Phenomena of Polarization Switching in Ferroelectrics**

Anton V. Ievlev, Sergei V. Kalinin and Olga Ovchinnikova; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

Polarization switching in ferroelectric materials underpins a broad gamut of applications ranging from random access memory, tunneling barriers, data storage, and ferroelectric ceramics. Classically, the polarization switches due to a co-existence of energetically equivalent crystallographic states, that can be altered with an external electric field. To stabilize polarization, charge discontinuity at surfaces and interfaces requires compensation, or screening, to avoid long-range electrostatic fields that destabilize the ferroelectric phase. Most studies consider polarization screening to be chemically inert; leaving the composition of the ferroelectric intact. However, analysis of extreme ferroelectric phenomena suggests higher complexity. It is well known that multiple polarization switching cycles can accumulate damage at interfaces, dubbed “ferroelectric fatigue.” Typically, tens or hundreds of thousands switching events are required, and the exact mechanisms remain controversial. Furthermore, polarization-dependent photovoltaic effects in perovskites suggest that even under optimal screening conditions a considerable electric field remains in the material. Thus, switching is associated with high fields, which can chemically alter material composition.

Here we utilize multimodal approach combining time of flight secondary ion mass spectrometry (ToF-SIMS) with atomic force microscopy (AFM) to explore the structure property interplay of ferroelectrics during polarization switching in lead zirconate titanate (PZT, PbZr₀.₂Ti₀.₈O₃) thin films. Using this multimodal imaging platform, we demonstrated that chemical phenomena plays significant role in ferroelectric switching process. Specifically, we found that local ferroelectric switching by the AFM tip, significantly alters the chemical composition in the 3-nm-thick surface layer of the sample, forming reversible concentration wave, of Pb²⁺ ions. Furthermore, investigations of the polarization cycling in the PZT sample with copper electrodes, showed penetration of the copper cations into the structure of PZT. This explains ferroelectric fatigue phenomenon, leading to decrease in spontaneous polarization with sample cycling.

Altogether, explored chemical phenomena associated with ferroelectric switching will enhance fundamental understanding of ferroelectric phenomena and aid in the practical application of ferroelectrics in devices.

This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility, and using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

**Reliability of PbZr₀.₅₂Ti₀.₄₈O₃ Thin Films for Actuators**

Susan E. Trolier-McKinstry, Wanlin Zhu, Kathleen Coleman, Betul Akkopru-Akgun, Michael Lanagan and Clive Randall; The Pennsylvania State University, University Park, Pennsylvania, United States.

Lead zirconate titanate (PbZr₀.₅₂Ti₀.₄₈O₃, or PZT) films are of interest for piezoelectric microelectromechanical systems as actuators, e.g. in inkjet printers, adjustable optics, micromirrors, and ultrasound transducer arrays. In many cases, these actuators are driven at higher electric fields than would be characteristic of bulk ceramic actuators. Thus, understanding the factors that control the electrical and mechanical reliability of these films under aggressive conditions for electric fields and strains is critical. To address this, acceptor (1-4% Mn) and donor (1-4%) doped PZT films were grown. Thermally stimulated depolarization current (TSDC) measurements in Mn doped PZT films showed one depolarization peak with an activation energy of 0.6-0.8 eV, associated with ionic space charge presumably due to ionic migration of oxygen vacancies. The magnitude of the depolarization current peak increases with increasing degradation times, suggesting the dissociation of defect dipoles during electrical degradation. A similar depolarization current peak attributed to existence of mobile oxygen vacancies was also observed for undoped and Nb doped PZT films; the magnitude of this peak increases on lowering Nb or PbO contents. An additional TSDC peak, associated with trapped charges was found in both Nb doped PZT films and undoped PZT films annealed under low PbO partial pressure. The trap depth is estimated to be 1.1±0.03 eV, which is attributed to trapped electronic charge carriers at reduced Ti on the B site. Electron energy loss spectroscopy studies of degraded Nb doped samples confirmed localized Ti reduction near the cathode. A model describing the failure mechanisms will be presented.

**4:00 PM EP01.07.05**

**Measurements of Polarization Switching Dynamics in the Tens of Picoseconds**

Aaron M. Hagerstrom¹, Eric Marks², Xiaohang Zhang², Christian J. Long¹, James C. Booth¹, Ichiro Takeachi¹ and Nathan D. Orloff¹; ¹National Institute of Standards and Technology, Boulder, Colorado, United States; ²University of Maryland, College Park, Maryland, United States.

Technological applications of ferroelectric materials often depend on their tuning under an applied electric field. In recent years, polarization switching processes have attracted interest for their role in transient negative capacitance, which could be used increase transistor energy efficiency. Switching processes also govern how quickly a microwave-frequency device based on ferroelectric materials can be reconfigured. Despite the technological motivations to study switching speed, high-frequency measurements remain difficult. In particular, separating the behavior of the measurement circuit from the behavior of the material under test is increasingly difficult with increasing frequency. Interpretation of measurements often requires complicated models of both the material and the measurement circuit. In this talk, we describe a new method for quantifying switching dynamics through nonlinear mixing products up to 40 GHz. From our measurement technique, we are able to empirically describe the dynamical switching behavior of the material under small signals in the tens of GHz without making any physical assumptions about the material itself. We apply this method to Ba₀.₅Sr₀.₅TiO₃ as a proof of concept, and show that our frequency-dependent results agree with a physical model derived from Landau-Ginzburg-Devonshire (LGD) theory.

Thermally Stable SrRuO4 Electrode for Ferroelectric BaTiO3 and Photocatalytic Rh: SrTiO3 films

Ryota Takahashi1,2 and Mikk Lippmaa1;1 Univ of Tokyo, Chiba, Japan; 2 JST PRESTO, Tokyo, Japan.

Sr:Ru:Otet is the n=1 member of the Srn+1RunO3n+1 Ruddlesden-Popper family and a well-known metallic oxide that becomes superconducting below 1.5 K. Since it is thermodynamically the most stable phase in this ruthenate family, it can be grown at very high temperatures compared to several other metallic oxides such as Fe3O4, SrRuO3, or (La,Sm)MnO3. Moreover, the oxygen pressure window is wider than for many other oxides, notably SrRuO3, that are commonly used as metallic electrodes in oxide device structures. We present the results of a study on the thermal stability of SrRuO4 thin film electrodes and demonstrate the usefulness of this electrode layer material for high-temperature growth of ferroelectric BaTiO3 films and photocatalytic Rh: SrTiO3 films.

The SrRuO4 electrode films were prepared on BHF-treated SrTiO3(001) substrates by pulsed laser deposition. Atomic force microscopy revealed atomically smooth surfaces for 20-nm-thick SrRuO4 films. To investigate the thermal stability, ferroelectric BaTiO3 thin films were deposited at 700-1000°C on the SrRuO4 electrode layer. Pyroelectric hysteresis loop measurements were used to verify that the BaTiO3 films grown on SrRuO4 electrodes were ferroelectric, implying that the SrRuO4 electrode layers were thermally stable even during high-temperature deposition at 1000°C in 100 mTorr of oxygen. The wide oxygen pressure window of SrRuO4 electrode was investigated by the deposition of Rh: SrTiO3 thin films for photoelectrochemical water splitting electrodes. At growth temperature of around 800°C in 10⁻¹⁰ Torr of oxygen, the SrRuO4 electrode formed an atomically sharp interface with the film even at high growth temperatures and low oxygen pressures, yielding atomically flat Rh: SrTiO3 photocathode films.

Improve Energy Harvesting from Ocean Wave Energy by Using 3D Printed Devices with Aim of Frequency Modulation in Piezoelectric Based Wave Energy Harvesters and Scavengers

Sina Baghban Kordmahale; Electrical Engineering, Texas A&M University, College Station, Texas, United States.

There are various methods to harvest sustainable energy from various resources (1, 2). We have used piezoelectric Macro Composite Fibers (MFCs) combined with soft material and 3D printed solid parts to harvest energy from the sea and ocean waves. Durable, low cost, low maintenance, and efficient wave energy harvesters alongside the availability of powerful waves can provide a sustainable green energy source for various applications. The commercialized wave energy harvesters have problems like: expensive complicated elements, heavy structures, too much mechanical and moving parts which will increase the unit price, high deployment, and maintenance expenses. In the proposed design, the flexible MFCs are sandwiched between two 3D printed slabs with saw-tooth surfaces and are encapsulated in a soft elastomer block. Ecoflex 030 is chosen as the soft elastomer (3, 4). The soft material casting method has been used to form the encapsulation and shape the Ecoflex based slabs (5). The different 3D printed blocks, with various saw-toothing periods and amplitudes, were used in this experiment to prove the hypothesis of efficiency of proposed design. In total, four different combination of period and amplitude of saw-tooth used in this experiment and it is approved that the higher amplitude and shorter period of saw-tooth on the surface, will cause on higher energy harvesting. The fabricated samples, placed and tested in a wave flume tank horizontally and the open circuit voltage and power measurement have done on the samples. The designed structure can harvest remarkably more energy in comparison with formerly designed wave energy harvesters which were just based on the soft materials, MFCs and anchoring in some cases. So this improved design could increase the efficiency of piezoelectric based wave energy harvesters and also can be a mesoscale model for piezoelectric based smaller scavengers. While the same design can be used for silicon-based mems structures, still the same 3D printing, like the one in this article, can be more economical for small scavengers too.

Stretchable, Transparent and Self-Healing Triboelectric Nanogenerators with Ionic Current Collector

Kaushik Parida and Pooi See Lee; Nanyang Technological University, Singapore, Singapore.

Triboelectric nanogenerators have emerged as a promising power source for portable and stretchable electronic devices. However most of the nanogenerators use metallic electrodes, thus the devices could not achieve high stretchability and transparency, simultaneously. This work demonstrates the use of an ionic conductor as the current collector in a triboelectric nanogenerator, resulting in a highly transparent, stretchable and self-healing device. The device has a transparency of 92% transmission, it can sustain a tensile strain up to 700%, and autonomously self-healable. The energy harvesting performance of ionic triboelectric nanogenerator is 12 times higher than that of the metallic based triboelectric nanogenerator. The resulting device demonstrates an extremely stretchable, highly transparent self-heal power source to be used as a power supplies for sensors, wearable electronics and soft robotics.

Electromechanical Properties of Flexible Piezoelectric Nanogenerator (PENG) Using Different Patterns of Vertically-Aligned BaTiO$_3$ Nanotubes

Camelle Kaye A. Aleman, James Albert B. Narvaez and Candy C. Mercado; University of the Philippines Diliman, Quezon City, Philippines.

With the advancement catered by the use of lead-free piezoelectric nanogenerators (PENGs) for flexible electronics in energy harvesting, the challenge is to design an efficient system which is high power-producing. For this study, structural engineering approach was implemented to improve the electromechanical response of PENGs. Effects of varying patterns of the one-dimensional, vertically-arrayed BaTiO$_3$ nanotubes used in PENG devices, theoretically balanced with concepts on pile patterning and geometries in building foundations, on their output power were observed. Different patterns of vertically-arrayed, tetragonal phase BaTiO$_3$ nanotubes were synthesized via in situ conversion of selectively-anodized TiO$_2$ nanotubes on Ti substrates using hydrothermal process. Selective anodization which established the patterning of the BaTiO$_3$ was achieved through photolithography using a negative photoresist dry mask. The patterns of two sets vary in the diameter (1 mm and 1.5 mm), and the arrangement (linear and staggered arrays) of the circles printed on the mask. The methodology produced highly crystalline BaTiO$_3$ nanotubes based on the obtained X-ray diffractogram and EDX analysis. SEM images showed that the synthesized nanotubes had an average length of 66 μm and inner diameter of 67 nm. In addition to this, the study established that selective anodization using photoresist dry film mask can be utilized in creating patterned BaTiO$_3$ without significant loss in accuracy of pattern. Using this material, PENG devices were fabricated. The PENGs comprised a sandwich structure of Ti- BaTiO$_3$ nanotube-graphite-Ti and were further made flexible by encapsulating the structure with polydimethylsiloxane. The cantilever-type PENG devices were subjected to repeated bending stresses using a rotating motor to determine the effect of different BaTiO$_3$ patterns on the output voltages of the devices under constant cyclical stress. It was observed that pile characteristics such as pile diameter, pile arrangement, and pile spacing which was brought about by the varied diameter and arrangement parameters, affect the output voltage and voltage behavior of the PENG devices. Decrease in both BaTiO$_3$ nanotube array spacing and pattern diameter, increases the lateral displacement of the piezoelectric material and decreases the pile stiffness, respectively; all conditions consequently leading to an increase in the output voltage of the device. It was observed that the voltage behavior is dependent on the pile-matrix-pile interaction which is affected largely by adjacent pile spacing. Furthermore, the piezoelectric test showed that the highest peak to peak output voltage generated by the unpoled devices reached up to 1.9 V using the pattern with linear arrays of smaller circle diameter. The research, overall, is majorly a proof of concept study wherein the aim was to see the effect of patterning the piezoelectric material on the output voltage values of the fabricated PENG devices.

Nobel Lead Free Relaxor Multiferroic for High Energy Storage Application

Mohan K. Bhattarai, Sita Dagu, Alvaro Instan and Ram Katiyar; Physics, University of Puerto Rico, Rio Piedras, San Juan, Puerto Rico, United States.

We synthesized modified Barium zirconate titanate electro ceramics by a conventional solid-state reaction method with stoichiometric formula Ba$_{1-2x}$La$_{2x/3}$Zr$_{0.30}$Ti$_{0.70-3y/4}$Fe$_2$O$_3$ (BLZTF), where $y = 0.01$ & $0.05 \leq x \leq 0.06$ & investigated its structural, microstructural, dielectric, electrical, ferroelectric and magnetic properties. X-ray diffractometry was used to investigate the phase purity and to derive the crystallographic parameters. A uniform distribution of grains on the surface of the sample was observed using electron micrographs (SEM) recorded on pellets. The stoichiometry of the chemical compositions was examined using energy dispersive x-ray (EDS) analysis method. We carried out dielectric measurements on Ag/PLZTS/Ag metal-ferroelectric-metal capacitors using impedance analyzer as a function of temperature (100-600 K) and frequency (10^2-10^6 Hz). We observed enhanced dielectric constant in doped BZT. The room temperature magnetic measurements (M-H) were obtained using a vibrating sample magnetometer. Additionally, we observed thin PE hysteresis loop, suggesting that synthesized materials is relaxor multiferroics and promising materials for high energy storage applications.

Foam-Type Piezoelectric Composite for Internal Cochlear Implant

Jeonjae Ryu, Jinwon Oh, Kwangsoo No, Seunghum Hong and Steve Park; KAIST, Daejeon, Korea (the Republic of).

A cochlear implant is a device for people with hearing loss caused by inner ear damages. Despite its great use to improve hearing, the microphone and other electronics of the cochlear implant, typically located outside the ear, are not aesthetically attractive. Therefore, many studies to insert a cochlear implant into the body have been conducted. In this study, we present a new approach for fabricating piezoelectric sensors that are attached on the cochlea. We made a foam-type piezoelectric composite not to interfere with the movement of auditory ossicles. Generally, to avoid the aggregation of piezoelectric particles in a polymer layer, MWCNT has been used, but it is being suspected for its toxicity. On the other hand, we coated biocompatible polydopamine on piezoelectric particles and then dispersed them in the PDMS layer. We calculated porosity of the composites and measured their stress-strain curves. We characterized the output performance as a function of the frequency of sound. We anticipate that the foam-type piezoelectric composite is promising as a sensor capable of detecting the sound pressure for cochlear implant.

Field and Frequency Dependence of Magnetodielectric Coupling in Ni/PZT/Ni Multiferroics

Fernando Aponte1, Roberto Masso1, Gopalan Srinivasan2 and R Palai1; 1University of Puerto Rico, San Juan, Puerto Rico, United States; 2Physics, Oakland University, Oakland, Michigan, United States.

Spin capacitors have the potential to store both the electronic charge and magnetic spin that can produce conventional electric current and spin polarized current. The time evolution of spin polarized electrons injected into the piezoelectric material can be used for accurate sensing of magnetoelectric fields. To further study the application of multiferroic spin capacitors for future use in memory applications, Ferromagnetic/Ferroelectric/ Ferromagnetic tri-layer artificial multiferroic structures in spin capacitor configuration were fabricated by sputtering ferromagnetic Nickel (Ni) electrodes on lead zirconate titanate (PZT). Magnetocapacitance, magnetooimpedance, and phase angle measurements were carried out by a wide range of frequencies (100 Hz – 5 MHz) and magnetic fields (0T – 2T) at room temperature. We also compared the magnetodielectric measurements of the Ni/PZT/Ni spin capacitor with Ni/PZT/Ag and Ag/PZT/Ag tri-layers structures and their behavior. Two PZT layer thickness were studied, including 200 μm and 1 mm PZT. Ni/PZT/Ni spin capacitor shows a significantly different behavior compared to conventional PZT capacitor with Ag electrode and mixed electrode capacitor with one ferromagnetic and one conventional electrode. The spin capacitor (Ni/PZT/Ni) with the 1 mm PZT layer show mayor resonance peaks at ~166 kHz and at ~890 kHz, where the first peak is not present in the other capacitor structures. Second level peaks are found at 231 kHz, 444 kHz, 2.03 MHz and at 3.2 MHz. This las peak in the spectrum is shared with the three structures. The second level peaks have and ~32% intensity compared to the major peaks at ~166 kHz and at ~890 kHz. There is a notable reduction on the intensity of the peaks when the ferromagnetic electrode is present, with the mayor difference between the conventional capacitor having a 83% higher intensity ($\epsilon=55586$) compared with the Ni/PZT/Ag capacitor ($\epsilon=10015$) and a 57% reduction between Ni/PZT/Ag and Ni/PZTNi. For the 200 μm sample, the three structures of capacitor share a very similar behavior, with a certain shift for the Ni/PZT/Ag capacitor, where Ni/PZT/Ni and the conventional capacitor share the resonance peak at ~260 kHz and Ni/PZT/Ag has a shift of 50 kHz.
towards higher frequencies (308 kHz). And similar to the 1 mm layer PZT samples, there is a reduction in dielectric peak permittivity, with the conventional capacitor being the highest and lowering with the presence of the ferromagnetic lanthanum oxide with a difference of 28% between the conventional capacitor and Ni/PZT/Ag, and a 33% difference in reduction between Ni/PZT/Ag and Ni/PZT/Ni. The Lorentz model was used to study the peaks behavior by fitting the equation into dielectric measurements per range of frequencies and obtaining information from selected peaks.

Ultrasfast Zero-Bias Photocurrent in GeSe Single Crystals—A Promising New Ferroelectric Photovoltaic Material Kateryna Kushnir1, Ying Qin2, Guangjiang Li1, Sehaattin Tongay3 and Lyubov V. Titova4; 1Worcester Polytechnic Institute, Worcester, Massachusetts, United States; 2School for Engineering of Matter, Transport and Energy, Arizona State University, Tempe, Arizona, United States.

Solar cells based on bulk photovoltaic effect (BPVE) may provide an efficient alternative to traditional p-n junction-based ones [1,2]. The prevailing mechanism behind BPVE is a shift current, a zero-bias photocurrent that can occur in a non-centrosymmetric material as excitation of an electron from the valence to the conduction band, resulting in a coherent spatial shift of the electron charge density. Ferroelectric semiconductors have been predicted to exhibit significant shift currents, spurring the search for ferroelectric semiconductor candidates for BPVE with bandgaps in the visible range [1-3]. Theory predicts that monolayer group-IV monochalcogenides are multiferroic and capable of generating significant shift currents [3,4]. Previously, we have demonstrated ultrasfast shift current following above bandgap excitation of GeS nanosheets [5].

Here, we present the evidence of a shift current response in a single crystalline GeSe with μm thickness. While the stacking sequence of the layers in this van De Waals material results in inversion symmetry in the bulk, this symmetry is broken at the surface, and a spontaneous surface polarization can exist in the same armchair direction as in a monolayer GeSe [3,4,6]. We have detected the ultrafast shift currents in GeSe single crystalline flakes using terahertz (THz) emission spectroscopy [5]. Detecting free space propagating electromagnetic pulses emitted by the sample excited at normal incidence by the ~ 100 fs, 800 nm or 400 nm pulses allows contact-free, all-optical monitoring of the transient photocurrents that result in this emission. We find that photoexcited GeSe crystals emit nearly single-cycle THz pulses in response to either 800 nm (1.55 eV) or 400 nm (3.10 eV) excitation. Excitation fluence, orientation and polarization dependence of the THz emission confirms that shift currents flowing along one crystallographic direction, presumably determined by the spontaneous polarization of the surface layer, are responsible for the observed emission. Stronger THz emission in response to 400 nm excitation, compared to the equivalent fluence of 800 nm excitation, stems from stronger absorption of 400 nm light by GeSe, which leads to the higher excitation of a surface layer. Highly efficient shift current photoexcitation in GeSe and the optical absorption that covers the entire visible range suggests applications of these layered materials in third generation BPVE photovoltaics.

Enhanced Photodetection of Au-g-C3N4/CdS/ZnO Based Flexible Heterojunction Device Utilizing Piezo-Phototronic Effect Sourabh Pal1, Sayan Bayan2 and Samit K. Ray2; 1Advanced Technology Development Centre, Indian Institute of Technology Kharagpur, Kharagpur, India; 2Department of Physics, Indian Institute of Technology Kharagpur, Kharagpur, India.

Two dimensional (2D) materials and their derivatives have witnessed the scientific community owing to their promising application in photonic and optoelectronic devices. In recent times, 2D graphic carbon nitride (g-C3N4) has been found to be a potential material for various photophysical properties. This n-type semiconductor is characterized by interesting electronic structure originating from the lone pair of nitrogen and electron delocalization in which the band gap can be easily tuned. Nanosheets of g-C3N4 both in the pristine form and in heterojunction with other semiconductors are found to be promising for optoelectronic device applications. The fabrication of heterostructured devices through the integration of g-C3N4 with various promising materials offer the basis of futuristic flexible optoelectronic nanostructures. Amongst different basis semiconductor nanostructures, zinc oxide (ZnO) is a well studied material owing to its distinguished performance in the field of optoelectronics. Apart from the well known ultraviolet (UV) light emission properties, piezoelectric properties of ZnO are also fascinating due to its tremendous scope in the application of high performance photodetectors. Coupling the piezoelectric properties with the semiconductor properties under mechanical stimuli can definitely lead to the modified output of the host material through modification in the local interface and charge-carrier transport. Herein, we report on efficient and enhanced photodetector in ZnO based hybrid heterojunction with CdS and Au nanoparticle loaded g-C3N4 nanosheets under bending state. In the present investigation, the scheme of g-C3N4/CdS/ZnO based heterojunction has been adopted due to elevate charge carrier separation under visible light, which can be further enhanced (~18 times at 530 nm) by plasmonic effects with the exploitation of Au loaded g-C3N4 nanosheets. Strain induced piezoelectric potential development in ZnO has also been witnessed in the hybrid heterojunction and it has been found this piezo-potential can efficiently trigger the photodetector response (~102 times as compared to normal state) through the band alignment at the interface of the hybrid heterojunction.

Large Local-Compressive Stress-Induced Improvements in Piezoelectric Characteristics of Lead Zirconate Titanate Thin Films on a Ni Nanodots-Array Chan Su Han, Ahra Cho, Da Bin Kim and Yong Soo Cho; Yonsei University, Seoul, Korea (the Republic of).

This manuscript introduces a nonconventional way to improve piezoelectric properties of PZT thin films substantially by forming Ni nanodots-array on a Si substrate with the assistance of uniform magnetic field upon deposition. The existence of Ni nanodots induces extrinsic compressive stress at the initial stage of film growth due to an enormous difference of ~94% in thermal expansion coefficient between the Ni and PZT film. The level of thermal mismatch is typically not allowable at the regular film interface. Specifically, heavily 12 mol% Nb-doping was selected for the sputtering process since the heavy doping has been recently reported to uniquely produce the in situ domain formation during deposition when combined exclusively with the Ir/TiW bottom electrode. Interestingly, the relatively high content of 12 mol% Nb is all dissolved into the perovskite structure without segregation. The final film/electrode structure corresponds to Pt/Nb-doped PZT/Ir/TiW/Ni nanodots/SiO2/Si. The role of an AlNiCo magnet used here provides uniform external magnetic field strength to facilitate consolidation of the Ni nanodots at high temperature. This nanodot approach induces local large compressive stress.
only around the region of Ni nanodots so that the film structure can be sustained. As a result of this unique local stress approach, a substantial enhancement of effective piezoelectric coefficient by ~33% is obtained from the changed crystal orientation and easier domain formation. The shift of polarization-electric field curve indicates the presence of internal field in the domain structure. This in situ process does not require the subsequent annealing and poling procedure, which have been commonly demanded for piezoelectric materials. So the adoption of Ni nanodots with the in situ processing creates very unique improvements.

ZnO-BaTiO3-Epoxy Multifunctional Electro-Active Thin Films—Enhancement in Electron Transport Regimes by Comparison of ZnO Nanowires and Nanoparticle Composites Walker Tuff1, Saqib Ahmed2 and Sankha Banerjee; 1; California State University, Fresno, Fresno, California, United States; 2Mechanical Engineering, Buffalo State College, Buffalo, New York, United States.

Piezoelectric and electro-active composites are investigated as new generation self-powered energy harvesting devices for a wide range of applications from the industrial to the medical field while maintaining high reliability, durability and sensitivity over wide range of frequencies. The electrical, dielectric and piezoelectric properties can be enhanced by embedding electro-active and conductive inclusions in the matrix material. The present work involves the fabrication of three-phase, multifunctional lead-free, BaTiO3-Epoxy-ZnO (nanowire) and BaTiO3-Epoxy-ZnO (nano-particle) composite and flexible thin films. The volume fraction of the BaTiO3 phase was held constant at 40%, while the volume fraction of the ZnO nanowire phase was varied from 1% to 10%. The work compares the role of ZnO nanowire and ZnO nano-particle inclusions distributed in an epoxy matrix to fabricate three-phase composites. The influences of several factors on the effective electromechanical properties of the composites are also analyzed. The dipoles of the electro-active phases were aligned using a plasma-microdischarge (Corona) poling technique. The piezoelectric strain coefficients, dielectric constant, dielectric loss tangent, capacitance, impedance, resistance, and conductance of the samples were measured and compared as a function of poling regime. The impedance and dielectric spectra of the composites were recorded over a frequency range of 20 Hz to 10 MHz. The fractured surface morphology and distribution of the phases were observed with the aid of Electron Dispersion Spectroscopy (EDS) and a Scanning Electron Microscope (SEM). The crystal structure of different phases in the composite were also characterized used Raman Spectroscopy.

EP01.08.11
Thickness Scaling of Ferroelectricity and Electrical Conductivity in Multiferroic BiFeO3 James Steffes1, Ramamoorthy Ramesh2 and Bryan D. Huey; 1; University of Connecticut, Storrs Mansfield, Connecticut, United States; 2University of California, Berkeley, California, United States.

Computed tomography atomic force microscopy (CT-AFM) is presented as a novel experimental modality for nanometer-scale measurements of the size-dependence of functional properties in the room temperature multiferroic BiFeO3. Intrinsic and extrinsic properties of ferroelectric thin films are known to have strong dependencies on electrical and mechanical boundary conditions, resulting in finite size effects in electronic and magnetic properties at length scales below several hundred nanometers. By combining recently-developed CT-AFM techniques with piezoresponse force microscopy (PFM) and conductive AFM (CAF), nanometer-scale three-dimensional imaging of ferroelectric domains and conductive defects at polarization discontinuities has been achieved in thin film BiFeO3. CT-AFM additionally provides a platform for quantifying the thickness dependence of the local spontaneous polarization, ferroelectric coercive field, and electrical conductivity in BiFeO3 across two decades of thickness. The thickness-resolved ferroelectric properties of BiFeO3 acquired with CT-AFM strongly correlate with both Landau-Ginzburg-Devonshire phenomenological theory and the semi-empirical Kay-Dunn scaling law for ferroelectric coercive fields, providing an unambiguous determination of a stable and switchable polar state in BiFeO3 at thicknesses below 5 nm. Complimentary tomographic PFM and CAFM data reveals the geometric dependence of polar discontinuities on the heterogeneous electrical conductivity of BiFeO3 as a function of film thickness, which shows strong agreement with the model of Schottky emission for bulk BiFeO3 as well as several electrically-conducting defect types in BiFeO3. Along with complementary transmission electron microscopy (TEM) analysis, this work provides new insights into the relationship between thickness and ferroelectric properties in heteroepitaxial multiferroics.

EP01.08.12

Ferroelectric perovskites such as barium titanate (BaTiO3) have had numerous applications in nonvolatile memories, transducers, micro sensors and capacitors because of their unique properties such as spontaneous polarization, piezoelectric and pyroelectric effects, as well as large dielectric constants. In order to design and optimize these devices, it is essential to obtain detailed, atomistic-scale insight of the BaTiO3 ferroelectric perovskite. Currently, there are three approaches to model the ferroelectric behavior of BaTiO3: Phenomenological, First-principles and Force field-based methods. Phenomenological models are not able to provide atomistic level description of the ferroelectric perovskites. First-principles methods such as the density functional theory (DFT) are considered as the most accurate models, however, because of heavy computational costs these methods can be only viable for relatively small systems and short time scales. Moreover, since the DFT models are mainly limited to zero Kelvin, most of ferroelectric properties of the perovskite materials such as hysteresis loop, sequential phase transitions and domain wall motions cannot be investigated using the first-principles methods. Force field based methods can provide the computational speed required to perform molecular dynamics (MD) simulations with system sizes and time scales sufficiently large to describe the full chemistry of the ferroelectric perovskites. ReaxFF reactive force fields first developed for hydrocarbons and later applied to different systems such as ceramics, metals and their oxides and provided precise results for those systems. We developed the first reactive force field for BaTiO3 systems which captures both chemical and electro-mechanical properties of the material. We performed realistic size molecular dynamics simulations to investigate the phase transition sequence, ferroelectric and thermal hysteresis loops for the BaTiO3 crystal structure. Furthermore, we investigated the effects of oxygen vacancies and different surface terminations on the material polarization.

EP01.08.13
Spiral Domain Walls in Ferroelectric PbTiO3 Thin Films Christopher T. Nelsen1, 2, 3, 3, 1, Zijian Hong1, Ayaj Yadav1, Sujit Das3, Anoop R. Damodaran1, Shang-Lin Hsu1, 1, Long-Qing Chen1, Lane W. Martin2 and Ramamoorthy Ramesh2, 2, 1; Lawrence Berkeley National Laboratory, Oak Ridge, Tennessee, United States; 2Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States; 3University of California Berkeley, Berkeley, California, United States; 4Pennsylvania State University State College, Pennsylvania, United States.

Defects in the ferroelectric topology such as domain walls are dynamically controllable low-dimensional entities that can manifest local non-bulk properties such as a 2D electron gas [1, 2]. Domain walls try to adopt electrical neutrality, i.e. the Polarization has a constant flux (∇ P = 0), and those that violate this either compensate the bound charge or low energy configurations including geometries that ensure a price of high electrostatic energy. As a result, charged domain walls can exhibit significant property differences to the bulk[2], but are typically metastable or present in low remnant polarization systems with a sufficient screening charge density such as improper ferroelectrics. In ferromagnetic systems, where screening charges are unavailable,

**Studies on Magnetic and Electrical Properties of Gallium Ferrite Multiferroic Thin Film**

Sita Dungu1, Dhiren K. Pradhan2, Shalini Kumari3, Mohan K. Bhattacharja4, Alvaro Insta1 and Ram S. Katiyar1; 1Department of Physics, University of Puerto Rico, San Juan, Puerto Rico, United States; 2Geophysical Laboratory, Washington, District of Columbia, United States; 3Department of Physics, West Virginia University, Morgantown, West Virginia, United States.

Magnetoelectric materials might hold the future for the ultimate memory, spintronics, and other multifunctional devices as they exhibit simultaneous ferroelectric and ferromagnetic behaviors and permit control and switching of the magnetic order parameters via an electric field, and polarization with a magnetic field. Orthorhombic gallium Ferrite is a prominent multiferroic due to its piezoelectricity and ferrimagnetism coupled with magnetoelectric effects. Herein we studied the dielectric, ferroelectric and magnetic behavior of ~ 200nm highly oriented orthorhombic GaFeO3 thin film deposited on a SrRuO3 buffered SrTiO3 substrate by optimized Pulsed Laser Deposition method. SrRuO3 was deposited at an optimized temperature of 680°C under an oxygen pressure of 200 mTorr, with a laser energy density ~ 1.5 J/cm² and a frequency of 10 Hz. Subsequently, GaFeO3 was grown on the top of SrRuO3 at 725°C with oxygen pressure 300mT and energy density ~ 2 J/cm² at a frequency of 5 Hz. The film was then cooled at the rate of 2°C/min under the pressure of 200mT. The 0-20 large angle x-ray scans (10° to 90°) showed highly oriented film grown at (001) direction without any secondary peaks. Surface morphology was analyzed with AFM studies which showed the film is smooth, free of microcracks, pores or holes with average surface roughness around 2-3 nm. Temperature-dependent magnetization behavior was studied at both field-cooled and zero-field-cooled conditions in between 5- 395 K using several magnetic fields (such as 100 Oe, 500 Oe, and 1000 Oe) identify the Neel transition temperature T_N around 225 K. Ferroelectricity of GaFeO3 was demonstrated by polarization hysteresis and PFM measurement. The film exhibits the net switching polarization of ~12 μC/cm² with a maximum field of 700kV/cm. The single phase RT GFO shows multiferroic behavior with a magnetoelectric coupling which might be a potential candidate for spintronic and microelectronic applications.

**Influence of Metal Element Addition on Crystal Structure of AIN Piezoelectric Thin Film**

Masato Uehara, Sri Ayu Anggraini, Hiroshi Yamada and Morio Akiyama; National Institute of Advanced Industrial Science and Technology, Saga, Japan.

It is vital to adopt piezoelectric materials for microelectromechanical systems (MEMS), where aluminum nitride (AIN) has been regarded as an attractive candidate for featuring a sensor, an energy harvester and a bulk acoustic wave resonator. Akiyama et al. have dramatically improved by Sc-Addition but the Sc-AIN is expensive for industrial uses. We succeeded in improvement of the piezoelectric coefficient by simultaneous addition of Mg-Nb. The improvement is comparable to Sc-AIN. According to other paper, Mg-Hf, Mg-Zr, and Mg-Ti are also effective. The lattice constant ratio c/a of wurtzite decreases by addition of the effective elements.

In this paper, we have investigated the influence of various element addition on AIN crystal structure. With single addition of Mg and Ca, considerable decrease of crystallinity was confirmed. This would be caused by a problem of charge compensation. In case of Nb and Ti, the crystallinity decrease was smaller but the other phase formation was observed. In case of Sc, above phenomena were not observed until addition ratio of 0.5. The change in the a-axis is similar for each element additions and increases monotonically. On the other hand, the change of c-axis was different. By Sc addition, the c-axis increased to the addition ratio of 0.3 and decreased with addition of more. For the other elements, the c-axis increased until the addition ratio at which crystallinity decrease or other phase formation was observed. Particular, by Nb and Ti addition, the c-axis increase was large. These ion radii are not particularly large, but rather the Ti ionic radius is the smallest. The large increase of c-axis can not be explained by ion radius. The electronegativity of Nb and Ti is large compared with Mg, Ca, and Sc, and the fraction of ionic bonding would be larger than them. The fraction of covalent and ionic bonding would be related with the change of crystalline structure such as c:a ratio. We think that by addition of Sc and Mg the fraction of ionic bonding would increase and the crystalline would soften, leading to piezoelectric increase of AIN.

**Stroboscopic Materials Testing by Synchrotron X-Rays on the Sub-Nanosecond to Picoseconds Time Scale**

Klaus-Dieter Liss1,2,3; 1Guangdong Technion - Israel Institute of Technology, Shantou, China; 2Technion – Israel Institute of Technology, Haifa, Israel; 3MMM, University of Wollongong, Wollongong, New South Wales, Australia.

X-ray diffraction is a very common method to analyze strain fields and crystallographic phases in a wide range of materials, including functional materials such as multiferroics. The presentation resumes my work on stroboscopically time resolved synchrotron X-rays probing materials under periodic external stimulus. Ultrasonic strain fields can be evaluated as a function of oscillation period, in both low and high frequency cases, where additional diffraction phenomena take place. Switching of electric fields in ferroelectric material reveal phase transformation response. An overview on the technique, examples and future potential, particularly to ferro and piezoelectrics will be given.

**EP01.08.17**

**Ferroelectric Lead Free Na0.52K0.44Li0.04Nb0.84Ta0.10Sb0.06O3 Material—Giant Electromechanical Response with Intrinsic Polarization and Resistive Leakage Analyses**

Abid Hussain and Binay Kumar; Department of Physics and Astrophysics, University of Delhi, New Delhi, India.

Environment friendly lead free Na0.52K0.44Li0.04Nb0.84Ta0.10Sb0.06O3 (NKLNTS) ceramic was synthesized by solid state reaction method in search of a potential candidate to replace lead based ceramics such as PbZrO3-PbTiO3 (PZT), Pb(Mg1/3Nb2/3)O3-PbTiO3 (PMN-PT) etc., for various applications. The ceramic was calcined at temperature 850 °C and sintered at 1090 °C. The powder XRD pattern revealed the formation of pure perovskite phase having tetragonal symmetry with space group P4mm of the synthesized ceramic. The surface morphology of the ceramic was studied using Field Emission Scanning Electron Microscopy (FESEM) technique. The well defined grains with homogeneous microstructure were observed. The average grain size was found to be ~ 0.6 μm. A very large value of piezoelectric charge coefficient (d33 ~ 754 pm/V) was obtained for the synthesized ceramic which indicated its
potential for use in transducers and actuators. In dielectric measurements, a high value of ferroelectric to paraelectric phase transition temperature (310°C) and a high value of maximum dielectric permittivity (2110 at 1 kHz) and a very small value of dielectric loss (<0.6) were obtained which suggested the utility of NKLNTS ceramic in high temperature ferroelectric devices. Also, the degree of diffuseness (γ) was found to be 1.61 which confirmed a relaxor ferroelectric behavior in NKLNTS ceramic. P-E hysteresis loop was traced and the value of spontaneous polarization was found to be ~11µC/cm² at room temperature. The pyroelectric coefficient was obtained to be very high (p ~ 1870 µCm²°C⁻¹) for the present case indicating its applicability in pyroelectric detector applications including fire and burglar alarms, infrared imaging, etc. NKLNTS ceramic showed fatigue free behavior over 10⁷ switching cycles. Remanent hysteresis task was performed to determine the true-remanent (or intrinsic) polarization of NKLNTS ceramic by eliminating non-switchable components which showed that a major portion (83.10 %) of the remanent polarization (P_r) is switchable in the sample which makes NKLNTS ceramic a suitable material for memory switching devices applications. Time-Dependent Compensated (TDC) hysteresis task was carried out which revealed resistive leakage free nature of the ceramic. The performance of NKLNTS ceramic was found to be superior to many lead based piezoceramics and hence can effectively replace them for use in piezoelectric, pyroelectric and long duration ferroelectric applications.

EP01.08.18
Thermal-Induced Ferroelastic Domains in Barium Titanate Qianwei Huang¹, Zhibin Chen¹, Feifei Wang², Simon Ringer¹,², Haosu Luo³ and Xiaozhou Liao¹; ¹School of Aerospace, Mechanical and Mechatronic Engineering, The University of Sydney, Sydney, New South Wales, Australia; ²Key Laboratory of Optoelectronic Material and Device, Department of Physics, Shanghai Normal University, Shanghai, China; ³Australian Centre for Microscopy and Microanalysis, The University of Sydney, Sydney, New South Wales, Australia; ³Key Laboratory of Inorganic Functional Materials and Devices, Shanghai Institute of Ceramics, Chinese Academy of Sciences, Shanghai, China.

Ferroelectric materials have extensive applications in electric devices due to their unique properties. The ferroelectric/ferroelastic domain structures in ferroelectric materials can be manipulated via external stimuli including heat, electric bias and mechanical stress. Previous researches on how heat (or temperature) affects ferroelectric domain structures were normally carried out at temperatures close to phase transition points. Here we show that temperature variation far away from a phase transition point could have a significant effect on the ferroelectric/ferroelastic domain structure in ferroelectric materials. Our results indicate that thermal-induced degradation or thermal stability of ferroelectrics is not negligible. In our work, barium titanate (BaTiO₃) single crystals were slowly heated to several temperatures in the range of ~ 40 – 60°C (the Curie point is ~120°C) in the transmission electron microscope (TEM) and were kept at each temperature for detailed structural characterization. As the temperatures were far below the Curie point and higher than the ambient temperature, the BaTiO₃ remains as a stable tetragonal phase. It is surprising to see that nano-sized lamellae based domains appeared along the [110] direction within the initial domains at a small temperature range of ~ 50°C. The new domain structure disappeared above or below the temperature range and the phenomenon was repeatable. The orientation of the newly formed domain walls indicated that the new domains were 90° ferroelastic domains. The mechanism for the formation of the new domain structure will be discussed based on detailed TEM investigation results.

EP01.08.19
Visualization of Domain Structure and Switching Property of Hf₀.₅Zr₀.₅O₂ for the Ferroelectric Field Effect Transistors Hoon Kim¹, Soekjung Yun¹, Seongwoo Cho¹, Myungsoon Seo², Min-Ho Kang¹, Yang-Kyu Choi¹ and Seungbum Hong¹; ¹Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); ²Department of Electrical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); ³Department of Nano-process, National NanoFab Center (NNFC), Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of). Zr-doped HfO₂ (HZO), a conventional gate dielectric material, has attracted much attention for displaying negative capacitance in Field Effect Transistors (FETs) and its potential application for next generation nonvolatile memory devices. Furthermore, compared to conventional ferroelectric materials, HZO is more suited to FET fabrication because of its higher scalability, thermal stability, and compatibility with Si processes. Despite the material’s potential, there is few research on its ferroelectric properties due to its limited window of allowable thickness at the nanoscale. Herein, we analyzed the ferroelectric properties and domain structures of HZO to understand the negative capacitance reported in HZO and mechanism behind ferroelectricity and related domain structure as well as its switching behavior at the nanoscale. First, in order to understand the switching characteristics of HZO thin films, we measured and analyzed the polarization versus electric field (PE) loops. Second, we investigated the domain structures of HZO using angle-resolved PFM, which entails using vertical and lateral PFM as well as the rotation angle of the sample to derive the sample’s complex polarization state. We envision that our results will elucidate the origin of negative capacitance in terms of the domain structure of HZO film and contribute to the development of ultralow power logic transistors and future nonvolatile memory devices.

EP01.08.20
Effects of Post Metal and Forming Gas Annealing on Characteristics of Ferroelectric FinFETs with HfZrO₂ Gate Dielectric Myungsoon Seo¹,², Min-Ho Kang¹, Wu-Kang Kim¹, Jae Hur¹, Soekjung Yun¹,², Hoon Kim¹, Seungbum Hong¹ and Yang-Kyu Choi¹; ¹School of Electrical Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); ²Foundry Business, Samsung Electronics, Yongin, Korea (the Republic of); ³National Nanofab Center, Daejeon, Korea (the Republic of); ⁴Department of Materials Science and Engineering, Korea Advanced Institute of Science and Technology, Daejeon, Korea (the Republic of); ⁵Memory Business, Samsung Electronics, Hwasung, Korea (the Republic of).

Since excellent ferroelectric (FE) characteristics were demonstrated with a CMOS-process compatible thin hafnium-based material, FE field-effect-transistors (FETs) have attracted considerable attention as a promising candidate for next-generation nonvolatile memory, analog synaptic devices for neuromorphic systems, and steep slope devices called negative capacitance (NC) FETs, with low power consumption. Among various HfO₂ thin film dopant materials suitable for FE operation, such as Si, Zr, Y, and Al, Zr is well-known as showing stable characteristics thanks to having almost identical chemical properties with Hf. HfZrO₂ (HZO) films consist of tetragonal, orthorhombic, and monoclinic phases. The orthorhombic phase is known to be responsible for the ferroelectricity of the thin film. Annealing after FE deposition, for example post metal annealing (PMA) or forming gas annealing (FGA), leads to crystallization which is a key factor in the final ferroelectric characteristics of the HZO thin film. Even though the effects of PMA and FGA on metal-ferroelectric-metal (MFM) capacitors have been investigated by several research groups, there has been no report on metal-ferroelectric-insulator-silicon (MFSIS) structured FE FETs yet. In this work, the effects of PMA and FGA on characteristics of a highly-scaled FE FinFET with a 10 nm thick HZO film were carefully investigated. The effects of PMA at temperatures from 400 °C to 900 °C for 30 s were examined. An FGA split experiment was conducted with various temperatures and hydrogen (H₂) gas content ratios. Changes of orthorhombic phase peak were investigated by spectral measurements with the grazing incidence X-ray diffraction (GI-XRD), and changes in domain behavior were also investigated using piezoresponse force microscopy (PFM). MFM capacitors with a TiN top and a Ti bottom electrode exhibited different butterfly-like features in capacitance-voltage (C-V) characteristics and polarization-electric field (P-E) hysteresis loops by splitconditions. Finally, the electrical characteristics of the highly-scaled FE FinFETs were compared to those of the MFM capacitors for the first time under various conditions. The FE FinFETs were fabricated with a fin width of 50 nm, a fin height of 100 nm, and a gate length of 120 nm on bulk silicon wafers with gate last processes. The optimized PMA and FGA conditions determined in this experiment are expected to provide insights into the use of FE FETs as next-generation memory, synaptic devices for neuromorphic
Magnetoelectric (ME) multiferroic materials are promising materials for this novel multifunctional applications. BiFeO₃ (BFO), ferroelectric Tc ~ 830 °C and antiferromagnetic TN ~ 370 °C, is one of the rarest single-phase room temperature multiferroic materials with many interesting physical phenomena. However, high leakage current of BFO and weak magnetoelectric (ME) coupling are detrimental for applications. A strong ME coupling is an important requirement for practical applications. To enhance the ME coupling in BFO, we doped with GdMnO₃ (GMO), an oxide ferromagnetic. In this present work, we report synthesis and characterized BFOₓ-GMO (BFO-GM) solid solutions (0.0 ≤ x ≤ 0.2) by auto-combustion method. The materials have been systematically characterized and examined to study the possibility of the compositional driven structural phase transition and its correlation with the ME coupling. The structural, microstructural, Raman spectroscopy, dielectric, ferroelectric, magnetic, and magnetoelectric properties were studied as a function of field (magnetic and electric), frequency, and temperature. For quantitative understanding, various modified theoretical models (Maxwell-Wagner, universal power law, Debye, etc.) were used to model the data. We found that BFO with 10% GMO doping shows strong ME effect. Details of this study will be discussed in the presentation.

**Easy Control of Ferroelectric Vortices Array by Sweeping Field**

Ye Ji, Lele Ma, Linjie Liu, Weijin Chen and Yue Zheng; State Key Laboratory of Optoelectronic Materials and Technologies, Sun Yat-Sen University, Guangzhou, China.

Plenty of novel ferroelectric domain structures are pursued for over a decade due to both theoretical interest (topology phase transition, emergent phenomena, etc.) and practical use. Specifically, ferroelectric vortex with at least two-fold chirality and small size, is a competitive candidate for high capacity memory storage. Accordingly, manipulation of vortex chirality is of fundamental significance. Several proposed approaches have made notable progress by introducing local field with distinctive origins such as external inhomogeneous electric field and mechanical dislocation to break the circular symmetry of vortex (or discrete rotational symmetry for flux-closure structure). However, these approaches are either hard to perform or need a priori knowledge of imperfection which severely restrict the universality. In this paper, we generalize the symmetry broken idea to the sweeping direction in a time-dependent sweeping process, facilitating a simple yet robust vortex switching method conducted by phase field modeling. We firstly consider that a biased tip sweeps over a vortex where the electric field is no need to be stronger than that totally destroys the vortex. The sweeping process will produce a dominant dipole region (DDR) which serves as a new nucleus. Based on this mechanism, we propose a BaTiO3/SrTiO3 (BTO/STO) composite nanowire system for 1D memory architecture where each BTO block can form vortex thus carry information with STO block being the isolation zone. The vortex orientation can be tuned as well for multi-bit storage. The sweeping method is successfully employed into this system under varies conditions. Note that the coupling between adjacent BTO blocks is tuned by thickness of STO blocks. While strong coupling may cause crosstalk, it also provides a new controlling factor within the framework of sweeping method. We observe that vortex switching process is effectively reduced under temperature field. Since the DDR exhibits no preferential orientation under temperature field, the neighboring part of adjacent BTO block behind the sweeping field will induce a DDR with same orientation to reduce gradient energy, therefore determines the final chirality. We hope the sweeping method will promote the understanding of vortex switching and be beneficial to device development.

**EP01.08.23**

**Strain, Temperature and Electric-Field Effects on the Phase Transition and Piezoelectric Responses of KₓNaₓNbO₃ Thin Films**

Mengjun Zhou1,2, Jianjun Wang2, Long-Qing Chen1,2 and Ce-Ween Nan1; 1School of Materials Science and Engineering, State Key Lab of New Ceramics and Fine Processing, Tsinghua University, Beijing, China; 2Department of Material Science and Engineering, The Pennsylvania State University, State College, Pennsylvania, United States.

KNbO₃-based solid solution system is environment-friendly with good electromechanical performance. This work established the misfit strain–strain and temperature–strain phase diagrams for KₓNaₓNbO₃ thin films and calculated the polarization switching, phase transition, and piezoelectric responses of KₓNaₓNbO₃ thin films under various strains, temperatures and electric fields. The results show that the piezoelectric coefficient d₃₃ can be enhanced near the phase boundaries. For the ferroelectric phase with nonzero out-of-plane polarization component, an optimal electric field is identified for maximizing d₃₃, which is desired in applications such as thin-film piezoelectric MEMS, transducers for ultrasound medical imaging and energy harvesting. The present results are expected to provide guidance for future experimental study of KₓNaₓNbO₃ thin films and the optimization of ferroelectric thin film-based devices.

**EP01.08.24**

**IR-Active Modes Detected by Tip-Enhanced Raman Spectroscopy in SrTiO3 Nanostructures—Field Gradient or Strain Gradient Contribution?**

Azza Hadi Youssef1, Chahinez Dab1, Jiawei Zhang1, Gitanjali Kolhatkar1, Alexandre Merlen2 and Andreas Ruediger1; 1Institut National de la Recherche Scientifique, Varennes, Quebec, Canada; 2IM2NP, UMR 7334 CNRS, Universities of Aix Marseille and Toulon, Toulon, France.

SrTiO₃ is an incipient ferroelectric perovskite, which has been extensively studied for its applications in electronics and electro-optic devices. When subjected to a biaxial strain, SrTiO₃ thin films show polar properties due to structural distortion. The structural distortion has a giant impact on the Raman modes, which correspond to the zone-center optical phonons symmetry, forbidden in bulk system. Raman spectroscopy of forbidden vibrational modes has been identified as a qualitative diagnostic tool for studying the strain effects and for providing vibrational spectroscopic information on the dynamic behavior of thin films. Tip-enhanced Raman spectroscopy (TERS), where the Raman and apertureless near-field scanning optical microscopy are combined with the contribution of a metallic tip, provides a comprehensive approach to those modes with improved sensitivity and spatial resolution.

In this work, we experimentally investigate strain-induced polarisation by monitoring vibrational Raman and IR-active modes in SrTiO₃ thin films (15 nm or less) deposited on platinized MgO (100) substrates by radio-frequency magnetron sputtering. In these films, the strain gradient is generated by the lattice-mismatch between the film and the substrate. We employ conventional Raman spectroscopy to investigate the effect of the interfacial strain gradient on the optical phonon modes of SrTiO₃ thin films. We detect first-order polar transverse optic T₁, T₂ and T₄ modes that indicate a lowering of the crystal symmetry for the SrTiO₃ and thus the appearance of spontaneous polarization generated in localized strained regions.

Second, to present an evidence of the existence of the nano-polar regions with respect to conventional Raman spectroscopy, (TERS) measurements were...
recorded on a SrTiO$_3$ thin film. The gold tip introduces an electric field gradient contribution to the signal amplification of the polar phonons and it images the surface of SrTiO$_3$ nanostructures based on the optical phonon mode response. Finally, we discuss the field gradient contribution to the significant signal enhancement as well as to the appearance of symmetry-forbidden IR-active modes and first-order Raman modes associated to the nano-polar regions induced by local structural distortions.

EP01.08.25

Nanoscale Linear Dielectric Constant Imaging Using $\partial C/\partial z$ -Mode Scanning Nonlinear Dielectric Microscopy

Yoshiomi Hiranaga and Yoshi Cho; Tohoku University, Sendai, Japan.

The continued miniaturization of electronic devices containing dielectric materials has increased the impact of nanoscale linear dielectric constant distributions on device characteristics [1]. As a result, more precise control of process damage is required to ensure the fabrication of reliable highly integrated devices, and the nanoscale analysis of dielectric constant has become important. Dielectric constant assessments over nanoscale regions require the measurement of capacitance with sufficiently high sensitivity. Various techniques for the measurement of local capacitance based on scanning probe microscopy (SPM) have been proposed to date, including scanning capacitance microscopy (SCM) [2], scanning microwave microscopy (SMM) [3], microwave impedance microscopy (MIM) [4] and scanning nonlinear dielectric microscopy (SNDM) [5]. SNDM is an especially useful technique as it is highly sensitive to variations in capacitance on the order of 10$^{-22}$ F$/\sqrt{Hz}$ [6]. As a result, SNDM can detect capacitance variations even when employing extremely sharp probe tips, and so is a very effective means of obtaining improved spatial resolution.

Conventional SNDM is typically used to determine nonlinear dielectric constant and to visualize dielectric (or electrical) anisotropy in ferroelectrics and semiconductors. In contrast, there have been only a few reports concerning linear dielectric constant imaging using SNDM [7-9]. Herein, we propose a novel method for linear dielectric constant imaging, termed $\partial C/\partial z$ -mode SNDM ($\partial C/\partial z$-SNDM), that substantially reduces the effects of stray capacitance and enables quantitative imaging with high spatial resolution. $\partial C/\partial z$-SNDM technique employs probe-height modulation to suppress disturbances originating from stray capacitance and to improve measurement stability. This method allows local dielectric constant distributions to be examined with extremely low noise levels (approximately 0.01 aF) by virtue of the highly sensitive probe. A cross-section of a multilayer oxide film was visualized using $\partial C/\partial z$-SNDM as a demonstration, and numerical simulations of the response signals were conducted. Moreover, the beneficial aspects of higher-harmonic response imaging are discussed herein, taking into account assessments of spatial resolution and quantitation.

EP01.08.26

Investigation of Piezoelectric Responses of BaTiO$_3$ Nanorod Bundle Arrays

Moon-hyeok Choi, Seon Min Jang, Sang-Mok Chang and Su Chul Yang; Department of Chemical Engineering, Dong-A University, Busan, Korea (the Republic of).

Low-dimensional piezoelectric nanostructures with nanoparticles, nanorods, thin films have been studied for potential applications of energy harvesters, self-powered sensors, and piezoelectric transistors. For a decade, one-dimensional (1D) nanostructures have been widely approached for miniaturization in piezoelectric field, however, there are still critical limitations of insufficient piezoelectricity and unstable standing on a conductive substrate.

In this study, lead-free BaTiO$_3$ nanorod bundle arrays (NBA) with highly piezoelectric properties were synthesized on conductive fluorine-doped tin oxide substrate via a two-step process consisting of TiO$_2$ epitaxial growth and BaTiO$_3$ conversion. First, in order to develop framework of NBA, effects of pH and Ti precursor on TiO$_2$ nanostructures were investigated with adjusting area density, aspect ratio and free standing. It is illustrated that area density was enlarged as an increase in Ti precursor concentration and increase in pH, respectively. Optimum TiO$_2$ NBA was found to exhibit single-rod diameter of 10 nm, bundle diameter of 100 nm, no-aggregation, and high area density over 60%. Next, M-shaped TiO$_2$ nanorod bundles were developed via chemical etching process to conduct complete perovskite BaTiO$_3$ conversion. During chemical etching, top surface was found to be more etched compared to side wall because of the higher surface energy of (001) with Z-axis than (110) with X and Y axis. As a result of XRD analysis, it is noted that the M-shaped nanostructure can offer large diffusion sites of Ba$_2^+$ ions determining perovskite phase. The effective BaTiO$_3$ conversion using M-shaped nanostructures was confirmed with volume expansion and ion mapping by SEM and STEM analysis, respectively. Finally, the final structure of perovskite BaTiO$_3$ NBA was found to exhibit a feasible piezoelectric response of 3.56 nm with a clear phase change of 180$^\circ$ from the single BaTiO$_3$ bundle, by point piezoelectric forced microscopy analysis. In conclusion, BaTiO$_3$ NBA with high piezoelectric properties could be a promising nanostucture for various nanoscale electronic devices.

Two-Dimensional Analysis of Nanoscale Contact Electrostatics in Hysteretic Materials—To Switch or Not to Switch, Part Trois

Sabine M. Neumayer, Sergei V. Kalinin, Nina Balke and Petro Maksymovych; Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.

A major task for piezoresponce force microscopy (PFM) is to detect and quantify piezoelectric displacements near the present sensitivity limit of ∼ 1 pm/V. Measuring the relatively weak piezoresponse is needed to probe new candidate ultrathin ferroelectrics, such as HfO$_2$ thin films and quasi-2D layered ferroelectrics, while high sensitivity measurements are likewise beneficial to understand the performance of sensors, actuators, energy harvesters. The challenge of the measurement is primarily rooted in the contribution of electrostatic interaction, thermal expansion and other forces to the net measured signal, which may obscure or even disguise the detection of piezoelectric response.

Recently, we applied contact mode Kelvin probe force microscopy (cKPFM) to differentiate electrostatic and piezoelectric contributions in PFM measurements [1,2]. In this talk, we will present a new approach to visualize and analyze cKPFM measurements aimed at improving and eventually automating the relevant data analysis. The approach, which we refer to as the field-response function, treats applied fields during the measurement and the write cycle on equal footing, thereby mapping the measured probe displacement onto a 2D grid of applied potentials. Though relatively simple, the change of the representation brings in significant benefits: (1) the relevant information of the cKPFM measurement is captured as a single image, presenting regions of stable, unstable or metastable states; (2) ferroelectric switching and electrict-type behaviors are clearly differentiated; (3) the response function can in general be acquired with arbitrary sequence of applied fields, not necessarily sequential voltage cycling; (4) from the few representative cases, such
as pre-breakdown window of lead zirconate titinate, it is becoming progressively clear that a simple picture of additive piezoresponse and electrostrictivity is not generally valid in FPM, even for well established ferroelectrics (5) fitting the whole field-response function enables further elucidation toward and subsequent supervised and unsupervised classification of characteristic responses, which we will demonstrate using Gaussian process regression combined with multivariate clustering analysis. These developments enhance the ability of FPM to probe “difficult” ferroelectrics and advance cKPFM toward to analysis of defect chemistry and more generally hysteretic materials, such as electrets, electroresistive, phase change materials and mixed electron-ion conductors. This research was sponsored by the Division of Materials Sciences and Engineering, BES, US DOE. Experiments were conducted at the Center for Nanophase Materials Sciences, a DOE Office of Science User Facility.

Carrier Concentration-Dependent Piezotronic and Piezo-Phototronic Effects in ZnO Thin-Film Transistor Zijian Pan, Wenbo Peng, Fangpei Li and Yongning He, Xi'an Jiaotong University, Xi'an, China.

The piezotronic and piezo-phototronic effects have been confirmed as promising methodologies to optimize the performances of electronic/optoelectronic devices. However, these strain-induced modulations (i.e., piezotronic and piezo-phototronic effects) are strongly dependent on the carrier concentration of the piezoelectric semiconductor. In this work, the carrier concentration dependence of both the piezotronic and piezo-phototronic effects are carefully and systematically investigated in ZnO thin-film transistors (TFTs) by varying manufacturing process and introducing 365 nm UV illumination to modulate the carrier concentration of ZnO film. The experimental results show that significant performance improvement can be obtained in the ZnO TFTs by the piezotronic and piezo-phototronic effects but strongly depend on the carrier concentration in the ZnO films: (1) For the moderate carrier concentration ZnO NW TFT, distinct performance improvement is achieved in the ZnO NW TFT by the piezotronic effect with a maximum enhancement of 48.89% in saturation field-effect mobility $\mu_{SF}$ observed. (2) Whereas, the photoresponse performance of the ZnO NW TFT to 365 nm UV illumination shows no modulation by the piezo-phototronic effect due to the screening effect that is dramatically strengthened/enhanced by the significant increase of the photogenerated carrier concentration. (3) For the ultra-low carrier concentration ZnO seed TFT, there is almost no change in performances of the ZnO seed TFT when introducing the piezotronic effect, which is because the ultra-low carrier concentration ZnO seed film exhibits “piezoelectric characteristic” much more than “semiconductor characteristic” and therefore its semiconductor characteristic is difficult to be modulated by the external compressive strain. (4) By introducing 365 nm UV illumination to the ZnO seed TFT, the photogenerated carrier concentration in ZnO seed film becomes moderate and therefore significant photoresponse improvement of the ZnO seed TFT is obtained by the piezo-phototronic effect with a maximum enhancement of 56.37% in photoresponsivity $R$ observed. In all, significant performances improvement can be obtained in the ZnO TFT by the piezotronic/piezo-phototronic effect only when the carrier concentration in the ZnO is moderate, while there is no obvious modulation in performances of the ZnO TFT when the carrier concentration is ultra-low or ultra-high. This study presents in-depth understanding about the carrier concentration dependence of the piezotronic and piezo-phototronic effects in ZnO TFT and also provides feasible, compatible and adjustable methodologies to enhance/optimize the performances of electronic/optoelectronic devices.

Water Actuation Through Nanomembranes Using Surface Acoustic Waves (SAW) Zamart Ramazanova1, Karbangali B. Tynyshtykbayev2 and Zinetula Z. Insepov3, 1School of Nuclear Engineering, Purdue University, West Lafayette, Indiana, United States; 2Condensed Matter Physics, National Research Nuclear University MEPhI, Moscow, Russian Federation; 3Nazarbayev University, Astana, Kazakhstan.

Nanofiltration technology for water desalination and other fluids purification from salts, germs, bacteria and viruses are based on the so called Nanopumping (NP) effect, when a fluid flow through nanomembranes and nanochannels is actuated using Surface Acoustic Waves (SAW) is presented. The paper considers processes of water nanofiltration through a carbon nanomembrane using ultrasonic waves, which generated surface acoustic waves (SAW) devices under different RF powers and frequencies. We considered droplet of water volume in the 2-20 $\mu$L range, and use SAW devices with different frequencies from 34 to 116 MHz. The effect of frequency on microfluidic performance, such as moving, atomization, and passage of nanodroplets has been studied using a video camera in a range of SAW power. This identified that SAW with higher resonant frequencies have increased power values for moving, atomization, and passage of droplets through nanopores. The device consisted of a Lithium niobate (LiNbO3) piezoelectric substrate and a carbon nanomembrane placed on the substrate. Such nanopumping devices will be of practical interest for the development of future energy sources, for fuel cells, hydrogen energy, pharmaceutical processes and nanomachine for medical robots, as well as for use in a wide variety of chemical, food and agricultural applications. It is demonstrated that the process of nanofiltration of water includes the processes of droplet moving, atomization and passage through nanoparticles and will be useful for future water desalination processes. The dependences of the travel time of droplet moving and atomization of water on the power, frequency and volume of the droplet were established. It is shown that with increasing of power and frequency of SAW, the filtration process proceeds rapidly and has a power-law character.

Pyroelectric Properties of BiFeO3 Thin Films Lei Zhang1, Olivier Paul1, Daniel Sando2, Gabe Velarde1, Shishir Pandya1, Nagarajan Valanoo2 and Lane W. Martin1, 2; 1Department of Materials Science and Engineering, University of California, Berkeley, Berkeley, California, United States; 2School of Materials Science and Engineering, University of New South Wales, Sydney, New South Wales, Australia; 3Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California, United States.

Pyroelectric materials that exhibit changes of spontaneous polarization with temperature variation are of great interest for application such as thermal sensing and waste-heat energy harvesting. Owing to large electrical fields that can be applied at modest voltages and the possibility of direct integration on semiconductors, pyroelectric thin films, in particular, have received considerable attention recently. Scientific investigation of pyroelectric thin films has, however, traditionally been challenging due to possible convoluted pyroelectric responses with thermally-stimulated currents that prevent an accurate determination of the intrinsic pyroelectric properties. Recently developed electrothermal test platforms which are microfabricated for the thin-film geometry, however, now allows for the direct measurement of pyrocurrent and an accurate extraction of pyroelectric coefficient utilizing phase-sensitive local heating and thermometry [1].

In this work, we leverage such an experimental approach to understand the pyroelectric response of one of the most widely-studied ferroelectric materials recently – BiFeO3. In particular, we explore the evolution of pyroelectric response as a function of strain – probing the effects in rhombohedral- and tetragonal-like, as well as mixed-phase versions of BiFeO3 heterostructures – with an emphasis on understanding how temperature-driven competition of different structural ground states impacts pyroelectric response. Here we study BiFeO3 films grown on a range of substrates including DyScO3 (wherein small compressive strains produce strained versions of the parent rhombohedral structure) and LaAlO3 (where large compressive strains produce both single-phase tetragonal-like and mixed-phase structures which exhibit intimate mixtures of the two structural polymorphs depending on the film thickness) [2]. Of great interest is the fact that the relative fraction of the rhombohedral- and tetragonal-like phases is strongly temperature- and electrical-field-
dependent. As such, the interconversion of the two phases with temperature change implies the potential for large changes in the out-of-plane spontaneous polarization. In turn, pyroelectric and ferroelectric dielectric and magnetoelectric effects make possible by the use of our novel microfabricated electrothermal device structures. This approach will provide a complete picture of the electrothermal response of this interesting system.

Room Temperature Ferroelectricity in Multiferroic Al$_x$Fe$_{2-x}$O$_3$ Epitaxial Thin Films
Badari Narayana A. Rao, Shintaro Yasui and Mitsuru Itoh; 1Tokyo Institute of Technology, Yokohama, Japan; 2Department of Chemistry, The University of Tokyo, Tokyo, Japan.

Single-phase multiferroic materials have attracted considerable attention among scientists, due to the strong drive in the industry towards device miniaturization, faster processing speed and addition of new functionalities. Currently, most of the discovered materials are multiferroic only at low temperatures, thereby hindering their induction into practical devices. $\alpha$-Al$_2$O$_3$-type Al$_x$Fe$_{2-x}$O$_3$ ($x$-AFO) oxides belong to a relatively new class of metastable multiferroic compounds (space group: Pmn2$_1$), which can be stabilized as thin films [1]. We have found that some compositions of $x$-AFO can exhibit both ferromagnetism and ferroelectricity at room temperature. The $x$-AFO system is attractive compared to other systems such as GaFeO$_3$ [2] since both Al and Fe are environment friendly, and abundantly available in the earth’s crust. Similar to GaFeO$_3$, the ferrimagnetic easy axis for $x$-AFO is observed along the a-axis and ferroelectricity along the c-axis [1]. Though epitaxial films of $x$-AFO have been grown earlier, only indirect evidences of room temperature ferroelectricity in $x$-AFO are available in literature till date [1,3]. Large leakage currents in these $x$-AFO films made it difficult to carry out ferroelectric and magnetoelectric measurements at room temperature. We have used pulsed laser deposition technique to successfully fabricate epitaxial thin films of $x$-AFO on Nb-doped SrTiO$_3$ (111) substrates. We were able to significantly reduce the leakage current for our films by careful tuning of deposition parameters, to attain films with very smooth surface and small grain size. Direct ferroelectric measurements could be carried out on the films at room temperature, showing good hysteresis loops for $x$-AFO ($x = 0.5 \pm 1.0$). While the ferroelectric characterization showed that the coercive electric field increases with increasing $x$, magnetic measurements showed that the coercive magnetic field decreases with increasing $x$. Furthermore, magnetocapacitance was observed at room temperature, thereby demonstrating their potential as a promising multiferroic material.

Yttrium Iron Garnet Waveguide for Forward Volume Spin Wave Interference
Taiichi Goto, Takuya Yoshimoto, Caroline A. Ross, Koki Sekiguchi, Alexander Granovsky, Yuichi Nakamura, Hironaga Uchida and Mitsuteru Inoue; 1Toyohashi University of Technology, Toyohashi, Japan; 2JST PRESTO, Kawaguchi, Japan; 3Massachusetts Institute of Technology, Cambridge, Massachusetts, United States; 4Yokohama National University, Yokohama, Japan; 5Lomonosov Moscow State University, Moscow, Russian Federation.

Yttrium iron garnets (YIG, Y$_2$Fe$_{12}$O$_{19}$) are well-known as an excellent material for spin wave (SW) waveguide because of its low magnetic damping constant. However, demonstrated functionalities of spin waves were limited because of the difficulty of fabrication and patterning of thin YIG films. In addition, the integration of SW-excitation antennas onto YIG waveguide is also important for device development.

In this study, ~50 nm thick single crystal YIG was grown on a 10 mm x 10 mm x 0.5 mm rare-earth substituted gadolinium gallium garnet (SGGG) substrate by pulsed laser deposition (PLD). The substrate was (111) oriented. The temperature of the substrate during growth was ~850°C under an oxygen pressure of 2.6 Pa. The base pressure was 2.0 x 10^-4 Pa. The grown YIG was characterized by 2g-w-x-ray diffraction. The x-ray was monochromated using two Ge(220) single crystals. The obtained diffraction pattern showed clear fringes, showing flat surface and the deposited thickness was ~50 nm. The reciprocal space map showed fully strained film state. The unit cell side length was 1.2476 nm. The magnetic properties were measured by vibrating-sample magnetometer, showing an in-plane coercivity of 0.37 Oe, an out-of-plane saturation magnetic field of 1.73 kOe, and a saturation magnetization of 1.80 kG (~143 emu/cc). The estimated magnetic anisotropy energy Ku was ~9.88 x 10^4 Goe. The strained lattice angle was 90.4°.

This YIG was patterned into 400 mm x 100 mm using phosphoric acid at 140°C, with the etching process being controlled using an oil bath. Its taper angle was 15° with respect to the in-plane direction. Osteo on this YIG waveguide, three coplanar waveguides were fabricated with ~50 nm distances and SW interference was demonstrated. A magnetic field of 2.80 kOe was applied perpendicular to the film. The phase of the SW was changed, and the synthesized SW based on interference was confirmed. These YIG was successfully patterned as SW waveguide and the uniformity of the quality single crystalline YIG was sufficiently high for showing SW interference. This was an important milestone of development of a SW integrated circuits.

In Situ Study of Inter-Ferroelectric Phase Transitions In Domain Engineered Ferroic Crystals
Markus G. Cain, Peter Fink, Margo L. Staruch, Paul Thompson and Didier Wermille; 1Electrosciences Ltd, Farnham, United Kingdom; 2U.S. Naval Research Laboratory, Washington, District of Columbia, United States; 3XMAS CRG, ESRF, Grenoble, France.

It is well established that domain engineered ferroelectric single crystals deliver an order of magnitude improvement in piezoelectric properties compared to conventional PZT. The unusual electromechanical properties of these domain engineered single crystals of Pb$_2$Zn$_{1/3}$Nb$_{2/3}$O$_3$–Pb$_4$Ti$_3$O$_{12}$ (PZN-PT) and PbMg$_{1/3}$Nb$_{2/3}$O$_3$–PbTiO$_3$ (PMN-PT) have been demonstrated for the compositions poised at the ferroelectric rhombohedral (FR) side of the morphotropic phase boundary (MPB), with domain engineering regarded as one of the most significant breakthroughs in relaxor ferroelectrics for enhanced actuation performance. To exploit the extremely large actuation capabilities of these new single crystal piezoelectric materials, the stability of their crystallographic variants is critical as well as the ability of the material to respond quickly to changes in electrical or stress fields. The latter is determined through an understanding of the dynamical nature of the materials’ domain switching response. In this work, we explored this stability using in situ electric field synchrotron X-ray diffraction at the XMaS beamline (BM28), at the European Synchrotron Radiation Facility (ESRF, Grenoble, France). The electric field induced and mechanical stress induced ferroelectric-ferroelectric phase transitions were studied as a function of frequency, field and static stress in the relaxor ferroelectric system Pb(In$_{1/2}$Nb$_{1/2}$)$_2$O$_3$–Pb(Mg$_{1/3}$Nb$_{2/3}$)$_3$O$_{12}$–PbTiO$_3$ (PIN-PMN-PT) (lead indium niobate – lead magnesium niobate – lead titanate) for compositions close to the morphotropic boundary. The novel in situ PE loop and strain measurement system was used on the XMaS facility, with strain measured using a strain gauge affixed to the side of the sample. The X-Ray data was collected in a synchronous manner to the application of electrical field.

Reference:
Preliminary results show that X-ray diffraction is in good agreement with macroscopic observations and phenomenological models confirming our proposed transformational pathway. Our data is taken using full 2D X-Ray images (Pilatus 2M camera) allowing us to very rapidly explore the nature of competing crystallographic transformations arising across quite a large reciprocal space. Finally, we performed glancing angle measurements that permit imaging of the crystallography just beneath the surface of the crystal face allowing calculation of strain transfer through heteroepitaxial interfaces in composite multiferroics. The phenomena presented in this work are envisioned to be universal in domain engineered ferroics enabling mechanical stress to be used for strain- and polarization-control of electromechanical energy conversion. The results shed more light on the nature of this reversible transformation between two ferroelectric phases, including the mechanism responsible for incredible lack of fatigue after millions of cycles, and advance towards the development of a wide range of ferroic and multiferroic devices.

**Structural Correlation of Ferroelectric Behavior in Mixed Hafnia-Zirconia High-k Dielectrics for FeRAM and NCFET Applications**

Vineetha Mukundan1, Karsten Beckmann1, Steven Consiglio2, Kandabara Tapily2, Robert Clark2, Gert Leusink2, Nathaniel Cady3 and Alain Diebold3; 1Colleges of Nanoscale Sciences and Engineering, SUNY Polytechnic Institute, Albany, New York, United States; 2TEL Technology Center, America, LLC, Albany, New York, United States.

The recent discovery of ferroelectric behavior in doped hafnia-based dielectrics, attributed to a non-centrosymmetric orthorhombic phase, has led to attractive applications such as negative differential capacitance field-effect-transistors (NCFET) and ferroelectric random access memory devices (FeRAM) [1]. Alloying with similar oxides like ZrO2, doping with specific elements such as Si, novel processing methods, encapsulation and annealing schemes are also some of the techniques that are being explored to target structural modifications and stabilization of the non-centrosymmetric phase. In this study, we utilized synchrotron-based x-ray diffraction in the grazing in plane geometry (GIIXRD) to determine the crystalline phases in hafnia-zirconia (HZO) compositional alloys deposited by atomic layer deposition (ALD). Here we compare and contrast the structural phases and ferroelectric properties of mechanically confined HZO films in metal-insulator-metal (MIM) and metal-insulator-semiconductor (MIS) structures. Both MIM and MIS structures reveals a host of reflections due to non-monoclinic phases in the d-spacing region between 1.75Å to 3.25Å [2-4]. The non-monoclinic phases are believed to consist of distorted tetragonal and orthorhombic phases and a suppression of the monoclinic phase in MIM structures compared to the MIS structures was observed. We also report the structural changes with different Hf/Zr ratios (1:4, 4:1 and 1:1) and overall thickness of the HZO film (10nm, 7nm, 5nm, and 3nm). The correlation of the electrical properties with the structural analysis obtained by GIIXRD highlights the route to obtaining non-centrosymmetric orthorhombic phases which enable ferroelectricity [5,6]. Additionally, this work highlights the importance of understanding the effects of the underlying substrate (metal vs. Si) for different target applications.

**Second Harmonic Generation in Ferroelectric HfO2 Based Metasurfaces**

Fei Huang1, 2, 6, Jun Qin1, 2, Xinyue Li1, 4, Longjiang Deng1, 2, Huigao Duan1, Jialiang Xu3, 4 and Lei Bi1, 2; 1National Engineering Research Center of Electromagnetic Radiation Control Materials, Chengdu, China; 2University of Electronic Science and Technology of China, Chengdu, China; 3Tianjin University, Tianjin, China; 4Collaborative Innovation Center of Chemical Science and Engineering, Tianjin, China; 5State Key Laboratory of Advanced Design and Manufacturing for Vehicle Body, Hunan University, Changsha, China; 6Department of Electronic Engineering, Stanford University, Stanford, California, United States.

Hybrid nonlinear photonic structures, in which nonlinear optical materials such as ferroelectrics are incorporated in the near field of a nanophotonic structure, provide a new way to significantly boost the nonlinear photonic effects at the nanoscale. However, several challenges prevent on-chip integration of such hybrid nonlinear metasurface with standard CMOS fabrication technologies, such as material compatibility, scaling and operation wavelength range. Recently, ferroelectric HfO2 thin films have attracted great research interest. As a widely applied high-K oxide material for gate dielectrics, this material is compatible with CMOS technologies. Room temperature ferroelectric properties in such materials can maintain down to a film thickness of 3-5 nm, with similar remnant polarization compared to thicker films. These unique properties ignite great research interest on this material for microelectronic applications. However, to the best of our knowledge, there has been no report on using such materials for second harmonic generation applications.

Here, we demonstrate an on-chip hybrid nonlinear metasurface for second harmonic generation using nanometer thick ferroelectric yttrium doped HfO2 thin films. XRD, hysteresis loop and PFM are measured to verify its ferroelectricity. Optical constant characterizations of ferroelectric HfO2 indicate an wide optical band gap of 4.8 eV for Y:HfO2 thin films. Gold metasurfaces with different grating width ranging from 50 nm to 125 nm are fabricated by EBL. By incorporating a 24 nm thick ferroelectric Y:HfO2 thin film in a plasmonic metasurface nanocavity, we observed one order of magnitude enhancement of SHG compared to bare ferroelectric HfO2 thin films. Moreover, a 3 fold enhancement of SHG is observed in the hybrid metasurface compared to a control device using non-ferroelectric HfO2 showing almost identical linear optical properties, demonstrating a major contribution of SHG from ferroelectric Y:HfO2. We also demonstrated good scalability of such devices down to a Y:HfO2 thickness of 13 nm with another 2 fold enhancement of SHG. Using numerical simulations, we demonstrate an SHG coefficient $\chi^{2}$ of 5 pm/V of the polycrystalline Y:HfO2 thin films, which is comparable to 5%MgO:LiNbO3 (9.4 pm/V) epitaxial thick films and UV transparent materials such as BaB2O4 (4.4 pm/V). These findings demonstrate the promising potential of ferroelectric HfO2 for on-chip nonlinear photonic devices, which also provide a general way of high efficiency SHG using on-chip hybrid nonlinear metasurfaces.

**EP01.08.36**

**Towards Infinite Polarization Retention in Thin-Film Small-Molecular Organic Ferroelectrics**

Indre Urbanaviciute1, Subham Bhattacharjee2, Michal Biler1, Tim Cornelissen1, Mathieu Linares1, Rint Sijbesma3 and Martijn Kemink1; 1IFM, Linköping University, Linköping, Sweden; 2Macromolecular and Organic Chemistry, Eindhoven University of Technology, Eindhoven, Netherlands; 3Theoretical Chemistry and Biology, KTH Royal Institute of Technology, Stockholm, Sweden.

With increasing demand for cheap, lightweight and flexible electronics, a matching memory technology is required. Ferroelectricity-based memory devices assure non-volatility and low energy consumption, while organic materials, potentially used for this purpose, guarantee easy processability, low cost and advantageous physical properties including flexibility. It has been speculated that a recently discovered class of organic ferroelectric materials – columnar discotic liquid crystals – could offer an intriguing possibility to extend bit density limits of the conventional memory devices.
devices substantially, if these discrete ferroelectric columns were addressed individually. However, despite being very well established in the field of electro-optics, ferroelectric liquid crystals lacked interest from a memory device perspective due to modest remnant polarization and/or poor polarization retention.

Here, we demonstrate how simple structural modification of a prototypical supramolecular ferroelectric liquid-crystal benzene-1,3,5-trisamide (BTA) leads to significant improvements in the main ferroelectric properties and results in materials with extrapolated data retention time of more than 10 years in thin-film solution-processed capacitor devices. The BTA is a C3 symmetry molecule consisting of a π-stacking benzene core, to which three free-to-rotate dipolar amide groups (O=C-NH), having a dipole moment of 3 Debye each, and flexible solubilizing alkyl (-CH2-)n chains are attached. We show that all the core properties of the ferroelectric – remnant polarization, coercive field, polarization retention time and operation temperature range – increases continuously in BTAs with shortening of the alkyl chain length (from C18H37 to C6H13). The optimal hexyl-tailed BTA material demonstrates performance close to that of P(VDF-TrFE): remnant polarization of ~60 mC/m2, fast polarization switching, low fatigue and polarization retention of several months at room temperature. Furthermore, if linear tails are changed to branched (achiral ethylhexyl and heptylhexyl), effectively infinite data retention is achieved. The origin of these improvements is discussed in context of electrostatic and steric interactions, as well as inherent morphological layer properties, the latter being the dominant.

Easy-processability, room temperature operation, remnant polarization as high as 40 mC/m2, and polarization retention exceeding commercial requirements distinguish the BTA material from other small-molecular organic ferroelectrics and makes it a perspective choice for applications that require cheap, flexible and lightweight ferroelectrics. The study results, furthermore, bring more understanding into the field and propose guidelines for further advancement in molecular engineering.

**Synthesis, Microscopy and Spectroscopic Characterizations of Rare Earth- Doped BaTiO3 Nanocubes for Optical and Ferroelectric Applications**

**Benard Kavey**

1Science of Advanced Materials, Central Michigan University, Mount Pleasant, Michigan, United States; 2Chemistry and Biochemistry, Central Michigan University, Mount Pleasant, Michigan, United States.

Rare-earth doped BaTiO3 nanocubes have been synthesized using a highly versatile, energy-efficient solvothermal route at temperatures as low as 150 °C. Transmission electron microscopy images of the as-synthesized Ba0.6-Ln3+TiO3 (0.01 ≤ x ≤ 0.09; Ln = La3+, Ce3+, Nd3+) showed highly monodisperse and self-assembled nanocubes with a mean particle size of 20 ± 2 nm for all nominal dopant compositions. High resolution transmission electron microscopy was used to explore in detail the atomic planes, polarization direction, distribution of individual dipoles and the ferroelectric domains within a single nanocube. Also, piezoelectric force microscopy and lithography techniques were employed to further understand the ferroelectric behavior of the Ln-doped BaTiO3 nanocubes. It was determined that all Ln-doped BaTiO3 nanocrystals present a ferroelectric behavior at room temperature with maximum values of the permittivity around the Curie temperature. Dielectric spectroscopy measurements were performed by using vacuum sintered pellets of the as-synthesized nanocubes and measured at both the megahertz and terahertz electric field frequencies. We observed significantly higher dielectric constant values up to 6000 for lower dopant concentrations. An FTIR technique was employed to study the surface characteristics of the nanocubes and the nature of binding of the capping ligand molecules to the surface of the nanocrystals. It was determined that the oleic acid ligand used as a capping agent binds to the Ba ions in the Ln-doped BaTiO3 crystal structure via a bidentate coordination mechanism. The insulating properties of the Ln-doped BaTiO3 was further determined using diffuse reflectance spectroscopy and the Kubelka-Munk theory of reflectance. The band gaps of the as-synthesized nanocubes were determined for all different Ln dopants and various concentrations.

**EP01.08.38**

**Electrostatic Force Driven Oxide Heteroepitaxy for Interface Control**

**Mengjiao Wu, Ren Zhaohui and Han Gaorong:** Materials Science and Engineering, Zhejiang University, Hangzhou City, China.

Oxide heterostructure interfaces create a platform to induce intriguing electric and magnetic functionalities for possible future devices. A general approach to control growth and interface structure of oxide heterostructures will offer a great opportunity for understanding and manipulating the functionalities. Here we report that an electrostatic force, originating from a polar ferroelectric surface, can be used to drive oxide heteroepitaxy, giving rise to an atomically sharp and coherent interface by using a low-temperature solution method. These heterostructures adopt a fascinating selective growth, show a saturation thickness and the reconstructed interface with concentrated charges accumulation. The ferroelectric polarization screening, developing from a solid-liquid interface to the heterostructure interface, is decisive for the specific growth. At the interface a charge transfer and accumulation take place for electrical compensation. The facile approach present here can be extremely useful for controlling oxide heteroepitaxy and producing intriguing interface functionality via an electrostatic engineering.

**Imaging and Engineering the Dynamic Motion of Multiferroic Device Walls by an Electron Beam**

**Michele Conroy**

1Alan Harvey, 2Charlotte Cochrane, 3Kalani Moore, 4Roger Whatmore, 5Alexei Gruverman, 6Marty Gregg and 7Ursel Bangert; 1Bernal Institute, University of Limerick, Limerick, Ireland; 2Centre for Nanostructured Media, Queen’s University Belfast, Belfast, United Kingdom; 3Imperial College London, London, United Kingdom; 4University of Nebraska Lincoln, Lincoln, Nebraska, United States.
Recently there has been a dramatic increase of research activity in multiferroic materials.1-4 More specifically in charged domain walls (DWs) within these materials.5,6 These previously overlooked features are now seen as new form of two-dimensional (2D) material in their own right. With all the potential unique characteristics that make 2D materials such as graphene, DWs have become a new field of research. The main aspect that sets DWs apart from other 2Ds is the ability to create, destroy, and move by an external field or physical force. They’re dynamic nature immediately suggests a potential role for them as interconnects in completely new forms of agile or adaptive nanoscale circuitry. In this study we use the electric field applied by the scanning electron microscope (SEM) probe to study the motion of charged DWs in the improper ferroelectric material Cu3BiTl3Cl7. By changing the applied voltage, current and magnification we conducted a detailed quantification of the DW dynamics due to applied electric field. Focused ion beam (FIB) lamellas were prepared of these selected regions within the bulk crystal and the DWs in cross-section were analyzed by transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM). Weak beam dark field TEM and selected area diffraction analysis revealed there was distinct domains within the cross sections after the SEM probe DWs studies. This was not seen in lamellas formed from regions with low dose imaging pre FIB lamella formation. Suggesting that above a certain dose, and thus electric field new DWs are formed. Additionally the geometry of the DWs seen in cross section are significantly different depending on their freedom of movement seen in the SEM probe study. 1 Evans, D. M. et al. SESSION EP01.09: Physics of Semiconducting Piezoelectric, Pyroelectric and Ferroelectric Materials
Session Chairs: Lauren Garten and Wilfrid Prellier
Thursday Morning, November 29, 2018
Hynes, Level 1, Room 103

8:00 AM *EP01.09.01 Quantifying Voltage-Modulated Electromechanical Sensitivity and Hysteresis Measurements on the Nanoscale Liam Collins1, Aleksander Labuda1, Olga Ovchinnikova1 and Roger Proksch1; 1Asylum Research, Santa Barbara, California, United States; 2Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, Oak Ridge, Tennessee, United States.
